We present in Table 4 the evaluation scores of our system as well as the official evaluation scores of subtask 3 of the TREC-TS 2015 challenge. The results for our systems are computed with the original evaluation script provided by the TREC-TS organizers. The evaluation results of the other systems are taken from the overview paper of the TREC-TS shared task (Aslam et al., 2015). Due to per-task normalization, metric values across the different subtasks at TREC-TS are not comparable. We only provide a lower bound evaluation of our system, generated by only using the annotations provided by the TREC-TS organizers. As described in Section 4.1, only a small subset of sentences in the corpus is annotated. All non-annotated sentences are considered to be unimportant by the evaluation script, which means that valuable sentences might be misinterpreted as noise when using this dataset without additional annotations. This disadvantage does not apply to the reference systems, since at least the top 60 sentences of each reference systems were labeled for each topic. In total, 57.99% of the sentences selected by our system were not annotated. We report this number for a better assessment of the performance of our system. Although our system might get penalized for valuable sentences, we outperform the other approaches. As described in Section 1, we expect that a sequential clustering approach should be able to detect important information very early. The timeliness of our approach (column E[Latency]) confirms this expectation and is an important factor for the superior performance of our system. We also observe that our system is able to generate a reasonable balance of precision ($n\mathbf{EG}(\mathcal{S})$) and recall ($\mathbf{C}(\mathcal{S})$).

System	$\mathcal{H}$	E[Latency]	$F_1(n\mathbf{EG}(\mathcal{S}), \mathbf{C}(\mathcal{S}))$	$n\mathbf{EG}(\mathcal{S})$	$\mathbf{C}(\mathcal{S})$
`SeqCluSum` (lower bound)	**0.1526**	**0.8013**	**0.1842**	0.1485	0.2426
Raza et al. (2015)	0.0853	0.3983	0.1773	0.1840	0.1710
McCreadie et al. (2015)	0.0639	0.5335	0.1189	0.0667	0.5459
McCreadie et al. (2015)	0.0508	0.6741	0.0758	0.0402	0.6590

Table 4: System results sorted by descending $\mathcal{H}$, the main metric used in the TREC-TS shared task. The columns $n\mathbf{EG}(\mathcal{S})$, $\mathbf{C}(\mathcal{S})$, and E[Latency] show the results according to evaluation metrics described in Section 4. Since the main metric is computed by building a harmonic mean of latency discounted versions of $n\mathbf{EG}(\mathcal{S})$ and $\mathbf{C}(\mathcal{S})$ there is no point in achieving high scores in one of these measures while achieving only a low score according to the other metric.

To find reasonable values for the parameters Θ and μ, we manually evaluated our system with a cross-validation. We did this by randomly splitting the topics in two evenly sized sets of topics and used one of the sets as test set while using the other one for parameter optimization. As described in Section 4.1, we did this on the basis of a sparsely labeled dataset. We expect better results if we could use more densely labeled data. We use the Cosine similarity with $\log +1$ IDF weighting and L2 normalization (cf. Section 5.2). We could not determine a superior boilerplate removal in Section 5.1 and Section 5.3 and therefore apply (Kohlschütter et al., 2010) since it is considered to be a well-known standard boilerplate removal system. During the cross-validation, we found $\mathcal{H}$ scores of 0.1664 and 0.1858 in the validation sets which resulted in $\mathcal{H}$ scores of 0.1550 and 0.1501 in the test sets. We report the averaged scores of both test sets in Table 4.

7 Discussion

The sequential clustering depends strongly on the accuracy of the used similarity measure. Since we only use predefined standard similarity measures, we assume that a more sophisticated selection of similarity measures could lead to an improvement of the performance. More abstract semantic methods or additional knowledge resources may model the semantic similarity of words and sentences better. We therefore assume that the performance of the similarity and redundancy detection can be further improved.

Another improvement of the similarity measure would be to utilize the weights of the tokens, which are used during the contextual measuring of importance also in the clustering. If we weight important tokens higher in the similarity measure, we could achieve that the clusters would be more focused on a particular information nugget.

The clustering can also be improved by introducing a re-clustering step, which could split a cluster into multiple clusters when the system detects that one cluster contains too diverse sentences. This is currently prevented by the parameter Θ. By enabling the system to execute a re-clustering step, this parameter could become obsolete. Furthermore, the system could merge multiple clusters to one cluster if it detects that the content of the clusters are more similar as the seed sentence suggested.

Our model relies heavily on centrality as a features to detect important information timely. Kedzie et al. (2015) mentioned that using centrality as signal for importance is problematic in IUS since it requires some time until an important information is central enough in the news stream. However, the burstiness of news streams can diminishes this issue. A system which is independent from the centrality features would nevertheless be able to detect new important information in big data streams earlier than our systems.

To evaluate our system, we used a cross-validation to optimize the parameters μ and Θ in validation sets and applied the values to test sets. This limits the performance of our system, since the topics have different sizes and different amounts of interesting information. Therefore, an extension of our system where the parameters μ and Θ are adaptive could further improve the performance. μ for example, could depend on the time since no update has been published. If there is a long time span with no updates, μ could be lowered to increase the probability that there will be a new message soon.

8 Conclusions

In this paper, we proposed `SeqCluSum`, a system for incremental update summarization based on sequential clustering and contextual importance measures. It combines the strength of the two prior proposed techniques, namely real-time processing pipelines or clustering approaches. The sequential clustering arranges similar sentences together while the contextual importance measures score the clusters and sentences according to their contextual importance. The contextual importance measures estimate the importance of information as well as their novelty jointly. The evaluation shows that even the lower bound scores of our system outperforms previous state-of-the-art systems. We obtain better latency and higher $\mathcal{H}$ scores, which means that our system detects important information earlier and with a better trade-off between precision and recall. We therefore conclude that sequential clustering in combination with contextual importance measuring is well-suited for the task of IUS. Furthermore, our system does not use the provided query and is hence able to detect important information without using query expansion, which was often used by previous systems to improve recall. We do not use any handcrafted knowledge bases to get additional domain-knowledge, which is another advantage of our system.

Abstract

Recently Wen et al. (2015) have proposed a Recurrent Neural Network (RNN) approach to the generation of utterances from dialog acts, and shown that although their model requires less effort to develop than a rule-based system, it is able to improve certain aspects of the utterances, in particular their naturalness. However their system employs generation at the word-level, which requires one to pre-process the data by substituting named entities with placeholders. This pre-processing prevents the model from handling some contextual effects and from managing multiple occurrences of the same attribute.

Our approach uses a character-level model, which unlike the word-level model makes it possible to learn to "copy" information from the dialog act to the target without having to pre-process the input. In order to avoid generating non-words and inventing information not present in the input, we propose a method for incorporating prior knowledge into the RNN in the form of a weighted finite-state automaton over character sequences. Automatic and human evaluations show improved performance over baselines on several evaluation criteria.

1 Introduction

Rule-based Natural Language Generation systems (Reiter and Dale, 2000) have been quite successful but they suffer from some limitations. They require extensive human effort and tend to produce fixed, repetitive outputs, which do not closely match human-like utterances. For this reason, there has been much interest recently in developing NLG systems which are, at least partially, able to learn from human produced data (Langkilde and Knight, 1998; Belz, 2008).

In the last couple of years, Neural Network (NN) based approaches have gained enormous popularity within statistical NLP generally, with applications to Machine Translation (Sutskever et al., 2014), Conversation Modelling (Vinyals and Le, 2015) and Parsing (Tai et al., 2015), to cite only a few. In particular, architectures based on Recurrent Neural Network (RNN) such as LSTMs (Hochreiter and Schmidhuber, 1997) and GRUs (Cho et al., 2014) have been succesfully used in Language Modelling tasks due to their ability to model sequential information with long-range dependencies.

An RNN-based approach to NLG has been recently proposed by Wen et al. (2015) in the context of a dialog system, where the input semantic representation is a Dialog Act (DA). The decoder uses words as the units of generation. This word-based model requires pre-processing the original data by substituting named entities with placeholders, a process called *de-lexicalisation*. This is necessary because a standard word-level RNN is not able to "copy" input entities into the target, but has to learn each correspondence individually, which it can only do with a lot of data.

Such a de-lexicalization approach has the advantage of reducing data sparsity, but it also suffers from various shortcomings: (i) it requires some reliable mechanism for named-entity recognition, (ii) it requires a post-processing "re-lexicalization" step, where the placeholders are replaced by the original named entities, (iii) it is unable to account for subtle morphological or lexical effects that a specific

* Work performed during Raghav Goyal's internship at XRCE in 2016.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1083–1092, Osaka, Japan, December 11-17 2016.

named entity may have on its context,[1] and (iv) it does not address the problem of multi-slots of the same type, as for instance when two restaurants are mentioned in the same input.

In this work, we propose to use a **character-level** model which does not suffer from the same sparsity issues as a word-level model, and therefore does not require de-lexicalisation. We show that this architecture, coupled with a bidirectional encoding and an attention mechanism (Bahdanau et al., 2014), is able to "copy" information from the dialog act into the target realization, and to produce reasonable results.

However, this model has two main defects. The first is that it can produce non valid words, the second that it can invent named entities not present in the dialogue act. In order to improve this, we propose to constrain the generation of characters through a certain weighted finite-state automaton that incorporates **prior knowledge**: (i) about well-formed strings of characters and (ii) about the fact that named entities in the realization originate from character strings present in the input.

The following points summarize the key contributions of this paper:

- We handle the NLG problem through an attention-based character-to-character model, in particular we encode the input semantics as a string of characters. By enabling copying at the character level, this prevents us from having to de-lexicalize some aspects of the input, as Wen et al. (2015) are obliged to do.

- In order to improve the quality of the generated utterances (avoiding the generation of non-words or the hallucination of named entities), we exploit *a priori* knowledge in the form of a weighted finite-state automaton that constrains the generated strings of characters to either conform to a predefined vocabulary of words, or to originate in portions of the semantic input. This automaton is integrated within the RNN by employing a generic "background-adaptor" mechanism, a technique recently proposed in (Dymetman and Xiao, 2016), which we explain briefly in a self-contained way.

We start in section 2 by defining the network architecture we apply to all our models and by explaining the background-adaptor technique. We proceed to give details of our different models in Section 3 and introduce a finite-state background over characters. In Section 4 we describe the experiments, with details about the dataset, implementation and evaluation; we also give examples illustrating differences between the models. In Section 5 we discuss related work and finally conclude in Section 6 with some perspectives.

2 Proposed Approach

2.1 The architecture

2.1.1 Recurrent Neural Network (RNN)

Our *encoder-decoder* RNN is based on LSTMs (Hochreiter and Schmidhuber, 1997), which have been shown to be effective in particular in Machine Translation (Sutskever et al., 2014). Our approach is close to that of (Bahdanau et al., 2014), who relax the constraint of having a limited, fixed, length vector representation of the source sentence by using the encoder to produce *bi-directional* embeddings of words of this sentence along with an *attention* mechanism; this mechanism dynamically weighs the source embeddings at each time step, thus enabling the network to "attend" to some specific parts of the (still accessible) input during generation.

In our case, the input (source) representation of the information to be realised by NLG is in the form of a dialog act, as in (Wen et al., 2015), for example:

Dialog Act: *inform(name='phoenix hotel'; area='civic center'; accepts_credit_cards='yes')*
Realization: *the phoenix hotel is near the civic center and accepts credit card -s .*

[1] For example, number or gender (in some languages) agreements between a restaurant name and the remainder of a sentence (French example: *le ritz (la belle époque) est situé (est située)* ...); or spurious repetitions of articles in hotel names (*the HOTEL_NAME is ...* → *the the renaissance is ...*).

While Wen et al. (2015) handle the dialog act as a binary vector encoding different slot-value pairs (after delexicalization), we instead directly encode it as a sequence of tokens, either at the word or at the character level.

2.1.2 Background-Adaptor RNNs

In certain of our experiments, we exploit a variant of recurrent networks which we will call "Background-Adaptor RNNs", which is based on a recent proposal by Dymetman and Xiao (2016) for incorporating prior knowledge in recurrent networks to help training in the presence of limited data.[2] We now briefly explain this technique, which is applied here for the first time to the problem of NLG and to character-based models.

Abstracting away from details, a standard RNN model defines a conditional probability distribution $p_\theta(x_{t+1}|x_1, x_2, ..., x_t; C)$, where C is the context of the model (for us, this is the input dialog act), where $x_1, x_2, ..., x_t$ are the already generated tokens, and where x_{t+1} is the token being generated; the matrix parameters of the models are denoted by θ. The background-adaptor technique extends this as follows:

$$p_\theta(x_{t+1}|x_1, x_2, ..., x_t; C) \propto \underbrace{a_\theta(x_{t+1}|x_1, x_2, ..., x_t; C)}_{\text{adaptor}} . \underbrace{b(x_{t+1}|x_1, x_2, ..., x_t; C)}_{\text{background}} . \quad (1)$$

The difference is that now p_θ is defined as a combined process, obtained by multiplying an "adaptor" a_θ, which is a standard RNN, with a "background" b, which is an arbitrary, *a priori* defined conditional language model; it is given externally and is fixed during training of the combined process. This process is simply obtained by the product of the adaptor and the background, normalized over the different possible vocabulary symbols x_{t+1} to obtain a probability distribution (as indicated by the proportionality symbol). Overall, the process is still only parametrized by θ, and training with it only requires a small modification of the log-loss for taking into account the background factor.

To provide some intuition, let us note that when the background process is a uniform distribution over the vocabulary, we are back to the usual RNN. The other extreme is when the background process exactly corresponds to the actual observed data, in which case the adaptor only has to learn to produce a (close to) uniform distribution (an easy task). The interesting cases are intermediary situations, where the background process incorporates some prior information (for example a generic language model trained on a large corpus), which the adaptor can leverage in order to more easily adapt to the training data (for example a small in-domain corpus). In our application, the background process will provide some hard or soft constraints that the generated symbols have to conform to, presented in the form of finite-state automata.

3 The Models

Word-based model (WORD)

Our first, word-based, model uses the encoder-decoder architecture with the attention mechanism described above. As mentioned earlier, for a word-based model the data has to be de-lexicalised first[3] i.e. the named entities, such as restaurant names, addresses, telephone numbers, etc., have to be replaced by place-holders such as REST_NAME, TEL_NUMBER, and the like. These entities are then re-lexicalized at the end of the decoding to form the final utterance.

[2]The log-linear RNNs introduced in (Dymetman and Xiao, 2016) go beyond background-adaptor RNNs as described here: we only exploit the part of log-linear RNNs concerned with the distinction between the "background" and the "adaptor", not the aspects having to do with log-linear features. The use of a background for supporting RNN training is also implicit in the semantic parsing paper (Xiao et al., 2016).

[3]To emphasize this point, let us note that, in standard word-based seq2seq RNNs, the input and output vocabularies are totally disjoint. In order to map the input word "Ritz" into the output word "Ritz", the RNN has to learn the mapping from scratch based on training data, and cannot rely on any a priori knowledge about the correspondence; if "Ritz" is rare (or nonexistent) in the training data, the mapping cannot be learnt reliably (or at all). By de-lexicalizing "Ritz" into the generic "HOTEL", both in the input and output, the training is much simplified: the RNN only has to learn to map "HOTEL" to "HOTEL", a much more frequent observation.

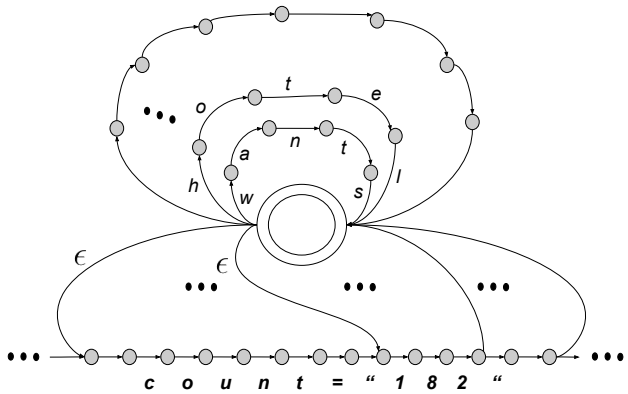

Figure 1: The Background FSA which shows the inclusion of target vocabulary words such as "hotel" and "wants" (top of the figure). Also, it is capable of accepting any substring from the dialog act such as the number "182" (bottom of the figure). The large central state is both initial and final.

Differently from (Wen et al., 2015), who use a one-hot encoding for the input DA, and also add a special gate mechanism to better control the consumption of slots, here we simply treat the DA as a sequence of word tokens.

Character-based model (C)

Our second model is a character-based model in which both the input and the output are character strings. Such models have been used in NMT (Neural MT) to tackle the problem of rare words (Ling et al., 2015; Luong and Manning, 2016). One advantage is that they work over a small vocabulary ($\sim$ 50 symbols), which they have each observed many times; in consequence, they have the ability to learn to map a character onto itself, if the context requires it. This copy mechanism is useful for carrying material from the original unprocessed input to the target, and, perhaps counter-intuitively, is not present in usual word-based RNNs, which have to learn each mapping from scratch (but see fn. 3, as well as the related work section 5 below about augmenting word-level RNNs with a copy ability).

Character-based model(s) with a Finite State Background (C-NWFSA and C-WFSA)

Our last class of models use a background-adaptor approach where the character-based model (adaptor) gets help from a finite-state automaton (FSA) which provides some prior knowledge (background).

The background FSA, in its non-weighted version (C-NWFSA) is illustrated in Figure 1. It accepts: (1) **All common words from the target vocabulary**: these words are all the words (around 500) that may appear in realizations, excluding the named-entities, independently of the DA input; (2) **All substrings from the source dialog act**: the FSA has the freedom to transition to and from any character position in the input DA; this acts as a prior, conditional on the input, which allows the adaptor to copy substrings, in particular named entities, from any part of the DA.

The idea behind this background automaton is that although the character-level model has the capacity to exploit dialog acts without de-lexicalisation (in contrast to the word-level models), nothing prevents it from generating on the one hand non-words, and on the other hand strings of characters that have no evidence in the DA. Through the "intersective" technique of equation (1), the background automaton b constrains the combined process p_θ to only produce common words or substrings of the DA. While the RNN adaptor a_θ works similarly similarly to model (C), the overall training loss depends on b also.

The FSA that we just described is the *unweighted* automaton (C-NWFSA), and its effect is strictly to accept or reject strings of characters. We also consider a *weighted* version (C-WFSA), with the same topology, but where the probabilistic weights on the arcs are parametrized (in a very elementary way) through a single parameter $\alpha \in [0, 1]$, as we now explain.

The total mass of transitions from the start state to one of the "common words" at the top of the figure is α, and the remaining mass $(1 - \alpha)$ is used for (epsilon) transitions to the character representation of

the DA at the bottom of the figure. Between the common words the mass is then distributed uniformly, and for edges from the start state to the DA, the mass is also distributed uniformly onto all the positions of the DA, that is, inversely proportionally to the length of the DA. Once on a position in the DA, the probability of escaping the DA back to the initial state is set to $1 - \alpha$, that of continuing in the DA to α. Overall a higher value of α indicates on the one hand that it is more difficult to "escape" from using common words once using common words, and also that once one is inside the DA, it is more difficult to escape from it back to the common words, which then encourages longer stretches of the DA to be produced once inside it. The way in which we fix α is detailed in section 4.

4 Experiments

4.1 Dataset

The datasets used for our experiments are those made available by Wen et al. (2015), in two domains, *hotel* and *restaurant*. Each set consists of DAs along with their natural language realisations. There are eight different DA types that indicate the communicative intent such as *inform*, *reject*, *confirm* etc. Each DA is a combination of slot-value pairs of the information to be conveyed, with a total of 13 different possible slots such as *name, pricerange, address* etc.

Each domain consists of roughly 5K samples, which we split in the ratio 8:1:1 into training, development and test.[4]

4.2 Implementation

The implementation is done using the Python libraries: Theano (Theano Development Team, 2016) and Lasagne (Dieleman et al., 2015). We implemented the attention mechanism (Bahdanau et al., 2014) by modifying the LSTM class of the Lasagne library. Also, the probability of the combined process c is calculated by element-wise multiplication of individual processes a_θ and b followed by normalization.

The FSA over characters is handled through PyFST[5], a python wrapper for OpenFST (Allauzen et al., 2007). We use this tool to perform the operations of ϵ-removal and determinization (otherwise delicate to program directly), in that order, from an initial non-deterministic weighted or unweighted FSA (which depends in part on the DA input). Finally, the automaton obtained is exported in matrix form to facilitate integration with Theano.

The models are all trained with the same configuration of hyperparameters: the forward and backward RNNs of the bidirectional encoder have 300 hidden units each, similarly the decoder RNN has 300 hidden units. The number of hidden units used in the single layer perceptron for calculating the attention weights is 100. For training, we use SGD together with Adam (Kingma and Ba, 2014) updates, with an initial learning rate of 0.001. A small minibatch of size 20 is chosen due to GPU memory constraints when storing FSA matrices for each sample contained in the minibatch. After the training procedure, beam search is used to sample utterances from the obtained conditional language model. A beam of length 5 is used to obtain the top 5 realisations and the one with highest probability is selected as the prediction.

The α parameter of the weighted FSA is fit to the data by performing a search over the list of values $[0.99, 0.95, 0.9, 0.8, 0.7, ..., 0.1]$. Log-likelihood of the training dataset is used as the optimization criterion, calculated as the sum of log probabilities of all target realizations present in the training set. The maximum likelihood is obtained for $\alpha = 0.9$, both for Hotel and for Restaurant, and this α is used in all our experiments.[6]

Also, the average number of states present in the deterministic weighted FSAs of the training samples is approximately 70K and 120K for the hotel and restaurant domain respectively.

[4]Note that we had to produce our own split, the data provided along with (Wen et al., 2015) does not specify their split, which prevents comparison with their results.

[5]https://github.com/vchahun/pyfst .

[6]As we already mentioned, our approach to fitting the automaton to the data with a single parameter α is simplistic. We could clearly use more parameters, and fit them through some EM procedure.

Model	BLEU	
	Hotel	Restaurant
WORD	0.4495	0.4322
C	0.4200**	0.3699**
C-NWFSA	0.4109**	0.3971**
C-WFSA	**0.4655**	**0.4381**

Table 1: BLEU scores of the models computed on the test set. Statistical significance is calculated using paired bootstrap resampling (Koehn, 2004) $^{**}p < 0.01$.

	Model	Adequacy		Fluency		
		Precision	Recall	No non-words	Non-redundant	Naturalness
Hotel	WORD	0.952*	**0.844**	0.989	0.941*	1.841*

Table 2: Human evaluation of top realisation of the models. Statistical significance is computed through a pairwise difference one-tailed Student's t-test between the model with maximum score against the others. $^{*}p < 0.05$, $^{**}p < 0.01$.

4.3 Evaluation

4.3.1 Automatic Evaluation

Automatic evaluation results are shown in Table 1, using BLEU-4 (Papineni et al., 2002).[7] The results are shown for the four models (WORD, C, C-NWFSA, C-WFSA) described earlier, evaluated over our test sets for Hotel (538 realisations) and Restaurant (520 realisations).

4.3.2 Manual Evaluation

The automatic metrics do not always correlate with human judgement, so we also perform manual evaluation, based on the following adequacy (information conveyed) and fluency (linguistic quality) scales:

1. **Adequacy:**
   - Precision (i.e. "Correctness") [1/0]: all information in the DA is present in the generated utterance (1=yes, 0=no).
   - Recall (i.e. "Completeness") [1/0]: all information in the utterance is present in the DA (1=yes, 0=no).
2. **Fluency:**
   - No non-words [1/0]: all tokens in the utterance are actual words (1=yes, 0=no).
   - Non-redundant [1/0]: there is no repeated information in the utterance (1=yes, 0=no).
   - Natural or "good english" [2/1/0]: the utterance is "good" english (grammatical and natural) (2=good,1=acceptable,0=not acceptable). This is the main linguistic quality measure.

The evaluation was conducted on the full test set, both for Hotel and Restaurant, and is reported in Table 2.

[7] We used the mteval-v13a.pl script with default options from http://www.itl.nist.gov/iad/mig/tests/mt/2009/.

	Selected samples from the Hotel domain
1	inform(name='the inn san francisco';address='943 s van ness ave';phone='4156410188') [C]: the address of the inn san francisco is 943 s van ness ave . their phone number is 4156410188 . [C-NWFSA]: the inn san francisco 's phone number is 4156410188 [C-WFSA]: the address of the inn san francisco is 943 s van ness ave . the phone number is 4156410188 . [WORD]: **the the** inn san francisco 's address is 943 s van ness ave and the phone number is 4156410188 .
2	inform(name='hotel des arts';price_range='moderate') [C]: the hotel des **artea** hotel is in the moderate price range . [C-NWFSA]: the hotel des arts is in the moderate price range . [C-WFSA]: hotel des arts is in the moderate price range . [WORD]: hotel des arts is moderate -ly priced .
	Selected samples from the Restaurant domain
3	inform(name='yummy yummy';price_range=cheap;good_for_meal=dinner) [C]: i have found a restaurant called **mimmmmey** is good for dinner . [C-NWFSA]: **mmy** much is a good restaurant is good for dinner . [C-WFSA]: yummy yummy is cheap and good for dinner . [WORD]: yummy yummy is a cheap dinner restaurant with a cheap price range .
4	inform(name='straits restaurant';price_range=expensive;food=singaporean;good_for_meal=dinner) [C]: straits restaurant is an expensive restaurant that serves singaporean food . [C-NWFSA]: straits restaurant is expensive and serves singaporean food for dinner . [C-WFSA]: straits restaurant is expensive and is good for dinner . [WORD]: straits restaurant is an expensive restaurant that serves singaporean food and is good for dinner .

Table 3: Example realisations of the models. The most probable realization from a beam of length 5 is shown in each case.

4.3.3 Discussion

In terms of BLEU scores, we observe that the character-based model with a weighted finite-state background (C-WFSA) is significantly better than the other character-based models, and slightly better than the (WORD) model.

In terms of manual evaluation, the results are a bit more contrasted. Overall, (C-WFSA) is significantly better than the other two character-based models, apart from the case of "non-redundancy", where it behaves in a quite similar way; this is however not very surprising, because nothing in the FSA background that we presented specifically controls for non-redundancy (the non-repetition of semantic material). (C-WFSA)

All the models are quite deficient in Recall, but (WORD) is a bit better there; again, the FSA background does not control for Recall. On the other dimensions than Recall, (C-WFSA) is slightly better than (WORD), but not always significantly; it is especially good in overall linguistic quality (Naturalness) and in Precision (which is something that the background more directly controls for); interestingly, the unweighted model (C-NWFSA) is significantly worse on precision than the weighted version.

4.4 Illustrations

Examples We show in Table 3 a few examples from the different models. Example (1) shows a case where (C) and (C-WFSA) are both correct, (C-NWFSA) is deficient in recall, and (WORD) after re-lexicalization produces a sequence of two 'the'. Example (2) is a case where (C) invents a named entity. In example (3), (C) also invents a named entity and (C-NWFSA) incompletely copies one. In Example (4), (C) and (C-WFSA) are both deficient in recall, but the other models are good.

Attention Heatmap Because of its independent interest, we also show in Figure 2 an "attention heatmap", here in the case of model (C), for the following example:

```
[DIALOG-ACT]: inform(name='noe 7s nest bed and breakfast';address='1257 guerrero st')
[REFERENCE]: * the address is 1257 guerrero st for noe 7s nest bed and breakfast. #
[REALISATION]: noe 7s nest bed and breakfast is located at 1257 guerrero st .
```

The input DA is written along the columns of the array and the corresponding target realisation is written along the rows. An x^{th} row in the array represents the weights given by the attention mechanism over the character embeddings of the source dialog act at the point where it is generating the y^{th} character of the realisation.

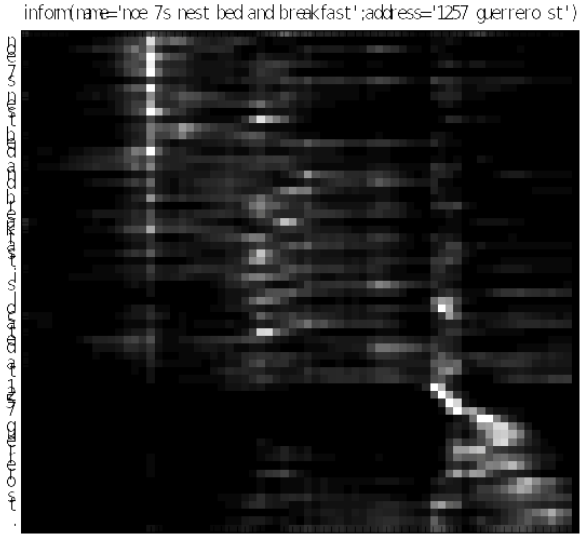

Figure 2: Attention heatmap for a selected example. The x-axis and y-axis denote the input DA and realisation respectively. Each pixel shows the attention weight (white largest) of the x^{th} source character at the point where the y^{th} target character is produced.

We observe a certain "2-block" structure of the attention, with the attention over the hotel slot value when generating the hotel name, over the address slot value when generating its address. The focus of attention is specially strong when generating the four digits 1,2,5,7; one should note that the (C) model has to learn to copy these digits one by one from the input to the target. By contrast, there is very little attention specifically paid to the initial part of the DA "i n f o r m (n a m e", because the little specific information contained there is easy to convey in a more distributed way over the whole input encoding.

5 Related Work

In the field of Neural Machine Translation (NMT), the problem of translating "rare words" such as named entities has recently attracted a fair amount of attention. The main approaches have been ones that either try to augment RNNs with some form of word-copying, or else have, similar to us, some character-level aspects.

Luong et al. (2014) preprocess the data and replace each unknown word in the target sentence by a placeholder token also containing a positional pointer to the corresponding word in the source sentence. Through these pointers, they learn an explicit mapping for copying unknown words from the source to the target. This is a bit similar to the de-lexicalization process of (Wen et al., 2015) in NLG, although the positional aspect might allow to handle several values associated with the same slot type.

Ling et al. (2015) tackle the problem of unseen words by proposing the use of a character-level model instead of a word-level model. As in our case, the limited vocabulary (namely, the different characters) is small enough that the model can learn to copy characters in certain contexts. This model is different from a strict character-level model as it introduces a hierarchy for forming words from characters instead of regarding a sentence as a flat string of characters. Luong and Manning (2016) also propose an hybrid word-character model to handle the rare word problem. For encoding the source sentence, they use a character-level model for rare words and a word-level model for frequent words. Then, for generating a target sentence, they use a word level model to get a first realisation of the target which contains <unk> for rare words and in a second step use a character-level model to generate a realisation of the rare word using contextual information.

Ling et al. (2016), in the context not of NMT this time, but of code generation, introduce a multiple predictor framework, where they can handle jointly the generation of generic code tokens and that of specific tokens for variable names and the like. They choose a character-level softmax for generating generic target tokens along with a pointer network (Vinyals et al., 2015) for copying specific tokens.

We are not aware of any prior work making use of models for *a priori* constraining the string of characters generated by an RNN, as we are doing here.

6 Conclusion

In this work we have proposed a character-level generator which is able to "copy" information from the source dialog act to the target utterance, and which uses original data without requiring pre-processing. By incorporating prior knowledge in the form of a finite-state automaton, exploiting a notion of "background-augmented" RNN, we discourage the character-level model from generating non-existing words or information for which there is no evidence in the input. Overall, the weighted version of the automaton performs much better than the version without prior knowledge, better than the non-weighted version of the automaton, and slightly better than the word-based version that requires de- and re- lexicalisation.

The main areas where our weighted automaton does not perform well (along with all other models, to different extents) are those of "Recall" (expressing all information present in the DA) and "Non-redundancy" (not expressing the same content twice). These are the same areas in which the original model of (Wen et al., 2015) introduced specific machinery, both in terms of a technique for controlling the "consumption" of slots, and of the use of a reranker on top of the operation of the RNN. As a perspective, we could also easily use a reranker, but as a continuation of our overall approach we would preferably incorporate the corresponding constraints as *a priori* knowledge, for instance by intersecting the current automaton with one that (i) forced certain substrings of the DA to appear in the target (improving recall), and (ii) prevented certain substrings to appear twice (improving non-redundancy).[8]

[8] One important potential advantage of the background approach over reranking is that it operates more locally and can be used in situations where a reranker would need to filter among a myriad of not-so-good candidates; additionally, the background is exploited by the adaptor when learning the parameters θ. We note also that the background approach does not require b to be realized by an automaton, but can be realized by any predefined process of the form described in (1).

Abstract

Readers usually rely on abstracts to identify relevant medical information from scientific articles. Abstracts are also essential to advanced information retrieval methods. More than 50 thousand scientific publications in PubMed Central lack author-generated abstracts, and the relevancy judgements for these papers have to be based on their titles alone. In this paper, we propose a hybrid summarization technique that aims to select the most pertinent sentences from articles to generate an extractive summary in lieu of a missing abstract. We combine i) health outcome detection, ii) keyphrase extraction, and iii) textual entailment recognition between sentences. We evaluate our hybrid approach and analyze the improvements of multi-factor summarization over techniques that rely on a single method, using a collection of 295 manually generated reference summaries. The obtained results show that the hybrid approach outperforms the baseline techniques with an improvement of 13% in recall and 4% in F1 score.

1 Introduction

PubMed Central[1] (PMC) is a repository of biomedical and life sciences journals supported by the U.S. National Library of Medicine (NLM). PMC provides access to the abstracts as well as the full-text content of biomedical articles. The open-access subset of PubMed Central contains over one million biomedical articles as of Fall 2015, and is widely used as a public resource to discover, read and build upon its vast portfolio of biomedical knowledge. Given the abundance and variety of information available within PMC, many user queries return a multitude of results, which makes it more difficult to identify relevant data. The amount of potentially relevant results often increases further due to information retrieval techniques such as query expansion using synonyms.

Article abstracts are usually considered to be entry points into the full-text. Abstracts often contain key health-outcome data and clinical findings that help identifying relevant data when narrowing down the number of returned results to a select few. The abstracts, however, are missing in 50,000 articles available within the open access subset of PMC. Therefore, for this large set of articles, the only way for the users to judge the relevancy of an article is either through the article title, which is not always reliable, or through the full-text of the paper, which can be time-consuming.

In this paper, we describe a novel hybrid approach that builds upon textual entailment, keyphrase extraction and health outcome detection to generate surrogate abstracts for biomedical articles where none are available. Using a set of 295 documents and manually generated extractive summaries that we make publicly available with this publication, we also analyze how this approach compares to baseline methods relying on a single technique.

2 Related Work

Single and multi-document text summarization of biomedical articles received much attention over the years. Lloret *et al.* developed COMPENDIUM, a text summarization system for generating abstractive and extractive summaries for individual biomedical papers (Lloret et al., 2013). They observed that

[1] http://www.ncbi.nlm.nih.gov/pmc

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1093–1100, Osaka, Japan, December 11-17 2016.

extractive methods are as effective as abstractive summarization or text generation. Kim *et al.* proposed a sub-topic or theme detection method for multi-document clustering and topical summarization of citation data (Kim et al., 2015).

Previous work shows that Recognizing Textual Entailment (RTE) can provide effective information for text summarization. RTE is the task of recognizing an inference relation between two sentences expressing the fact that the meaning of one sentence is entailed by the other (Androutsopoulos and Malakasiotis, 2010; Dagan et al., 2013). In particular, Entailment-based minimum vertex cover method (Gupta et al., 2014) is an RTE method for single document summarization using graph-based algorithms. Textual entailment and logic segmentation based methods also improved performance for single document summarization (Tatar et al., 2008).

Keyword identification methods were also used in single and multiple document summarization and document clustering (Frigui and Nasraoui, 2004; Hammouda et al., 2005), as well as summary generation based on the salience of sentences (Erkan and Radev, 2004). A more detailed survey of summarization methods is presented in (Nenkova and McKeown, 2012).

In this paper, we propose a novel hybrid approach that combines both textual entailment and keyword extraction for the construction of relevant extractive summaries. We particularly show that such combination yields more comprehensive and informative summaries for a variety of documents. Another contribution of our work is a manually created collection of summaries for 295 documents that have no author-generated abstracts. The summaries created by two experts are released with this paper.

3 Methods

In this section, we first describe three baseline methods for abstract generation, where the abstract is generated by combining the top five scoring sentences according to each method, in the order in which they appear in the original text. Second, we describe our method for the recognition of entailment relationships between sentences. Thereafter, we present our hybrid approach that aggregates the best-performing baseline methods and exploits textual entailment relationships in the article full-text to enrich the set of selected sentences.

3.1 Summary Generation based on Health Outcome Identifier (HO)

We used an existing Health Outcome identifier, previously shown to perform well on extracting health outcomes, also called bottom-line, from PubMed abstracts (Demner-Fushman et al., 2006). The health outcome detector employs an ensemble of rule-based, Naïve Bayes, n-gram based, position based, document-length based and semantic classifiers to compute the likelihood scores for each sentence in the article to contain a health outcome. The rule-based classifier analyzes each sentence for existence of cue phrases such as "significantly greater" and "dropout rate". The Naïve Bayes classifier generates a likelihood score based on a bag of words representation of the sentence. The n-gram based classifier looks for uni- and bi-grams that provide a high information gain measure and are strong positive predictors of outcomes such as "superior" and "especially useful". Positional and document length classifiers factor the position of a given sentence in the supplied text and the length of each sentence to provide probability estimates for containing health outcomes. The semantic classifier uses the results of a biomedical concept-extractor that detects presence of biomedical concepts belonging to outcome-related semantic types, such as diseases, symptoms, and medications, within the sentence and concept discovery information from previous sentences to generate a likelihood score. Finally, the probability scores from each classifier are combined to compute the final score $S(x)$ for each sentence x:

$$S(x) = \sum_{k=1}^{n} \alpha_k P_k(x)$$

Where P_1(x), ..., P_n(x) are the probability scores from various classifiers and (α_1, ..., α_n) are the coefficients or weights used to add the likelihood scores.

3.2 Summary Generation based on Keyphrase Extraction

A *keyword* is "a single word that is highly relevant" and a *keyphrase* is "a sequence of two or more words that is considered highly relevant". Our two remaining baseline methods for summary generation are inspired by (Luhn, 1958; Edmundson, 1969) and identify salient sentences to be selected based on detection of keywords or multi-word keyphrases. More precisely, the task is to identify "key sentences" within a given text, defined as the sentences that contain more keyphrases or keywords compared to others. Each method uses a different algorithm for extracting keyphrases from a given text. The extracted keyphrases are then normalized before being used to generate a score for each sentence, using the frequency of contained keywords. The two methods are described below.

3.2.1 Keyphrase Extraction with KEA

The Keyphrase Extraction Algorithm (KEA), developed by (Witten et al., 1999), uses a Naïve Bayes classifier to identify key phrases within text and a discretization scheme developed by (Fayyad and Irani, 1993) based on Minimum Descriptor Length Principle. The algorithm first splits the input text into phrase boundaries, based on punctuation and word boundaries, to look for sequences of words of length up to three to be used as candidate phrases for further examination. Candidate phrases that end in a stopword or occur only once in the text are dropped. Next, the Naïve Bayes model is used on each candidate phrase with feature values t (for $TF \times IDF$) and d (for $distance$) to compute probabilities $P[yes]$ and $P[no]$ that candidate phrase is a keyphrase in the document. The overall probability that the candidate phrase is a keyphrase is then calculated as:

$$p = \frac{P[yes]}{(P[yes] + P[no])}$$

Finally, candidate phrases are ranked according to the above value and the top n keywords are returned, where n is the number of requested keywords. In our experiments, KEA was restricted to output no more than 15 keyphrases per document.

3.2.2 Keyphrase Extraction with Microsoft Text Analytics (MSTA)

The Microsoft Azure Machine Learning suite provides access to Text Analytics web services, which is based on Microsoft Office's sophisticated Natural Language Processing toolkit. MS Text Analytics was used in our experiments to extract keyphrases from the full-text article. For our task, parts of article text were broken into chunks of successive sentences up to 1000 characters long to support the web-service requirement of maximum text length per individual request.

3.2.3 Keyphrase Normalization and Sentence Ranking

Before sentence ranking, a normalization step is performed to remove selected keywords that also occur as complete words within other keyphrases. Acronyms with all uppercase characters are always selected and not filtered during the normalization step. An example of the keyword normalization step is shown below:

$$microCT\ scans,\ microCT \longrightarrow microCT\ scans$$

$$Italian\ Purine\ Clubs,\ Italian\ Purine,\ Purine\ Clubs \longrightarrow Italian\ Purine\ Clubs$$

Once the keyphrase normalization is complete, article sentences are ranked in the order of keyphrase frequency, counting multiple occurrences of the same keyphrase as one. The keyphrase frequency, i.e. the number of keyphrases contained in each sentence is later used to identify target areas of the article text that are relatively more informative compared to others.

3.3 Hybrid Approach Using Baseline Methods and Textual Entailment

Our hybrid approach uses the output of both Health Outcome identification method and KEA keyphrase extraction method to identify a set of candidate sentences, C, as an initial summary. The next factor in the hybrid approach is based on inference relations obtained by recognizing textual entailment between article sentences.

3.3.1 Recognizing Textual Entailment

Textual entailment between two sentences of the same article is recognized using a feature-based classifier. We use a set of similarity measures as learning features. We will refer to it as SimSet in the remainder of the paper.

For a sentence pair (S_1, S_2), three features are computed after stopword removal and word stemming. The first feature is the word overlap between S_1 and S_2. The second feature is the Dice coefficient based on the number of common bigrams. The third feature is the maximum similarity value between five similarity measures: Levenshtein distance, Dice coefficient, Jaccard similarity, Cosine and Word Overlap.

We trained our RTE classifier on the SNLI corpus (Bowman et al., 2015) which contains 570K sentence pairs annotated with three labels: entailment, contradiction and neutral. The authors showed that the size of this corpus allows lexicalized classifiers to outperform some existing sophisticated entailment models. Also, the tested RNN models (a plain RNN and an LSTM RNN) and the feature-rich/lexicalized model show similar performance when trained on the full corpus.

In the scope of our study, we converted the contradiction and neutral labels to the same non-entailment class. Table 1 presents the results of our classifier using the SVM and Logistic Regression algorithms. We apply our RTE method to all possible sentence pairs in each article of our collection.

Classifier	**Accuracy**
SimSet (SVM)	75.86
SimSet (Logistic Regression)	75.64
Lexicalized classifier (Bowman et al., 2015)	75.00

Table 1: 2-class test accuracy on the SNLI corpus for recognizing textual entailment.

3.3.2 Improving Summaries Using Textual Entailment Graph Traversal

The extracted entailment relations are used to generate one or more directed graphs. The vertices V in these directed graphs are the article sentences for which entailment is detected, and the edges E represent directional entailment relations.

The next step involves iterating over each candidate sentence, $C_i \in C \cap V$, involved in at least one entailment relation and selected by the baseline systems. The sub-graph starting at node C_i is then traversed to check if there exists a sentence $V_j \neq Ci$ directly entailed by C_i, or indirectly entailed through a descendant of C_i such that $f(V_j) > f(C_i)$, for a given function f. If such a sentence is found, and has not been previously selected during similar optimization, then V_j is recorded to replace C_i in the final summary.

After the above iteration has been performed for each sentence in $C \cap V$, any unexplored graphs, formed by vertices $V_{rem} \subseteq V - C$ and disjoint from the candidate sentences obtained in earlier steps, are explored beginning from the source node to select additional sentences (one sentence for each disjoint entailment graph). This helps in the enrichment of the final summary by selecting vital hypothesis chains missed by the baseline systems. This allows addressing scenarios where the entailment relations discovered in the article involve other sentences that were not previously selected by the baseline systems, i.e. $C \cap V = \varnothing$. For our various experiments, function f was designed to prefer: i) shorter sentences (Hybrid MinLength), ii) longer, more informative sentences (Hybrid MaxLength) and iii) sentences with higher scores from baseline systems (Hybrid MaxScore).

4 Experiments & Discussion

4.1 Evaluation Dataset

Our experiments were conducted on 295 articles (the evaluation dataset) taken from the open-access subset of PMC. We picked a predetermined number of articles at random from 16 different article types, a classification provided by PMC for each article (e.g., research article, patient's case description or review articles) to ensure a diverse evaluation collection. Table 2 shows the breakup of our evaluation

dataset by article type. We note here that the articles selected for evaluation did not contain author-generated abstracts, so we had to manually generate a reference set of extractive summaries ("Golden Summaries") to be used in the evaluation of the baseline and hybrid system generated summaries.

Table 2: Article Type counts in the Evaluation Dataset.

4.2 Manual Extraction of Reference Summaries

Two experts, a clinician trained in medical informatics and a medical librarian, were asked to extract "golden summaries" from the articles in the evaluation dataset. Articles of various types were uniformly distributed between the human evaluators. The task was to identify and select key article sentences from the article text. The preferable length in number of sentences for reference summaries was set at 10 sentences, but the system allowed human evaluators to override this limit and adjust it to the minimal length needed to capture all key points of an article. It is important to specify here that manually extracting and compiling reference summaries is highly laborious and required the experts to read the supplied articles, hence being more time-consuming than using author supplied abstracts for evaluations. Figure 1 shows our sentence selection interface for reference summary extraction.

The manually extracted reference summaries are available for download at `https://archive.nlm.nih.gov/ridem/infobot_docs/reference-summaries{.zip,.tar.gz}`

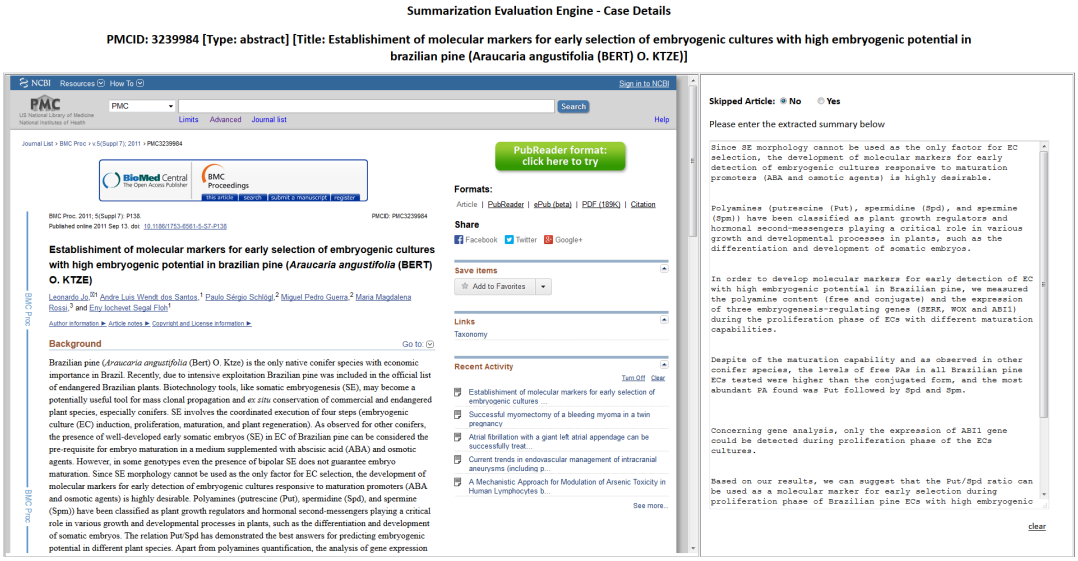
4.3 Judging Baseline System Summaries for Content and Coverage

An additional evaluation task for the human evaluators was to judge the summaries generated by the three baseline systems for content coverage and potential usefulness by rating the baseline summaries on a scale of 1-5 (1=Not at all, 5=Perfect) for the below criteria:

- Is the summary informative?
- Does the summary reflect the most important issues?
- Does the summary capture the bottom-line?

For this task, the generated summaries from three baseline systems were presented to the human evaluators unlabeled and in random order. Table 3 shows for each baseline system the number of articles where the evaluators judged the baseline system summary as acceptable or better (Score, $S_{criterion}$, greater than or equal to 3) for each of the above mentioned criteria. Figure 2 shows our interface for recording such judgements.

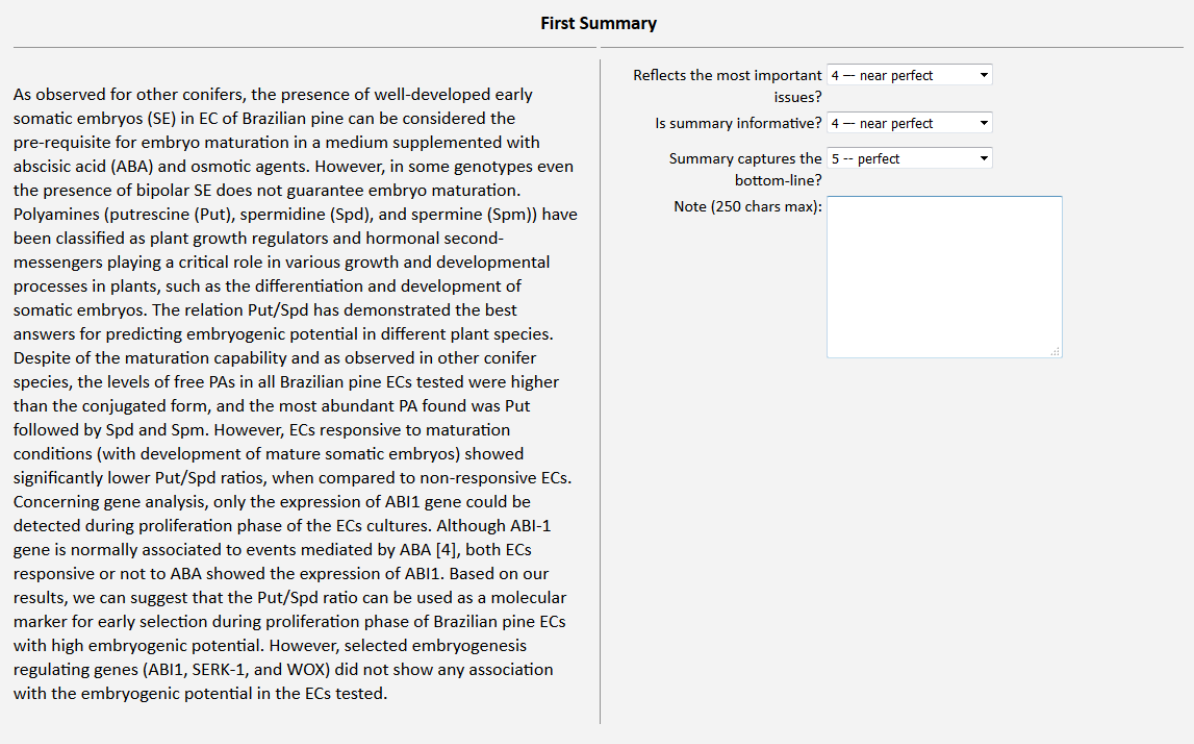
Figure 1: Interface for reference summary sentence selection.



System	Informative ($S_{info} \geq 3$)	Overall Rating ($S_{imp.issues} \geq 3$)	Bottom Line ($S_{bottom} \geq 3$)
HO	242	208	228
KEA	258	228	181
MSTA	244	212	155

Table 3: Manual evaluation of the automatically generated baseline summaries.

Figure 2: Interface for the evaluation of unlabeled baseline summaries.



Based on the preliminary results shown above and the Rouge-2 scores provided in the next section, we decided to base our hybrid approach on the HO and KEA baseline systems and to further improve the combined summaries using Textual Entailment relations recognized in the article text.

4.4 Rouge-2 Evaluation of Generated Baseline and Hybrid Summaries

In addition to manual evaluation of the baseline summaries, we compared them with the hybrid summaries as whole paragraphs to human extracted "golden summaries" using the recall based evaluation metric ROUGE-2 (with stopword removal) for automatic overlap measurement. Table 4 and Table 6 present the Rouge-2 results for the baseline systems and hybrid systems respectively.

System	R (%)	P (%)	F (%)
HO	27.97	27.96	27.13
KEA	28.42	29.44	28.03
MSTA	24.90	20.71	21.99

Table 4: ROUGE-2 evaluation results for summaries generated by baseline systems.

We also tested for, and observed a low overlap between baseline summaries generated by HO and KEA-based systems, which indicates that a hybrid approach could be more comprehensive and likely to outperform individual systems in terms of content recall and coverage. We also observed that in 46 of 130 cases in which an entailment relation was present, our feature-based RTE classifier was able to correctly identify at least one relation involving a sentence that was also selected as prominent by human evaluators. Table 5 presents the summary overlap between baseline systems and inter-annotator agreement.

System	R (%)	P (%)	F (%)
HO Vs. KEA	21.85	19.69	20.21
Inter-Annotator	46.33	42.99	43.47

Table 5: ROUGE-2 results for HO and KEA summary overlap and inter-annotator agreement.

System	R (%)	P (%)	F (%)
Hybrid MinLength	38.82	27.88	31.73
Hybrid MaxLength	41.76	27.41	32.18
Hybrid MaxScore	39.87	27.71	32.88

Table 6: ROUGE-2 evaluation results for summaries generated hybrid systems.

4.5 Discussion

Using a hybrid approach to abstract generation significantly improved the recall while still providing similar precision values, despite the fact that hybrid summaries are generally longer compared to baseline systems. More generally, our experiments show that combining multiple single-factor techniques like keyword extraction, health outcome detection and utilizing semantic relations in text using textual entailment works well for different kinds of articles, and is more likely to outperform traditional baseline approaches for text summarization.

5 Conclusion

We presented a new hybrid approach combining textual entailment and keyword extraction for the summarization of biomedical articles. Our results show that such combination yields substantial improvement in recall while maintaining the precision at the same level. In future work, we plan to incorporate named entity recognition and use the extracted named entities as additional keywords to improve precision and to apply a similar approach to multi-document summarization.

Abstract

Natural language generation (NLG) is the task of generating natural language from a meaning representation. Rule-based approaches require domain-specific and manually constructed linguistic resources, while most corpus based approaches rely on aligned training data and/or phrase templates. The latter are needed to restrict the search space for the structured prediction task defined by the unaligned datasets. In this work we propose the use of imitation learning for structured prediction which learns an incremental model that handles the large search space while avoiding explicitly enumerating it. We adapted the Locally Optimal Learning to Search (Chang et al., 2015) framework which allows us to train against non-decomposable loss functions such as the BLEU or ROUGE scores while not assuming gold standard alignments. We evaluate our approach on three datasets using both automatic measures and human judgements and achieve results comparable to the state-of-the-art approaches developed for each of them. Furthermore, we performed an analysis of the datasets which examines common issues with NLG evaluation.

1 Introduction

Natural language generation (NLG) is the task of generating natural language from a machine-interpretable meaning representation (MR). Traditionally, NLG systems tend to be rule-based and require domain-specific language resources (i.e. sentence plans, aggregation rules, ordering information, etc.) to be manually authored for a particular task, e.g. weather reporting (Reiter et al., 2005), route navigation (Dale et al., 2003), or ontology descriptions (Bontcheva and Wilks, 2004; Androutsopoulos et al., 2013).

From a machine learning perspective (ML) perspective, NLG is a complex structured prediction task due to its large output space, which is the set of all possible NL utterances. To limit the output space, many ML-based approaches rely on aligned training datasets (Mairesse et al., 2010; Dethlefs et al., 2013) that specify the words that each MR element is responsible for, and phrase templates. While these enable a variety of models to be trained, their applicability is restricted as they need additional manual annotation.

More recently, ML-based approaches focused on learning NLG models from unaligned training data. Dušek and Jurcícek (2015) learn how to incrementally generate deep-syntax dependency trees of candidate sentence plans specifying which MR elements to be mentioned and the overall sentence structure, however the surface realization (i.e. the actual NL word generation) is performed using rules based on the frames of an English-Czech dependency treebank, a resource that may not be available for certain domains or languages. In another approach, Wen et al. (2015) use a Long Short-term Memory (LSTM) network to learn from unaligned data and jointly address sentence planning and surface realization. They augment each cell of the LSTM with a gate that conditions it on the input MR. However the LSTM is trained using cross-entropy at the word level, thus unable to take into account interactions among the word being considered and words to be predicted later in the sentence, an issue which was ameliorated by training a backward LSTM to re-rank the best-scoring outputs generated by the forward one.

In this paper, we propose an ML-based approach that learns sentence planning and surface realization from unaligned training data using the imitation learning Locally Optimal Learning to Search (LOLS)

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1101–1112, Osaka, Japan, December 11-17 2016.

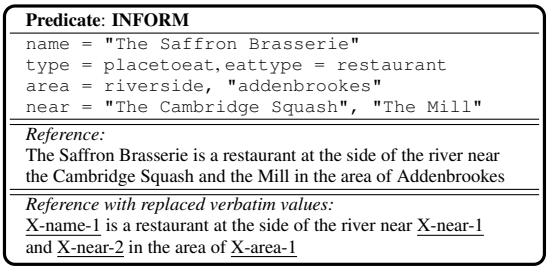

Figure 1: Sample MR and corresponding NL utterance from the BAGEL dataset.

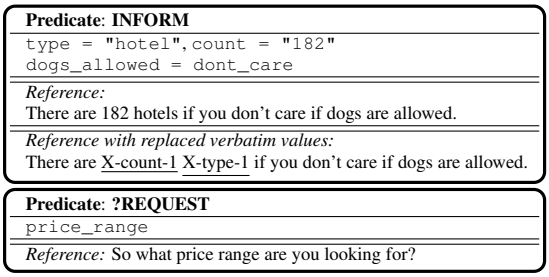

Figure 2: Sample MRs and corresponding NL utterances from the SF datasets.

framework (Chang et al., 2015). Similar to other imitation learning algorithms for structured prediction such as DAGGER (Ross et al., 2011), LOLS reduces structured prediction to classification with greedy inference thus avoiding the enumeration of all outputs, while also ameliorating the issue of error propagation. Unlike other structured prediction frameworks, LOLS is able to learn using non-decomposable loss functions. Thus it is well-suited to learning NLG systems where measures such as BLEU (Papineni et al., 2002) or ROUGE (Lin, 2004) that do not decompose over single words are commonly used for evaluation. Thus we are able to learn the interactions of the word currently being predicted with those to be predicted later in the sentence. We further propose a variant of LOLS using sequence correction and updates (Collins and Roark, 2004), and an exponential decay schedule (Daumé III et al., 2009) . We compare against the systems by Dušek and Jurcícek (2015) and Wen et al. (2015) on their respective datasets (three datasets across two domains) and show that the NLG system proposed achieves comparable results in both automatic and human evaluations.[1]

2 Natural language generation

The NLG process takes as input a meaning representation (MR) consisting of a predicate followed by an unordered set of attributes and corresponding values; the output is a NL sentence. Figures 1 and 2 show samples from the BAGEL (Mairesse et al., 2010) and SF datasets (Wen et al., 2015) that we are considering in this work. The predicates in each MR are utterance-level labels that represent the overall function of the utterance, e.g. whether the utterance should *inform* the user of the attributes and values, or whether it should *request* them from the user. Each attribute may have multiple values, which may be either strings that appear verbatim in the references (e.g. "the Saffron Brasserie", "hotel"), constants from a controlled vocabulary (e.g. `placetoeat`), or boolean (e.g. `yes`, `no`).

We preprocess the MR-NL pairs by replacing verbatim strings with variables ("X-") in the MRs and NLs, which results in the same delexicalized MR paired with multiple NL references (see Figures 1 and 2). Note that the second MR in Figure 2 contains no verbatim strings, and its reference is not modified. Multiple references for the same MR can be beneficial since they capture lexical variation for the same meaning, but also pose a challenge to model learning as they provide ambiguous training signal.

We formulate the generation of a NL utterance from a MR as a sequence of two types of actions, content prediction actions a_c and word prediction actions a_w (Alg. 1). To generate an NL utterance, each content prediction action selects which attribute c should be expressed next; in the case of multiple-valued attributes, one value is chosen based on their order of appearance in the training data. Once the content prediction action sequence is completed, for each selected attribute c, we generate a sequence of words chosen from its corresponding dictionary D_c. This dictionary consists of all the words that we have observed to co-occur with attribute c in the training data. Content and word prediction have special termination actions (END_{attr} and END_{word} respectively). The generation process can stop without exhausting all attributes in the MR thus making it possible to omit information deemed redundant (e.g. that a restaurant is a place to eat). From the action sequence produced, it is straightforward to derive the final sentence by keeping the word prediction actions; the content prediction actions are discarded.

[1] All code is available at `https://github.com/glampouras/JLOLS_NLG`

Algorithm 1: NLG process

Input: meaning representation MR with set of attributes C, attribute dictionaries $D_c, \forall c \in C$
Output: action sequence A

do
  predict attribute $c \in C \cup \{END_{attr}\}$ and append a_c to A_c
  remove c from C
while $a_c \neq END_{attr}$
for a_c *in* A_c **do**
  do
    predict word $w \in D_c \cup \{END_{word}\}$ and append a_w to A_w
  while $a_w \neq END_{word}$
$A = (A_c, A_w)$

Fig. 3 illustrates the action sequence to generate the NL sentence for the MR of Figure 1. The first set of actions is to choose amongst the attributes (`eattype`, `name`, `near`, or the content termination action END_{attr}), and if necessary also choose which value to express (e.g. for `area`, either `riverside` or `X-area-1`). Following this, for each chosen attribute and value we generate an appropriate sequence of word prediction actions (e.g. "at", "the", "side", "of", "the", "river") followed by the END_{word} action denoted by "|" (top part of Fig. 3). Content prediction actions are only used indirectly to generate the sentence; thus different sequences can result in the same sentence, as shown in the bottom part of Fig. 3.

The NLG process defined in this section assumes we train two types of classifiers, one for the content prediction actions and one for word prediction actions for each attribute. If we had alignment information, it would be possible to extract data to train both types of models, either independently (Angeli et al., 2010) or jointly. However, we do not assume access to such information. Instead, we take advantage of the ability of imitation learning algorithms such as LOLS to learn with non-decomposable loss functions by only needing to evaluate complete output predictions instead of individual actions. In NLG's case, this means we do not require explicit supervision for the content and word prediction actions, but only a way to evaluate complete generated sentences against the reference using measures such as BLEU.

3 Locally Optimal Learning to Search

Here we describe how we learn the content and word classifiers we introduced in Section 2. As input to the algorithm (Alg. 2), we assume a set of training instances $\mathcal{S}$ and a loss function ℓ that compares complete NL sequences generated for MRs in $\mathcal{S}$ against references for that MR, e.g. using BLEU or ROUGE. In addition, an expert policy π^{ref} must be specified which will be acting as an oracle during training, returning the best content or word action possible given the words predicted already and the gold standard NL reference for the instance. We describe the expert policy and loss function in detail in separate subsections. Finally, the learning rate β is also part of the input. The output is a learned policy consisting of one classifier for content prediction and one classifier for word prediction for each attribute c, whose label set is the attribute dictionary D_c. These classifiers are learned using a cost-sensitive classification (*CSC*) learning algorithm (*CSCL*). In *CSC* each training example has a vector of misclassification costs, thus rendering some mistakes on some examples more expensive than others.

Before the training iterations begin, a policy π_0 (i.e. content and word classifiers) is initialized on

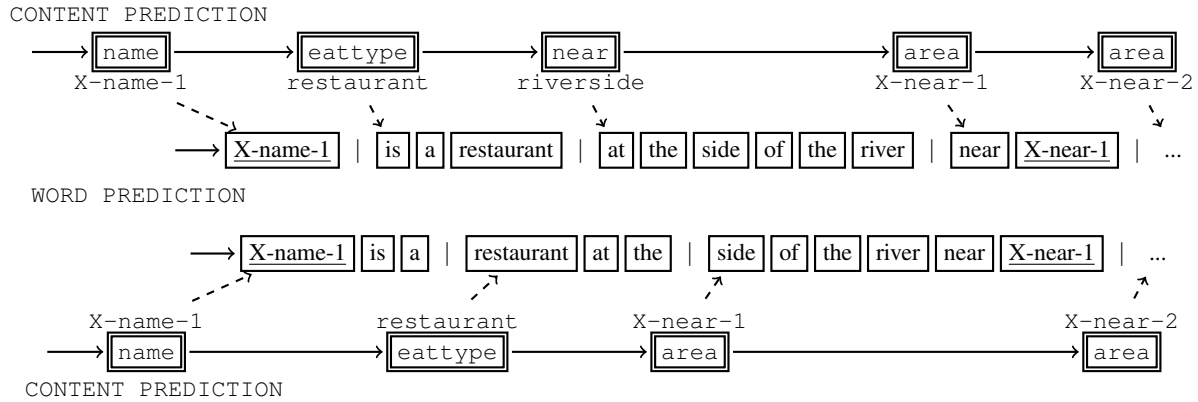

Figure 3: NLG process example with two different content and word prediction action sequences.

Algorithm 2: Locally Optimal Learning to Search (LOLS) for NLG

Input: training instances $\mathcal{S}$, expert policy π^{ref}, loss function ℓ, learning rate β, CSC learner *CSCL*
Output: Learned policy H_N

1 Initialize a policy π_0
2 **for** $i = 0$ **to** N **do**
3 CSC examples $E = \emptyset$
4 $p = (1 - \beta)^i$ // exponential decay
5 **for** s ***in*** S **do**
6 Predict A by executing $\pi_i(s)$ // roll-in
7 **for** *action* a_t ***in*** A **do**
8 Let $\pi^{out} = \pi^{ref}$ with probability p, otherwise $\pi^{out} = \pi_i$
9 **foreach** *possible action* a_t^j **do**
10 $a\prime_{t+1:T} = \pi^{out}(s; a_{1:t-1}, a_t^j)$ // roll-out
11 Assess $c_t^j = \ell(a_{1:t-1}, a_t^j, a\prime_{t+1:T})$
12 Create a feature vector $\Phi_t = f(s, a_{1:t-1})$
13 Add (Φ_t, c_t) to E
14 Set $a^\star = a_t^j$ with minimum c_t^j // find best possible action
15 **if** $a_t \neq a^\star$ **then**
16 evaluate only the next E actions $a_{t+1} \dots a_{t+E}$ **in** A
17 then replace A by executing π^{ref} for actions $a_{1:t+E}$
18 and $\pi_i(s)$ for actions $a_{t+E+1:T}$ // sequence correction
19 Learn $\pi_{i+1} = CSCL(\pi_i, E)$ // update
20 $H_N = avg(\pi_0, \dots, \pi_N)$

the training data. For every instance s of the training data S, the algorithm predicts an action sequence $\{a_0 \dots a_T\}$ (line 6, roll-in) using the learned policy π_i of the previous iteration (if it is the first iteration, this is the initial learned policy π_0), using the NLG process defined in Alg.1. At each timestep t of this sequence, the algorithm considers all actions a_t^j that the (content or word) classifier could take (line 9). In order to estimate the cost of each action a_t^j, the algorithm produces an action sequence $\left\{a_{1:t-1}, a_t^j, a\prime_{t+1:T}\right\}$ (line 10, roll-out) assuming action a_t^j was taken, and assesses it according to the loss function ℓ (line 11). Thus the algorithm learns whether to select an attribute or generate a word by taking the corresponding action and assessing its effect on the quality of the complete NL. A *CSC* training example is generated from these costs (line 12-13), which will be used to update the appropriate classification model in the learned policy. The features Φ_t are extracted from the input MR and all previous actions and the partial NL corresponding to them (line 12) thus capturing (possibly long-range) dependencies between actions. Finally, all the policies trained at the end of each iteration are averaged into a final policy (line 19). The learned policies consisting of classifiers, unlike the expert policy π^{ref} which is available only for the training instances, can generalise to unseen data.

When examining all possible actions, the algorithm generates the rest of the alternative sequence (roll-out) $\{a\prime_{t+1:T}\}$ according to either the expert policy π^{ref} or the learned policy π_i, depending on the probability p. In its original specification (Algorithm 1 by Chang et al. (2015)), LOLS chooses which policy to use for each roll-out separately (π^{out} is set inside the foreach loop) and may use a different policy to perform the roll-out for each possible action, but we use the same policy (expert or learned) for all actions to ensure that their costs are calculated consistently. We update this probability p (line 4) at the start of each training iteration, according to the learning rate β. Chang et al. (2015) set this probability to a fixed value throughout all iterations, but we opted to follow SEARN's exponential decay schedule (Daumé III et al., 2009), to increasingly move away from the expert policy as we found it to work better in initial experiments; we discuss this further in section 4.2. By gradually decreasing the use of π^{ref} in the roll-outs, the costs used to train the classifiers are adjusted to their own predictions, thus teaching them to predict actions jointly.

3.1 Expert policy

The expert policy π^{ref} is invoked when assessing possible actions using roll-outs (line 10). Given the sequence of actions already taken $\{a_0 \dots a_t\}$, it acts as an oracle that returns the best possible action

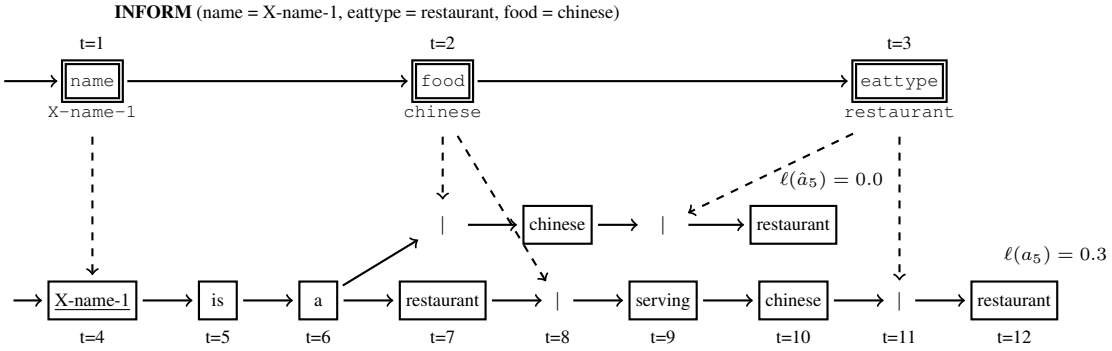

Figure 4: LOLS roll-in (bottom) and roll-out (upper branch) trajectories. Content and word actions are in single and double boxes respectively.

to take, according to the NL reference for the training instance. If a word action is to be predicted by the expert policy we locate the word that makes the sequence (ignoring content actions) best match (i.e. minimize the loss function to) the NL reference. In order to return content actions though, an optimal expert policy would need access to alignments between the MR and the NL reference, which we assume we don't have. Instead, we define a simple heuristic alignment approach that augments the training data with noisy alignments, resulting in a suboptimal expert. LOLS is particularly suitable for this as it can learn with suboptimal expert policies (Chang et al., 2015). This is due to assessing the costs for all possible actions via roll-outs evaluated using the loss function against the (gold) reference, from which the classifier can learn to prefer actions that could contradict those returned by the expert policy. Additionally, in LOLS there is no per-time step mixing of expert and learned policies (i.e. all actions in a single roll-out are predicted by either the expert or the learned policy), which makes designing the expert policy much simpler overall; this is important in tasks like NLG where the optimal action changes drastically when mistakes happen, which is unlike tasks like POS tagging.

The naive alignment used in the expert policy uses the following heuristics. The verbatim values of the MR are simply aligned with their occurrences in the NL reference. The constant values are compared with all unaligned word n-grams in the reference, and aligned with the most similar one according to their character-based Levenshtein distance. For boolean attributes, or attributes with the `dont_care` value, we compare the attribute name with the unaligned n-grams (e.g. aligning `dogs_allowed="yes"` to "allows dogs") instead of the value. Finally, inferred alignments are expanded to unaligned words on the right and left side of the sequence until an already aligned word (or punctuation) is found.

Figure 4 illustrates how examining all possible actions at each time step can overcome the errors in the naive alignments. The content sequence has already been predicted (top of the figure), and at timestep $t = 7$, the classifier returns action $a_7 =$ "restaurant". However, later on the sequence we need to predict words for the attribute `eattype`, for which the classifier (due to the naively aligned training data) is likely to repeat the word "restaurant" leading to an unnatural utterance. So, given this action ($\hat{a}_7 =$ "restaurant"), the resulting sequence has a cost of $\ell(a_7) = 0.3$. By examining all possible actions, the algorithm can surmise that if the classifier stops generating words about the current attribute ($\hat{a}_7 =$ "restaurant"), it would lead to a more natural utterance, and hence a lower loss ($\ell(\hat{a}_7) = 0.0$) which will update the learned policy accordingly. An alternative course of action would be for the classifier to learn to stop generating words about the attribute `eattype` at action $\hat{a}_{12} =$ "restaurant".

3.2 Loss function

In LOLS the loss function is only used to compare complete action sequences against references (line 11). Therefore, it does not need to decompose over individual actions and allows us to use measures like BLEU (Papineni et al., 2002) or ROUGE (Lin, 2004) as loss functions. These measures can consider multiple references for the same MR, which is useful in learning lexical variation, i.e. multiple ways of expressing the same meaning. The loss function is used to assess roll-outs obtained by both learned and expert policies when assessing both action types. In this way, content actions, which are ignored by the loss function, are evaluated based on their impact on word predictions that follow them. When invoking

the expert policy for content actions, the loss function only checks if the reference contains the attributes in the roll-out. We examine the impact of various loss functions in section 4.2.

Additionally, the loss function penalizes actions that are certain to lead to undesirable behavior, i.e. repeating words, producing a termination action without having generated anything, predicting attributes not present in the MR, or attributes whose dictionary does not contain the word(s) that should follow.

3.3 Sequence correction

Another modification we introduced to the original LOLS algorithm is sequence correction in which soon after the first suboptimal action a_t (i.e. not having the minimum cost among those possible) of the roll-in trajectory is encountered (lines 14-18), we attempt to correct the errors encountered so far in the sequence before examining further actions. We allow the algorithm to examine at most E actions ($a_{t+1} \dots a_{t+E}$) following the first suboptimal one (line 16) before re-predicting the roll-in trajectory using the expert policy π^{ref} up to and including the final examined action $a_{1:t+E}$, and using the policy π^{out} to predict the rest of the sequence $a_{t+E:T}$ (lines 17-18). We then proceed with examining the next action a_{t+E+1} of the new corrected sequence. If suboptimal actions are encountered further in the new sequence, sequence correction may again be performed and the sequence re-predicted.

We found this to be helpful in avoiding generating noisy *CSC* training examples. Consider the reference "'X-name-1 is a hotel that allows dogs" and the predicted (incorrect) partial output "X-name-1 is a dog". When assessing the action for the next word, it is likely that predicting "that" or "hotel" will result in lower cost than END_{word} since a loss function such as BLEU or ROUGE would reward the increased word overlap. Assuming that we extract the previous word as a feature in line 12, this would result in learning that predicting "hotel" after "dog" is beneficial. However, this appears to be the case due to the the loss function and the incorrect partial prediction. Correcting the sequence after we encounter the suboptimal word action "dog" to "'X-name-1 is a hotel" will provide the appropriate context for the next action's *CSC*; most of the features Φ_t are extracted from this context. The intuition is similar to the early updates in the incremental perceptron proposed by Collins and Roark (2004).

3.4 Comparison to other Imitation Learning frameworks

In previous subsections, we introduced three modifications to the LOLS framework: 1) the use of SEARN's exponential decay schedule when determining the π^{out} policy, 2) the use of the same policy (expert or learned) for actions in the same step of the sequence, instead of potentially using a different policy for each roll-out, and 3) using sequence correction when encountering suboptimal actions in the sequence.

The main difference of LOLS to other imitation learning frameworks is how the roll-in and roll-out predictions are performed. LOLS performs each roll-in deterministically using the expert policy π^{ref}, while the SEARN and DAGGER (Ross et al., 2011) frameworks roll-in using mixtures of the learned and expert policies; however, partially using the expert policy to roll-in limits those algorithms' capability to learn from the classifiers' mistakes. For roll-out, SEARN stochastically uses a mixture of the learned and expert policies, similarly to LOLS. DAGGER does not employ roll-outs, but uses the expert policy (also referred to as dynamic oracle) to "teach" the correct action to the classifier; this means that it cannot be used to learn using non-decomposable loss functions. Later, a variant of DAGGER, coined V-DAGGER (Vlachos and Clark, 2014), introduced roll-outs to the framework (again using a stochastic mixture of the two policies). AGGREVATE (Ross and Bagnell, 2014) uses a similar roll-in strategy to LOLS, but the expert policy is used exclusively for each roll-out; in the case of NLG, where the expert policy is suboptimal (see section 3.1), this may introduce noise to the classifier.

4 Data and experiments

4.1 Implementation details

We use the adaptive regularization of weight vectors (AROW) algorithm (Crammer et al., 2013) for cost-sensitive classification learning. We train separate content and word classifiers for each predicate, and predicate-attribute combination, respectively. Both types of classifiers (word or content action classifiers) exploit features from the immediately preceding words, attributes and attribute-value pairs, and from

language models estimated on the classifier's corresponding training data. They also consider features based on the input MR, such as which attributes and values have already been mentioned and which have not, and, specifically for the word classifiers, whether a word partly or wholly expresses a value.

During training, we also prevent the classifiers from generating more actions than what has been observed in the training data. Finally, the NL utterances are generated in a "delexicalized" form, but we replace the variables with the corresponding values in post-processing; this is the reverse procedure of replacing verbatim values with variables as shown in Figures 1 and 2. The same system is applied to all datasets discussed in the following sections, and its code will be publicly available upon publication.

4.2 Experiments with the SF datasets

The two SF datasets were created by Wen et al. (2015) and contain MRs about hotels and restaurants respectively.[2] The hotel dataset consists of 5,192 MRs with a single NL reference each. They contain 8 predicates (`inform`, `confirm`, etc.) and 12 attributes, some of them unique to each dataset. Each attribute can take at most one value (or be empty). Following Wen et al. (2015) we partitioned the data into a training, validation, and testing set in a 3:1:1 ratio. We also created multiple references for each validation and test MR as they did, by grouping all delexicalized references that correspond to the same delexicalized MR. We then repopulate the references according to the MR's values.

Figure 5 shows heat maps of BLEU-4 (top set) and ROUGE-4 (bottom set) scores our system achieved on the validation set of the SF hotel dataset for different values of the learning rate β and the sequence correction parameter E; the notation *"std"* denotes that no sequence correction was used in that configuration. The heat maps are also grouped by which loss function was used in each configuration. By comparing the best configurations, we can conclude that using sequence correction leads to slightly better results (a 1.56 difference on average in BLEU). In figure 6 we show how the learned policy is improved with each epoch of LOLS ($\pi_0 \ldots \pi_3$); note that figure 5 shows the best epoch of each configuration.

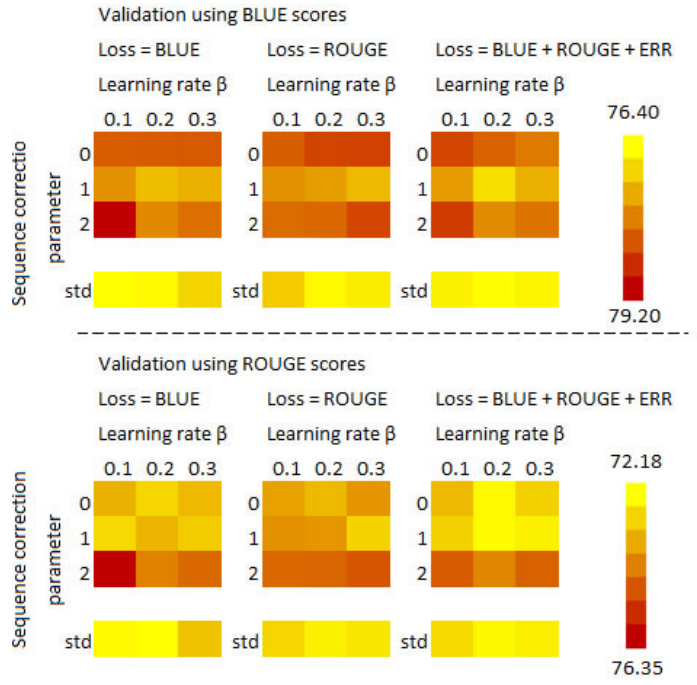

Figure 5: Result heat map for SF hotels across different parameters.

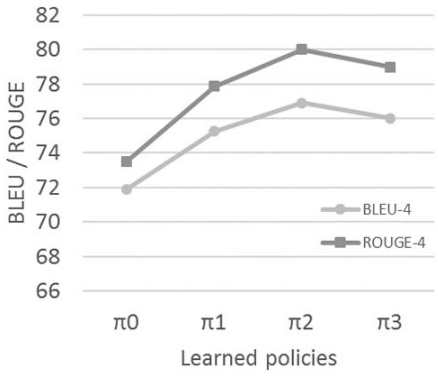

Figure 6: Result heat map for SF hotels across different parameters.

As loss functions to LOLS we tried BLEU-4, ROUGE-4, and the harmonic mean of BLEU-4, ROUGE-4 and ERR(%). In essence, BLEU measures the precision of the sentence's content while ROUGE measures the recall. We opted to use ROUGE-4 rather than other variants of ROUGE since it has been shown to

[2] SF is freely available for download at: https://www.repository.cam.ac.uk/handle/1810/251304

correlate better with human assessments in summarization tasks (Graham, 2015). ERR(%) measures what portion of the MRs is not expressed in the NL sentence; it is defined as the number of attribute-value pairs in the MR that are not expressed in the generated NL sentence to the total number of attribute-value pairs in the MR. We can map the values of the MR to the NL sentence similarly to how we calculate the naive alignments (see section 3.1). By comparing these loss functions on the heat maps of Figure 5, we find that there is very little difference between them (0.12 difference on BLEU, and 0.36 on ROUGE). We decided to use the harmonic mean in our experiments since it captures more information.

Additionally, we tried setting a fixed value to probability p (see line 4 in algorithm 2) as per Chang et al. (2015) instead of using SEARN's exponential decay schedule (Daumé III et al., 2009). When comparing the best configurations on the validation set (with no sequence correction), using a fixed value seems to be slightly worse than using an exponential decay schedule (0.89 BLEU difference in SF hotel).

To assess the impact of naive alignments (see section 3.1) on our system we tried initializing the policy π_0 on random alignments. In this case, the values of the MR are aligned with words in the NL reference randomly. Subsequently, the random alignments are expanded alternatively to unaligned words similarly to naive alignment expansion as described in section 3.1. The best configuration with random alignments, as expected, performs worse to using naive alignments (25.84 difference in BLEU), but LOLS still improves on the initial policy (5.49 improvement on π_0). While all results reported above are on the SF hotel dataset, similar conclusions can be drawn for the other datasets we examined.

	SF RESTAURANT								
	FULL TEST (1040 MRS)			UNIQUE (158 MRS)			NON-OVERLAPPING (13 MRS)		
	BLEU	ROUGE	ERR(%)	BLEU	ROUGE	ERR(%)	BLEU	ROUGE	ERR(%)
WEN	74.50	77.75	2.54	52.97	43.52	6.29	27.04	20.44	10.38
LOLS	66.01	64.56	0.15	49.44	38.52	0.58	28.21	21.47	0.00

	SF HOTEL								
	FULL TEST (1076 MRS)			UNIQUE (96 MRS)			NON-OVERLAPPING (11 MRS)		
	BLEU	ROUGE	ERR(%)	BLEU	ROUGE	ERR(%)	BLEU	ROUGE	ERR(%)
WEN	86.54	84.36	0.88	66.37	56.19	3.99	37.24	27.27	6.82
LOLS	80.00	76.88	0.25	68.65	68.37	0.52	33.31	27.01	3.63

Table 1: Results on the SF datasets.

Finally, we use the test set to compare against the results of Wen et al. (2015), while setting the parameters based on the validation set results. Our test set results are summarized in Table 1; we report BLEU-4, ROUGE-4, and ERR(%). The BLEU-4 and ERR(%) scores of Wen et al. (2015) have been updated after personal communication with them; both are now computed using the same implementation of the measures. The scores are calculated on the full test set, as well as two smaller subsets. The first subset consists exclusively of the unique MRs in the test set (i.e. no MR appears more than once in the unique subset). The results in the unique subset may be more indicative of a system's performance as the distribution of MRs in the test set is unbalanced, e.g. an extreme case in the full test set, is the MR `goodbye()` which appears 176 times. Comparing the two systems, we see that LOLS performs worse in terms of BLEU and ROUGE, but also has lower ERR(%); this indicates that our system tries to include more attributes in the NL sentences. However, when looking at the scores in the unique MR subset, the difference between the two systems narrows, with almost no difference in the SF hotel dataset.

Examining the test set further, we noticed that there is a big overlap between the training, validation and test sets when we consider the MRs in their delexicalized form (see sction 2). Given that both our and Wen et al. (2015)'s models are trained on the delexicalized forms of the training MRs that means that the evaluation is, in part, performed on MRs that have already been encountered during training. In an effort to more accurately assess how the models generalize to unseen input, we define a second subset of the test set, consisting of the unique MRs whose delexicalized version does not appear in either the training nor validation data (i.e. non-overlapping MRs). As it turns out, these are only 11 and 13 non-overlapping MRs in the SF hotel and restaurant datasets respectively. Comparing the two systems in this second subset shows little difference between them; however we cannot draw any conclusions as the subset is very small. We show below some output utterances from Wen et al. (2015)'s system and ours:

MR: inform(type=restaurant,count='239',good_for_meal=dont_care,food=dont_care)

WEN: I have found 239 restaurants serve any meal if the food type is not an issue.

LOLS: There are 239 restaurants if you do not care about the meal and food.

MR: inform(name='kean hotel',has_internet='no')

WEN: We're sorry, the Kean hotel does not have access to the internet.

LOLS: We're sorry, the Kean hotel does not have internet.

4.3 Experiments with the BAGEL dataset

The BAGEL dataset was developed by Mairesse et al. (2010) and contains 202 MRs, each corresponding to 2 NL references.[3] The dataset describes restaurants, and contains one predicate (`inform`) and 8 attributes (see Figure 1). Each attribute can take multiple values, which are either verbatim strings or constants.

	BLEU	ROUGE	NIST	ERR(%)
DUSEK				
Basic perceptron	52.35	46.43	4.777	23.90
+ Diff-tree upd.	56.75	50.82	5.137	25.10
+ Future promise	56.71	48.08	5.441	24.16
LOLS	54.22	47.39	5.547	16.66

Table 2: Results on the BAGEL dataset.

In this section we are comparing against Dušek and Jurcícek (2015), who based their work on the BAGEL dataset. We include results from three variations of their system, the first using only a perceptron to score the output, the second augmented with differing tree updates and the last with future promise estimations. Following their work, we use 10-fold cross validation, with no overlap between MRs in the training set and the test set; we obtained and use the same folds. Their scores have been recalculated using the same implementation of the measures we use. The BAGEL dataset has no separate development set, so we tuned our system's parameters using 10-fold-cross-validation as well.

Table 2 shows our results; we report BLEU-4, ROUGE-4, NIST (Doddington, 2002), and ERR(%). We have achieved better NIST scores than Dušek and Jurcícek (2015)'s, with slightly worse BLEU-4 and ROUGE-4 scores. Our lower ERR(%) suggests that our system includes more information (i.e. attributes-value pairs) into the sentences, which may account for the slightly worse BLEU and ROUGE scores. Another explanation for Dušek and Jurcícek (2015)'s performance is, as stated before, that their surface realization is performed using rules based on the frames of an English-Czech dependency treebank.

4.4 Human evaluation

To better assess the perceived quality of our system's output, we showed pairs of MRs and generated utterances for all datasets to 202 human judges, not involved in the work of this article. They were all fluent, though not native, English speakers. We generated 1076 + 1040 + 202 texts from the MRs of the SF hotel, SF restaurant, and BAGEL data sets using our NLG system, and also obtained the respective texts that Wen et al. (2015) and Dušek and Jurcícek (2015) generated in their work using their best configurations. Each MR and generated utterance was shown to (at least) three human judges, in random order. For each pair, the judges were asked to either score the generated utterance in terms of fluency, and informativeness; a scale from 1 to 6 was used. Each judge scored fluency and informativeness on separate sets of texts, to minimize correlation between the criteria. Among the texts that every judge scored, was a small subset of texts whose quality in regards to each other was known beforehand. We used that subset to filter out unreliable human judges that did not score these texts as expected.

	BAGEL		SF RESTAURANT		SF HOTEL	
	Dušek and Jurcícek (2015) + Future promise	LOLS	Wen et al. (2015)	LOLS	Wen et al. (2015)	LOLS
Fluency	5.15*	4.79*	4.49	4.23	4.41	4.68
Informativeness	4.53*	5.24*	5.29	5.36	5.36	5.19

Table 3: Human evaluation on BAGEL and SF datasets.

[3] BAGEL is freely available for download at: http://farm2.user.srcf.net/research/bagel/

Table 3 shows the results of the human evaluation, averaged over all the texts. In the BAGEL dataset, our system performs slightly worse in terms of fluency, but is perceived as more informative. In the SF restaurant dataset, our system performs worse in terms of fluency and better in informativeness, while in the SF hotel dataset, our system performs better in fluency and worse in informativeness. However, no statistically significant difference was detected in the SF datasets for both of these criteria.[4] Table 4, shows the results if we isolate the human judgements for the subset of non-overlapping MRs (see section 4.2); we see that the differences between the systems are much clearer but again we must state that no safe conclusions can be drawn from that small a subset.

	SF RESTAURANT		SF HOTEL	
	Wen et al. (2015)	LOLS	Wen et al. (2015)	LOLS
Fluency	3.53	3.23	2.38	4.22
Informativeness	4.90	5.23	4.65	4.30

Table 4: Human evaluation on the non-overlapping MRs of the SF datasets.

5 Related work

Apart from the works we compared against, only Konstas and Lapata (2013) and Mei et al. (2016) do not need pre-aligned data. Konstas and Lapata (2013)'s approach incorporates the work of Liang et al. (2009) that learns a generative semi-Markov model to calculate the alignments. We note that this alignment model is developed on the datasets considered, and does not generalize equally well to other datasets (Angeli et al., 2010). On the other hand, the naive alignments we infer are much simpler and we improve them by joint learning of word and content action prediction with respect to the sentence-level evaluation via BLEU and ROUGE. Concurrently, Mei et al. (2016) introduced an encoder-aligner-decoder model to perform content selection and surface realization without pre-aligned data. Their work employs bidirectional LSTM-RNN models, similarly to the work of Wen et al. (2015), and a coarse-to-fine aligner. Unfortunately, they do not report results in the datasets we performed our evaluation on, do not compare against Wen et al. (2015), and their code was unavailable when we were preparing this article.

Imitation learning algorithms for structured prediction have been applied successfully to a variety of tasks, such as dependency parsing (Goldberg and Nivre, 2013) and dynamic feature selection (He et al., 2013). Vlachos and Clark (2014) applied a variant of DAGGER (Ross et al., 2011) to learning a semantic parser from unaligned training examples, which is the reverse task to NLG, i.e. predicting the MR given the NL utterance. To circumvent the lack of alignment information they resorted to defining a randomized expert policy similar to the heuristic one we define, but NLG poses a greater challenge since the output space is all English sentences possible given the vocabulary considered.

Finally, we believe that the main benefit of our imitation learning approach, namely that it is able to learn using a non-decomposable loss function, is orthogonal to using continuous representations such as the hidden state and memory cell in the LSTM of Wen et al. (2015). Recent work by Ranzato et al. (2016) showed how RNNs can be trained at the sequence level (as opposed to the word level) with non-decomposable loss functions in the context of machine translation using imitation learning, and such an approach would also be applicable to NLG.

6 Conclusions

In this work, we adapted the Locally Optimal Learning to Search algorithm (Chang et al., 2015) to learn an NLG system from unaligned training data, focusing on its ability to learn with non-decomposable loss functions and suboptimal expert policies. We compared our approach to two recently proposed approaches for learning NLG from unaligned data on datasets they were developed on (three datasets across two domains) and achieved comparable results in automatic evaluation. We also performed human evaluation which showed that our system performs comparably, though its fluency requires improvement on MRs with multiple attributes.

[4] We performed Analysis of Variance (ANOVA) and post-hoc Tukey tests ($\alpha = 0.05$); * denotes statistical significance.

Abstract

We propose a phrase-based approach for generating product review summaries. The main idea of our method is to leverage phrase properties to choose a subset of optimal phrases for generating the final summary. Specifically, we exploit two phrase properties, *popularity* and *specificity*. *Popularity* describes how popular the phrase is in the original reviews. *Specificity* describes how descriptive a phrase is in comparison to generic comments. We formalize the phrase selection procedure as an optimization problem and solve it using integer linear programming (ILP). An aspect-based bigram language model is used for generating the final summary with the selected phrases. Experiments show that our summarizer outperforms the other baselines.

1 Introduction

With the growth of the Internet over the decades, e-commerce is becoming more and more popular. Product reviews are helpful for both merchants and customers. Merchants analyze the reviews to get feedback to improve their products. Customers make use of the reviews to get a better understanding of the product. The opinions in the reviews can help them make the final decision. However, the vast availability of such reviews becomes overwhelming to users when there is just too much to digest. Product review summarization is the task to address this problem. It summarizes the large number of reviews and generates a short readable summary which contains the overall rating of the opinions in the reviews.

Traditional extractive summarization has been studied for a long time, such as (Hovy and Lin, 1999; Kupiec et al., 1995; Paice, 1990). Recently, there are also a number of studies on abstractive summarization, such as (Banerjee et al., 2015; Bing et al., 2015; Liu et al., 2015). However, applying traditional summarization methods directly on product reviews doesn't yield satisfying results. This is due to that product review summarization is quite different from traditional extractive summarization. From the perspective of data size, the number of reviews of a product is often much larger than that of traditional data such as news articles. Another important difference is that sentences in product reviews are usually colloquial and contain lots of noises. Directly extractive summaries may contain a large number of undesired information.

A number of researchers have studied the task of review summarization. (Ganesan et al., 2010) proposed a graph-based method for generating ultra concise opinion summaries of products. They used predefined rules for finding valid sub-paths in the graph and converted those sub-paths into sentences. Since the sentence generation was rule-based, their method didn't provide a well-formed grammatical summary. (Gerani et al., 2014) generated product review summaries by using discourse structure. After simplifying the discourse graph, they used a template-based NLG framework to generate natural language summaries. Their summary produced a statistical overview of the product but lacked detailed information. (Ganesan et al., 2012) proposed some heuristic rules to generate phrases, they used a modified mutual information function and an n-gram language model to ensure the representativeness and readability of the phrases. However, their method didn't consider the descriptiveness of the phrases.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers,
pages 1113–1124, Osaka, Japan, December 11-17 2016.

We propose a phrase-based approach for generating product review summaries. We provide users with information that cover the most popular opinions in the original reviews targeting at each aspect. We use phrases as the basic unit of our summary, instead of sentences. We adopt the phrase definition in (Lu et al., 2009), that each phrase is composed by a pair of head term and modifier. The head term of a phrase denotes an *aspect* of the product, and the modifier denotes the *opinion* towards the aspect. For example, a phrase about the screen of a cellphone, "stunning [*modifier*] screen [*head*]". Based on the structure of phrases, we define two phrase properties, *popularity* and *specificity*. *Popularity* models how popular the phrase is in the original reviews. *Specificity* models how descriptive the modifier is to the head term. These two properties indicate the most important features of phrases in a good summary. We formalize this problem as an optimization problem and solve it using integer linear programming (ILP). A bigram aspect-based language model is used to order the selected phrases by aspects to form the final summary.

To summarize, our contributions are as follows:

- We propose a phrase-based approach for generating product review summaries. Our method leverages phrase properties, i.e., specificity and popularity, to choose popular and descriptive phrases from the original reviews.
- We formalize the summarization task as an optimization problem, and solve it using integer linear programming (ILP).
- We evaluate our summarization algorithm with both preference evaluation and qualitative evaluation. Our system performs better than other baselines in both evaluations.

The rest of this paper is organized as follows: In Section 2, we will present our phrase-based review summarization algorithm. In Section 3, we will describe the dataset and experiment results. In Section 4, we will describe the related work. In Section 5, we will summarize our work.

2 Summarization Algorithm

Our summarization algorithm takes a set of reviews of one product and a set of aspects as input and generates a summary based on the properties of the phrases extracted from the input reviews. The first step is phrase extraction. Phrases are extracted from the reviews using a given list of aspects. There are various methods for extracting aspects (Hu and Liu, 2004a; Hu and Liu, 2004b; Kim et al., 2011; Lu et al., 2009). In this paper, we do not focus on aspect extraction but consider them as the input. Each of the extracted phrases is tagged with its corresponding sentiment orientation. The second step is optimal phrase selection. We calculate properties of the phrases and select a subset of optimal phrases for constructing the final summary. We formalize this selection problem as an optimization problem and solve it using integer linear programming (ILP). The third step is aspects ordering. We use an aspect-based bigram language model to decide the order of the aspects in the final summary. In the last step, summary generation, phrases are filled into their corresponding aspect placeholders to form the final summary. The summarization framework is shown in Figure 1.

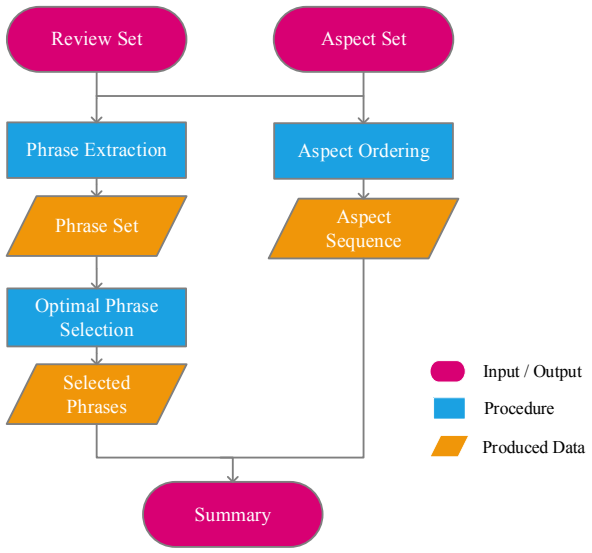

Figure 1: The overall framework of our summarization algorithm.

2.1 Phrase Extraction

In product reviews, most opinions are expressed in concise phrases, such as "camera is excellent" or "stunning screen". We adopt the phrase definition in (Lu et al., 2009), that each phrase can be parsed into a pair of a head term and a modifier. [1]

Aspect. An *aspect* denotes some specific feature of the product. For each aspect, there is a set of *aspect keywords* describing the corresponding aspect.

For example, available aspects of cell phones may include "appearance", "screen", "battery", etc. The aspect keywords set of "appearance" may include "appearance", "design", "surface", etc. Each keyword in the same keywords set is describing the same aspect.

Phrase. A phrase $p = (w_h, w_m)$ is in the form of a pair of a head term w_h and a modifier w_m. The head term is an aspect keyword of the product and the modifier expresses some opinion towards the aspect.

For example, "camera [*head*] is excellent [*modifier*]" and "stunning [*modifier*] screen [*head*]".

Phrase extraction is based on lexical and syntactic rules. First we perform part-of-speech (POS) tagging on the reviews.[2] Then we extract phrases from the reviews with Algorithm 1.

The input of the algorithm is the reviews of one product, denoted as R, and the keywords of all aspects, denoted as K. The output of the algorithm is a list of phrases denoted as P, with the corresponding indexes of the reviews denoted as $Index$, from which each phrase is extracted.

Algorithm 1 Phrase Extraction

Input:
Reviews of one product, $R = \{r_i\}_{i=1}^{n}$
Keywords, $K = \{k_j\}_{j=1}^{m}$
Output:
Phrases P and the corresponding indexes $Index$

```
1:  for each r_i in R do
2:    for each k_j in K do
3:      if ExistKeyword(k_j, r_i) then
4:        w_h ← k_j
5:        pos ← GetPosition(k_j, r_i)
6:        if ExistModifier(r_i, pos) then
7:          w_m ← GetModifier(r_i, pos)
8:          p ← (w_h, w_m)
9:          P ← P + {p}
10:         Index ← Index + {i}
11:       end if
12:     end if
13:   end for
14: end for
```

(1) For each review in R, first we check whether there are any aspect keywords in the review. If any aspect keywords are found (Line 3), then for each keyword found in the review, we set w_h as the aspect word (Line 4).

(2) From the position where we found the aspect word (Line 5), we do a forward and backward search to find the nearest adjective word. If the adjective word is found (Line 6), then set w_m as the adjective word (Line 7). If the adjective word is modified by an adverb, then the adjective word along with the adverb become the modifier w_m. If the adjective word is modified by a negative word, the negative word is also included in the modifier. This is handled by the function $GetModifier(r_i, pos)$. For example, in the phrase "screen/n is/v not/adv very/adv clear/adj", the modifier w_m is "not very clear".

(3) If both the head term w_h and the modifier w_m are found, a phrase $p = (w_h, w_m)$ is extracted, along with the index of the corresponding review (Line 8 - 10).

2.2 Optimal Phrase Selection: Definitions

In this section, we select a subset of optimal phrases from the phrase set. The subset should best represents the overall opinions expressed in the original reviews.

It is intuitive that a phrase is more likely to be included in a summary if it represents most of the users' opinion. For example, if there are 75% of the reviews containing the phrase "camera is excellent" while

[1] We demonstrate our summarization algorithm with running examples in English, but the datasets we use in our experiments are in Chinese.

[2] We use THULAC (`http://thulac.thunlp.org/`) as the POS tagging tool.

there are only 15% of the reviews containing other phrase "photo quality is very bad", then we should choose the former one as a candidate, because it is more popular in the original reviews.

On the other hand, for phrases describing the same aspect, we prefer the one whose modifier describes its head term more descriptive, i.e., the one which is more specific. For example, there are two phrases about the same aspect: "screen is clear" and "screen is good", we prefer "screen is clear" because that the modifier "clear" is more specific and better expresses the characteristic of the aspect "screen" while the modifier "good" is more general and can be used to describe other aspects.

A phrase is considered to be a candidate of the summary if it is popular in the original reviews and its modifier is specific to its head term. To better describe the phrase properties proposed above, we give the definition of *popularity* and *specificity* formally.

Definition 1 (Popularity). For a phrase p, let R_p denote the set of reviews that contain p, let R_{all} denote the set of all reviews. The *popularity* of phrase p is defined as:

$$\text{Popularity}(p) = \frac{|R_p|}{|R_{all}|} \tag{1}$$

where $|R|$ is the size of the review set R.

For a phrase set P, $p_i \in P$, $i = 1, \ldots, n$, let R_{p_i} denote the set of reviews that contain p_i, let R_{all} denote the set of all reviews. $\text{Popularity}(P) = |\cup R_{p_i}|/|R_{all}|$.

Suppose that we want to calculate the popularity of the phrase "long battery". Let's say there are 120 reviews in total and 25 of them contain the phrase "long battery", then the popularity of the phrase is $\text{Popularity}(\text{"long battery"}) = 25/120 = 0.21$.

Definition 2 (Specificity). For a phrase $p = (w_h^p, w_m^p)$, w_h^p denotes the aspect keyword of p, and A_p denotes the aspect that w_h^p belongs to, i.e., $w_h^p \in A_p$. w_m^p denotes the modifier of p. $P_{w_m = w_m^p}$ denotes the set of phrases whose modifier $w_m = w_m^p$, and $P_{w_h \in A_p, w_m = w_m^p}$ denotes the set of phrases whose head term $w_h \in A_p$ and modifier $w_m = w_m^p$. The *specificity* of phrase p is defined as:

$$\text{Specificity}(p) = \frac{|P_{w_h \in A_p, w_m = w_m^p}|}{|P_{w_m = w_m^p}|} \tag{2}$$

For a phrase set P, $p_i \in P, \quad i = 1, \ldots, n$, $\text{Specificity}(P) = \sum_i \text{Specificity}(p_i)$.

For example, suppose that we want to calculate the specificity of the phrase "beautiful design". The head term of this phrase is "design" and it belongs to the aspect *appearance*. The modifier term of this phrase is "beautiful". Let's say that there are 50 phrases whose modifier is "beautiful" in total, and there are 42 phrases whose modifier is "beautiful" and whose head term belong to the aspect *appearance*, then the specificity of the phrase is $\text{Specificity}(\text{"beautiful design"}) = 42/50 = 0.84$.

2.3 Optimal Phrase Selection: Problem Formalization

To select the optimal subset of phrases, we combine popularity and specificity to form an optimization problem. We use an integer linear programming (ILP) library[3] to solve this problem. We maximize $\text{Popularity}(P)$ and $\text{Specificity}(P)$ of a phrase set P together with the following constraints:

- **Length Constraint:** The total length of the summary is no longer than L_s.
- **Aspect Constraint:** For each aspect, the number of phrases in the cluster is no more than L_a.
- **Consistency Constraint:** For phrases in the same aspect, the sentiment orientation of these phrases should agree with each other.

To define the problem formally, let p_i denote the ith phrase in the phrase set P_{all}, and let r_j denote the jth review in the review set R_{all}. Let x_i represent a binary variable, that can take 0 or 1, depending on

[3] `http://sourceforge.net/projects/lpsolve/`

whether the ith phrase is selected for the final summary or not, and let y_j also represent a binary variable, that denotes whether the jth review is selected or not. Let P_{sel} denotes the set of phrases which are selected for the final summary. The objective function can be denoted as:

$$\begin{aligned} F(x_1, \ldots, x_n, y_1, \ldots, y_m) &= \text{Specificity}(P_{sel}) + \text{Popularity}(P_{sel}) \\ &= \sum_i \text{Specificity}(p_i) \cdot x_i + \frac{1}{|R_{all}|} \sum_j y_j \end{aligned} \tag{3}$$

The length constraint can be denoted as:

$$\sum_i l(p_i) \cdot x_i \leq L_s \tag{4}$$

where $l(p_i)$ denotes the length of phrase p_i. This constraint limits the total length of the summary to be no longer than L_s.

The aspect constraint can be denoted as:

$$\sum_{p_i \in P_{A^k}} x_i \leq L_a, \quad \forall A^k \tag{5}$$

where A^k denotes the kth aspect, and P_{A^k} denotes the set of phrases whose head term $w_h \in A^k$. These constraints limit the phrase number of each aspect to be no more than L_a.

The consistency constraint can be denoted as:

$$\left| \sum_{p_i \in P_{A^k}} o(p_i) \cdot x_i \right| = \sum_{p_i \in P_{A^k}} x_i, \quad \forall A^k \tag{6}$$

where $o(p_i)$ denotes the sentiment orientation of phrase p_i. $o(p_i) = 1$ if the sentiment orientation of phrase p_i is positive, and $o(p_i) = -1$ if the sentiment orientation of phrase p_i is negative. These constraints ensure that phrases in the same aspect have the same sentiment orientation.

There are other constraints to ensure the consistency between the phrase set and review set:

$$x_i \cdot Occ_{i,j} \leq y_j, \quad \forall i, j \tag{7}$$

$$\sum_i x_i \cdot Occ_{i,j} \geq y_j, \quad \forall j \tag{8}$$

where $Occ_{i,j}$ is a binary value, $Occ_{i,j} = 1$ if and only if phrase p_i is in review r_j, i.e., $p_i \in r_j$. Equation (7) means that if phrase p_i is selected ($x_i = 1$), then any review r_j that $p_i \in r_j$ is also selected ($y_j = 1$). Equation (8) means that if review r_j is selected ($y_j = 1$), then at least one phrase p_i that $p_i \in r_j$ is selected ($x_i = 1$).

2.4 Aspects Ordering

When writing comments, customers tend to first mention the aspect they care about most. We determine the aspect order by finding the most common aspect sequence in the original reviews. By this means, the generated summary would be more natural and coherent to human-generated reviews. Since we are only interested in the relative order of two adjacent aspects, we use an aspect-based bigram language model that assign probabilities to sequence of aspects.

For each review r, let $\Gamma(r)$ denote a function that maps each review to its corresponding aspects sequence, i.e., $\Gamma(r) = s_r$, where $s_r = [a_1^r, a_2^r, \ldots, a_q^r]$ is a sequence of aspects, and a_i^r is the ith aspects in the review r. Let $S = \{\Gamma(r) | r \in R\}$ denote the set of all aspect sequences for all reviews, let A denote the available aspect set, for any $a_i, a_j \in A$, $s_k \in S$,

$$p(a_i | a_j) = \frac{\sum_k I(a_i a_j \in s_k)}{\sum_k I(a_j \in s_k)} \tag{9}$$

where $I(x) = 1$ if x is true, otherwise $I(x) = 0$. For an arbitrary aspect sequence $s = a_1, a_2, \ldots, a_r$, the probability of the sequence is:

$$p(s) = p(a_1)p(a_2|a_1)\ldots p(a_r|a_{r-1}) \tag{10}$$

The objective sequence is the sequence that has the maximum probability in the language model and each aspect appears and only appears in the sequence once:

$$s^* = \arg\max p(s) \tag{11}$$

where $s = a_1, a_2, \ldots, a_n$, n is the number of aspects, $a_i \neq a_j, \forall i, j, i \neq j$.

2.5 Summary Generation

The summary generation procedure is quite straightforward. We sort the phrases in the optimal phrase set by the order of their corresponding aspects, and the final summary is a sequence of these phrases.

For phrases which have different aspects, the order of them is the same as the order of the corresponding aspects in the aspect sequence. For phrases which have the same aspect, the order is the same as the descending order of the size of the corresponding review set. Specially, if two phrases in the same aspect have the same head term, we merge their modifier term into one. For example, "screen is big" and "screen is clear" can be merged into "screen is big and clear".

Table 1 shows an example summary generated by our system.[4]

屏幕舒服、效果出色，电池耐用、续航长，做工精致，质量很棒，性能优越，速度快，性价比极高，价格适中，像素一般，摄像头很一般，外观漂亮、好看，软件太少、不丰富，界面十分简洁，画质清楚，操作简单、简洁，音效不错，音质特好，内存不够、较小，信号相当不错，通话声音清晰，按钮位置不好，机身重、太大。
Screen is comfortable and display is excellent. Battery is durable and lasts long. Exquisite workmanship and good quality. Performance is superior and fast. Price is cost-effective and affordable. Camera is very general. Appearance is beautiful and nice. Software is not rich. Interface is very simple. Picture is clear and of good quality. Operation is simple. Sound quality is especially good. Memory is not enough. Signal is quite good. Clear voice calls. Button location is not good. Body is heavy and too big.

Table 1: Example summary generated by our system.

3 Experiments

3.1 Data Preparation

Phrase Extraction. We construct our experiment dataset using customer reviews of 10 cellphones. The reviews are collected from `jd.com`, `zol.com` and `weibo.com`. All of the reviews are written in Chinese. We get 33,948 reviews in total. We construct 17 aspects manually, each aspect contains about 6 aspect keywords on average. With these aspect keywords, we perform phrase extraction on the review dataset. Each of the extracted phrases is then tagged with its corresponding sentiment orientation. In total, we have extracted 44,461 phrases, i.e., 1.31 phrases per review on average. 83% of the extracted phrases are positive, while 17% are negative.

Sentiment Detection. We train an SVM classifier to classify the sentiment orientations for the phrases. We use words as features and the corresponding values are binaries which indicate whether the words are present or not. First we drop words with frequency lower than 100, then we rank words by their chi-square values in descending order and choose the first third of all words as the feature words. We use `svmlight`[5] with default parameters to implement our classifier.

We use the review data for cell phones from `jd.com`. Since a single review may contain different sentiment orientations, we split each review into short sentences by a splitting delimiter set, which contains punctuations such as "，。；：！？ ". For each short sentence, we ask two annotators to judge the sentiment

[4]The summary is in Chinese and we translate it into English manually.

[5]`http://svmlight.joachims.org/`

orientation as "positive", "negative" or "neutral". Conflicting results are reviewed by a third annotator. We are only interested in short sentences with opinions, so we drop those tagged with "neutral". We get 182,120 short sentences in total, 72.5% are positive and 27.5% are negative. Since the same opinion word may have different orientations in different aspects, we cluster the short sentences by their aspects and train an SVM classifier for each aspect separately. For each of the 17 aspects, we randomly select 320 short sentences for testing, and the rest are used for training. The overall performance of sentiment classification is shown in Table 2. This result shows that out SVM classifier performs good enough for our review summarization task.

Precision		Recall		F1		Accuracy
Pos	Neg	Pos	Neg	Pos	Neg	All
91.8	91.2	92.3	90.7	92.0	90.9	91.5

Table 2: % of precision, recall, F1 and overall accuracy on sentiment classification

3.2 Baselines

The evaluation of review summarization is a very challenging task. On one hand, to the best of our knowledge, there is no dataset of product reviews with human written summaries. On the other hand, since the amount of product reviews is often large, it is quite difficult to generate human written summaries.

We evaluate the summaries generated by our system (denoted as **ReviewSum**) with a state-of-the-art extractive baseline, a state-of-the-art abstractive baseline and a simplified version of our system. The details of the baselines are described as follows:

1) LexRank: LexRank (Erkan and Radev, 2004) is a graph-based extractive summarization method which computes sentence importance based on the concept of eigenvector centrality in a graph representation of sentences. In the experiment, first we cluster sentences by their aspects. Then for each sentence cluster, LexRank is performed for summary generation. The final summary is generated by putting summaries of different aspects together in the same aspect order of ReviewSum.

2) Opinosis: Opinosis (Ganesan et al., 2010) is a novel graph-based summarization method which generates concise abstractive summaries of highly redundant opinions. In the experiment, for each aspect, we build an Opinosis graph and get the top candidate summaries. The final summary is generated by putting summaries of different aspects together in the same aspect order of ReviewSum.

3) BasicSum: BasicSum is a simplified version of our summarization method. Instead of popularity and specificity, TF-IDF score is used in the objective function. The objective function of BasicSum can be denoted as:

$$F(x_1, \ldots, x_n) = \sum_i \text{tf-idf}(p_i) \cdot x_i \tag{12}$$

where tf-idf(p_i) is the TF-IDF score of phrase p_i, and x_i is a binary value representing whether phrase p_i is selected in the final summary or not.

3.3 Experiments Evaluation

Due to the lack of human written summaries as gold standard, we perform two tasks to evaluate the summaries generated by our system. Task 1 is pairwise user preference evaluation and Task 2 is user scoring evaluation.

In Task 1, we run six pairwise comparisons of four summaries generated by our method and baselines. For each comparison, two summaries of the same product are shown to the annotators in random order. The name of the product and the original reviews are also shown to the annotators. For two summaries S_1 and S_2, annotators need to make a choice in the following three options: 1) Prefer S_1, 2) Prefer S_2, 3) No preference. Note that the exact names of S_1 and S_2 are hidden to annotators.

In order to ensure the quality of the evaluation, annotators are instructed to read the original reviews first before they make their choice. Annotators are specially instructed that their choice should based

on "*overall satisfaction with the information provided by the summary and intuitive feelings about the summary*".

In Task 2, we ask annotators to evaluate four aspects of each summary. The aspects considered during the evaluation include Grammaticality, Non-Redundancy, Consistency and Descriptiveness. Each aspect is rated with a score from 0 (bad) to 10 (excellent). Annotators are instructed to read the summary carefully and rate each aspect with scores matching the quality of the corresponding aspect.

20 annotators participate in Task 1 and Task 2, 10 annotators for each task. All of them are native Chinese speakers with experiences of product review writing. In Task 1, each comparison is evaluated by at least 5 annotators, and more than 300 comparison results are generated. In Task 2, each summary is rated by at least 5 annotators, and more than 160 rated scores are generated.

3.4 Results and Discussions

Sys I	**Sys II**	No pref	Pref Sys I	Pref Sys II	Agreement
BasicSum	LexRank	8%	42%	50%	0.2
BasicSum	Opinosis	2%	22%	76%	0.5
LexRank	Opinosis	12%	32%	56%	0.6
LexRank	ReviewSum	8%	14%	**78%**	0.8
BasicSum	ReviewSum	14%	0%	**86%**	0.8
Opinosis	ReviewSum	8%	18%	**74%**	0.6

Table 3: Results of pairwise comparison preferences. Statistically significant improvements ($p < 0.01$) over the baselines are demonstrated by bold fonts.

Preference Evaluation. Table 3 shows the results of Task 1. The first two columns denote systems compared in each comparison. The following three columns indicate the percentage of preference decisions for each preference category. Statistically significant improvements ($p < 0.01$) of our system over the baselines are demonstrated in bold fonts. The last column indicates the agreement rate of preference comparisons for different systems. Specifically, in our experiments, we treat one pairwise comparison as in agreement if four (out of five) annotators give the same preference decision. Table 4 shows system preference results of each product. System preferences are computed based on the results of pairwise comparison. For each system, the preference is the number of times annotators prefer the system, divided by the total number of comparisons for the system. For example, we have three systems A, B and C. A is preferred over B 10 out of 20 times, and A is preferred over C 25 out of 30 times, then the overall preference of A is $(10 + 25)/(20 + 30) = 70\%$.

Products	BasicSum	LexRank	Opinosis	ReviewSum
Galaxy S5	7%	27%	60%	**87%**
iPhone 5S	20%	40%	53%	**80%**
iPhone 5C	7%	20%	67%	**87%**
Ascend P7	20%	33%	60%	**80%**
Lumia 1320	33%	60%	13%	60%
Sony l36h	33%	20%	40%	**80%**
HTC One	27%	53%	20%	**93%**
LG G2	20%	27%	67%	67%
Galaxy Note 4	13%	33%	67%	**80%**
Galaxy Grand 2	33%	7%	53%	**80%**
Total	21%	32%	50%	**79%**

Table 4: System preference results of each product. Statistically significant improvements ($p < 0.01$) over the baselines are demonstrated by bold fonts.

From Table 3 and Table 4 we can see that our system significantly outperforms BasicSum. The only difference between BasicSum and our system is the objective function. Our system uses popularity and specificity of the phrases while BasicSum uses TF-IDF score. The result shows that popularity and specificity can prominently improve the quality of the summary. In fact, popularity and specificity improve the descriptiveness of the summary significantly, which we will discuss later.

The results in Table 3 and Table 4 show statistically significant improvements in pairwise comparisons of our system over the extractive baseline (LexRank) and the abstractive baseline (Opinosis). Due to the limitations of sentence-based extractive models, summaries produced by LexRank contain long sentences with useless information, while our system produces phrase-based summaries without unwanted information. Opinosis produces much shorter and concise summaries than LexRank, but the grammar of the sentences are not very well. In our method, phrases are generated in a concise manner by joining aspect and opinion together. The generated summaries are clear and well-formatted.

Qualitative Evaluation. Table 5 shows the results of Task 2. In order to avoid scoring varies per person, rating scores are normalized by each annotator, i.e., for each annotator, scores in range $[s_{min}, s_{max}]$ are remapped into range $[0, 10]$. The first column denotes systems in the rating task, the following four columns denote average scores of each system in four different aspects: grammaticality, non-redundancy, consistency and descriptiveness.

Systems	Grammaticality	Non-Redundancy	Consistency	Descriptiveness
BasicSum	6.46	4.89	6.92	3.42
LexRank	4.13	5.31	6.56	5.54
Opinosis	5.83	6.38	7.58	6.17
ReviewSum	**6.87**	6.07	7.41	**8.15**

Table 5: Results of aspects rating scores.

The results in Table 5 show that our system achieves the best score in grammaticality and descriptiveness. This exactly matches what we expect from our method that outputs well-formatted summaries by choosing neat and descriptive phrases. Also, our system is doing better than BasicSum and LexRank in non-redundancy. TF-IDF scores are used in BasicSum for phrase selection, and this will cause phrases with similar opinion words being selected (such as *good*, *very good*, etc.), which results in the increase of redundancy. LexRank extracts sentences directly from reviews, and information redundant may also be included. In consistency, our system performs nearly as good as Opinosis.

4 Related Work

Our work is related to aspect-based opinion summarization, which can be divide into three distinct steps: aspect extraction, sentiment detection and summary generation.

Aspect extraction involves identifying salient aspects within the text to be summarized. (Lu et al., 2009) used shallow parsing to identify aspects for short comments. (Popescu and Etzioni, 2007) used a web-based domain-independent information extraction system to extract aspects from parsed review data. (Hu and Liu, 2004a) and (Hu and Liu, 2004b) used supervised association rule mining-based approach to perform the task of aspect extraction. (Zhuang et al., 2006) used a feature list combining the full cast of all movies and a regular expression set to identify features in movie reviews. (Ku et al., 2006) used paragraph level frequencies as well as document level ones to help identify features.

Sentiment detection is the task of detecting sentiment orientation (positive or negative) on the aspect or feature. (Lu et al., 2009) used a learning-based method for sentiment detection. (Hu and Liu, 2004a; Hu and Liu, 2004b) used an effective method based on WordNet. (Ku et al., 2006) also used a set of positive and negative words from GI and CNSD to predict sentiments of aspects. (Zhuang et al., 2006) used dependency relationships to identify opinions associated with feature words.

Summary generation involves aggregating the results of aspect extraction and sentiment detection and generate the final opinion summary in an effective and easy to understand format. Statistical summary

is the most commonly adopted format, such as (Hu and Liu, 2004a; Hu and Liu, 2004b; Hu and Liu, 2006; Zhuang et al., 2006). (Titov and McDonald, 2008b) used a topic modeling method to provide a word level summary for each topic. (Popescu and Etzioni, 2007) also provided a word level summary by ranking opinion words associated to features and showing the strongest opinionated word for each aspect. (Mei et al., 2007) scored the probability of each sentence using TSM model and generated a sentence level summary. (Ku et al., 2006) used TF-IDF to score sentences and select the most relevant and discriminative sentence to be shown as summary. Besides texts, aggregated ratings can also be shown for summary, such as (Lu et al., 2009). (Ku et al., 2006) and (Mei et al., 2007) showed summary as a timeline with opinion changes over time.

5 Conclusion

In this paper, we propose a phrase-based summarization algorithm for the task of product review summarization. The proposed phrase selection scheme can fully utilize the characteristics of review sentences and capture the main information. We propose two properties of phrases, popularity and specificity, to score the phrase. Integer linear programming (ILP) is used to optimize the objective function. We use an aspect-based bigram language model to determine the aspect order of the candidate phrases to make the generated summaries more fluent and natural. Experimental results show that our system outperforms state-of-the-art systems in most cases. Our proposed summarization algorithm can produce concise, well-formatted and descriptive summaries of product reviews.

Abstract

We present a novel approach to automated question generation that improves upon prior work both from a technology perspective and from an assessment perspective. Our system is aimed at engaging language learners by generating multiple-choice questions which utilize specific inference steps over multiple sentences, namely coreference resolution and paraphrase detection. The system also generates correct answers and semantically-motivated phrase-level distractors as answer choices. Evaluation by human annotators indicates that our approach requires a larger number of inference steps, which necessitate deeper semantic understanding of texts than a traditional single-sentence approach.

1 Introduction

Exam questions are an indispensable tool for teachers to assess their students' understanding of material. Thus, automatic question generation from text is a key natural language processing technology to aid teachers in examining learners' reading comprehension. Past studies in education showed that higher-level questions, in contrast to simple factoid questions, have more educational benefits for reading comprehension (Anderson and Biddle, 1975; Andre, 1979; Hamaker, 1986). However, most of existing approaches to question generation have focused on generating questions from a single sentence, relying heavily on syntax and shallow semantics with an emphasis on grammaticality (Mitkov and Ha, 2003; Chen et al., 2009; Heilman and Smith, 2010; Curto et al., 2011; Becker et al., 2012; Lindberg et al., 2013; Mazidi and Nielsen, 2014). A problem with this approach is that the majority of questions generated from single sentences tend to be too specific and low-level to properly measure learners' understandings of the overall contents of text. In other words, what is assessed by such question generation systems ends up essentially being the ability to compare sentences, just requiring learners to find a single sentence that has almost the same surface form as a given interrogative sentence. Results of simple sentence comparisons do little to contribute towards the goal of assessing learners' reading comprehension.

In this work, we propose a question generation approach that engages learners through the use of specific *inference steps* over multiple sentences, namely coreference resolution and paraphrase detection, requiring more semantic understanding of text. We primarily use event and entity coreference as a source of producing questions from multiple sentences. Grounded by the past studies in education, we believe that such high-level questions are more sophisticated and educationally valuable for testing reading comprehension than questions generated by the traditional single-sentence approaches. Our question generation strategy is novel in two ways. First, it employs event and entity coreference between antecedents and referring mentions spanning multiple sentences. This requires learners to resolve the coreference and understand the contents of the text semantically. Second, it makes use of paraphrases when generating questions. The resulting questions are able to check learners' lexical knowledge.

To ensure that the resulting multiple choice question is an adequate test of the learner's reading comprehension, incorrect answers, i.e., distractors are necessary. The distractor candidates must be selected to ensure difficulty (Candidate Selection) and compared against the correct answer to ensure that there is only one correct answer overall and the question remains solvable (Reliability Checking). Most systems

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1125–1136, Osaka, Japan, December 11-17 2016.

currently generate word-level distractors for testing grammar, and are intimately tied to the question generation method. Our distractor generation method is capable of automatically generating phrase-level distractors leveraging event triggers and event-event relations for the purpose of testing reading comprehension. The results of our experiments show that our method produces comparable results across two different methods of question generation, thus remaining robust to different question generation methods.

Our question generation system is aimed at enhancing the reading comprehension ability of language learners, more specifically, students who learn English as a second language (ESL). Therefore, our ultimate goal is to generate multiple-choice questions from plain texts in an arbitrary domain. However, the state-of-the-art in extracting semantic representations of event and entity relations from text does not perform well enough to support our question generation approach. Thus, the evaluation of question generation relying on automated semantic relation extraction is not practical at this time. Therefore, in this work we use texts and expert human annotations from the ProcessBank corpus[1] (Berant et al., 2014) to facilitate our semantics-oriented question generation.

Our contributions are as follows:

1. This is the first work to automatically generate questions from multiple sentences, involving specific inference steps such as coreference resolution and paraphrase detection. Our experiments show that questions generated by our approach require taking a larger number of inference steps while ensuring comparable grammatical correctness and answer existence, as compared to questions generated by a traditional single-sentence approach.
2. We also present a complementary system which generates questions based on patterns extracted from relationships between events and entities in the passage. This approach produces a higher number of questions without the need for any manual intervention for the generation of patterns, although less reliable compared to the previous question generation system.
3. To complement the complex questions generated from multiple sentences, our system also generates phrase level distractors aimed at challenging comprehension by using event-event relation annotations. The results of our experiments show that the quality of the generated distractors remains robust across two different methods of question generation.

2 Related Work

Among a considerable amount of prior work on question generation spanning nearly four decades, we focus mainly on two families: (1) *syntax-based transformation* and (2) *shallow semantics-based transformation*. Syntax-based transformation uses the output of syntactic parsers, and changes syntactic structures of sentences to convert them into interrogative sentences as questions (Wolfe, 1976; Mitkov and Ha, 2003; Judge et al., 2006; Heilman and Smith, 2010; Curto et al., 2011). In contrast, shallow semantics-based transformation uses the output of shallow semantic parsers and additional knowledge bases, and generates questions from sentences based on their semantic structures (Chen et al., 2009; Mannem et al., 2010; Becker et al., 2012; Yao et al., 2012; Mazidi and Nielsen, 2014). Both groups generate questions based on a single sentence of text, relying heavily on its argument structures in question construction and mostly emphasizing grammaticality in evaluation. Labutov et al. (2015) have recently presented an approach to generate high-level questions using ontology-derived templates. Our approach differs from theirs in that we leverage semantic representations of text to inject specific inference steps, such as event and entity coreferences, into the process of answering system-generated questions.

In the context of computer-assisted language learning, intelligent tutoring systems have been traditionally employed for generating questions in various domains (Koedinger et al., 1997; Vanlehn et al., 2005). Some of the research in this area uses questions as a way of engaging students in ongoing dialogue (Graesser et al., 2001; Piwek and Stoyanchev, 2010). Our underlying motivation to enhance the reading comprehension ability of non-native English readers aligns best with the Reader Specific Lexical Practice (REAP) system (Heilman et al., 2006) and the SmartReader system (Azab et al., 2013). Though very promising, state-of-the-art approaches in this area have not dealt with multiple sentences to generate questions, either. Our work is aimed at addressing this challenge.

[1] See Section 3.1 for details of this corpus.

Prior work in distractor generation has been mostly studied on cloze (gap-fill) questions. Distractor generation for cloze questions often comprises two steps. *Candidate Selection* controls the type and difficulty of the items, and is intimately tied to the intent and target audience for the questions. This step may take advantage of available datasets such as the Lang-8 corpus[2] to identify confusion pairs and use the most frequent learner confusions as distractors (Sakaguchi et al., 2013) or the set of English language prepositions for use as distractors in preposition testing tasks (Lee and Seneff, 2007). *Reliability Checking* ensures that the question remains solvable, i.e., there is a total of one correct answer only (Zesch and Melamud, 2014).

In most cases, however, only the question and the correct answer are available, and distractors have to be automatically generated using these as input. Random generation of distractors (Mostow and Jang, 2012), distractors with a corpus frequency comparable to the correct answer (Hoshino and Nakagawa, 2007), morphologically, orthographically or phonetically similar words as distractors (Pino and Eskenazi, 2009), and semantically similar words selected using taxonomies (Hoshino and Nakagawa, 2007; Mitkov et al., 2009), thesauri (Sumita et al., 2005; Smith et al., 2010) or an additional layering of semantic relatedness to the context (sentence or paragraph) (Pino and Eskenazi, 2009; Agarwal et al., 2011; Mostow and Jang, 2012) are all valid strategies for the generation of distractor items. However, most of these methods generate word-level distractors for testing grammar rather than comprehension. Moreover, distractor generation is often tied to the method of generating questions. Our method automatically generates phrase-level distractors for testing reading comprehension, and is decoupled from the method used for question generation.

3 Generating Questions and Multiple-Choice Answers

Our system comprises a question generation component and a distractor generation component. We show a high-level overview of the system in Figure 1. The question generation component first detects question targets, and then generates questions triggered by the targets as correct answers. This component implements two different template-based algorithms, as described in Section 3.2 and Section 3.3. Given a tuple (text, question, answer) as input, the distractor generation component generates n distractors per question. The resulting tuple (question, answer, distractors) forms a multiple-choice question as the final output of our system.

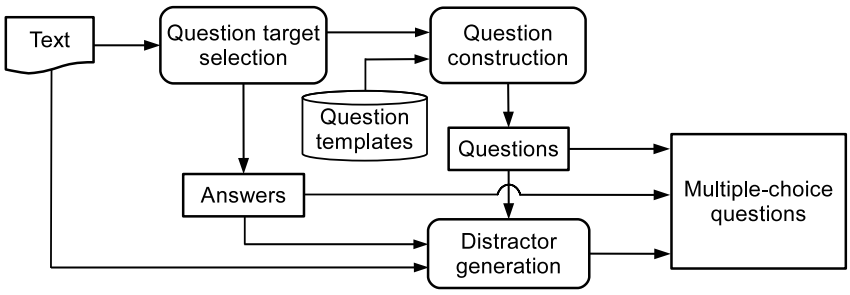

Figure 1: A high-level overview of our multiple-choice question generation system.

3.1 The ProcessBank Corpus

In order to generate questions from multiple sentences using reliable annotation of event and entity coreference, we use the ProcessBank corpus[3], particularly utilizing the expert annotation of events and entities, as described in Section 1. The corpus consists of 200 paragraphs about biological processes, extracted from the high school level textbook *Biology* (Campbell and Reece, 2005). Such textbooks are ideal sources to test learners' reading comprehension from an educational perspective. The corpus includes rich process structures annotated by biologists, shown in Figure 2. More specifically, the expert annotation comprises entity mentions, entity coreference, event triggers (without any event types), arguments (with semantic roles), and event-event relations such as event coreference and causal relations.

[2]A corpus of manually annotated errors by ESL learners, available at `http://cl.naist.jp/nldata/lang-8/`

[3]`http://www-nlp.stanford.edu/software/bioprocess/`

Each event in the corpus represents a biological process. A trigger is defined as a word or a phrase that expresses the process most clearly, and an argument is defined as a phrase denoting entities that participate in the process. The corpus also includes multiple-choice questions per paragraph, created by the biologists. We refer to these expert questions to devise our question templates.

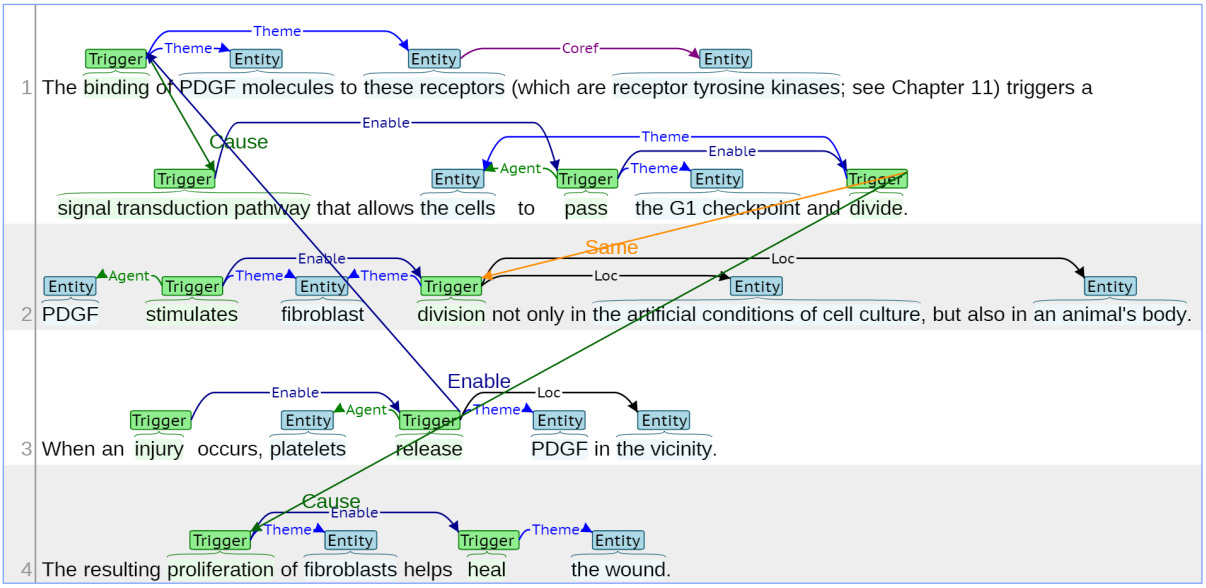

Figure 2: A paragraph with annotation of events, entities and their relations in ProcessBank. A 'Same' link means event coreference, whereas a 'Coref' link means entity coreference.

3.2 Question Generation using Coreferences and Paraphrases

Our first question generation system (QG1) is aimed at generating questions from multiple sentences using three semantic relations: event coreference, entity coreference, and paraphrases. We recognize that one of the key learning points for biology students is the order of biological processes (events) because many of the expert questions in ProcessBank ask about it. Based on this observation, we devise question patterns and templates shown in Table 1. As seen in this table, pattern P2 and P3 focus on the order of biological processes. However, the whole question generation strategy, including P2 and P3, does not rely on any domain-specific knowledge or rules on biology, but instead it makes use of domain-independent semantic relations, such as event coreferences and causal relations. Hence, the question generation strategy is not restricted to the biology domain, and is portable to other domains from an algorithm perspective.

QG1 consists of two parts: **answer generation** and **question construction**. It first finds question patterns applicable to the given text. For example, pattern P3 is applicable to the paragraph of Figure 2 since "divide" (E1) in the first sentence and "division" (E2) in the second sentence are coreferent, and only the former trigger has a 'Cause' relation to "proliferation" (E3). This pattern match means that "proliferation" can be an answer. We then make use of arguments of the answer trigger to generate a more complete answer, obtaining "proliferation of fibroblasts". Next, the algorithm constructs a question given the matched pattern. In the case of the example above, "division" is a nominal trigger. Thus, the algorithm uses question template T5, and creates a question "What is a result of the fibroblast division not only in the artificial conditions of cell culture, but also in an animal's body?" As seen in this example, the algorithm takes advantage of the fact that E2 lacks a piece of information that E1 has in P1, P2 and P3. We only use event coreference E1-E2 where E1 and E2 exist in different sentences, ensuring that questions are generated from multiple sentences.

We also give examples to illustrate how to generate questions based on entity coreferences and paraphrases in Figure 3 and Figure 4, respectively. Pattern P4 applies to Figure 3 because "they" (En1) in the second sentence is coreferent with "a few tumor cells" (En2) in the first sentence, and the former

Semantic relation	Question patterns	Answer	Question templates
Event coreference	P1. 	En1	T1. What [*verbal trigger + subsequent arguments*]?
	P2. 	E3	T2. What causes [*nominal trigger + subsequent arguments*]? T3. What makes it happen to [*verbal trigger + subsequent arguments*]? T4. What makes it happen that [*event clause*]?
	P3. 	E3	T5. What is a result of [*nominal trigger + subsequent arguments*]? T6. What happens when [*event clause*]?
Entity coreference	P4. 	En2	T1. What [*verbal trigger + subsequent arguments*]?
Paraphrase	P5. 	En1	

Table 1: Question patterns and templates using event coreference, entity coreference, and paraphrases. In question patterns, En denotes an event trigger, and Enn an entity mention. A straight line denotes a coreference link, a dashed arrow an 'Agent' relation, and a straight arrow a relation which is 'Cause', 'Enable' or 'Result'. An event clause in question templates is defined as a text span including an event trigger and its arguments.

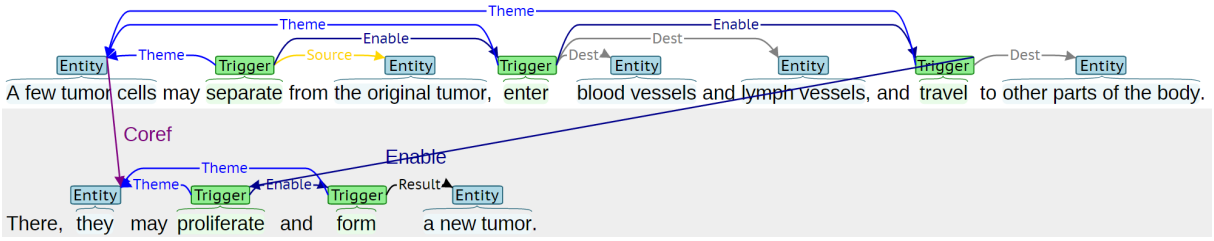

Figure 3: An example text to generate a question using an entity coreference.

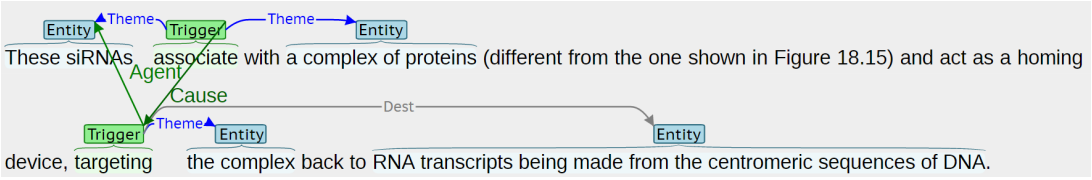

Figure 4: An example text to generate a question using a paraphrase.

entity is an agent of triggers "proliferate" and "form". Given that, "a few tumor cells" can be an answer, and the system can generate a question "What may proliferate and form a new tumor?" Similarly, P5 applies to Figure 4 because "these siRNAs" are an agent of trigger "targeting", and "complex" has a paraphrase "composite". Since "these siRNAs" are coreferent with "siRNAs" in the previous sentence (not appearing in Figure 4), a system can generate an answer "siRNAs" and a question "What targets the composite back to RNA transcripts being made from the centromeric sequences of DNA?" Note that the paraphrase "composite" is inserted into the question.

3.3 Question Generation using Concept Relationships

Our alternate question generation system (QG2) uses question patterns from events and entities in the passage and their relations. In this system, we rely on the fact that we can extract the question patterns based on the relations between entities and events in a passage. The relations between these events and entities span across multiple sentences, and thus most questions are generated from multiple sentences. We first extract generic patterns from the existing questions and relations, and then apply them to unseen passages to generate new questions. Since we rely on generic patterns, a significant number of questions might not have answers in the passage in comparison to QG1. For example, let us consider the relation (*Entity Theme Trigger*), for which one of question patterns is "What happens because of *Entity Trigger*?". A sample question from the passage in Figure 2 is "What happens because of PDFG release?" which does not have a valid answer in the passage. The ambiguity of the *Theme* relation gives rise to question patterns that might or might not have a correct answer in the passage. Alternatively, let us consider the relation (*Trigger_1 Enables Trigger_2*). One possible question can be "*What is enabled by Trigger_1*?" which would have *Trigger_2* as the correct answer. We then apply this pattern to other passages when triggers have the same kind of relations. Patterns from the *Enables* relation tend to have an answer when they are applied to new passages. Table 2 shows a sample of possible relations from the passage shown in Figure 2.

Relation	Entity	Location	Theme	Event Trigger	Event Trigger	Coreference
Enable	–	–	–	injury	release	–
Agent	the cells	–	–	pass	–	–
–	divide	–	–	–	–	division
Theme	–	–	–	binding	PDFG molecules	–

Table 2: A sample of possible relations for the passage in Figure 2.

Some sample questions that can be generated from this passage are shown below.

1. What event enables *Event_Trigger* (division)?
2. What would happen without *Event_Trigger* (the binding) of *Event_Trigger* (PDFG molecules)?
3. What happens after *Event_Trigger* (passage) of a *Entity* (the cells)?

Table 3 shows some of the relations and question templates extracted from the ProcessBank corpus.

Question pattern	Question template
Entity *Result* Trigger	What event should occur before the *Trigger* of *Entity*?
Trigger_1 *Super* Trigger_2	What would happen without *Trigger_1* in *Trigger_2*?
Entity *Theme* Trigger	What would happen without the *Trigger* of *Entity*?
Entity *Location* Trigger	Where was *Trigger* in *Entity*?
Trigger_1 *Cause* Trigger_2	What is caused by *Trigger_1*?

Table 3: Entity-trigger relations as question patterns and their associated question templates.

3.4 Distractor Generation

Our distractor generation method can be described as a sequence of the following steps.

1. **Generation of an event graph using event triggers and event-event relations**. The method first forms an event graph as a basis to find possible distractors. Event triggers act as nodes of the graph whereas event-event relations act as edges of the graph. Coreferent nodes in this initial graph are collapsed together to construct the final event graph.
2. **Mapping a question and its correct answer onto the event graph**. In this step, we identify the nodes (event triggers) corresponding to those present in the question and the correct answer. The identified nodes are not used for the generation of distractors. This ensures the reliability of generated distractors, and serves as our *Reliability Checking* step.
3. **Selection of event triggers for distractor generation**. Nodes (event triggers) in the event graph, which are not the ones identified in the previous step, serve as potential candidates for generating distractor items. While informed selection strategies such as the use of causal relations and information regarding prior and subsequent events could have been used to select distractors, they are effective only if the correct answer is known with complete certainty. To combat the stochasticity around the correctness of the answer generated by our question generation methods, we employ random selection from among the potential candidates. We randomly select three nodes as distractors from the list of nodes identified as potential candidates (after removing the nodes in the question and the correct answer). This serves as our *Candidate Selection* step.
4. **Construction of distractor items**. A distractor item is constructed by selecting the phrase comprised of a selected node (event trigger) and its surrounding entities, provided no comma or period is encountered. We resolve entity and event coreferences associated with terms in this step ito produce the final distractor items.

Let us consider as an example the passage shown in Figure 2. Step 1 generates the event graph obtained from this passage as shown in Figure 5. The nodes "divide" and "division" are coreferent, and therefore have been collapsed into a single node "divide/division" along with their edges. Now consider

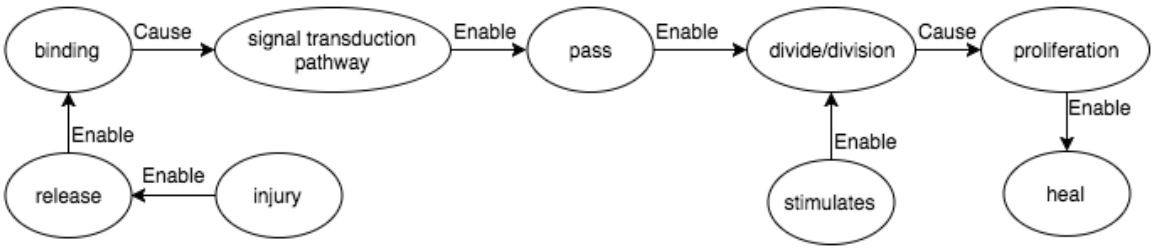

Figure 5: An event graph generated from the passage in Figure 2.

the question and answer we saw associated with this passage in Section 3.2:

- Question: "What is a result of the fibroblast division not only in the artificial conditions of cell culture, but also in an animal's body?"
- Answer: "Proliferation of fibroblasts"

Step 2 recognizes that the nodes "divide/division" and "proliferation" in the event graph are the triggers that the question and answer refer to. We can now use any of the other event triggers from the event graph to generate our distractor items. Since we collapse coreferent nodes, we can guarantee that the nodes selected will not refer to the same triggers as the ones in the question or the answer (*Reliability Checking*). From among the remaining nodes, step 3 randomly selects "binding", "stimulates" and "release" for distractor generation. Lastly, step 4 generates phrases with these triggers and their surrounding entities after entity and event coreference resolution, and constructs the distractor items shown below.

- Distractor 1: binding of PDGF molecules to receptor tyrosine kinases
- Distractor 2: PDGF stimulates fibroblast
- Distractor 3: platelets release PDGF

4 Experiments and Results

To assess the performance of our system, two human annotators evaluate our question generation component and distractor generation component. For a meaningful comparison on question generation, we

use the question generation system by Heilman and Smith (2010) as a baseline. Let MH refer to the baseline. In our experiments, we generate 200 questions from each system, and generate 3 distractors per question.

4.1 Evaluation Criteria for Generated Questions and Distractors

It is important to evaluate generated questions, but this is not straightforward mainly due to the wide variety of acceptable natural language expressions. We use three metrics for the evaluation.

Grammatical correctness judges whether a question is syntactically well-formed. It does not evaluate whether a question is semantically coherent, ignoring the meaning of the question. Our three point scale for this metric is based on the number of grammatical errors.

- 1 (best): The question has no grammatical errors.
- 2: The question has 1 or 2 grammatical errors.
- 3 (worst): The question has 3 or more grammatical errors.

For consistency in counting grammatical errors, we define common grammatical errors in English: spelling errors, run-on sentences, lack of subject-verb agreement, lack of pronoun-antecedent agreement, misplaced modifiers, missing or erroneous quantifiers, prepositions or determiners, erroneous verb forms or nominalization, incorrect word choice, and other errors.

Answer existence identifies whether the answer to a question can be inferred from the passage associated with the question. Note that the answer must be inferred using the passage information only, without relying on external knowledge beyond the passage. Even if a system generates a question while making a specific target its answer, it could be impossible that the target is the answer due to the lack of a valid inference path from the question to the target as its answer. This metric is intended to penalize such questions. Our two-point scale for this metric is:

- 1 (yes): The answer to the question can be inferred from the passage.
- 2 (no): The answer to the question cannot be inferred from the passage.

In addition to answer existence, we also evaluate the correctness of system-generated answers. For this, we use the following three-point scale ratings: correct (1), partially correct (2), and incorrect (3).

Inference steps concern how many semantic relations humans need to understand in order to answer a question. This metric directly evaluates our central idea: inference steps for answering a question. We define the following set of semantic relation types to be considered as inference:

- Event coreference within input text and event coreference between input text and a question.
- Entity coreference within input text and entity coreference between input text and a question.
- Paraphrases in input text and a question.
- Negation, which is a binary relation about logical truthness.

Distractor quality is a rating to measure how appropriate a distractor is for a given question and its correct answer. We set up a three-point scale for rating generated distractors as follows:

- 1 (worst): A distractor is confusing because it overlaps the correct answer partially or completely.
- 2: A distractor can be easily identified as an incorrect answer.
- 3 (best): A distractor can be viable.

As for rating 2, we look for a particular reason for being easily eliminated, such as the distractor is not present in given text.

4.2 Results of Question Generation

We show our results of question generation in Table 4. QG1 achieved more inference steps compared to QG2 by 0.49 and compared to MH by 0.60, while it gained comparable ratings of grammatical correctness and answer existence. We computed the inter-annotator agreement with Cohen's Kappa for each of the criteria mentioned in Section 4.1. Overall, we have a kappa value of 0.55, 0.58 and 0.49 for grammatical correctness, answer existence and inference steps respectively. This result implies moderate agreement. Table 5(a) shows our results for answer correctness. We observe that QG1 tends to generate questions with more incorrect answers than MH.

System	Grammatical correctness			Answer existence			Inference steps		
	Ann 1	Ann 2	Total	Ann 1	Ann 2	Total	Ann 1	Ann 2	Total
QG1	1.52	1.48	1.50	1.17	1.26	1.21	0.80	0.71	**0.76**
QG2	2.13	2.07	2.10	1.58	1.75	1.67	0.31	0.20	0.27
MH	1.42	1.25	**1.34**	1.20	1.14	**1.17**	0.13	0.19	0.16

Table 4: The performance comparison in question generation. Numbers in grammatical correctness and answer existence are average ratings, and lower is better. Numbers in inference steps are average inference steps, and higher is better.

System	Ann 1	Ann 2	Total
QG1	1.35	1.57	1.46
MH	1.08	1.13	1.11

(a) Average ratings of answer correctness in 200 questions. Lower numbers are better. Scores range from 1-3, with 1 a correct answer.

System	Ann 1	Ann 2	Total
QG1	1.98	1.90	1.94
MH	1.93	1.88	1.91

(b) Average ratings of distractors on the same set of 100 questions that the both human evaluators rate as answer existence 1 ("an answer exists"). Higher numbers are better. Scores range from 1-3, with 3 a viable distractor.

Table 5: Results of answer correctness (Table 5(a)) and distractor generation (Table 5(b)).

4.3 Results of Distractor Generation

To make the evaluation of distractor generation reasonable, we need the same set of questions as input for QG1 and MH. Both of the two evaluators rate answer existence 1 on 129 questions generated from QG1 and on 127 questions generated from MH. We randomly select 100 questions from each of the question sets. We show our results of question generation in Table 5(b). Our method achieves an average distractor score of around 2 with a majority of the distractors being rated 2.

5 Discussion

As described in Section 3.2, QG1 attempts to generate questions involving at least one inference step. The average inference step of 0.76 in Table 4 means that the algorithm fails to generate intended questions approximately once out of every four times. A common source of these errors is that some other events can be associated with the event in the question by a different relation (e.g., 'Super'), and they can be an answer to the question. The most common kind of grammatical errors in questions generated by the QG2 system were nominalization ("grow" vs "growth") and verb form ("is uses" instead of "is used"). In terms of inference steps, 'entity coreference' occurred most often. In contrast, QG1 commonly made "determiner" errors in the case of question patterns involving a nominal trigger. For instance, "natural selection" is a noun phrase which does not need an article, but QG1 mistakenly adds "the" in front of it.

The distractor generation component needs to generate distractors as close to a rating of 3 as possible. However, distractors labeled as 2 ("easily eliminated") often occur because they come from events preceding the event described in the question or from events following the results of the events described in the question. A better understanding of cause-and-effect or temporal relations in event graphs might reduce the selection of these easily identified distractors.

We also faced some issues in evaluating system output. The number of grammatical errors assigned can depend on annotators' opinions on how the errors should be corrected. Different corrections could be reached by a different number of steps, changing the evaluation. Thus, differences in opinion on the correct form of the question impacted inter-annotator agreement. Another challenge concerned evaluating the inference steps needed to answer the generated questions. This evaluation requires annotators to identify semantic relations (i.e., event and entity coreferences, negations, and paraphrases) in the texts and count the number of steps needed to answer the question. In some cases, it was not clear how many steps to count, when there were several event mentions in a coreference chain.

6 Conclusion and Future Work

We have presented two different methods that automatically generate questions from multiple sentences. The first method requires learners to take specific inference steps such as event and entity coreferences over multiple sentences. The second method generates questions using patterns extracted from the relations between entities and events in a corpus. Our experiments showed that questions generated by both methods require more inference steps than questions generated by a traditional single-sentence approach. In particular, the first method outperforms the baseline system in terms of the number of inference steps by 0.60 on average, while ensuring comparable grammatical correctness and answer existence. Grounded by past studies in education, we believe that our system-generated questions are more sophisticated and educationally valuable for testing reading comprehension because they require more semantic understanding of text. Our distractor generation approach uses event triggers and event-event relations to generate distractors by building an event graph that lends itself to superior Reliability Checking. We observed that the quality of the generated distractors remains robust across two different methods of question generation.

There are a number of avenues for future work. Although our question generation strategy is domain-independent as described in Section 3.2, some question patterns such as the ones focusing on the order of events (biological processes) might not be useful in other domains. One could explore more domain-adaptable question generation strategies. In another direction, one can extend our system to achieve an end-to-end system which generates multiple-choice questions directly from input text by leveraging automated high-performance semantic parsers, instead of relying on human annotations of a particular corpus. As for distractor generation, one can look at more intelligent ways of generating distractor items from the event graph using causal relations and the knowledge of prior and subsequent events. From a perspective of evaluation, a real user test with non-native English readers is also important. The real-test evaluation will allow us to know how many of the system-generated questions are usable in the real test, obtain the insights of what questions are truly important for language learners' reading comprehension, and capture the rationale behind distractors (e.g., the most confusing distractor patterns) based on an analysis of readers' performance. One could also explore methods to automatically carry out one or more of our evaluation processes. As we argued in this paper, our question generation strategy lends itself to language learners' reading comprehension. In addition, our research can also be useful to the task of creating exam questions and answers, since manual creation is normally quite time-consuming. Automatically generated questions and multiple-choice answers make the creation of exam QAs more efficient.

Abstract

Despite the growing number of Computational Construction Grammar implementations, the field is still lacking evaluation methods to compare grammar fragments across different platforms. Moreover, the hand-crafted nature of most grammars requires profiling tools to understand the complex interactions between constructions of different types. This paper presents a number of evaluation measures, partially based on existing measures in the field of semantic parsing, that are especially relevant for reversible grammar formalisms. The measures are tested on a grammar fragment for European Portuguese clitic placement that is currently under development.

1 Introduction

Computational Construction Grammar allows computational linguists to formalize their hypotheses and intuitions about certain linguistic phenomena and explore how these representational choices affect the processing of natural language utterances (Schneider and Tsarfaty, 2013). In this sense, it follows in the footsteps of Generalized Phrase Structure Grammar (GPSG) (Gazdar et al., 1985), Lexical Functional Grammar (Bresnan et al., 2016), Head-Driven Phrase-Structure Grammar (HPSG) (Pollard and Sag, 1994) and Combinatory Categorial Grammar (CCG) (Steedman, 2000). Yet, different from these other approaches, it adheres to the principles of Construction Grammar (CxG) (Goldberg, 2005; Östman and Fried, 2005; Hoffmann and Trousdale, 2013).Therefore, constructions are treated as first-class citizens in the grammatical organisation of a language. They are viewed as learned mappings between form (sounds, morphemes, syntactic categories) and function (semantics, pragmatics, etc.). Because there is no strict separation between the lexicon and the grammar, semi-productive idioms like "X let alone Y" are treated in the same way with lexemes and core syntactic patterns (Fillmore et al., 1988). We can distinguish three main computational frameworks that are currently active within the Construction Grammar community: Embodied Construction Grammar – ECG (Bergen and Chang, 2005), Fluid Construction Grammar – FCG (Steels, 2004; Steels, 2011) and more recently Template Construction Grammar – TCG (Barrès and Lee, 2014).

The evaluation of computational construction grammars is currently not reaching further than proof-of-concept grammar fragments that show how to implement a certain language phenomenon and demonstrate the resulting grammar by means of web demonstrations or its use in a simulation-based robotic environment (Trott et al., 2015). There are two reasons for the lack of widely used evaluation metrics in CxG: (i) Different from data-driven approaches, construction grammars are not built automatically from annotated treebanks and therefore do not reach a wide coverage in the traditional sense. Instead, both ECG and FCG allow the grammar writer to test a number of sentences automatically when loading the grammar fragment and return the average base parse for these (geometric mean of the number of parses per sentence). (ii) Different from syntactic parsers that concentrate on the syntactic accuracy of the syntax trees that their grammars derive, computational construction grammars focus on semantic accuracy as a metric that better meets their objectives. However, semantic accuracy is harder to measure than syntactic accuracy because it requires textual corpora annotated with large formal meaning representations that are agreed upon by different grammar developers.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1137–1146, Osaka, Japan, December 11-17 2016.

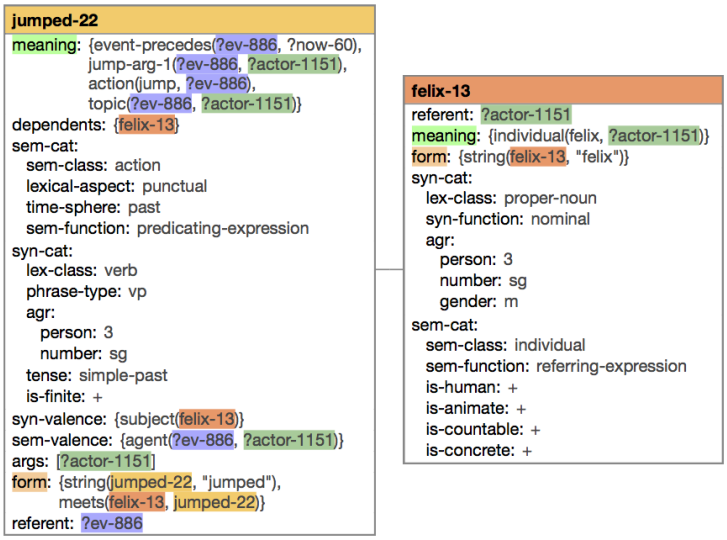

Figure 1: Resulting transient structure after parsing "Felix jumped". Features cut across argument structure, information structure and functional structure.

The field of computational CxG is reaching a certain level of maturity in terms of linguistic phenomena that are treated and publications that accompany grammars (e.g. (van Trijp, 2015) for FCG and (Trott et al., 2015) for ECG), and has clearly demonstrated the feasibility of implementing the constructional approach in a full-fledged computational framework (Schneider and Tsarfaty, 2013). The time has come to evaluate these implementations so that they can be compared within the field and benchmarks can be created. We therefore suggest a number of metrics for parsing (comprehending an utterance into a meaning representation) and production (formulating an utterance from a meaning representation) of a test suite that addresses a specific linguistic phenomenon. Because computational CxG fragments are hand-crafted precision grammars rather than data-driven approaches, broad-coverage newspaper corpora are not interesting test beds for evaluation since they are not constrained towards the phenomena of study. Rather, we suggest to compile a test suite of sentences taken from linguistic research in the area that the grammar is focusing on.

Before explaining the actual metrics we designed, our contribution first argues, in Section 2, for the usefulness of including CxG in computational linguistics. Section 3 then draws parallels between the fields of semantic parsing and computational construction grammar in terms of semantic representations, before Section 4 presents metrics we propose to evaluate grammars in the latter formalism. The case study then shows the use of these metrics in a sample grammar for European Portuguese in Section 5. Finally, Section 6 concludes.

2 Why Constructions?

Computational CxG views production and comprehension in terms of a chain of consecutive operations over a linguistic structure, called the transient structure, a feature structure consisting of units that are made up of non-typed feature-value pairs, which maintains a temporary state of knowledge. A sequence of transient structures on a particular execution chain is called a linguistic pathway (Steels, to appear). One of the characteristics of CxG is its "insistence on simultaneously describing grammatical patterns and the semantic and pragmatic purposes to which they are dedicated" (Fillmore et al., 1988) so transient structures, as well as constructions, need to be able to represent information from a multitude of different perspectives. A construction schema, or in short, a construction, is an abstract schema that can be used to "expand any aspect of a transient structure from any perspective and it can consult any aspect of this transient structure to decide how to do so" (Steels, to appear).

The result of construction application is thus a transient structure from which semantic or formal information can directly be extracted, without additional steps. Figure 1 shows the resulting transient

structure after parsing the intransitive sentence "Felix jumped" with a dependency-style grammar. The meaning features of both units form together the complete understanding of the sentence. Through variable equalities, Felix is linked to the first argument of the jump action and the topic of the sentence. Of course, the meaning predicates in this example are merely illustrative here and are subject to choices that the grammar engineer makes.

Not only the resulting transient structure can be valuable in the evaluation procedure but also the constructions that built the structure should be considered. In the case of "Felix jumped", a two-word utterance, at least five constructions have been at work to construe its interpretation. Two lexical constructions covering the words themselves, one tense construction to situate the event in the past (and indicate that it is not the adjective "jumped"), one argument structure construction linking the Felix to the actor or the jumping event (intransitive) and one information structure construction identifying "Felix" as the topic of the sentence.

3 Semantic Parsing

Semantic parsers – similar to Computational Construction Grammar implementations – are not interested in building well-formed syntactic trees but instead map sentences into formal meaning representations (Mooney, 2007). They are used in domains such as question answering, where natural-language questions are converted into formal queries, and are typically built over databases with unsupervised (e.g. (Poon and Domingos, 2009)) or supervised (e.g. (Berant et al., 2013)) learning algorithms. To go beyond simple query formulation towards complex knowledge extraction, a recent approach by (Parikh et al., 2015) uses distant supervision methods to learn a semantic parser from a database of complex events and unannotated texts.

While testing, the retrieved meanings are compared to a gold standard annotation to calculate the precision and recall of the parser. Three main ways to calculate precision and recall can be distinguished, ranging from less to more fine-grained analyses:

1. The retrieved meaning/formulated query is correct when it matches the gold standard. Recall is then the number of correct meanings divided by the number of sentences. Precision is the number of correct meanings divided by the number of sentences for which the parser produced a meaning. An example of a system that employs this measure is the Cocktail system (Tang and Mooney, 2001).

2. Instead of using a binary measure, one can calculate the overlap in attribute-value pairs between the retrieved meaning and the gold standard. Recall is then the percentage of recovered attribute-value pairs per sentence, averaged over the test set. An example of a semantic parser that calculates this overlap is the (Zettlemoyer and Collins, 2007) parser for the ATIS flight info domain.

3. The Smatch score (Cai and Knight, 2013) measures the overlap between meaning representations while taking into account variable bindings. It is determined by calculating the maximum possible F-scores for alternative bindings. This calculation process can be seen in Table 1 for a small exemplifying sentence "a boy is", with the following gold standard and parsed meanings (in Abstract Meaning Representation):

   gold standard meaning: *instance(?x, boy)* $\wedge$ *attribute(?x, single)* $\wedge$ *instance(?y, be)* $\wedge$ *attribute(?y, currently-being)* $\wedge$ *is(?y, ?x)*

   parsed meaning: *instance(?a, boy)* $\wedge$ *attribute(?b, single)* $\wedge$ *instance(?b, be)* $\wedge$ *is(?a, ?a)*

	Matched	Precision	Recall	F-Score
x = a y = b	2	2/4	2/5	0.44
x = b y = a	1	1/4	1/5	0.22
			S-score:	0.44

Table 1: Calculation of the normal Smatch score.

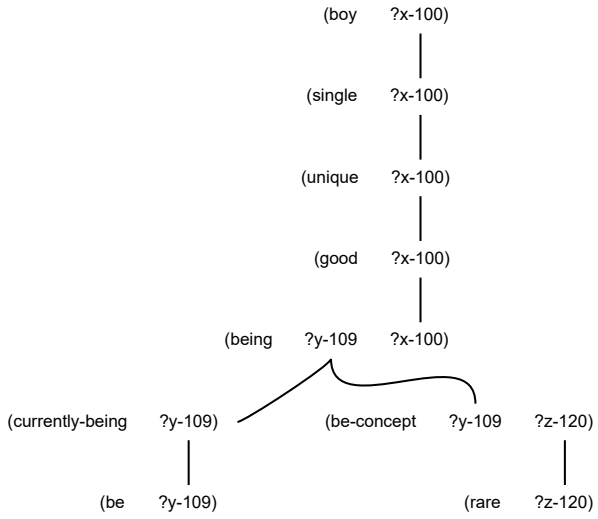

Figure 2: Fully connected meaning after parsing the sentence "A good boy is rare".

Given the existing variables, there are two possible bindings. The *?x* is either bound to *?a* or *?b*, and the same is true for *?y*. There are 5 relations in the gold standard, but only 4 in the generated meaning. Replacing the variables with *?x = ?a; ?y = ?b* gives two matches between the meanings: *instance(?x, boy) = instance(?a, boy)* and *instance(?y, be) = instance(?b, be)*. This makes the precision 2/4 and the recall 2/5, leading to an F-score of 0.44, which is the maximum amongst all the possible bindings. Therefore, 0.44 is also the Smatch score (S-score) for the two meanings.

The S-score is interesting for evaluating construction grammars, because the meaning representation obtained in Fluid Construction Grammar can be directly converted to Abstract Meaning Representation (AMR). AMR has two types of relations: a relation between a concept and a variable (instance and attribute relations); and a relation between two variables (argument relations). The AMR version of the meaning network in Figure 2 would become: *instance(?x, boy)* $\wedge$ *attribute(?x, single)* $\wedge$ *attribute(?x, unique)* $\wedge$ *attribute(?x, good)* $\wedge$ *instance(?y, be)* $\wedge$ *attribute(?y, currently-being)* $\wedge$ *arg(?y, ?x)* $\wedge$ *arg (?y, ?z)* $\wedge$ *instance(?z, rare)*. All the concepts related to the "boy" use the same variable *?x*, and the concept "rare" is connected with the verb "be", which is happening at present and corresponds to the being *?x*, "boy" which is *?z*, "rare". The nodes in the graph are second order logics predications, where properties and relations can be objects as well. For instance, the meaning of "a good boy is rare" could be: *(boy ?x)* $\wedge$ *(single ?x)* $\wedge$ *(unique ?x)* $\wedge$ *(good ?x)* $\wedge$ *(be ?y)* $\wedge$ *(currently-being ?y)* $\wedge$ *(being ?y ?x)* $\wedge$ *(be-concept ?y ?z)* $\wedge$ *(rare ?z)*. All the concepts related to the "boy" use the same variable *?x*, and the concept "rare" is connected with the verb "be", which is happening at present and corresponds to the being *?x*, "boy" which is *?z*, "rare".

4 Proposed Metrics

The remainder of this section explains the two accuracy metrics in more detail. For comprehension, a variant of the Smatch score is proposed that takes into account subparts of the meaning graph. For production, we present the longest common substring measure, with two variants. Finally, a single profiling measure is included to quantify the efficiency of the grammar in comprehension and production.

Reinterpreting Smatch Let us consider that we were evaluating a hypothetical precision grammar with the goal of identifying nouns and their modifiers, but that lacked any constructions for verbs. Then, the S-score of 0.44 (obtained in Table 1), while important for understanding the broad accuracy of the grammar, might not really tell us how the grammar is doing in terms of identifying the nouns. For expressing this in an explicit way, we might also want to have a specific smatch score to calculate the accuracy only for this phenomena. Unfortunately, due to the relational nature of the different parts of the

sentence, it is not possible to separate what is being studied from what is not, since the identification of its relations is also important.

A compromise between what is studied and what we can measure was found for enabling us to calculate a more specific S-score, while keeping the same process of finding the maximum F-score. This is done by annotating the variables in the gold standard that are more important for the phenomena being studied. In this case, it would be *x*. Then, we disregard any relation that does not contain this variable in it, and we accept partial matchings. Even, if *is(?y, ?x)* did not totally match, but the noun was identified in the correct position, it would still be counted. Table 2 shows the calculation for the same sentence ("a boy is"), but considering only the variable *x*. There are three relations to be considered in the gold standard and two in the meaning obtained, regardless of the variable bindings. The matches are still two, but the precision and recall increase, leading to a S-score of 0.8

	Matched	Precision	Recall	F-Score
x = a y = b	2	2/2	2/3	0.8
x = b y = a	1	1/2	1/3	0.4
			S-score:	0.8

Table 2: Calculation of the specific Smatch score.

The S-score obtained for a specific phenomenon should not be presented on its own, because it would lead to an erroneous understanding of the grammar accuracy over the whole corpus. However, together they give a better understanding how the grammar is working. For instance, in this example, the grammar only parses this sentence into its meaning with a 0.44 accuracy, yet the noun identification is mostly correct, which is what actually tell us if the grammar is working for what it was proposed.

Calculating reproducibility The FCG grammar has an additional problem that is usually not faced in semantic parsers: the fact that the full meaning of a sentence is correctly obtained does not necessarily mean that the original utterance can be reproduced. FCG does not work with templates or libraries of sentences, instead the sentence will be reproduced based on the syntactic aspects of the grammar. While word order does not pose any problems in parsing and can indeed help to guide the comprehension process, it can become an issue in production that gets worse when sentence length increases. It is also particularly hard in languages that do not follow a rigid word order, where a different but correct sentence can also be produced without any change in meaning.

Measures that evaluate the correctness of the sentence that is produced are essential to have a complete understanding of the accuracy of FCG due to its bidirectional nature. The most obvious measure would be to compare the sentence obtained with a set of possible acceptable sentences that can be generated back with the same meaning. However, this binary measure does not convey much information. Instead, we propose to use the Longest Common Subsequence (LCS) algorithm to obtain the percentage of the sentence that was correctly generated. LCS is an algorithm that given two sequences, $X = [x_1, x_2, .., x_i]$ and $Y = [y_1, y_2, .., y_j]$, can find the maximum length subsequence between them, defined as a strict increasing sequence of indices of X $[1, 2, .., k]$ such that $x_{ij} = z_j$ (Cormen, 2009). The number of words in the maximum length common subsequence divided by the number of words in the original acceptable sentences, will then gives us an estimation of the percentage of the sentence that the grammar was able to generate back. This measure is not new, and has been previously used to evaluate machine translated texts by (Lin and Och, 2004).

Because the comprehension process might lead to partial meanings, we distinguished between two variants of the LCS measure. One for sentences that were successfully parsed, leading to a fully connected network and one for the unsuccessful ones that might only lead to the production of partial sentences.

Grammar efficiency Construction application may generate a large search. Multiple constructions can expand the same transient structure at a certain time step, or a single construction can expand the transient structure in more than one way. Splits in the search tree can be the result of ambiguities in processing, but

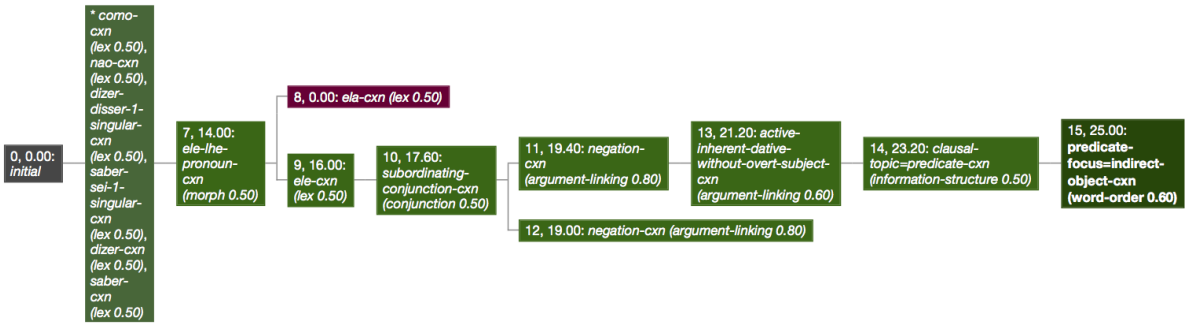

Figure 3: The comprehension process of "não sei como disser-lhe" has an efficiency of 13/14 (not considering the red node, where the second unification step failed).

often originate in sloppy grammar design. Measuring grammar efficiency (at least in terms of additional nodes generated in the search tree) is done by dividing the number of search nodes in the branch that leads to the solution (when all goal tests succeed) by the total number of nodes in the tree. When efficiency equals to 1, no additional nodes are created. The grammar efficiency of the comprehension example in Figure 3 equals 13/15. We see that one of the two additional nodes is red, indicating that it passed the first unification step (conditional part) but failed when unifying the contributing part of the construction. This node do not create additional search since they have no further children. A more informative grammar efficiency measure would perhaps only consider the succeeded nodes. In that case, the example sentence "não sei como disser-lhe" has an efficiency of 13/14 (0.93).

5 Case Study

To better understand how one can interpret the proposed metrics and how they differ from traditional approaches, we include the evaluation of an European Portuguese (EP) grammar fragment that is under development in FCG. It should be noted, however, that this grammar fragment is only here to exemplify how the metrics can be used during grammar developing and evaluation phase. We do not make any claims regarding the grammar itself. The chosen fragment focuses on pronominal clitics. Clitics in EP can be positioned following the verb (enclisis) or preceding the verb (proclisis). Correct clitic placement does not depend on the finiteness of the verb (as in other Romance languages) but is instead determined by the phrasal context. Hence, the coverage of different contexts is an important consideration in the evaluation of such a grammar. Therefore, we built our own test suite by collecting 67 sentences from linguistic research papers dedicated to this phenomenon (Madeira, 1992; Luís et al., 2004; Luís and Otoguro, 2011), and annotated them manually. To create the grammar, lexical constructions were automatically generated from the test suite words based on their grammatical categories, but the core grammatical constructions were hand-crafted considering the linguistic concept being studied, and do not represent necessarily all grammatical intricacies present in the test suite sentences.

The normal S-score gives us an F-score of 0.75 ± 0.21, while the specific S-score returns a slightly higher value of 0.79 ± 0.32. These numbers tell us that the grammar is not covering all necessary aspects to comprehend all the sentences but it is better in the clitics placement than it would seem, as the specific S-score is higher than the general one. To get a better understanding of which parts of the grammar are still not satisfactory, the example sentences were annotated with the proclisis trigger they contain, or else tagged as enclisis. Table 3 shows the average S-scores for seven triggers, together with their standard deviation. Between brackets the number of example sentences is shown. The operator adverb and the relative clauses results exemplify the biggest discrepancies between the two S-scores: 0.62 vs 0.84 and 0.63 vs. 0.80, respectively. This shows that while the grammar fragment is not very good at handling the sentences containing this concepts, the position of the clitics is still correctly identified. Looking into the sentences, we understand that they have more complex verbal forms that are not well processed by the grammar because they were not implemented. The opposite situation does also occur where the general score is higher than the specific. For instance, the enclisis results present a F-score of 0.75 vs 0.73, which

Clitics Position	Triggers	S-score		LCS	
		Normal	Specific	Successful	Unsuccessful
enclisis (28)	none (28)	0.75 ± 0.20	0.73 ± 0.38	0.87 ± 1.43	0.49 ± 0.63
proclisis (39)	negation (6)	0.77 ± 0.25	0.81 ± 0.79	1.00 ± 0.00	N/A
	wh-question (5)	0.88 ± 0.18	0.86 ± 0.28	0.90 ± 0.12	0.33 ± 0.00
	relative clause (7)	0.62 ± 0.08	0.84 ± 0.25	0.43 ± 0.68	0.37 ± 0.10
	fronted focus (8)	0.70 ± 0.22	0.88 ± 0.23	0.84 ± 0.33	0.42 ± 0.01
	operator adverb (3)	0.63 ± 0.23	0.80 ± 0.28	0.40 ± 0.00	0.20 ± 0.00
	undefined-subject (3)	0.89 ± 0.09	0.89 ± 0.16	1.00 ± 0.00	N/A
	downward quantifier (7)	0.78 ± 0.20	0.79 ± 0.30	0.74 ± 0.63	0.14 ± 0.30

Table 3: Accuracy and reproducibility results for the EP grammar case study. All the results are presented by the concepts being studied, the proclisis triggers.

means that although it seems to perform generically well in those sentences, the positioning of the clitics is incorrect more often than predicted by the general score.

Table 3 also includes the Longest Common Substring results. Two scores are kept: the leftmost column includes the LCS for sentences that were produced from meanings that passed all goal tests (and have thus a higher chance of success). The rightmost column shows the scores for productions whose initial meaning networks were extracted from a comprehension process that failed. No score is shown when the case did not happen. The biggest issue in getting the word order right seems to occur in the relative clauses (0.43) and the operator adverbs (0.40). The latter allow multiple grammatically correct word orders in EP, whereas we only include the first solution.

When it comes to grammar efficiency, Figure 4 (on the left) shows the results ordered by sentence length (3–7). We see indeed that the efficiency does not scale well when longer sentences are parsed (and the same goes for production). Less than 20% of all search nodes are used by the branch that leads to the solution. To get an idea of the complexity of the grammar Figure 4 (on the right) plots the number of constructions that is needed to parse a sentence. Sentences of length 3 require on average 9 constructions and the number increases with steps of 2 with every word that is added.

The grammar fragment presented in this section covers a very basic grammatical phenomenon of positioning the clitics correctly. Yet, being basic it has several intrinsic aspects that are fundamental to get right to process it correctly, especially if we want to have grammars that generate grammatically correct sentences. A traditional metric of accuracy or even the normal S-score metric would give an unfair comparison between this fragment grammar and a corpus-based grammar. While, the latter might be better at covering all the sentences provided in a corpus or in a test suite, it might always fail in the processing of this phenomena. While the former grammar not being constructed for a wide coverage

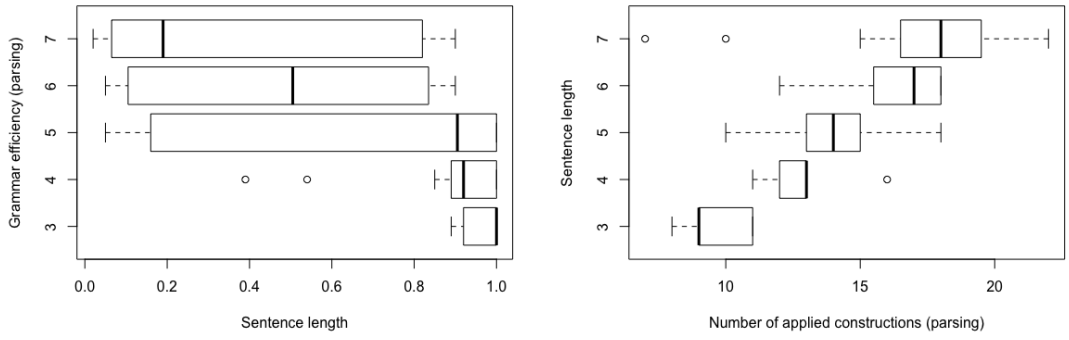

Figure 4: The efficiency and complexity of the EP grammar in function of the sentence length.

might be better at handling this phenomena. The specific s-score when used together provides us with further information to understand how the grammar differs in a more detailed level. Furthermore, this score and the additional profiling metrics for efficiency are very useful for grammar engineers during the grammar developing phase to understand where their grammar falls short and should be further developed. The LCS in FCG provides a further insight into the accuracy of the generated sentences which tells us how well the grammar understands and generates the sentence back.

Using the AMR annotation for evaluating grammar is a relatively costly process. However, it is becoming increasingly necessary to have a semantically annotated corpus in addition to the more traditional syntactical tree-based annotation. Furthermore, there are some strategies that can decrease the burden on the annotators: (1) if only a partial phenomena is being studied, then it might be reasonable to have only partial annotations; (2) it is possible to distribute the phenomena per annotator, thus decreasing the learning curve; (3) it is possible to provide the sentences already generated by the grammars and ask the annotators to fix the errors based on their cognitive understanding of the meaning and/or a set of rules provided.

6 Conclusions

Taking inspiration from existing measures in semantic parsing and machine translation, we proposed two new metrics for evaluating computational Construction Grammar implementations: the S-score, with a variant for focusing on the parts of the meaning graph that are tackled by the grammar fragment; and the LCS score, indicating the reproducibility of the retrieved meaning network. Used in addition to more traditional metrics, these scores give insights about the exact type of phenomena that can be handle by a precision grammar, which is important to distinguish grammars that cover a large number of sentences but invariably fail in processing specific phenomena and grammars that cover a small set of sentences but can deal well with a specific phenomena. Additionally, some profiling measures are also suggested to give an idea of the grammar efficiency and complexity. We hope the proposed metrics help grammar engineers to better understand the complex interactions between the constructions in their grammars and the phenomena being covered by it.

Abstract

Methods for text simplification using the framework of statistical machine translation have been extensively studied in recent years. However, building the monolingual parallel corpus necessary for training the model requires costly human annotation. Monolingual parallel corpora for text simplification have therefore been built only for a limited number of languages, such as English and Portuguese. To obviate the need for human annotation, we propose an unsupervised method that automatically builds the monolingual parallel corpus for text simplification using sentence similarity based on word embeddings. For any sentence pair comprising a complex sentence and its simple counterpart, we employ a many-to-one method of aligning each word in the complex sentence with the most similar word in the simple sentence and compute sentence similarity by averaging these word similarities. The experimental results demonstrate the excellent performance of the proposed method in a monolingual parallel corpus construction task for English text simplification. The results also demonstrated the superior accuracy in text simplification that use the framework of statistical machine translation trained using the corpus built by the proposed method to that using the existing corpora.

1 Introduction

Text simplification is the process of rewriting a complex text into a simpler form while preserving its meaning. The purpose of text simplification is to assist the comprehension of readers, especially language learners and children. Recent studies have treated text simplification as a monolingual machine translation problem in which a simple synonymous sentence is generated using the framework of statistical machine translation (Specia, 2010; Zhu et al., 2010; Coster and Kauchak, 2011a; Coster and Kauchak, 2011b; Wubben et al., 2012; Štajner et al., 2015a; Štajner et al., 2015b; Goto et al., 2015). However, unlike statistical machine translation, which uses bilingual parallel corpora, text simplification requires a monolingual parallel corpus for training. While bilingual parallel data are available in large quantities, monolingual parallel data are hard to obtain because simplification of a complex text is not a by-product of other tasks. Monolingual parallel corpora for text simplification are available in only seven languages—English (Zhu et al., 2010; Coster and Kauchak, 2011b; Hwang et al., 2015; Xu et al., 2015), Portuguese (Caseli et al., 2009), Spanish (Bott and Saggion, 2011), Danish (Klerke and Søgaard, 2012), German (Klaper et al., 2013), Italian (Brunato et al., 2015), and Japanese (Goto et al., 2015). In addition, only the English corpora are open to the public. We therefore propose an unsupervised method [1] that automatically builds monolingual parallel corpora for text simplification without using any external resources for computing sentence similarity.

In this study, a monolingual parallel corpus for text simplification is built from a comparable corpus comprising complex and simple texts. This was done in two steps. First, we compute the similarity for all combinations of complex and simple sentences using the alignment between word embeddings. Second, we extract sentence pairs whose similarity exceeded a certain threshold. Figure 1 gives an overview of the method. Monolingual parallel corpus can be used for text simplification in the framework of SMT.

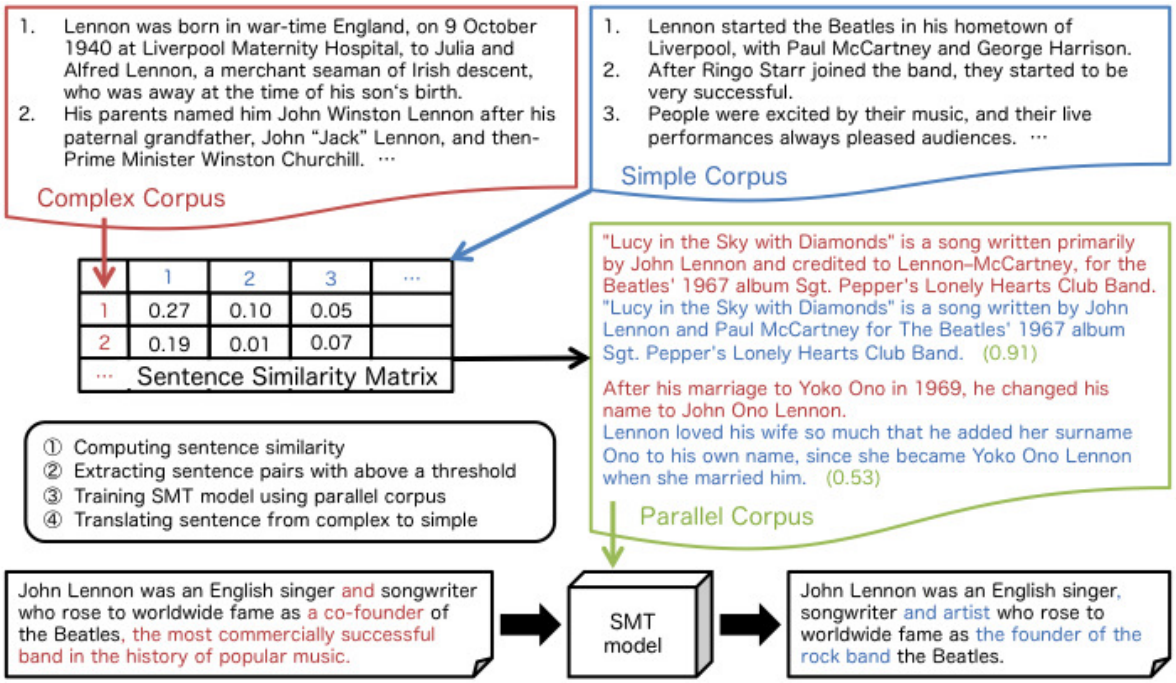

Figure 1: Process flow of building a monolingual parallel corpus and simplifying a sentence using the SMT framework.

We evaluated our proposed method using a benchmarking dataset [2] to construct a corpus for English text simplification. The benchmark dataset contains pairings of complex and simple sentences with a binary label of parallel (the sentence pair is synonymous) or nonparallel (the sentence pair is not synonymous). Intrinsic evaluation using this dataset showed that the proposed method had an improved F1 score. In addition, we built a statistical machine translation model trained on the resulting corpus and compared it with one trained on the existing corpora. Extrinsic evaluation using statistical machine translation for text simplification demonstrated the improved BLEU score of the proposed method.

Our contributions are summarized as follows:

- The proposed method improved the binary classification task between monolingual parallel data and nonparallel data by 3.1 points (0.607 → 0.638), compared with the F1 score from a previous study, and demonstrated high accuracy in building a monolingual parallel corpus for text simplification.
- The SMT-based text simplification model trained using the corpus built by the proposed method had a BLEU score 3.2 points higher (44.3 → 47.5) than an SMT-based text simplification model trained using the state-of-the-art monolingual parallel corpus.
- The proposed method can build a monolingual parallel corpus for text simplification at low cost because it does not require any external resources such as labeled data or dictionaries when computing sentence similarity.

2 Related Work

The statistical machine translation framework has become widely used in text simplification. In English, text simplification using a monolingual parallel corpus extracted from the English Wikipedia and Simple English Wikipedia has been actively studied. Coster and Kauchak (2011b) simplified sentences using the standard phrase-based SMT toolkit Moses (Koehn et al., 2007) and evaluated it using the standard automatic MT evaluation metric BLEU (Papineni et al., 2002). In addition to generic SMT translation models, specialized translation models such as targeting phrasal deletion have been proposed (Zhu et al., 2010; Coster and Kauchak, 2011a; Wubben et al., 2012). These studies reported that models specialized

[2] http://ssli.ee.washington.edu/tial/projects/simplification/

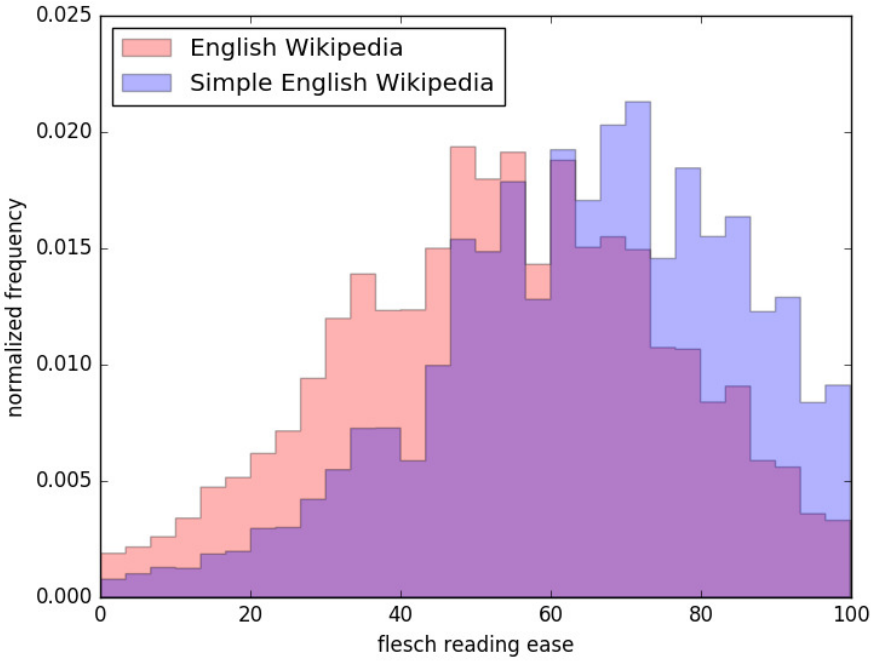

Figure 2: Readability score distribution of English Wikipedia and Simple English Wikipedia. A higher score in Flesch Reading Ease indicates simpler sentences.

in text simplification improved readability and the BLEU score. In languages other than English, text simplification using SMT has been studied for Portuguese (Specia, 2010), Spanish (Štajner et al., 2015b), and Japanese (Goto et al., 2015). We follow these works in applying SMT to text simplification, whilst improving the quality and quantity of the monolingual parallel corpus using an unsupervised method.

Three monolingual parallel corpora for English text simplification have been built from English Wikipedia and Simple English Wikipedia. First, Zhu et al. (2010) [3] pioneered automatic construction of a text simplification corpus using the cosine similarity between sentences represented as TF-IDF vectors. Second, Coster and Kauchak (2011b) [4] extended Zhu et al. (2010)'s work by considering the order of the sentences. However, these methods did not compute similarities between different words. In text simplification, it would be useful to consider similarities between synonymous expressions when computing the similarity between sentences, since concepts are frequently rewritten from a complex to a simpler form. Third, Hwang et al. (2015) [2] computed the similarity between sentences taking account of word-level similarity using the co-occurrence of a headword in a dictionary and its definition sentence. We also consider word-level similarity to compute similarity between sentences but using word embeddings to build a text simplification corpus at low cost without requiring access to external resources.

These text simplification corpora built from English Wikipedia and Simple English Wikipedia received some criticism. Xu et al. (2015) point out that Zhu et al. (2010)'s corpus has 17% of sentence pairs unaligned (two sentences have different meanings or only have partial content overlap) and 33% of sentence pairs become more complex (the simple sentence has the same meaning as the original sentence but is not simpler). However, Simple English Wikipedia contains simpler expressions in general. Figure 2 shows the distribution of the readability scores of Simple English Wikipedia and English Wikipedia. It clearly illustrates that Simple English Wikipedia contains easier sentences than English Wikipedia and supports that it is a good source for text simplification. Štajner et al. (2015a) investigated the quality and quantity of a monolingual parallel corpus using the framework of statistical machine translation and showed that sentence pairs with a moderate level of similarity are effective for training text simplification models. Therefore, we use the sentence similarity method to accurately measure the moderate level of

[3] https://www.ukp.tu-darmstadt.de/data/sentence-simplification/simple-complex-sentence-pairs/

[4] http://www.cs.pomona.edu/~dkauchak/simplification/

similarity.

To address the challenge of computing the similarity between sentences containing different words with similar meanings, many methods have been proposed. In semantic textual similarity task (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirre et al., 2015), sentence similarity is computed on the basis of word similarity following the success of word embeddings such as word2vec (Mikolov et al., 2013a). For example, a supervised approach using word embeddings when obtaining a word alignment achieved the best performance in SemEval-2015 Task 2 (Sultan et al., 2015). Word embeddings have also been used in unsupervised sentence similarity metrics (Mikolov et al., 2013b; Song and Roth, 2015; Kusner et al., 2015). These unsupervised sentence similarity metrics can be applied to the automatic construction of a monolingual parallel corpus for text simplification, without requiring the data to be labeled.

3 Sentence Similarity based on Alignment between Word Embeddings

We propose four types of sentence similarity measures for building a monolingual parallel corpus for text simplification, based on alignments between word embeddings that have achieved outstanding performance on different NLP tasks. The methods discussed in Sections 3.1-3.3 are the sentence similarity measures proposed by Song and Roth (2015) for a short text similarity task. The Word Mover's Distance (Kusner et al., 2015) discussed in Section 3.4 is another sentence similarity measure based on alignment between word embeddings that is known to achieve good performance on a document classification task.

3.1 Average Alignment

The sentence similarity $\mathrm{STS}_{\mathrm{ave}}(x, y)$ between sentence x and sentence y is computed by averaging the similarities between all pairs of words taken from the two sentences, as follows:

$$\mathrm{STS}_{\mathrm{ave}}(x, y) = \frac{1}{|\boldsymbol{x}||\boldsymbol{y}|} \sum_{i=1}^{|\boldsymbol{x}|} \sum_{j=1}^{|\boldsymbol{y}|} \phi(x_i, y_j) \tag{1}$$

Here, x_i denotes the i-th word in the sentence x ($\boldsymbol{x} = (x_1, x_2, \ldots, x_{|\boldsymbol{x}|})$), y_j denotes the j-th word in the sentence y ($\boldsymbol{y} = (y_1, y_2, \ldots, y_{|\boldsymbol{y}|})$), and $\phi(x_i, y_j)$ denotes the similarity between words x_i and y_j. We employed the cosine similarity as the word similarity $\phi(x_i, y_j)$.

3.2 Maximum Alignment

Average alignment, discussed in Section 3.1, is an intuitive method. However, it is not possible that all word pairs have a high similarity $\phi(x_i, y_j)$, even when considering synonymous sentence pairs. Moreover, it is often the case that many word similarities $\phi(x_i, y_j)$ are noise and are near to zero. Therefore, we utilize only accurate alignments by computing the sentence similarity $\mathrm{STS}_{\mathrm{asym}}(x, y)$ from the most similar word y_j for each word x_i rather than averaging the word similarities between all pairs. Here $\mathrm{STS}_{\mathrm{asym}}(x, y)$ is an inherently asymmetric score. Therefore, we obtain the symmetric sentence similarity $\mathrm{STS}_{\mathrm{max}}(x, y)$ by averaging the two similarities $\mathrm{STS}_{\mathrm{asym}}(x, y)$ and $\mathrm{STS}_{\mathrm{asym}}(y, x)$ as follows:

$$\mathrm{STS}_{\mathrm{asym}}(x, y) = \frac{1}{|\boldsymbol{x}|} \sum_{i=1}^{|\boldsymbol{x}|} \max_j \phi(x_i, y_j), \quad \mathrm{STS}_{\mathrm{max}}(x, y) = \frac{1}{2}(\mathrm{STS}_{\mathrm{asym}}(x, y) + \mathrm{STS}_{\mathrm{asym}}(y, x)) \tag{2}$$

3.3 Hungarian Alignment

Average alignment and *maximum alignment* can be considered as sentence similarity measures based on many-to-many word alignments and many-to-one word alignments, respectively. However, since these methods compute the word alignments independently, they do not take into account the sentence-level consistency of alignments. To address this lack of global alignment, we represent two sentences x and y as a bipartite graph in which the vertices consist of words that occur in each sentence and the edges reflect their word-level similarity. The graph is then used to define sentence similarity. This bipartite

graph is a weighted complete bipartite graph whose edge is assigned a word similarity $\phi(x_i, y_j)$ as a weight. The one-to-one word alignment that maximizes the sum of the word similarities is obtained by finding the maximum matching of the bipartite graph. This maximum matching problem can be solved using the Hungarian algorithm (Kuhn, 1955). The sentence similarity $\mathrm{STS}_{\mathrm{hun}}(x, y)$ is then computed by selecting a word $h(x_i)$ using the Hungarian algorithm for each word x_i:

$$\mathrm{STS}_{\mathrm{hun}}(x, y) = \frac{1}{\min(|\boldsymbol{x}|, |\boldsymbol{y}|)} \sum_{i=1}^{|\boldsymbol{x}|} \phi(x_i, h(x_i)) \tag{3}$$

3.4 Word Mover's Distance

Word Mover's Distance (Kusner et al., 2015) also considers the global consistency of word alignments when computing sentence similarity based on a many-to-many word alignment. This is a special case of the Earth Mover's Distance (Rubner et al., 1998) which solves the transportation problem of transporting words from sentence x to sentence y.

$$\mathrm{STS}_{\mathrm{wmd}}(x, y) = 1 - \mathrm{WMD}(x, y), \qquad \mathrm{WMD}(x, y) = \min \sum_{u=1}^{n} \sum_{v=1}^{n} \mathcal{A}_{uv} \psi(x_u, y_v) \tag{4}$$

$$\text{subject to} : \sum_{v=1}^{n} \mathcal{A}_{uv} = \frac{1}{|\boldsymbol{x}|} freq(x_u), \qquad \sum_{u=1}^{n} \mathcal{A}_{uv} = \frac{1}{|\boldsymbol{y}|} freq(y_v)$$

Here $\psi(x_u, y_v)$ denotes the dissimilarity (distance) between the two words x_u and y_v. We used the Euclidean distance to denote the word dissimilarity $\psi(x_u, y_v)$. Here, $\mathcal{A}_{uv}$ denotes a weighted matrix of flow from word x_u in the sentence x to word y_v in the sentence y, n denotes the vocabulary size, and $freq(x_u)$ denotes an occurrence frequency of the word x_u in the sentence x.

4 Experiments for Building a Monolingual Parallel Corpus for Text Simplification

We built a monolingual parallel corpus for text simplification by aligning sentences from a comparable corpus using sentence similarity, based on the alignment between word embeddings, and evaluated the effectiveness of the proposed method from the quality of the corpus. First, we evaluated the proposed method in binary classification of a sentence pair as parallel or nonparallel. Next, we built a monolingual parallel corpus for text simplification using the proposed sentence similarity measure, and evaluated it qualitatively. Finally, we trained text simplification models using the SMT framework on our corpus and on existing corpora, to compare their effectiveness.

4.1 Binary Classification between Parallel and Nonparallel Sentences

Hwang et al. (2015) built a benchmark dataset [2] for text simplification extracted from the English Wikipedia and Simple English Wikipedia. They defined four labels: *Good (G) ("The semantics of the sentences completely match, possibly with small omissions.")*, *Good Partial (GP) ("A sentence completely covers the other sentence, but contains an additional clause or phrase that has information which is not contained within the other sentence.")*, *Partial ("The sentences discuss unrelated concepts, but share a short related phrase that does not match considerably.")*, and *Bad ("The sentences discuss unrelated concepts.")*. They annotated 67,853 sentence pairs (277 *G*, 281 *GP*, 117 *Partial*, and 67,178 *Bad*). We classified a sentence pair as parallel or nonparallel using this benchmark dataset to evaluate the sentence similarity measures. We conducted experiments in two settings: a setup (*G vs. O*), in which only sentence pairs labeled *G* were defined as parallel, and the other setup (*G + GP vs. O*), in which sentence pairs labeled either *G* or *GP* were defined as parallel. We evaluated the performance of the binary classification using two measures, the maximum F1 score (MaxF1) and the area under the curve (AUC).

Noise in the word alignment for *average alignment*, *maximum alignment*, and *hungarian alignment* was removed by aligning only those word pairs (x_i, y_j) which had a word similarity $\phi(x_i, y_j) > \theta$. This threshold θ was tuned to maximize MaxF1. We employed 0.89 and 0.95 in the binary classification of *G*

Method		*G vs. O*		*G + GP vs. O*	
		MaxF1	AUC	MaxF1	AUC
Zhu et al.	(Hwang et al., 2015)	0.550	0.509	0.431	0.391
Coster and Kauchak	(Hwang et al., 2015)	0.564	0.495	0.415	0.387
Hwang et al.	(Hwang et al., 2015)	0.712	0.694	0.607	0.529
Additive embeddings		0.691	0.695	0.518	0.487
Average alignment		0.419	0.312	0.391	0.297
Maximum alignment		0.717	0.730	**0.638**	**0.618**
Hungarian alignment		0.524	0.414	0.354	0.275
Word Mover's Distance		**0.724**	**0.738**	0.531	0.499

Table 1: Binary classification accuracy of parallel and nonparallel sentences. *Good (G) vs. Others (O)* is defined for sentence pairs where the label *G* denotes parallel. *G + Good Partial (GP) vs. O* regards the label *GP* as parallel in addition to the label *G*. The labels *G* and *GP* refer to bi- and uni-directional entailment, respectively.

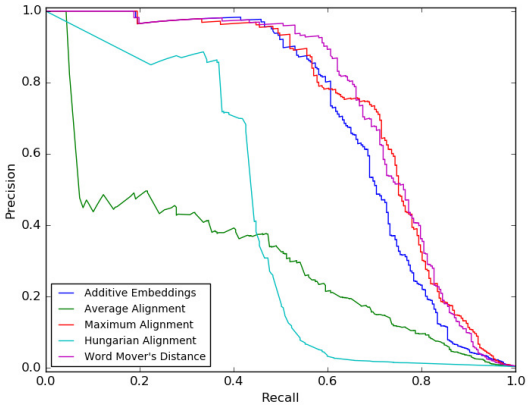

Figure 3: PR curves in binary classification of *G* and *O*.

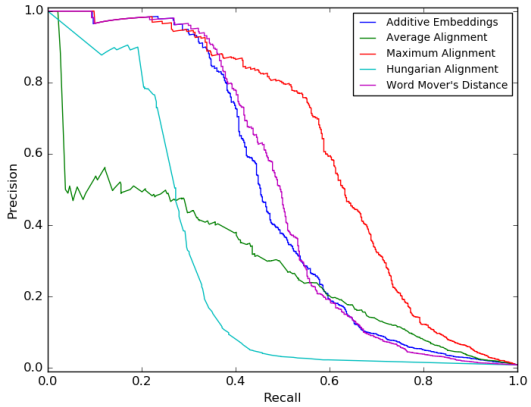

Figure 4: PR curves in binary classification of *G + GP* and *O*.

vs. O and *G + GP vs. O* for *average alignment*, 0.28 and 0.49 in the binary classification of *G vs. O* and *G + GP vs. O* for *maximum alignment*, and 0.98 in the binary classification of *G vs. O* and *G + GP vs. O* for *hungarian alignment*.

Table 1 compares sentence similarity measures in the binary parallel and nonparallel classification task. The top three methods in the upper row are taken from previous studies of monolingual parallel corpus construction for text simplification, and the five methods in the lower rows are the sentence similarity measures based on the word embeddings. *Additive embeddings* provides yet another baseline method, in which sentence embeddings are composed by adding word embeddings without word alignment, and sentence similarity is computed using the cosine similarity between sentence embeddings. We used publicly available [5] pretrained word embeddings to compute sentence similarity. From Table 1, it can be seen that *Word Mover's Distance* performed best in the binary classification task between *G vs. O*, whereas *maximum alignment* performed best in the binary classification task between *G + GP vs. O*.

Figures 3 and 4 show the Precision-Recall curves in the binary classification task between parallel and nonparallel sentences. Figure 4 shows that *maximum alignment* performed better than the other sentence similarity measures based on word embeddings, in the binary classification between *G + GP vs. O*.

Text simplification must take account not only of paraphrases from a complex expression to a simple expression but also of the deletion of unimportant parts of a complex sentence. It is therefore important to include both *G* sentence pairs, where the simple sentence is synonymous with the complex sentence, and *GP* sentence pairs, where the complex sentence entails the simple sentence. For this reason, *maximum alignment*, which performed best in classification between *G + GP vs. O*, was the preferred measure for

[5] https://code.google.com/archive/p/word2vec/

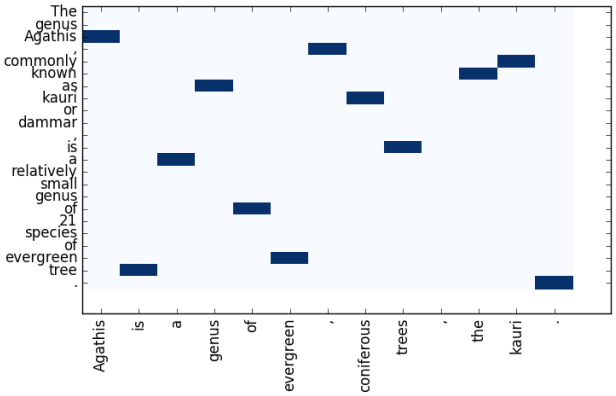

Figure 5: Hungarian word alignment matrix. A vertical axis indicates a sentence from English Wikipedia. A horizontal axis indicates a sentence from Simple English Wikipedia.

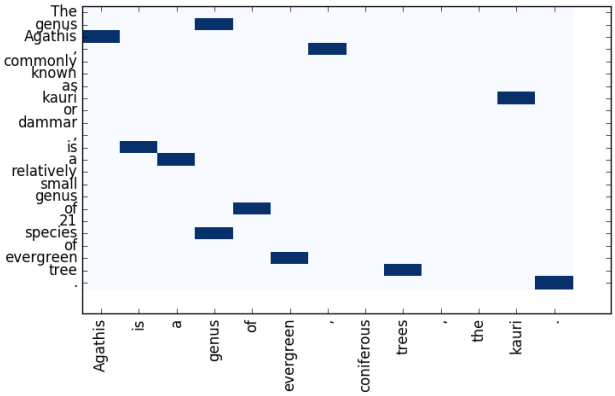

Figure 6: Maximum word alignment matrix. A vertical axis indicates a sentence from English Wikipedia. A horizontal axis indicates a sentence from Simple English Wikipedia.

computing sentence similarity in text simplification.

The experimental results demonstrate the effectiveness of *maximum alignment* in text simplification tasks, but why *maximum alignment* is the best? We present two illustrative figures to explain the reason. First, in *hungarian alignment* (Figure 5), false word alignments such as "as, genus," "tree, is," and "commonly, kauri" are found because of the restriction of one-to-one word alignment on the whole. Second, in *maximum alignment* (Figure 6), correct word alignments such as "genus, genus," "species, genus," "tree, trees," and "kauri, kauri" are found because many-to-one word alignment is searched greedily. It may identify ambiguous pairs such as "genus, genus" and "species, genus," but symmetrization of many-to-one alignment succeeds in reducing this type of noisy alignment. The restriction of *hungarian alignment* is too strict to correctly align content words between the sentences since even function words need to be aligned one-by-one. Also, in text simplification tasks, many-to-one alignment is more appropriate than one-to-one alignment because paraphrase between a phrase and a word occurs frequently.

4.2 Building an English Text Simplification Corpus

We built a monolingual parallel corpus for text simplification from English Wikipedia (normal) [6] and Simple English Wikipedia (simple) [7] using the *maximum alignment* that performed best in the previous experiment. First, we paired articles from the normal and simple editions by an exact match of titles, obtaining 126,725 article pairs. Sentence extraction using WikiExtractor [8] and tokenization using NLTK 3.2.1 [9] gave an average number of words per sentence of 25.1 for the normal articles and 16.9 for the simple articles. The average numbers of sentences per article were 57.7 and 7.65, respectively.

We computed the sentence similarity of all pairings of normal and simple sentences using *maximum alignment*. We based the threshold for word similarity and sentence similarity on the experimental results shown in Table 1. We aligned only those word pairs with a word similarity equal to or greater than 0.49, and aligned only those sentence pairs with a sentence similarity equal to or greater than 0.53. As a result, we obtained 492,993 sentence pairs from 126,725 article pairs.

Table 2 shows examples from the monolingual parallel corpus for text simplification with sentence similarity. We found synonymous expressions (purchased → bought) in sentence pairs with a similarity greater than 0.9 and deletion of unimportant parts of a sentence (such as ...) in sentence pairs with a similarity equal to or greater than 0.7. We also found sentence pairs with only a few words in common with a similarity less than 0.7.

4.3 English Text Simplification

We trained SMT-based text simplification models using our corpus and existing text simplification corpora (Zhu et al., 2010; Coster and Kauchak, 2011b; Hwang et al., 2015). The results were compared to evaluate the effectiveness of our text simplification corpus. We treated text simplification as a translation problem from the normal sentence to the simple one and modeled it using a phrase-based SMT trained as a log linear model. In each corpus, we randomly sampled 500 sentence pairs for tuning with MERT (Och, 2003) and used the remainder for training. Moses was used as the phrase-based SMT tool. We employed GIZA++ (Och and Ney, 2003) to obtain the word alignment, and KenLM (Heafield, 2011) to build the 5-gram language model from the entire Simple English Wikipedia [7]. As test data, we used 277 sentence pairs labeled *G* and 281 sentence pairs labeled *G + GP* from the Hwang et al. (2015) dataset and evaluated the accuracy using BLEU.

Table 3 shows the number of sentences, range of vocabulary, average number of words per sentence, and BLEU scores of the text simplification models trained on each corpus. The text simplification model trained on our corpus achieved the best BLEU score. To compare the learning curves of our corpus with that from Hwang et al. (2015), we recorded the BLEU scores while changing the corpus size. We discovered that the difference in performance was not only due to the corpus size, as the BLEU scores of the model trained on our corpus remained higher than those of the model trained on the Hwang et al. (2015) corpus at all corpus sizes. The model trained on the Coster and Kauchak (2011b) corpus performed slightly better than that trained on our corpus in 100,000 sentence pairs of a *G* (bi-directional entailment) test set; however, in a *G + GP* (uni-directional entailment) test set that requires more various

Table 4: Examples of text simplification trained on different text simplification corpora.

substitution and phrasal definition, the model trained on our corpus performed slightly better than their corpus.

Our corpus gave a larger difference in the average number of words between normal and simple sentences than the other corpora, with values closer to the average numbers of words per sentence in the entire Wikipedia (25.1 and 16.9, respectively). This suggests that *maximum alignment* was able to compute sentence similarity more accurately than the other measures regardless of the sentence length.

Table 4 shows examples of text simplification trained on different text simplification corpora. The model trained on our corpus generated a simple sentence that appropriately entailed the reference. The model trained on the Coster and Kauchak (2011b) corpus simplified the input sentence appropriately but also performed incorrect substitutions and generated an ungrammatical sentence. The model trained on the *G + GP* part of the Hwang et al. (2015) corpus did not rewrite the input sentence. The model trained on the Zhu et al. (2010) corpus used almost the same amount of Coster and Kauchak (2011b)'s corpus but performed incorrect substitutions and generated an ungrammatical sentence. Coster and Kauchak (2011b) extended Zhu et al. (2010)'s work by considering the order of sentences. In a Wikipedia article, sentences are arranged in a characteristic order, e.g., a definition sentence appears in the first sentence. Therefore, they may obtain similar sentence pairs effectively. In contrast, our simple proposed method achieved equivalent or higher performance than their method without considering any ordering of sentences.

5 Conclusions

We proposed an unsupervised method for building a monolingual parallel corpus for text simplification. Four types of sentence similarity metric were proposed, based on alignment between word embeddings. Experimental results demonstrated the effectiveness of the sentence similarity measure using many-to-one word alignment to align each word in the complex sentence with the most similar word in the simple sentence. Our proposed method achieved state-of-the-art performance in both an intrinsic evaluation based on classifying sentence pairs from the English Wikipedia and Simple English Wikipedia into a parallel and nonparallel data, and in an extrinsic evaluation in which a complex sentence was translated into a simple sentence.

We successfully built an English monolingual parallel corpus for text simplification from comparable corpus with different levels of difficulty. However, such large-scale comparable corpus is unavailable in many languages. In future work, we will build a monolingual parallel corpus from a raw corpus by combining our sentence similarity measure with a readability assessment. Specifically, we will divide the raw corpus into complex and simple corpora based on readability, and use the paired corpora to align complex sentences with simple ones. This approach should be applicable to any language, and open new opportunities in the field of text simplification.

Abstract

This paper presents an approach combining lexico-semantic resources and distributed representations of words applied to the evaluation in machine translation (MT). This study is made through the enrichment of a well-known MT evaluation metric: METEOR. This metric enables an approximate match (synonymy or morphological similarity) between an automatic and a reference translation. Our experiments are made in the framework of the *Metrics* task of WMT 2014. We show that distributed representations are a good alternative to lexico-semantic resources for MT evaluation and they can even bring interesting additional information. The augmented versions of METEOR, using vector representations, are made available on our *Github* page.

1 Introduction

Learning vector representations of words using neural networks has generated a strong enthusiasm in the NLP research community. In particular, many contributions were proposed after the work of (Mikolov et al., 2013a; Mikolov et al., 2013b; Mikolov et al., 2013c) on training word embeddings. The main reasons for this strong interest are: the proposal of a simple and efficient neural architecture to learn word vector representations, the availability of an open source tool *Word2Vec*[1] and the rapid structuring of a user community[2]. Later on, several contributions have extended the work of Mikolov on word vectors to phrases (sequences of words) (Mikolov et al., 2013b; Le and Mikolov, 2014a) and to bilingual representations (Luong et al., 2015). All these vector representations capture similarities between words, phrases or sentences at different levels (morphological, semantic).

However, although these representations can be semantically informative, they do not exactly replace fine-grained information available in lexical-semantic resources such as *WordNet* (Fellbaum, 1998), *BabelNet* (Navigli and Ponzetto, 2010), or *DBnary* (Sérasset, 2012). Such lexical resources are also more easily interpretable by humans as shown in (Panchenko, 2016), but their construction is costly while word embeddings can be trained *ad infinitum* on any monolingual or bilingual corpora.

In short, both approaches (lexical resources and word embeddings) have their pros and cons. However, few studies have attempted to compare and combine them. Pioneering work of Faruqui et al. (2014) proposed to refine representations learning using lexical resources. The idea is to force words connected in the lexical network, to have a close representation (for example through a synonymy link). The technique proposed is evaluated on several benchmarks (word similarity, sentiment analysis, finding of synonyms). More recently, Panchenko (2016) and Rothe and Schütze (2015) extended word embeddings to sense embeddings and tried to compare them to lexical synsets.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1159–1168, Osaka, Japan, December 11-17 2016.

Contributions: this article attempts to review the contribution of vector representations to measure sentence similarity. We compare them with similarity measures based on lexical resources such as *WordNet* or *DBnary*. Machine Translation (MT) evaluation was identified as a particularly interesting application to investigate, since MT evaluation is still an open problem nowadays. More precisely, we propose to augment a well known MT evaluation metric (METEOR (Banerjee and Lavie, 2005)) which allows an approximate matching (through synonymy or morphological similarity) between MT hypothesis and reference. The augmented versions of METEOR proposed (using word embeddings, lexical resources or both) allow us to objectively compare the contribution of each approach to measure sentence similarity. For this, correlations between METEOR and human judgements (of MT outputs) are measured within the framework of WMT 2014 *Metrics* task. The code of the augmented versions of METEOR is also provided on our *Github* page[3].

Outline: in section 2 (Related Work), we quickly present METEOR, lexical resources and word embeddings. Section 3 presents our propositions to augment METEOR in order to conduct a fair comparison between lexical resources and vector representations respectively. Section 4 presents our experiments made within the framework of WMT 2014, as well as quantitative and qualitative analyses. Finally, section 5 concludes this work and gives some perpectives.

2 Related Work

2.1 An automatic metric for MT evaluation: METEOR

2.1.1 The origins

METEOR was proposed to compensate BLEU's and NIST's weaknesses (Papineni et al., 2002; Doddington, 2002). In short, METEOR was created to better correlate with human judgements by using more than word-to-word alignments between a hypothesis and some references. The alignment is made according to three *modules*: the first stage uses exact match between word surface forms (*Exact* module), the second one compares word stems (*Stems* module) and the third one uses synonyms (*Synonym* module) from a lexical resource such as WordNet (available for English only in METEOR).

One contribution of this paper is to propose an alternative to *Stems* and *Synonym* modules: our proposed add-on will be called *Vectors* module later on.

2.1.2 Recent extensions of METEOR

METEOR-NEXT (Denkowski and Lavie, 2010a) was proposed to better correlate with HTER (Human-targeted Translation Edit Rate – *HTER* (Snover et al., 2006)). HTER is a semi-automatic post-editing based metric, which measures the edit distance between a hypothesis and a reference. METEOR-NEXT proposes to go further than just word-to-word alignment by using phrase-to-phrase alignments. For this, phrase databases were created for several languages like English (Snover et al., 2009), German, French or Czech (Denkowski and Lavie, 2010b). More recently, another version called *METEOR Universal* used bitexts to extract paraphrases (Denkowski and Lavie, 2014).

METEOR was also extended by using Word Sense Disambiguation (WSD) techniques (Apidianaki and Marie, 2015). The authors used *Babelfly* (Moro et al., 2014) for several langage pairs (translation from French, Hindi, German, Czech and Russian to English). A better correlation with human judgement at segment level was observed using WSD in METEOR.

Finally, to extend the use of *Synonym* module to target languages others than English, Elloumi et al. (2015) proposed to replace WordNet by DBnary (Sérasset, 2012). The new target languages equipped with a *Synonym* module were French, German, Spanish, Russian and English.

2.2 Lexical resources

2.2.1 WordNet

WordNet is a well known lexical resource for English. Created at the University of Princeton (Fellbaum, 1998), it is used in several NLP tasks such as Machine Translation, Word Sense Disambiguation,

[3] https://github.com/cservan/METEOR-E

Cross-lingual Information Retrieval, etc. WordNet links nouns, verbs, adjectives and adverbs to a set of synonyms called "synsets". Each synset represents a specific concept.

Synsets are linked to each other according to semantic, conceptual and lexical relations. Words with multiple meanings correspond to multiple synsets and meanings are sorted according to their frequency. WordNet is available in several languages (Arabic, French, etc.) but these versions are not freely available. In METEOR, only English WordNet is used to match hypothesis and reference words according to their meanings. It contains more than 117,000 synsets.

To extract lemmatized forms, METEOR uses a function called *Morphy-7WN1* which firstly checks special cases in an exception list and secondly uses rules to lemmatize words according to their syntactic class.

2.2.2 DBnary

DBnary is a multilingual lexical resource in RDF format (Klyne and Carroll, 2004). This resource has been collected by Sérasset (2012). Lexical data are represented using the LEMON vocabulary (McCrae et al., 2011). Most Part-of-Speech tags are linked with *Olia standards* or *Lexinfo* vocabularies (Chiarcos and Sukhareva, 2015; Cimiano et al., 2011) which makes them reusable in many contexts.

DBnary is downloadable or available online through a SPARQL access point. Lexical data are automatically extracted from Wiktionary, Wikipedia's dictionary for 21 languages[4].

	English	French	Russian	German
Number of entries	620 K	322 K	185 K	104 K
Number of meanings	498 K	416 K	176 K	116 K
Number of synsets	35 K	36 K	31 K	33 K

Table 1: Detail of the data used from DBnary for the languages targeted in this paper.

Among available lexical data, one may find 2.9M lexical entries (with parts-of-speech, canonical form for all of them, along with pronunciations when available and inflected forms for some languages). Lexical entries are subdivided into 2.5M lexical senses (with their definitions and some usage example).

DBnary also contains more than 4.6M translations going from the 21 extracted sources languages to more than 1500 different target languages. Additionally, DBnary contains lexicosemantic relations (syno/anto-nyms, hypo/hypero-nyms, etc.). Table 1 shows the size of the data for languages involved in the experiments later reported in this paper. Additional figures are available on the DBnary public web site[5].

Lemmatized forms for DBnary are based on the *TreeTagger* module (Schmid, 1995), which enables us to find the corresponding synsets.

2.3 Monolingual and bilingual embeddings

2.3.1 Overview

Learning word embeddings is an active research area (Bengio et al., 2003; Turian et al., 2010; Collobert et al., 2011; Huang et al., 2012). The main idea is to learn a word representation according to its context: the surrounding words (Baroni and Zamparelli, 2010). The words are projected on a continuous space and those with similar context should be close in this multi-dimensional space. When word vectors are available, a similarity between two words can be measured by a metric such as a cosine similarity.

Using word-embeddings for machine translation evaluation is appealing since they can be used to compute similarity between words or phrases in the same language (monolingual embeddings capture intrinsically synonymy or morphological closeness) or in two different languages (bilingual embeddings allow to directly compute a distance between two sentences in different languages). We use the *MultiVec* (Bérard et al., 2016) toolkit for computing and managing the continuous representations of texts. It includes word2vec (Mikolov et al., 2013a), paragraph vector (Le and Mikolov, 2014b) and bilingual distributed representations (Luong et al., 2015) features.

[5]`http://kaiko.getalp.org/about-dbnary/`

2.3.2 Use of vector representations in NLP evaluation

Zou et al. (2013) proposed to use bilingual word embeddings to detect similarities for word alignment. This information is used as an additional parameter in a phrase-based machine translation system. (Banchs et al., 2015) proposed to explore a metric funded on latent semantic analysis (Salton et al., 1975) to extract semantic embeddings and measure the similarity between two sentences. Finally, these word embeddings were used to enrich ROUGE, a metric for evaluating automatic summarization (Ng and Abrecht, 2015).

As far as MT evaluation is concerned, Gupta et al. (2015) proposed a metric based on neural network language models jointly with dependency trees to link an hypothesis to a reference. Meanwhile, Vela and Tan (2015) proposed an approach to model document embeddings to predict translation adequacy.

These works are close to ours but they propose metrics which need to be learned and optimized to a specific task or domain. In our work, we use word embeddings trained once and for all on a (large) general corpus. Our detailed methodology to augment METEOR metric is presented in the next section.

3 Augmented METEOR

3.1 Data and protocol

We evaluate our augmented METEOR through WMT14 framework (*metrics* task (Machacek and Bojar, 2014)). This framework enables us to estimate the correlation of proposed evaluation metric with human judgements for several machine translation outputs and several language pairs (English-French, English-German, English-Russian, and vice versa). In our experiments, we use segment level Kendall's τ correlation coefficient, as proposed in WMT14 (based on systems ranking at sentence level by humans, compared to automatic metric ranking).

We augment METEOR in two ways: firstly, we replace the use of lexical resources by the use of word embeddings. In other words, we replace *Stem* and *Synonym* modules by our new *Vector* module. Secondly, we combine lexical resources and word embeddings by using jointly *Stem*, *Synonym* and our *Vector* module.

To summarize, the following variants of METEOR are evaluated:

- *METEOR Baseline*: the METEOR score is estimated using *Exact*, *Stem*, *Synonym* and *Paraphrase* modules for English as a target language and *Exact*, *Stem* and *Paraphrase* modules for other target languages,
- *METEOR DBnary*: similar to *METEOR Baseline* but *Synonym* module is available for any target language since it uses DBnary resource instead of Wordnet,
- *METEOR Vector*: the *Stem* and *Synonym* modules are replaced by the *Vector* module ;
- *METEOR Baseline + Vector*: the *METEOR Baseline* configuration is augmented with the *Vector* module ;
- *METEOR DBnary + Vector*: the *METEOR DBnary* configuration is augmented with the *Vector* module.

3.2 *METEOR DBnary*

As mentioned in section 2.1, the *Synonym* module of METEOR uses WordNet's synsets (117K entries for English). As an alternative, we use another lexical resource: DBnary (Sérasset, 2012), as proposed recently by Elloumi et al. (2015). This allows us to use *Synonym* module for any target language: French, German, Spanish, Russian and English.

More precisely, synonym relations are extracted from DBnary using SPARQL request on the DBnary server[6]. We extract data for English, French, Russian and German languages. The extraction process outputs relations in the following format: $lemma \rightarrow Synonym$. Then, these data are projected to the

[6] http://kaiko.getalp.org/about-dbnary/online-access/

WordNet format used in METEOR code. This process gives an identifier (ID) for each lemma and builds a list of synonym IDs for each lemma such as: $lemma \rightarrow ID\_Syn_1,\ ID\_Syn_2,\ ID\_Syn_3$.

The first two lines of Table 3 compare *METEOR DBnary* and *METEOR Baseline* for several French-English MT systems submitted to WMT14 (Bojar et al., 2014).

METEOR DBnary improved the score by 0.7 points from *METEOR Baseline*. In other words, DBnary seems to match more synonyms than WordNet, despite the fact that WordNet is 3.3 time bigger than DBnary in English. This could be due to the fact that WordNet has only 4 morpho-syntactic categories (Noun, Verbs, Adjectives and Adverbs) while DBnary has more morpho-syntactic categories.

3.3 *METEOR Vector*

As mentioned in section 2.3.2, we propose to replace lexical resources by word embeddings. Word embeddings capture the context of the words. Consequently, similar word vectors may correspond to synonyms or morphological variants (see section 2.3).

Language	Corpora	# of lines	# of source words	# of target words
French–English	Europarl V7 + news commentary V10	2.2 M	67.2 M	60.7 M
German–English	Europarl V7 + news commentary V10	2.1 M	57.2 M	59.7 M
Russian–English	Common Crawl + news commentary V10 + Yandex	2.0 M	47.2 M	50.3 M

Table 2: Bilingual corpora used to train the word embeddings for each language pair.

In our *Vector* module, the matching between two words is done using a similarity score derived from the cosine similarity. If the similarity score is higher than a threshold, the words are considered as matched (potential synonyms or morphological proximity). In our experiments, we evaluate using: (a) a default threshold fixed to 0.80 (b) an oracle threshold obtained empirically on the WMT14 data set (Machacek and Bojar, 2014).

Table 2 summarizes data used to train monolingual word embeddings and bilingual word embeddings. These word embeddings were trained with a CBOW model, a vector size of 50 and a windows size ± 5 words, thanks to the MultiVec toolkit (Bérard et al., 2016).

Metrics	Systems: online A	online B	online C	rbmt 1	rbmt 4
METEOR Baseline	36.33	36.71	31.19	33.00	31.65
METEOR DBnary	36.93	37.33	32.01	33.69	32.42
METEOR Vector	37.00	37.34	31.87	33.67	32.34
METEOR Baseline + Vector	37.08	37.40	31.96	33.75	32.45
METEOR DBnary + Vector	37.53	37.88	32.60	34.32	33.05

Table 3: METEOR scores (all configurations) on the *newstest* corpus of the WMT14 translation evaluation task from French to English.

The results presented in table 3 show that word embeddings (*Vector* module) can efficiently replace lexical resources (*Synonym* and *Stem* modules) to match words in the translation hypothesis with those in the reference. In addition, their combination shows a good potential to match even more words between hypothesis and reference. In the next section, we evaluate if the proposed versions of *augmented* METEOR better correlate with human judgements.

4 Correlations of Augmented METEOR with Human Judgements

4.1 Results of different METEOR configurations

In these experiments, we present results obtained with the *Vector* module based on two threshold values: a default one (0.80) and an oracle one which maximizes the correlation with human judgement.

Table 4 presents the correlation scores obtained within the framework of WMT14 metrics task (Machacek and Bojar, 2014)[7]. The evaluation is done according to several translation tasks: from English to French (en–fr), German (en–de) and Russian (en–ru), and vice versa. French, German and Russian

[7]For better readability, we do not add standard deviations in the tables. These numbers will be, however, provided in supplementary material put on the paper web page (`https://github.com/cservan/METEOR-E/paper`).

as target languages represent a growing difficulty due to their morphology. English as target language allows to compare the lexical databases (Wordnet *vs* DBnary).

To English. Firstly, when the translation direction is to English, we can observe that *METEOR Baseline* and *METEOR Vector* get equivalent results in average. *METEOR DBnary* also obtains similar results to *METEOR Baseline*. When we combine WordNet lexical resource and word embeddings (*METEOR Baseline + Vector*), the reference score is increased by $0,005$ points. If the combination is done with DBnary's lexical data (*METEOR DBnary + Vector*), the improvement is similar.

For *Vector* module, optimization of the threshold slightly improves the average correlation. Combination of *METEOR Baseline + Vector* or *METEOR DBnary + Vector* improves by $0,002$ points when the threshold is optimized.

From English. Secondly, when the translation direction is from English, we can observe an improvement of the correlation score obtained with *METEOR DBnary*, compared with *METEOR Baseline*. This is due to the fact that for French, German and Russian as target languages, *METEOR Baseline* does not use any *Synonym* module. Our *METEOR Vector* with the default threshold also gets better correlation scores compared to *METEOR DBnary* ($+0.003$ points in average). The combinations *METEOR Baseline + Vector* and *METEOR DBnary + Vector* further improve correlations with human judgements ($+0.001$ points in average). Finally, when we use an oracle threshold for *Vector* module, improvements are bigger and can reach 0.013 points in average, compared to *METEOR Baseline*.

Language pairs	fr–en		de–en		ru–en		Average	
Metric	Threshold	τ	Threshold	τ	Threshold	τ	Threshold	τ
METEOR Baseline	–	0.406	–	0.334	–	0.329	–	0.356
METEOR DBnary	–	0.408	–	0.334	–	0.328	–	0.357
METEOR Vector	0.80	0.407	0.80	0.332	0.80	0.328	0.80	0.356
METEOR Baseline + Vector	0.80	0.407	0.80	0.343	0.80	0.332	0.80	0.361
METEOR DBnary + Vector	0.80	0.407	0.80	0.337	0.80	0.338	0.80	0.361
METEOR Vector	0.89	0.411	0.78	0.333	0.80	0.328	0.82	0.357
METEOR Baseline + Vector	0.73	0.412	0.80	0.343	0.88	0.333	0.80	0.363
METEOR DBnary + Vector	0.73	0.413	0.79	0.338	0.80	0.338	0.77	0.363
Language pairs	en-fr		en-de		en-ru		Average	
Metric	Threshold	τ	Threshold	τ	Threshold	τ	Threshold	τ
METEOR Baseline	–	0.280	–	0.238	–	0.427	–	0.315
METEOR DBnary	–	0.284	–	0.239	–	0.435	–	0.319
METEOR Vector	0.80	0.290	0.80	0.241	0.80	0.436	0.80	0.322
METEOR Baseline + Vector	0.80	0.288	0.80	0.241	0.80	0.440	0.80	0.323
METEOR DBnary + Vector	0.80	0.289	0.80	0.242	0.80	0.439	0.80	0.323
METEOR Vector	0.72	0.295	0.79	0.241	0.72	0.439	0.74	0.325
METEOR Baseline + Vector	0.86	0.296	0.79	0.242	0.79	0.445	0.81	0.328
METEOR DBnary + Vector	0.88	0.294	0.75	0.245	0.79	0.443	0.81	0.327

Table 4: Correlation score at segment level between several METEOR configurations and human judgements (WMT14 framework). Scores obtained with the *Vector* module are presented firstly with the default threshold (0.80) and secondly with the oracle threshold (under the dashed line).

4.2 Investigating more embeddings configurations

In the previous section, *METEOR Vector* used a simple and monolingual word embedding configuration. This section investigates more configurations (monolingual and bilingual) to improve METEOR.

In this experiment, we focus only on *METEOR Vector*. Indeed, the *monolingual (baseline)* shown in table 6 corresponds to the line *METEOR Vector* in Table 4. Firstly, we propose to train our embeddings on bitexts (Table 2) using *bivec* approach (Luong et al., 2015). We also try to train pseudo-bilingual embeddings on a pseudo bitext with target language text and POS tags (see an example in Table 5). The main idea is to strongly link words with their syntactic class when learning word embeddings. We

madam president , on a point of order .	$\Leftrightarrow$	NOUN NOUN PUNCT ADP DET NOUN ADP NOUN PUNCT

Table 5: Example of bitext where the target side is replaced by POS.

call this kind of model *pseudo-bilingual with POS*. In the same way, we train bilingual models called *pseudo-bilingual with lemmas*, where the POS tags are replaced by lemmas. In addition, we also learn word embeddings with lemmas only and bilingual models with lemmas only.

Models:	*monolingual (baseline)*	*bilingual*	*pseudo-bilingual with POS*	*pseudo-bilingual with lemmas*	*monolingual (lemmas)*	*bilingual (lemmas)*
To English	0.356	0.354	0.355	0.354	0.357	0.357
From English	0.322	0.322	0.320	0.325	0.324	0.318

Table 6: Average correlation score at segment level for *METEOR Vector* with several training configurations of word embeddings with the default threshold (0.80).

In the Table 6, we compare several training configuration of the word embeddings through the same protocol as previous section (only average correlations are reported while the detailed results will be provided as supplementary material on the paper web page). When we observe the average results, the *bilingual* embeddings seem not to be as efficient as the monolingual baseline. The pseudo-bilingual approaches with POS and Lemmas obtained slightly the same results as the monolingual baseline regarding all the configurations we have. Finally, the monolingual model learned on lemmas (instead of words) tends to be slightly better when the translation direction is to English. However, this trend should be confirmed in a future investigation.

4.3 Discussion

The correlation scores obtained with the enriched metric tend to suggest that distributed representations are as powerful as lexico-semantic resources for automatic MT evaluation. Furthermore, vector representations can bring additional information, and they are definitely useful when no lexical resource is available in the target language.

Considering the average correlation scores obtained, the configurations *METEOR Vector* and *METEOR DBnary* are comparable, except on German language, for which *METEOR Vector* obtained a better correlation score. On the other hand, when we combine lexical data with *Vector* module (*METEOR DBnary + Vector*), we observe a small increase of the correlation score, in particular when threshold is tuned, which suggests a tunable version of METEOR.

Finally, several embeddings variants were trained but it seems that monolingual models are efficient enough for the specific task (MT evaluation) considered here.

4.3.1 Examples

To illustrate the word matching obtained by our versions of METEOR, we analyze two examples from the evaluation data set. In these examples, we present the alignments obtained with *METEOR DBnary + Vector*.

hypothesis:	je pense qu' il est concevable que ces données soient employées pour le bénéfice mutuel .
Reference:	j' estime qu' il est concevable que ces données soient utilisées dans leur intérêt mutuel .

Table 7: First example from the system *rbmt 1* evaluated with the combination *METEOR DBnary + Vector*. The relations detected with the lexical resource DBnary are framed in continuous line while those obtained thanks to the distributed representations are framed in dotted line.

The example presented in table 7 shows *rbmt 1* system output submitted during the WMT14 translation task. *METEOR baseline* found only alignments for words with the same surface forms (*"qu' ", "il", "est"*, etc. – these forms are found identical thanks to the *Exact* module and are not highlighted here). The *Synonym* module based on DBnary makes it possible to find a correspondence between words *"employées" – "utilisées"* and *"pour" – "dans"*. Lastly, *Vector* module indicates that words *"pense"* and *"estime"* are contextually closed, just as the words *"je"* and *"j"'*. When the example is only evaluated with *METEOR Vector*, words *"employées"* and *"utilisées"* are also paired with the default threshold (0.80). On the other hand, the words *"bénéfice"* and *"intérêt"* are paired by the module *Vector* only if the decision threshold is lowered to 0.75.

In the second example presented in table 8, the hypothesis is provided by *rbmt 4* system. As in the previous example, the correspondences found with *Synonym* module based on DBnary (framed by one

hypothesis:	le créateur de SAS disait il faisait un genre du feuilleton géopolitique .
Reference:	le père de SAS disait faire un genre de feuilleton géopolitique .

Table 8: Another example scored with the combination *METEOR DBnary + Vector*.

continuous line) are supplemented by those found by *Vector* module (dotted line): *Synonym* module found *"créateur"* – *"père"* and *"faisait"* – *"faire"*; while *"du"* and *"de"* are aligned thanks to *Vector* module.

These examples illustrate the complementarity between lexical resources and word embeddings for sentence similarity detection. Word vectors can enable to match important words (like *"pense"* and *"estime"* in our first example), but also empty words (like *"du"* et *"de"* in our second example).

4.3.2 Limitations of Word Embeddings

So far, we did not deal with Out-Of-Vocabulary (OOV) words in *METEOR Vector*. By OOV we mean words that do not have a vector representation because they were not found in the training corpus for word embeddings. In that case, no matching can occur between the word in the hypothesis and words in reference. Consequently, it might be interesting to carefully select the training corpus for word vectors so that it will be close enough to the machine translation outputs to evaluate. This could be considered in future works.

5 Conclusion and Perspectives

In this paper, we proposed to compare text similarity measures based on vector representations with similarity measures based on lexico-semantic resources. Our work was applied to machine translation evaluation and we extended an existing evaluation metric called METEOR. Our experiments have shown that word vector representations can be useful when no lexical resource is available in the target language. Moreover, it seems that these representations can bring complementary information in addition to lexical resources (experiments done for French, English, German and Russian as target languages).

Our future works on this topic will focus on the use of phrase embeddings to complement the *Paraphrase* module of METEOR. We also plan to introduce a *syntax flavor* in our *Vector* module by weighting the cosine distances differently according to the morpho-syntactic category of the words. Finally, we will study the adaptation of our approach to other metrics such as TER-Plus, for instance.

The tool, the data and the models presented in this paper will be put online[8] to facilitate reproducibility of the experiments we carried out.

Abstract

One of the main obstacles, hampering method development and comparative evaluation of named entity recognition in social media, is the lack of a sizeable, diverse, high quality annotated corpus, analogous to the CoNLL'2003 news dataset. For instance, the biggest Ritter tweet corpus is only 45 000 tokens – a mere 15% the size of CoNLL'2003. Another major shortcoming is the lack of temporal, geographic, and author diversity. This paper introduces the Broad Twitter Corpus (BTC), which is not only significantly bigger, but sampled across different regions, temporal periods, and types of Twitter users. The gold-standard named entity annotations are made by a combination of NLP experts and crowd workers, which enables us to harness crowd recall while maintaining high quality. We also measure the entity drift observed in our dataset (i.e. how entity representation varies over time), and compare to newswire. The corpus is released openly, including source text and intermediate annotations.

1 Introduction

Businesses, governments, and communities increasingly need real-time information from dynamic, large-volume media data streams, such as blogs, Facebook, and Twitter. In particular, the automatic detection of mentions of people, organizations, locations, and other entities (i.e. Named Entity Recognition) is a key step in numerous social media analysis applications, e.g. competitor and brand monitoring (Mostafa, 2013), debate and election analysis (Mascaro and Goggins, 2012; Tumasjan et al., 2010), disaster response (Kedzie et al., 2015; Neubig et al., 2011), and health- and well-being applications (Coppersmith et al., 2014; Choudhury et al., 2013).

NER methods (typically trained on longer texts, such as news articles), have been shown to perform poorly on shorter and noisier social media content (Ritter et al., 2011). Therefore, recent Twitter NER work (Ritter et al., 2011; Liu et al., 2011; Derczynski et al., 2015) has focused on improving the state-of-the-art, through new methods. The challenges come from named entities (NEs) typically being out-of-vocabulary (OOV) as compared to the training newswire data; the shorter context; and lack of sufficiently large NE annotated social media datasets.

In more detail, Table 1 shows that there are less than 90 thousand tokens of publicly available NE-annotated tweet datasets, and even those have shortcomings in terms of annotation methodology (e.g. singly annotated), low inter-annotator agreement, and stripping of important entity-bearing hashtags and user mentions. At the same time, Ritter et al. (2011) demonstrated that blending gold-standard newswire training data with social media training data - in order to increase the size of the dataset and better generalize - leads to worse performance. Lastly, as this paper demonstrates, existing NER datasets suffer from poor temporal diversity, making the trained NER models sensitive to the entity drift phenomenon.

We address these challenges through building a sizeable manually-annotated corpus – the Broad Twitter Corpus (BTC). In order to maximize diversity, the BTC is stratified for time, including social media posts from a six-year period, drawn from different parts of year, days of the month, and times of the day. Secondly, it is drawn from different places, accounting for different variants of English and the

Table 1: Characteristics of openly-available social media NER corpora. PLO standards for Person, Location, Organization NE types.

different entities found in various regions of the English-speaking world. Finally, it is partially socially segmented, including reactions to news stories, non-professional content, and text from the "twitterati".

The corpus is made freely available in various formats; the source text is included under Twitter's revised 2015 licensing guidelines, as are the intermediate annotations.

2 Corpus Construction

The goal of the corpus is to provide a representative example of named entities in social media. Social media is said to contain more variance than some other text types, like newswire. It certainly is authored by a broader demographic than newswire (Eisenstein, 2013), and contains a variety of styles and formality registers, unlike other user-generated content such as Youtube comments or SMS (Hu et al., 2013). Changes in general discourse subject are also said to present more quickly in social media, creating topic shifts of both greater magnitude and higher frequency than other text types. We focus on Twitter, using this as the "model organism" of social media text (Tufekci, 2014), to assemble a corpus that is capable of catching these variances.

2.1 Annotation Scheme

The BTC corpus is divided into segments, where the documents within each segment share a common theme (see Table 2). The documents consist of the social media message – i.e. tweet – complete with its JSON metadata. The text of the tweet is then annotated with into sentences and tokens, using the TwitIE tokenizer (Bontcheva et al., 2013).

Tokenisation presents some issues in tweets. Classic schemas like PTB do not work well with constructs like smilies or URLs. To address this, we use the TwitIE tokeniser (Bontcheva et al., 2013) which is roughly based on TweetMotif and the twokeniser tool (O'Connor et al., 2010). Of note, we separate the preceding symbol in mentions and hashtags (the @ or # characters) as a distinct token, but still include this in entity spans.

The main question was which entity classes should be covered in the corpus. Some Twitter corpora have used ten top-level Freebase categories (Bollacker et al., 2008; Ritter et al., 2011)[1] or have included products (see Table 1). For expert-based annotation methodologies Hovy (2010) recommend at most ten, ideally seven, categories. In crowdsourcing, successful tasks tend to present even fewer choices – in most cases between two and five categories (Sabou et al., 2014).

Therefore, we chose to focus on the three most widely used entity categories: Person, Location, and Organization (Table 1). Apart from being well understood by annotators, these three categories offer straightforward mapping to the other existing Twitter datasets, so all could be used in combination, as training data, if needed. An initial pilot (Bontcheva et al., 2014a) also included a fourth class, "Product", but crowd workers struggled to annotate these correctly and with good recall, so they were dropped.

For polysemous entities, our guidelines instructed annotators to assign the entity class that corresponds to the correct entity class in the given context. For example, in "*We're driving to Manchester*", Manchester is a location, but in "*Manchester are in the final tonight*", it is a sports club – an organization.

Special attention is given to username mentions. Where other corpora have blocked these out (Rowe et al., 2013) or classified them universally as person (Ritter et al., 2011), our approach is to treat these as named entities of any potential class. For example, the account belonging to Manchester United football club would be labeled as an organization.

[1]Categories used: company, facility, geo-location, movie, music artist, person, product, sports team, TV show and other.

Section	Region	Collection period	Description	Annotators	# Tweets
A	UK	2012.01	General collection	Expert	1000
B	UK	2012.01-02	Non-directed tweets	Expert	2000
E	Global	2014.07	Related to MH17 disaster	Crowd & expert	200
F	Stratified	2009-2014	Twitterati	Crowd & expert	2000
G	Stratified	2011-2014	Mainstream news	Crowd & expert	2351
H	Non-UK	2014	General collection	Crowd & expert	2000

Table 2: Segments of the corpus. A region of "stratified" indicates that data was taken from six regions in the English-speaking world that had a sufficient crowdsourcer workforce to ensure annotator diversity.

2.2 Corpus Diversity

In order to maximize diversity of English social media content, our methodology samples tweets along three dimensions: spatial, temporal and social.

The spatial dimension aims to account for linguistic variation in social media across English-speaking countries. In particular, the discussed entities vary from one region to the next, e.g *Justin Trudeau* in Canada vs. *Theresa May* – in the UK. For these reasons, data is collected from the USA, the UK, New Zealand, Ireland, Canada and Australia.[2]

The temporal dimension is key for being able to make models more resilient towards temporal entity drift (Masud et al., 2010; Magdy and Elsayed, 2016), i.e. the change in entities mentioned at different time periods. For example, *George Bush* or *Pamela Anderson* in the 1990s vs Angelina Jolie and Tiger Woods in 2010, or Santa near Christmas and Guy Faulks in UK tweets in the early winter.

We aim to capture this drift in the BTC by collecting posts over a number of years,[3] as well as being taken from different times of years, days in the month, and times of day. In contrast, previous social media NE corpora were gathered during narrow contiguous time periods (Ritter et al., 2011).

The final, social dimension again aims to account for variation in linguistic styles across different kinds of Twitter users. For instance, verbal communication behaviors such as g-dropping are often copied into typed social media messages (Eisenstein et al., 2010). To try to capture these, the corpus collects data from different segments, explicitly taking in content from well-known public figures, news outlets, well-known social media figures, plus a large volume of randomly-selected posts.

2.3 Corpus Segmentation

The dataset is organized into multiple segments (Table 2) to reflect the diversity criteria and annotation approach (expert vs. crowd). English tweets were filtered using langid.py (Lui and Baldwin, 2012).

Segment A comprises a random sample of UK tweets, collected after New Year, annotated by multiple NLP experts. This data was used for calibration, so includes both expert input and crowd correction.[4]

Segment B is similar to segment A. In this segment we focused on non-directed tweets – i.e. those that are not private replies and so do not begin with a username mention. These were found to be more likely to contain a named entity based on sampling the Ritter et al. (2011) corpus.

Segment E is a small sample focused on a specific event, the crash of flight MH17 over Ukraine. It contains commentary from different places and social levels, contributing different kinds of language and reactions. The entities here have a wide range and are generally from outside the English-speaking world, often instead being Ukrainian, Dutch or Malaysian. This provides needed diversity in names, as well as examples of L2 English language use around NEs (i.e., from non native speakers).

Segment F comprises content from popular individuals that provide twitter-based commentary – the "twitterati". These are stratified across the six English-speaking regions listed above, as well as a general global section. Authors are from the worlds of celebrity, music, politics, sports, journalism; they are a

[2]While there are other countries with English as a first language, such as Botswana and Singapore, we were constrained by the number of local crowd workers we could access (see Section 3.1).

[3]Taken from an archive of Twitter "garden hose" data, a fair 10% sample (Kergl et al., 2014).

[4]The crowd correction is via feedback from its use as gold test data; see Section 3.1.

Annotator group	Recall over final annotations	F1 Agreement
Expert	0.309	0.835
Crowd	0.837	0.350

Table 3: Comparison of expert and crowd annotators over segment A, for calibration. Note higher recall but lower agreement in crowd. Agreement is F1 lenient with micro-averaging.

mix of both principals in the fields and also commentators. This content is reasonably unique to social media, often being too low-impact, speculative or controversial to reach mainstream news.

Segment G contains, in contrast, tweets from mainstream news in the six English-speaking regions, e.g. CNN in the US, SMH in Australia, RTE in Ireland, CBC in Canada and so on. Many local outlets that do not have an international edition are also included.

Segment H is the most varied. To balance the UK bias of segment B, this segment excludes tweets of UK origin (according to the Twitter metadata). The segment is stratified for month of year, time of day, and day of week, giving an even spread over many temporal cycle types in the collection period.

3 Annotation Process

To make annotation scalable and of high quality, while ensuring sufficient annotator variety, corpus annotation was carried out using a mix of NLP experts and paid-for crowdsourcing. The annotation process follows general best practices in crowdsourced corpus annotation (Callison-Burch and Dredze, 2010; Alonso and Lease, 2011; Sabou et al., 2014). For example, task design is kept clean (a critical factor, more important than e.g. interface language – (Khanna et al., 2010)), and the process developed over pilot and refinement iterations.

Tasks were built in GATE and jobs automatically managed through through Crowdflower (Bontcheva et al., 2014b). First segments were entirely annotated and adjudicated by experts as calibration. To maximize annotator focus, images attached to tweets or featuring in content (e.g. news stories) linked to from tweets are shown alongside the task, for worker priming (Morris et al., 2012).

A majority of crowd workers use crowd work as their primary income. We calculate task mean completion times and reward work so that it pays *above* the minimum wage in our country.

3.1 Annotator recall

To annotate text with diverse content, annotators with diverse knowledge are needed. Typical named entity cues, such as capital first letters, are often missing in social media; extra knowledge is one way of compensating for these. We introduce the concept of "annotator recall", which describes the ability of annotators to identify NE mentions, partly based on their own knowledge. The breadth of social media content makes annotation harder for experts. For example, none of the experts we asked during annotation (or the attendees of talks we gave on the topic) could initially explain the entity *KKTNY* in the text "*KKTNY in 45mins!!!!!*", without referring to external resources. However, the crowd, being more diverse, was sometimes able to identify and ground this expression.[5]

To assess annotator recall, we compared expert and crowd annotation over segment A. First, this segment was annotated by a mixture of expert annotators, with each document doubly-annotated and results expert adjudicated. Crowd annotators were then also asked to annotate this data using the same guidelines, and the results compared, shown in Table 3.

In general, the crowd found more entities than experts (Table 3). That is to say, crowd recall over the oracle annotation of the data was higher. However, agreement was lower in the crowd. This was handled by including human expert adjudication over all segments. Further, to improve corpus-level knowledge diversity, each worker was limited to a maximum of 50 tasks.[6] Details of the adjudication process are given in Section 3.2.

[5]The entity colloquially refers to a television program, "Kim and Kourtney Take New York"; from Ritter et al. (2011) data.

[6]Each task involves annotating five tweets for one entity type; each tweet was annotated by five to seven different workers.

Agreement level	IAA (max-recall vs. expert)	IAA (naïve)
Whole document	0.839	n/a
Person entity	0.920	0.799
Location entity	0.963	0.861
Organization entity	0.936	0.954
All entities	**0.940**	**0.877**

Table 4: Inter-annotator agreement breakdown.

	Feature	Count
Dataset	Documents	9 551
	Tokens	165 739
Entities	Person	5 271
	Location	3 114
	Organization	3 732
	Total	12 117

Table 5: Corpus size statistics

After merging in these crowd annotations, a random set of 100 documents were taken from this segment and used as gold test data in later tasks. Gold test data is used to assess performance of individual workers online, by being seeded among real annotation tasks. Performance on gold test data estimates the quality of an annotator's work. Annotators are made aware of results of this process and can highlight incorrect gold test data. The gold test data also provides qualification training for workers; they must perform well on gold test data before accessing real tasks. This gold test set was used throughout the remainder of the corpus annotation, providing quality control and crowd annotator training.

Spatial variation also played a role in crowd annotator recall. Based on the crowd vs. expert comparison data, there were multiple cases where the annotation was deemed "easy" by experts, but the crowd would still miss it. Investigation suggested that annotators based in the same country as the origin tweet had better recall on these entities. Conversely, annotators working on documents from other countries had lower recall. As matched geographic contexts tend to produce better results, during annotation, the geographically stratified parts of corpora were issued only to crowd workers in the same region, in order to maximize recall and local knowledge.

3.2 Adjudication

Adjudication is an important step in refining annotator data. In the case of crowdsourced annotations, further economies of scale can be afforded by automating adjudication; tools already exist for this, such as MACE (Hovy et al., 2013). However, auto-adjudication is poorly equipped to handle exceptional circumstances; further, it is hard to judge its impact without human intervention. The construction of the BTC involved a combination of automatic and human adjudication.

Primarily, we found there were problems with recall. Often, only a single crowd worker or expert would annotate a given (correct) entity. Under traditional agreement-based measures, this singleton annotation would be in the minority, and so likely removed in a typical adjudication step. Given our and others' experiences with annotator recall and diversity (Balog et al., 2012; Difallah et al., 2013), we find this method inappropriate. Further, this annotator behavior has implications for inter-annotator agreement (IAA); perfectly adequate aggregate annotations will nevertheless have reduced agreement. Therefore, naïve IAA measures (such as Fleiss' κ) risk under-reporting multiple annotator performance in high-diversity text. Also, while IAA is sometimes used as a correlate of task understanding, here it also reflects annotator world knowledge.

Workers are continually monitored using 100 documents from segment A, which removes workers having too low performance on reference tasks. This ensures annotator quality while simultaneously permitting variance in annotator knowledge.

To manage annotator sparsity (see Section 3.1), we experimented with a simple automatic adjudication rule. Any time a span is annotated by a worker, that span is placed in the final set. Adjacent annotations of the same type are concatenated. This is the "max-recall" method. We apply max-recall to all original expert and crowd annotations; then, an expert adjudicator evaluates annotator max-recall output to provide a final gold version. Hapax legomena are not unusual, given the diverse subject matter, though only retained after best-effort verification by the expert. Agreement figures are given in Table 4, as well as standard annotator performance.

In our experiments, we measured naïve IAA as the proportion of annotators agreeing on each token of an entity. This gives a per-entity agreement figure. The per-entity is then micro-averaged across the entire corpus, to show the level of annotator agreement, with some ability to account for variance in

entity bounds. This method does not give generous score, but fits our scenario of having many annotators, which makes pairwise comparison awkward. Indeed, even under this measurement regime, IAA levels were respectable.

3.3 Results

In total, the final corpus contained 9 551 documents. In these, there were 165K tokens and 12K entity mentions. Details are given in Table 5; the comparison of this dataset to other social media named entity corpora is in Table 1. Over the annotation process, we collected 125K annotations from 755 workers. These comprised eight experts and a total of 747 crowd workers. Inter-annotator agreement was 0.94, with max-recall autoadjudication followed by a final expert confirmation adjudication step.

4 Drift Analysis

We have described three dimensions for variation: temporal, spatial, and social. This section examines the difference in entities found across the corpus.

Year	1996	2009	2010	2011	2012	2013	2014
Our corpus	0	3	5	127	2414	275	6022
Ritter (2011)	0	0	6902	0	0	0	0
CoNLL'03	1358	0	0	0	0	0	0

Table 6: Volume of tweets in corpus by year; darker background means higher volume.

4.1 Data Selection Comparison

The selection of texts affects the kinds of entities and entity contexts that will be found. Getting a good range is important, as discussed in Section 2. The corpus aims to establish a good spatial, temporal and social range of NEs. This section describes the variation present in the corpus along each of these dimensions, and compares it to two other major NER datasets: the CoNLL 2003 shared task data (Tjong Kim Sang and Meulder, 2003), and Ritter et al. (2011)'s NER data.[7] The other social media corpora mentioned earlier are distributed as plain text, without timestamps or messages IDs, which precludes their analysis.

The temporal distribution is described and compared to the CoNLL2003 and Ritter datasets by year (Table 6), month (Table 7), day of month (Table 8), day of week (Table 9), and time of day (Table 10).[8] Temporal data is based on the local time. Note that both the Ritter and CoNLL data are confined to narrow ranges, the former having been collected in a short period on one day, and the latter having training data from a few days in the summer of 1996 and test data from later the same year (6/7 December). These two corpora are therefore constrained to anachronistic terminology, with the Ritter data also having socially constrained data (i.e., it is only from people active during one Friday evening – September 17, 2010).

4.2 Spatial Entity Diversity

Different regions are likely to mention different entities. The corpus contains two segments that are subdivided into various country-specific strata. To measure the spatial diversity of named entities, we compare the density of entity mentions that are specific to each region, against the rest of the segment.

[7]Many thanks to Alan Ritter for providing references to the original tweet IDs, which allowed this metadata to be captured.
[8]No time of day data was present in the CoNLL dataset.

Table 10: Volume of tweets by time of day.

Novel entities are calculated as the proportion of all entities that occur uniquely in one region. This is based on the assumption that if entities are distributed evenly across the world, i.e. region has no effect, then entity mentions sampled from any given region will roughly match the total. Conversely, if entity mentions do vary by region, then the proportion of novel entities in any coherent region will be higher. For calibration, we also include the global portion of segment F and all of the global segment H. Singleton mentions are removed to smooth the data. Results are given in Table 11, showing high regional variance. Most regions' surface forms are novel, i.e. unique to that region; the U.S. may have the lowest proportion of novel NEs because U.S. users make up a large proportion of global users. The "global" category has the largest size. This is required to give a broad enough picture of globally common entities to make inter-regional comparisons meaningful. The side effect a disproportionate novel part.

5 Entities in Social Media

Having examined diversity in the underlying text, we next analyze characteristics of entities. We qualitatively examine surface forms, and compare entity distribution in social media to that in newswire.

5.1 Common Surface Forms

Table 12 presents the most frequent surface forms in our corpus and also in the CoNLL'03 NER annotated data. The latter comes from news, based on the RCV1 corpus, which is largely US-based newswire from the 1990s (Rose et al., 2002) written by white working-age men (Eisenstein, 2013).

Temporal concept drift (Masud et al., 2010) is evident here. For example, the most frequently-mentioned person entities have different surface forms, while referring to the same concept. The lexical representation of "the President of the US" has changed from *Clinton* to *Obama*. Similarly, the leader of Russia is present but with a different word; *Yeltsin* in the older newswire, *Putin* in modern social media.

The top locations mentioned remain largely the same level and granularity, being countries that are major actors on the global scale or in the Anglosphere. Extra presence in the social media data of items like *Dublin*, *Ontario* and *Melbourne* may be attributable to our sampling, which more evenly distributed across English speaking nations than a population-weighted or social media presence-weighted approach.

We also see that celebrity figures, such as *@justinbieber* and *Kate Middleton*, are more prevalent in the social media top ranking – as are journalists, such as *@timhudak* and *David Speers*. However, the CoNLL data does contain a large number of sportsmen, as it is rich in cricket reportage; e.g. *Wasim*

[9]Segment E has Russian and Ukrainian media coverage, promoting mentions of this entity. This excludes RT as "retweet".

Region	Distinct surface forms	Forms only in this category	% Novel
Australia	116	95	81.90
Canada	109	94	86.24
Ireland	105	83	79.05
New Zealand	58	52	89.66
United Kingdom	203	144	70.94
United States	135	84	62.22
Global	628	582	92.68

Table 12: Top 20 most frequent surface forms of each entity type, in the CoNLL'03 data (newswire from RCV1) and from our Twitter data.

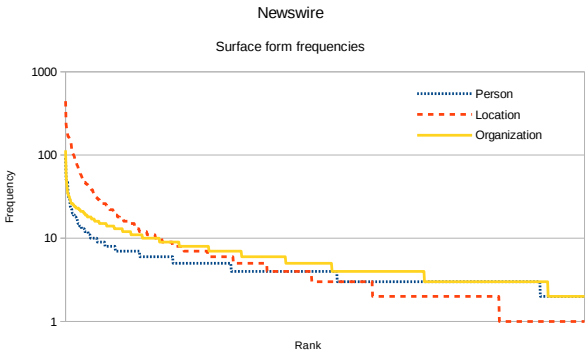

Figure 1: Frequency-Rank curve for entities in CoNLL'03 data.

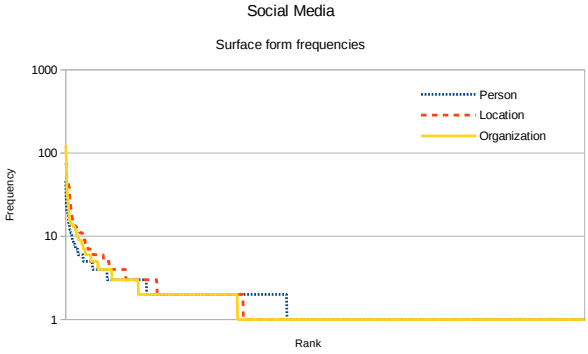

Figure 2: Frequency-Rank curve for entities in the Broad Twitter Corpus.

Akram and *Moin Khan*. This may be attributable to the specific social stratification of the newswire subsample found in the CoNLL data; i.e., it covers little outside of global and business affairs, and only one sport. Alternatively, a cricket championship may have been underway during the narrow date range from which this data was sampled. In any event, one would not expect these names to occur in modern datasets. Further, context around cricketers probably makes poor training examples for general Person entities. In contrast, social media data focuses on a broad range of popular figures and even personal names not found in the public sphere (like *NICOLA*).

Regarding organizations, both datasets are rich in sports clubs, with the typical location/organization metonymy found in that regard (e.g. *DETROIT* can refer to a place or sports club). The CoNLL data is rich in major league baseball data, but poor in its editorial reportage, explaining the high incidence of U.S. sport club mentions but with no frequent baseball personalities. BTC data includes large social media and other internet-based enterprises among its most frequently mentioned organizations. Both datasets also frequently discuss news outlets, possibly due to self-promotion in their own coverage.

5.2 Surface Form Distribution

The frequencies of entity mentions can be used to describe the corpus. We measure frequency-rank curves over the Broad Twitter Corpus and compare them to newswire data (the CoNLL'03 dataset). Frequency rank curves for all three entity types are shown in Figures 1 and 2.

	Social media			Newswire		
	Person	**Location**	**Organization**	**Person**	**Location**	**Organization**
Total weight	5 271	3 114	3 732	10 053	10 572	9 268
h-index	11	15	14	18	44	23
Tail weight	5 048	2 547	3 263	9 399	6 098	8 425
Head proportion	4.23%	18.21%	12.57%	6.51%	42.32%	9.10%

Table 13: Measuring the contribution of the head of entity surface form frequency/rank curve.

In a corpus covering a very narrow topic range, one might expect a small range of entities to be mentioned frequently, and comprise the majority of entity mentions in that corpus. This could be called head-heavy, as the entity mention frequency mass is concentrated in the head of the curve, not the tail. To measure the head-heaviness of these distributions, we first determine the h-index for each entity class (i.e. the lowest entity frequency that is larger than the number of times it is seen) and use this to bisect the curve into head and tail. The frequency mass of the head is then measured as a proportion of the whole. Results are given in Table 13, without disambiguating metonymies. Note that, while in general the head makes up for fewer of the entities in social media when compared to newswire, this is not the case for organization entities. These are slightly more diverse in newswire, with the mass of the head making up only 9.1% of all mentions, compared to 12.57% in tweets. This may be due to the focus on major league baseball teams in the news data.

6 Conclusion

Social media is an important resource and presents many challenges, though the paucity and bias of existing datasets hampers NER research in this text type. This paper presents a large, high-quality corpus for social media that addresses these problems, and demonstrated the breadth and quality of the annotated data. The dataset can be freely downloaded from `http://www.gate.ac.uk/wiki/broad-twitter-corpus.html`, including both all original text (under Twitter license) and also tools for reconstructing the annotated corpus.

Acknowledgements

We are grateful to all our annotators, including among others Dominic Rout, Diana Maynard, Konstantin Yershov, Marta Sabou, Roland Roller, Michał Łukasik, Johann Petrak, Patrick Paroubek, Nattapong Sanchan, Gerhard Wohlgennant, Adam Funk, Amel Fraisse, Arno Scharl, and our many crowd workers across the globe. Alan Ritter of Ohio State University gave us excellent help with references to the original JSON for the 2011 corpus, pivotal to our analyses. Graham Dove of Aarhus University gave tips for our visualisations, which benefit both us and hopefully the reader. Semantic overfitting: what 'world' do we consider when evaluating disambiguation of text?

Abstract

Semantic text processing faces the challenge of defining the relation between lexical expressions and the world to which they make reference within a period of time. It is unclear whether the current test sets used to evaluate disambiguation tasks are representative for the full complexity considering this time-anchored relation, resulting in semantic overfitting to a specific period and the frequent phenomena within. We conceptualize and formalize a set of metrics which evaluate this complexity of datasets. We provide evidence for their applicability on five different disambiguation tasks. To challenge semantic overfitting of disambiguation systems, we propose a time-based, metric-aware method for developing datasets in a systematic and semi-automated manner, as well as an event-based QA task.

1 Introduction

Semantic processing defines a relation between natural language and a representation of a world it refers to. A challenging property of natural language is the time-bound complex interaction between lexical expressions and world meanings. We use *meaning* in this paper as an umbrella term for both concepts and (event and entity) instances, and *lexical expression* as a common term for both lemmas and surface forms. We can define this interaction as a set of relations, both sense relations and referential relations, that exists within a language community in a certain period of time, e.g. one or a few generations. The people belonging to these generations share one language system that changes relatively slowly but during their lives there are many rapidly changing situations in the world that make certain meanings and expressions dominant and others not. Likewise, we expect that a generation uses a certain set of lexical expressions out of the available set in relation to a set of meanings that balances the trade-off between learning many expressions and resolving extreme ambiguity of a small set of expressions.

The task of interpreting lexical expressions as meanings, known as disambiguation, has been addressed by the NLP community following a "divide & conquer" strategy that mostly ignores this complex time-bound relation. Over the years, this resulted in numerous separate disambiguation tasks each with a specific set of datasets restricted to a small bandwidth with respect to the dynamics of the world and the large scope of the possible meanings that lexical expressions can have. By dividing the problem into different tasks on relatively small datasets, researchers can focus on specific subproblems and have their efforts evaluated in a straightforward manner. Datasets have been developed independently for each task, intended as a test bench to evaluate the accuracy and applicability of the proposed systems. Official evaluation scripts have been created for most datasets to enable a fair comparison across systems.

The downside of this practice is that task integration is discouraged, systems tend to be optimized on the few datasets available for each task, and the dependencies of ambiguities across tasks in relation to the time-bound contextual realities are not considered. As a result, there is little awareness of the overall complexity of the task, given language as a system of expressions and the possible interpretations given the changing world over longer periods of time. Systems are thus encouraged to strongly overfit on a single task, a single dataset, and a specific 'piece' of the world at a specific moment in time.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1180–1191, Osaka, Japan, December 11-17 2016.

Each text forms a unique semantic puzzle of expressions and meanings in which ambiguity is limited within the specific time-bound context, but is extreme without considering this context. The main question we thus put forward and address in this paper is how to enhance disambiguation tasks to cover the full complexity of the time-bound interaction between lexical expressions and meanings (in the broad sense of the word as defined here). We therefore first propose a number of metrics that formally quantity the complexity of this relation and apply this to a wide range of available datasets for a broad range of semantic tasks. Secondly, we provide evidence for the limitations of the current tasks and, thirdly, we present a proposal to improve these tasks in the hope that we challenge future research to address these limitations.

The paper is structured as follows. We motivate the importance and relevance of this temporal interaction for both concept- and instance-based disambiguation tasks in Section 2. Following up on previous research (Section 3), we define a model of the complex interaction (Section 4), and we conceptualize and formalize a collection of metrics in a generic manner (Section 5). Moreover, we apply these metrics to quantify aspects of existing evaluation sets (Section 6). In Section 7, we propose two approaches for creating metric-aware test sets that include a temporal dimension. The paper is concluded in Section 8.

2 Temporal Aspect of the Disambiguation Task

We live in a dynamic and rapidly changing world: some companies expand their offices all around the globe, while others collapse; people become celebrities overnight and are forgotten only several years afterwards. Similarly, a whole range of mainstream technological concepts of today's world have only been known since the last few decades. These observations have a big impact on the dynamics of a language system, since the relation between language expressions and meanings follows the changes in the world. To some extent this is reflected in new expressions and new meanings but most strongly this is reflected in the distributional usage of expressions and their dominant meaning.

For instance, the dominant meaning of the terms *mobile*, *cell*, and *phone* is the same for the contemporary, especially young, generations: mobile phone. On the other hand, older generations also remember different dominant concepts from the 80s and 90s: *mobile* being typically a decoration hanging from the ceiling, *cell* usually being a unit in a prison or body tissue, while *phone* referring to the static devices found at home or on the streets. The dominant meanings of the 80s and 90s have been replaced by new dominant meanings, whereas the younger generation may have lost certain meanings such as the decoration. Similarly, football fans remember two different superstar *Ronaldo* players which have been dominant one after the other: the Brazillian striker and the Portuguese Ballon d'Or award winner.

What is shown by these examples is that not only new meanings appear and old meanings become obsolete but that, more strongly, the usage distribution of competing meanings changes over time. As the mobile phone gains popularity and the mobile decoration gets replaced by others, people refer to the mobile phone more often than the traditional mobile decoration. Hence, in a later point of time, the most commonly used meaning for *mobile* changes, even though both meanings are still possible. Similarly for the *Ronaldo* case: in 2016 one can still refer to both players, but the dominant meaning is now the Portuguese player.

We also observe a relation between the variety of lexical expressions used to refer to a meaning, and its dominance of usage. As the mobile phone gained popularity, its set of associated expressions expanded from only *mobile phone* to also: *mobile*, *phone*, *cell phone*, and *cell*. On the other hand, when referring to a prison cell without a specific context, one should nowadays explicitly use the full expression *prison cell* instead of just *cell*.

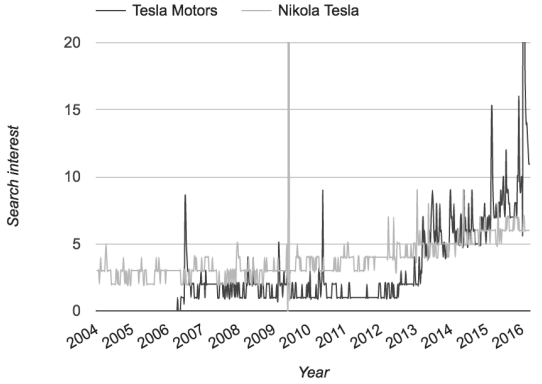
To measure the usage distribution of competing meanings, we could use online resources that track these distributions over time, such as Google Trends[1] and Wikipedia Views.[2] We present the usage distribution for instances denoted by *Tesla* in Figure 1a, and for concepts expressed with the expression *cloud* in Figure 1b. These plots demonstrate the ways in which the distribution of usage changes both for instances and concepts as a function of the temporal dimension. As we discussed in Section 1, the notion

[1] https://www.google.com/trends/

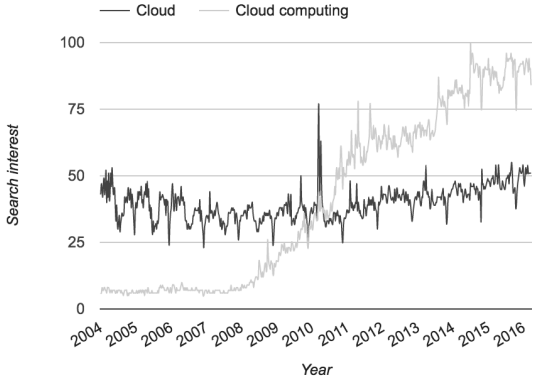
[2] http://stats.grok.se/

Figure 1: Usage distribution for ambiguous concepts and instances based on Google Trends data.

(a) Usage of two dominant meanings for *Tesla*. The black line depicts the usage of *Tesla Motors Company*, while the gray line represents *Nikola Tesla*.



(b) Usage of two dominant meanings for *cloud*. The black line depicts the usage of the clouds in the sky, natural objects placed in the atmosphere. The gray line stands for the modern meaning of cloud as an Internet-based type of computing.



of time and its role in this mapping between expressions and meanings has not been taken into account in the creation of existing disambiguation datasets. This observation points to a serious weakness in the representativeness of existing datasets for the full complexity of the disambiguation task. Consequently, systems are not encouraged to focus on the temporal aspect of the task but in reality the same language system is still used for many different situations within a changing world. While this works for humans, this is not yet solved for machines.

3 Related Work

The three problems enumerated in Section 1 have been addressed to some extent in past work.

Several approaches have attempted to resolve pairs of disambiguation tasks jointly. Examples include: combined Entity Linking (EL) and Word Sense Disambiguation (WSD) (Hulpuş et al., 2015; Moro et al., 2014), combined event and entity coreference (EvC and EnC) (Lee et al., 2012) and resolving WSD and Semantic Role Labeling (SRL) together (Che and Liu, 2010). Although some task combinations are well-supported by multi-task datasets, such as CoNLL 2011 and 2012 for joint coreference (Pradhan et al., 2011; Pradhan et al., 2012), and Moro and Navigli (2015) for WSD and EL, still many multi-task systems have to be evaluated on separate datasets. Notable efforts to create multi-task annotated corpora are the AMR Bank (Banarescu et al., 2013) and the MEANTIME corpus (Minard et al., 2016a).

Properties of existing datasets have been examined for individual tasks. For WSD, the correct sense of a lemma is shown to often coincide with the most frequent sense (Preiss, 2006) or the predominant sense (McCarthy et al., 2004). In the case of McCarthy et al. (2004), the predominant sense is deliberately adapted with respect to the topic of the text. Our work differs from McCarthy et al. (2004) because they do not consider the temporal dimension. As a response to sense-skewed datasets, Vossen et al. (2013) created a balanced sense corpus in the DutchSemCor project in which each sense gets an equal number of examples. Similarly, Van Erp et al. (2016) conclude that EL datasets contain very little referential ambiguity. Evaluation is focused on well-known entities, i.e. entities with high PageRank (Page et al., 1999) values. Additionally, the authors observe a considerable overlap of entities across datasets, even for pairs of datasets that represent entirely different topics. Cybulska and Vossen (2014) and Guha et al. (2015) both stress the low ambiguity in the current datasets for the tasks of EvC and EnC, respectively. Motivated by these findings, Guha et al. (2015) created a new dataset (QuizBowl), while Cybulska and Vossen (2014) extended the existing dataset ECB to ECB+, both efforts resulting in notably greater ambiguity and temporal diversity. As far as we are aware, no existing disambiguation dataset has included the temporal dependency of ambiguity, variance, or dominance.

The problem of overfitting to a limited set of test data has been of central interest to the body of

work focusing on domain adaptation (Daume III, 2007; Carpuat et al., 2013; Jiang and Zhai, 2007). By evaluating on a different domain than the training one, these efforts have provided valuable insights into system performance. However, to our knowledge, this research has also not addressed the temporal aspect of the task.

We therefore propose to take this a step further and examine system performance with respect to a set of metrics, applicable over disambiguation tasks, thus setting the stage for creation of metric-aware datasets. We expect that these metrics show reduced complexity within well-defined temporal and topical boundaries and increased complexity across these boundaries. More extensive datasets than existing single- and multi-task datasets, driven by metrics on ambiguity, variance, dominance and time, would challenge semantic overfitting.

4 Semiotic Generation and Context Model

We want to model the relation between expressions and meanings in the world within a generation that shares the same language system, as well as the fluctuation in usage of expressions and meanings over time within this generation. We therefore assume that for each language community at a specific time, there exist a set of meanings M in the world and a set of lexical expressions L in a language. The relation between these sets is many-to-many: each lexical expression L_i can refer to multiple meanings $M_1, M_2, ...$ (ambiguity) and each meaning M_j can be verbalized through multiple lexical expressions $L_1, L_2, ...$ (variance). As we discuss in Section 2, the sets of M, L, their relations, and especially the distributions of these relations, are dynamic, i.e. they can change over time. We denominate this model "Semiotic Generation and Context Model", because it captures the distribution changes in the semiotic relation between meanings and lexical expressions, given the context of the changes in the world and within the language system of a generation.

In practice, we study available proxies of the world at a moment in time and of the language of a generation which capture this relation at a given time snapshot: lexical resources are considered as a proxy of the language system of a generation and the dataset is considered as a proxy for the world at a particular moment in time creating a specific context. We analyze the time-anchored interaction between M and L in the datasets proxy and measure this against their interaction in the resources proxy to provide insight on how representative the datasets are for the task. Note that the proxies of datasets and resources cover only a subset of the language used within a generation, and (consequently) only a subset of all possible meanings. While not ideal, this is the best we have because there is no way to capture all language used within a generation nor possibly list every possible meaning, especially considering that we can always create new meanings, e.g. by inventing some non-real world ones.

5 Methodology

Based on the Semiotic Generation and Context Model, we now define and formalize a number of metrics that qualify datasets for disambiguation tasks. In this Section, we describe these metrics and explain the tasks we focus on. Furthermore, we enumerate the design choices that guide our pick of datasets and we elaborate on the datasets we analyze.

5.1 Metrics

Mean Observed Ambiguity (MOA)
We define observed ambiguity of an expression as the cardinality of the set of meanings it refers to within a dataset (O_{L_i}). For example, the expression *horse* has 4 meanings in WordNet but only the chess meaning occurs in the dataset, resulting in an observed ambiguity of 1. The Mean Observed Ambiguity (MOA) of a dataset is then the average of the individual observed ambiguity values.

Mean Observed Variance (MOV)
We define observed variance of a meaning as the cardinality of the set of lexical expressions that express it within a dataset (O_{M_j}). The chess meaning of *horse* also has *knight* as a synonym but only *horse* occurs in the dataset, hence an observed variation of 1. The Mean Observed Variance (MOV) of a dataset is then the average of the individual observed variance values.

Mean Observed Dominance of Ambiguity (MODA)
We define dominance of ambiguity as a frequency distribution of the dominant meaning of a lexical expression. For example, *horse* occurs 100 times in the data and in 80 cases it has the chess meaning: the dominance score is 0.8. The Mean Observed Dominance of Ambiguity (MODA) of a dataset is the average dominance of all observed expressions.

Mean Observed Dominance of Variance (MODV)
We define the notion of dominance of variance, as a frequency distribution of the dominant lexical expression referring to a meaning. If *horse* is used 60 times and *knight* 40 times for the same meaning then the observed dominance of variance is 0.6. The Mean Observed Dominance of Variance (MODV) of a dataset is then the average dominance computed over all observed meanings.

Entropy of the Meanings (Normalized) of a Lexical Expression (EMNLE)
We define an alternative notion of dominance, based on entropy, in order to consider the distribution of the less dominant classes in a dataset. We introduce $p(M_j|L_i)$: a conditional probability of a meaning M_j based on the occurrence of a lexical expression L_i. We compute this probability using the formula $p(M_j|L_i) = \frac{p(M_j,L_i)}{p(L_i)}$, a ratio between the number of common occurrences of M_j and L_i, and on the other hand, occurrences of L_i alone. We combine the individual conditional probabilities for L_i in a single information theory metric of entropy, $H(O_{L_i})$:

$$H(O_{L_i}) = \frac{-\sum_{j=1}^{n} p(M_j|L_i) log_2 p(M_j|L_i)}{log_2(n)} \tag{1}$$

For example, given 100 occurrences of the lexical expression *horse*, where 80 occurrences refer to the the chess meaning and 20 to the animal meaning, the entropy of the expression *horse* would be 0.72. To compute a single entropy (EMNLE) value over all lexical expressions in a dataset, we average over the individual entropy values:

$$EMNLE(O_L, R_L) = \frac{1}{n}\sum_{i=1}^{n} H(O_{L_i}, R_{L_i}) \tag{2}$$

Entropy of the Lexical Expressions (Normalized) of a Meaning (ELENM)
We introduce $p(L_i|M_j)$: a conditional probability of a lexical expression L_i based on the occurrence of a meaning M_j. We compute this probability using the formula $p(L_i|M_j) = \frac{p(L_i,M_j)}{p(M_j)}$, a ratio between the number of common occurrences of M_j and L_i, and on the other hand, occurrences of M_j alone. We combine the individual conditional probabilities for M_j in a single information theory metric of entropy, $H(O_{M_j})$:

$$H(O_{M_j}) = \frac{-\sum_{i=1}^{n} p(L_i|M_j) log_2 p(L_i|M_j)}{log_2(n)} \tag{3}$$

Suppose the meaning of horse as a chess piece is expressed 60 times by the lexical expression *horse* and 40 times by *knight*, then the entropy of the chess piece meaning of *horse* is 0.97. To compute a single entropy (ELENM) value over all meanings in a dataset, we average over the individual entropy values:

$$ELENM(O_M, R_M) = \frac{1}{n}\sum_{j=1}^{n} H(O_{M_j}, R_{M_j}) \tag{4}$$

Relation between Observed and Resource Ambiguity (RORA)
We define resource ambiguity of a lexical expression as the cardinality of the set of meanings that it can refer to according to a lexical resource (R_{L_i}). Then we define the ratio between observed and resource ambiguity for a lexical expression as:

$$ratio_{amb}(O_{L_i}, R_{L_i}) = \frac{|\{M_j : M_j \in O_{L_i}\}|}{|\{M_j : M_j \in R_{L_i}\}|} \tag{5}$$

In the case that only 1 out of 4 resource meanings is observed in the dataset, for example only the chess meaning of *horse*, this would lead to a $ratio_{amb}$ value of 0.25. To compute the RORA value of a dataset, we average over the individual ratios:

$$RORA(O_L, R_L) = \frac{1}{n}\sum_{i=1}^{n} ratio_{amb}(O_{L_i}, R_{L_i}) \tag{6}$$

Relation between Observed and Resource Variance (RORV)

We define resource variance of a meaning as the cardinality of the set of lexical expressions which can verbalize it (R_{M_j}). Then we define the ratio between observed and resource variance for a given meaning:

$$ratio_{var}(O_{M_j}, R_{M_j}) = \frac{|\{L_i : L_i \in O_{M_j}\}|}{|\{L_i : L_i \in R_{M_j}\}|} \tag{7}$$

Suppose that the expressions *horse* and *knight* can refer to the meaning of chess piece according to a resource, but only the expression *horse* refers to it in a particular dataset, this would lead to a $ratio_{var}$ value of 0.5. To compute the RORV value of a dataset, we average over the individual ratios:

$$RORV(O_M, R_M) = \frac{1}{n}\sum_{i=1}^{n} ratio_{var}(O_{M_j}, R_{M_j}) \tag{8}$$

Average Time-anchored Rank (ATR)

Since the relevance of meanings is not constant over time, we define the popularity of a meaning in a point of time, $popularity_{M_j}(t)$. A lexical expression can potentially denote multiple meanings, each characterized with a certain degree of time-anchored popularity. Likewise, we order the list of candidate meanings for a given lexical expression based on their popularity at the moment of publishing of the dataset document. For example, if the dataset covers news about a chess tournament, we will see a temporal peak for the chess meaning of *horse* relative to the other meanings. The popularity rank of each meaning, including the correct gold standard meaning, is its position in this ordered list. By averaging over the ranks of all golden candidates we can compute the Average Time-anchored Rank of the golden candidates in a dataset, which gives an indication about the relation between the relative temporal popularity of a meaning and the probability that it is the correct interpretation of an expression, varying from stable to extremely dynamic relations. An ATR rank of a dataset close to 1 indicates a strong bias towards the popular meanings at the time of creation of the dataset.

Average Time-anchored Relative Frequency of Usage (ATRFU)

The potential bias of meaning dominance with respect to its temporal popularity can alternatively be assessed through its frequency of usage at a point of time. We denote the usage of a meaning with U_{M_j}. For a given lexical expression, we compute the relative temporal frequency of usage (FU) of the golden meaning relative to the frequency of usage of all candidate meanings:

$$FU_{M_j}(t) = \frac{U_{M_j}(t)}{\sum_{i=1}^{n} U_{M_i}(t)} \tag{9}$$

The average relative frequency of usage at a given time point (ATRFU) is an average of the frequency values of all gold standard meanings in a dataset. We introduce this metric in order to gain insights into the popularity difference between the competitive meanings at a given time period. This metric would allow us, for instance, to detect that in July 2014 *the United States men's national soccer team* was much more popular than *the women's national soccer team*, while *Tesla Motors* was only slightly more popular than *Nikola Tesla* in May 2015.

Dataset Time Range (DTR)

We define DTR as a time interval between the earliest and the latest published document of a dataset:

$$DTR = [min(date_{doc}), max(date_{doc})] \tag{10}$$

where $date_{doc}$ is the publishing date of a document. For instance, the DTR of the MEANTIME (Minard et al., 2016b) dataset is $[2004, 2011]$.

5.2 Tasks

We demonstrate the applicability of the metrics defined in Section 5.1 on a selection of disambiguation tasks. We cover both concept-oriented tasks (WSD and SRL), as well as instance-based tasks (EL, EnC, and EvC).[3] In Table 1, we specify the model components per disambiguation task, enabling the metrics to be computed. The metrics concerning lexical resources (WordNet (Fellbaum, 1998) for WSD, and PropBank (Kingsbury and Palmer, 2002) for SRL) are only computed for the concept-oriented tasks. Whereas lexical resources, such as WordNet and PropBank, can be seen as reasonable proxies for most of the expressions and concepts known to a generation, it is more difficult to consider databases of instances, such as DBpedia,[4] to approximate all the possible instances that expressions, e.g. *Ronaldo*, can refer to. This is especially the case for events, e.g. the goals *Ronaldo* scored, or the *Ronaldo* t-shirts being sold in a fan shop. There is hardly any registry of real world events independent of the mentions of events in text. Likewise, we only find a few *Ronaldo* entities in DBpedia. Despite its impressive size, DBpedia only covers a very small subset of all instances in the world.

Task	Lexical expression	Meaning	Resource
WSD	lemma	sense	WordNet
SRL	predicate mention	predicate	PropBank
EL	entity mention	entity	DBpedia
EnC	entity mention	entity	DBpedia
EvC	event mention	event	/

Table 1: Task specification of model components.

5.3 Datasets

The choice of datasets conforms to the following rationale. We consider test datasets with running text in English,[5] because we assume that they are the most natural instantiations of the interaction between lexical expressions and meanings and tend to report on the changes in the world. Moreover, such datasets lend themselves better for joint tasks. Finally, we favor publicly available datasets which are commonly used in recent research.

The chosen datasets per disambiguation task are as follows.

WSD The following datasets were taken into consideration: Senseval–2 (**SE2 AW**): All-Words task (Palmer et al., 2001) ; Senseval-3 (**SE3 task 1**): Task 1: The English all-words task (Snyder and Palmer, 2004) ; SemEval-2007 (**SE7 task 17**): Task-17: English Lexical Sample, SRL and All Words (Pradhan et al., 2007) ; SemEval–2010 (**SE10 task 17**): Task 17: All-Words Word Sense Disambiguation on a Specific Domain (Agirre et al., 2010); SemEval–2013 (**SE13 task 12**): Task 12: Multilingual Word Sense Disambiguation (Navigli et al., 2013). The number of test items per competition ranges from roughly 500 to 2500 instances. All most frequent sense baselines are around 65%, except for **SE10 task 17**, in which the focus was on domain-specific WSD, resulting in a most frequent sense baseline of 55%.

SRL For Semantic Role Labelling, we selected the CoNLL-2004 Shared Task: Semantic Role Labeling (**CoNLL04**) (Carreras and Màrquez, 2004). In total, 9,598 arguments were annotated for 855 different verbs.

EL We consider the following datasets: AIDA-YAGO2 (**AIDA test B**) (Hoffart et al., 2011), **WES2015** (Waitelonis et al., 2015), and **MEANTIME** (Minard et al., 2016b). We analyze the commonly used test B collection from the AIDA-YAGO2 dataset, which contains 5,616 entity expressions in 231 documents. WES2015 contains 13,651 expressions in 331 documents about science, while the MEANTIME corpus consists of 120 documents regarding four topics, with 2,750 entity mentions in total.

EnC Guha et al. (2015) created a dataset, QuizBow, for nominal coreference, containing 9,471 mentions in 400 documents. The data annotated comes from a game called quiz bowl.[6]

[3] Note that in the case of SRL we focus on the expression-to-meaning mapping of predicates and do not analyze roles.

[4] `http://dbpedia.org`

[5] Our analysis in this paper is performed on 13 English datasets. The metrics we define in Section 5.1 can easily be applied to many other languages. Namely, the resource-dependent metrics (RORA and RORV) can be applied to the wide range of languages in which DBpedia/WordNet/PropBank are available (for an illustration, DBpedia is currently available in 125 languages). Furthermore, all other metrics rely solely on the annotated textual content within a corpus, which makes them applicable for any language.

[6] `https://en.wikipedia.org/wiki/Quiz_bowl`

EvC we consider three event coreference corpora: EventCorefBank (**ECB**) (Lee et al., 2012), **ECB+** (Cybulska and Vossen, 2014), and EventNuggets (**TAC KBP '15**) (Mitamura et al., 2015). ECB contains 480 documents spread over 43 topics, while its extension ECB+ contains an additional 502 documents spread over the same set of topics. The training corpus of TAC KBP '15 contains 7,478 event coreference chains (hoppers).[7]

6 Analysis

In this Section, we study to what extent datasets cover the complexity of the disambiguation task.[8]

Task	Dataset	MOA	MOV	MODA	MODV	EMNLE	ELENM
WSD	SE2 AW	1.20	1.06	0.94	0.98	0.13	0.05
	SE3 task 1	1.21	1.05	0.94	0.98	0.13	0.04
	SE7 task 17	1.14	1.04	0.95	0.98	0.10	0.03
	SE10 task 17	1.25	1.06	0.93	0.98	0.13	0.05
	SE13 task 12	1.10	1.06	0.97	0.98	0.14	0.05
SRL	CoNLL04	1.20	1.00	0.96	1.00	0.09	0.00
EL	AIDA test B	1.09	1.35	0.98	0.91	0.05	0.22
	WES2015	1.06	1.33	0.97	0.88	0.05	0.21
	MEANTIME	1.19	4.63	0.98	0.64	0.04	0.55
EnC	QuizBowl	1.59	1.80	0.92	0.74	0.13	0.46
EvC	ECB	1.61	3.87	0.89	0.61	0.19	0.65
	ECB+	2.09	3.40	0.85	0.66	0.27	0.57
	TAC KBP '15	4.97	1.22	0.69	0.94	0.47	0.12

Table 2: Observed ambiguity, variance and dominance.

According to Table 2, high complexity in both directions, i.e. high ambiguity and variance, is rare, though the extent of this complexity varies per task. The datasets evaluating WSD, SRL, and EL almost have a 1-to-1 mapping between lexical expressions and meanings, while coreference datasets have higher ambiguity and variance. This can be due to the following reasons: 1. Some of the coreference datasets deliberately focus on increasing ambiguity. 2. An inherent property of coreference seems to be high variance. Similarly, our dominance metrics (MODA/MODV and EMNLE/ELENM) demonstrate a strong bias in our datasets: typically, for any of the datasets, approximately 90% of the occurrences belong to the dominant class on average.

Task	Dataset	ATR	ATRFU
EL	WES2015	1.92	0.53
EL	MEANTIME	1.51	0.51

Table 3: ATR and ATRFU values of the datasets.

Task	Dataset	RORA	RORV
WSD	SE2 AW	0.26	0.38
	SE3 task 1	0.23	0.37
	SE7 task 17	0.20	0.36
	SE10 task 17	0.25	0.40
	SE13 task 12	0.26	0.40
SRL	CoNLL04	0.63	1.00

Table 4: RORA and RORV values of the datasets.

Concerning the concept-oriented tasks, Table 4 shows a notable difference in the complexity of the interaction between the proxies of datasets and resources.[9] Between 74 and 80% of the resource ambiguity per expression is not represented in the datasets, whereas this is the case for 60-64% of the resource

[7] We were unable to obtain the test data for the TAC KBP '15 dataset, hence our analysis is performed on the training data.

[8] The metrics and the analyses of the datasets can be found at `https://github.com/cltl/SemanticOverfitting`.

[9] While computing RORA and RORV, we ignore cases with resource ambiguity and variance of 1.

variance per concept. This is an indication of strong semantic overfitting of the data to a small selection that is not representative for the full potential of expressions and meanings. Furthermore, we observe that this representativeness is relatively constant across concept datasets, which in part can be explained by the fact that the WSD and SRL datasets mainly stem from the same time period (Figure 2), and even from the same corpus (Hovy and Søgaard, 2015). One could argue that the data is correctly representing the natural complexity of a specific time period and genre but it does not challenge systems to be able to shift from one situation to another. We also note a temporal discrepancy between the concept- and instance-based datasets, with the instance-based systems being evaluated on more recent data.

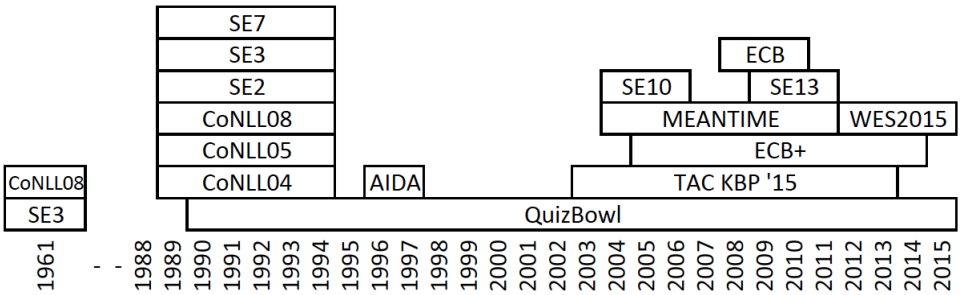


Figure 2: DTR values of the datasets

To understand further the time-bound interaction in our datasets, we study them together with time-bound resources. While our lexical resources and instance knowledge sources contain very little temporal information, we rely on query monitoring websites (Wikiviews and GoogleTrends) to get an indication of the usage of a meaning over time. In Table 3, we show the temporal popularity of entities among their candidates in our datasets according to our web sources.[10] We note a correspondence between the dominance of entities in datasets and their frequency of usage at that time, which exposes a bias of existing datasets towards the most popular entities at the time of their creation.

Our analysis reveals that the existing disambiguation datasets show a notable bias with respect to the aspects of ambiguity, variance, dominance, and time, thus exposing a strong semantic overfitting to a specific part of the world, while largely ignoring long tail phenomena. Typically this is the part of the world that is best known within the context of a generation at a moment of time. This implies that our datasets have a strong bias towards meanings that are popular at that particular moment in time and do not represent the temporal relativity of this bias. Although our metrics provide us with a valuable set of insights into the evaluation datasets, complementary statistical measures should be introduced in the future to capture individual distinctions blurred by averaging over a dataset. These could measure the distribution of ambiguity and variance, their relation to dataset size, and outliers.

7 Proposal for improving evaluation

The direct contribution of our work lies in metric-based evaluation of datasets and resources for systems, which helps interpreting their ability to cope with alterations of ambiguity, variance, dominance, and time. Provided that a collection of multi-task annotated data is available at a central place, our metrics could be applied to output a dataset following certain criteria, e.g. a test set annotated with WSD and EL, whose ambiguity and variance are both between 1.2 and 1.4, and whose documents have been created in the 90s. The practical obstacle is the availability of input data, which can be addressed by the following (semi)automatic expansion method: 1. Collect annotated data and split the data according to time periods. 2. Collect annotated expressions from the data with their dominant meanings. 3. Retrieve

[10]Due to the non-availability of information for the other tasks, we only analyze the temporal dominance for the EL task, even though the set of represented entities in DBpedia is not complete (as discussed in Section 5.3). In our analysis, we only consider ambiguous expressions that can denote more than one entity candidate. The candidates were obtained from the Wikipedia disambiguation pages. From Wikiviews, the month of the document creation time was used for the dominance information.

new documents using unsupervised techniques in which these expressions occur with evidence for usage in other meanings than the dominant one in the existing datasets. Evidence can come from meta data, unsupervised clustering, and temporal and topical distance from annotated data. 4. Fix alternative meanings for all tokens in the new texts (one meaning-per-document), if necessary applying additional disambiguation tools. Add this data as silver data to the collection. 5. If necessary, re-annotate silver data manually or add annotations for other tasks.[11] 6. Spread documents over different time periods for both annotated gold data and silver data to obtain sufficient variation in time-bound contexts. Provided that this acquisition procedure is successful, selecting a dataset would require almost no effort, which enables creation of many, well-motivated datasets. Consequently, the dynamic nature of this process would challenge semantic overfitting.

In case the proposed data acquisition procedure proves too hard or too laborious to realize, we propose an alternative, namely an event-based Question Answering (QA) task, extensively elaborated on in Postma et al. (2016), whose dataset would contain documents gathered in a smart automatic way. The data acquisition procedure for this dataset is driven by multiple confusion factors: ambiguity, dominance, variance, time, location, and topic. This data would reflect a high degree of ambiguity and variance and would capture a wide range of small real-world phenomena. In order to perform on this task with a good accuracy, the systems will be required to exhibit a deeper semantic understanding of the linguistic tail of the disambiguation tasks we analyze in this paper. However, the only task that will explicitly be evaluated is the QA task itself, which means that the annotation task would be largely reduced to the components necessary for the questions and answers.

The resulting time-aware evaluation datasets, originating from both the annotation-based and QA-based approaches, allow the community to test understanding of language originating from different generations and communities, and a community's language usage in relation to different world contexts. It would also assess to what extent a disambiguation system can adapt to language use from another time slice than the one trained on, with potentially new meanings and expressions, and certainly a different distribution of the expression-meaning relation. We believe this challenges semantic overfitting to one single part and time of the world, and will inspire systems to be more robust towards aspects of ambiguity, variance, and dominance, as well as their temporal dependency.

8 Conclusion

We qualified and quantified the relation between expressions and meanings in the world for a generation sharing a language system, as well as the fluctuation in usage of expressions and meanings over time. We proposed the Semiotic Generation and Context Model, which captures the distribution changes in the semiotic relation given the context of the changing world. We apply it to address three key problems concerning semantic overfitting of datasets. We conceptualize and formalize generic metrics which evaluate aspects of datasets and provide evidence for their applicability on popular datasets with running text from five disambiguation tasks. We observe that existing disambiguation datasets show a notable bias with respect to aspects of ambiguity, variance, dominance, and time, thus exposing a strong semantic overfitting to a very limited, and within that, popular part of the world. Finally, we propose a time-based, metric-aware approach to create datasets in a systematic and semi-automated way as well as an event-based QA task. Both approaches will result in datasets that would challenge semantic overfitting of disambiguation systems.

Abstract

There are growing needs for patent analysis using Natural Language Processing (NLP)-based approaches. Although NLP-based approaches can extract various information from patents, there are very few approaches proposed to extract those parts what inventors regard as novel or having an inventive step compared to all existing works ever. To extract such parts is difficult even for human annotators except for well-trained experts. This causes many difficulties in analyzing patents. We propose a novel approach to automatically extract such keywords that relate to novelties or inventive steps from patent claims using the structure of the claims. In addition, we also propose a new framework of evaluating our approach. The experiments show that our approach outperforms the existing keyword extraction methods significantly in many technical fields.

1 Introduction

Recently there are growing needs for analyzing patents. Many companies want to analyze large amount of patents for various purposes like patent retrieval or analyzing technical trends, etc. For searching and analyzing large amount of patents, NLP-based approaches are adequate, and many approaches are developed (for example (Abbas et al., 2014)). Several keyword extraction methods are proposed in the context of patent retrieval or information extraction from patents. Most of them use traditional unsupervised approaches like BM25 (Robertson and Zaragoza, 2009) or supervised approaches like CRF (Lafferty et al., 2001). While BM25 tends to extract keywords that are characteristic to each patent, CRF is applied to extract various kinds of Named Entities such as technologies, effects, and attributes. (for example in (NTCIR, 2010),(Nishiyama et al., 2010)).

However, considering the original purpose of submitting patents, patents must contain rich information not limited to the above examples. Especially, every patent must contain what the inventors think as novel or having an inventive step compared to the all existing works ever. There is no doubt that extracting such keywords is quite important and applicable to all other patent analysis like patent retrieval or analyzing technical trend, etc. To our knowledge there are very few works that explicitly try to extract those keywords that relate to the novelties or the inventive steps of each patent (we will call these keywords as keywords of novelties in this paper).

In general patent retrieval task, various kind of weights are calculated for keywords/keyphrases. But these weights don't necessarily reflect the degree of the novelties. Several approaches seem to extract novel parts of each patent implicitly, but they don't go so far as to extract keywords of novelties. Besides, in patent retrieval, similar patents often have different surface expressions especially on the novel parts, resulting in the situation that the performance in patent retrieval task is not necessarily related to the performance of extracting the novel part. This means that the extracting keywords of novelties cannot be evaluated directly in patent retrieval task.

In this paper, we propose a new approach of extracting keywords of novelties from patent claims. Among various parts in patent applications, patent claims are the most crucial parts that define the scope

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1192–1200, Osaka, Japan, December 11-17 2016.

of protection and contain all of the important parts of the invention. Since patent claims are written in a specific manner, usual NLP approaches may fail to extract useful information. Therefore, we assume several underlying structural rules in patent claims and utilize these assumptions in extracting keywords.

In addition, we also propose a new framework of evaluating our approach.

In section 2, we first explain patent claim structures and related work to extract those structures. Then we briefly introduce some approaches of keyword extraction from patents. In section 3 we propose a novel approach to extract keywords of novelties. And in section 4, we introduce a new framework of evaluating the performance of our approach. Section 5 shows the experimental setting and the evaluation results of our proposed approach compared to other keyword extraction approaches. Section 6 describes some concluding remarks and future application using our approach.

2 Related Work

Several attempts are made to implicitly extract keywords of novelties for each patent, mainly in the context of patent retrieval. Patent retrieval is a task to extract similar patents when a target patent is given.(Patent retrieval includes those concepts such as invalidity search and prior art search.) Among naive approaches that use common techniques in information retrieval (IR), some utilize the features that are specific to patent claims, which result in better performance than using usual IR techniques.

Although each patent claim is a plain text without apparent sections, it is built under some rules. There is no doubt that utilizing these rules achieves better performance in extracting information from patent claims.

2.1 Patent Claim Structures

Patent claims have specific structures, and it is difficult to understand the contents except for experts. Each patent has one or more claims. In case a patent has multiple claims, these claims are divided into two kinds of claims; independent claims and dependent claims. Each claim can be decomposed to several structural elements. There are also several types for claim structure like Jepson type or Markush type. For example, Jepson type has two parts in a claim, preamble and body. In addition, each claim must declare a subject matter, which corresponds to a noun phrase in a specific position of the claim.

To extract those structures automatically, several approaches exist. For example, Sheremetyeva et al. have decomposed each claim to structural elements using POS-tags (Sheremetyeva et al., 1996), Parapatics et al. have categorized claims into several types using cue phrases (Parapatics and Dittenbach, 2009), and Shinmori et al. have proposed to apply Rhetorical Structure Theory (RST) for parsing structural elements (Shinmori et al., 2003).

2.2 Keyword Extraction from Patent Documents

Keyword extraction is an important task for every kind of documents, and many approaches are suggested. The most known approaches are tf-idf, BM25 and TextRank. These approaches are also applicable to patent claims, but these are not designed to extract keywords of novelties, and tend to achieve low performance in various patent analysis.

For example, TextRank approach is applied (Verma and Varma, 2011) to the whole patent application or to a specific part of a patent like patent claim, abstract, or detailed description in order to extract important keywords for invalidity search. But they did not intend to extract such keywords of novelties. Besides, they did not utilize claim structure.

Word age of each term is introduced to measure the degree of the novelties for each patent (Hasan et al., 2009) in order to score novelty of each patent. Word age represents how long the term exists in a corpus (time span from the time when it first appeared to the time when the target patent submitted), and it represents novelty to some extent. But it is obvious that word age highly depends on the corpus, technical field or surface expressions, which is not related to what inventors think as novel part. Moreover, inventors don't necessarily use new keywords to describe the novel part of of their inventions.

Other than those approaches that directly extract important keywords from patent claims, there are some approaches that patent-specific keyword extraction are used.

Shinmori et al.(2003) proposed an approach to extract such keywords/keyphrases that are representative in each structural element in patent claims by using some morphological patterns after decomposion of claims to structural elements(Shinmori et al., 2003).

Takaki et al.(2004) first decomposed each claim into structural elements, and calculated the importance of each element by a measure of how each term in the element is locally distributed in those elements (Takaki et al., 2004). Their approach seems to grasp one side of patent claim structure, and their approach is effective in patent retrieval task to some extent.

Lin et al.(2010) tried more systematic approach utilizing patent claim structure for patent retrieval (Lin et al., 2010). They built a claim tree by extracting the relations between independent/dependent claims and the structural elements for all patents, then search the similarities of the claim trees. They extracted relevant keywords of each structural element from patent specifications (not from claims) using term frequency in the specifications and calculating mutual information of terms selected from claim and specification.

These patent-specific methods extract keywords from various aspects, but none of them directly tried to extract keywords of novelties for each patent.

There are other approaches to extract keywords from patent claims using claim structures, but the focuses are only limited to discriminations like preambles/bodies (Mase et al., 2005) or the subject matters.

3 Extraction of Keywords Related to Novelty from Patent Claims

Compared to the related work, our approach is built under some assumptions of claim structures. Using these assumptions we propose a new approach to extract keywords of novelties from patent claims.

3.1 Assumptions of Claim Structures

One main reason that a patent is constructed from multiple claims is that an applicant want to protect the scope as broad as possible after registration by a patent office. Patent offices in many countries examine patent claims, and if one idea already exists in prior art or easily imaginable from prior art, they refuse the claim. However, if there is a claim that describes a bit smaller scope of the rejected claim, and the scope is invalidated by any prior art, this claim is granted. Therefore, applicants tend to submit multiple claims in one patent with some hierarchical structures of dependencies. In general, a dependent claim describes smaller scope than that of the ”parent” claim. This means that a dependent claim focuses on an important part of the parent claim to secure this part. In many cases, this important part (that the applicant wants wider scope as possible) describes the novelties or the inventive steps that the inventor wants to claim, or describes the area the patent is applicable.

Besides, each claim usually has multiple structural elements. Since a claim must contain every element that is necessary, part of the elements are necessary to construct the subject matter but not directly related to the novelties or the inventive steps of the patent. This also suggests that elements are related to each other somehow. These relations might represent some process flows or adding functions/features to other elements. Then we can interpret these relations as some kind of hierarchies. Therefore, just like dependent claim structures, we can rebuild structural elements in a claim into some hierarchical structures.

Figure 1 shows an example of hierarchical structures. The element 1-4 is in the claim 1, and the dependent claim 2 and claim 3 depends on the element 2 and 4 respectively.

Now there is another rule in writing a claim; there must be no unnecessary element appeared in a claim. This is because an unnecessary element narrows the scope of the patent, and applicants never want this situation. Suppose that a claim has an additional new element which depends on an key element containing novelties of the patent (this new element might use the output of the key element's process or add some features to the key element), then the claim has only a limited scope compared to the claim without the additional element. This means that a properly written patent claims contain only a few key elements and these key elements should be placed in a lower level of the hierarchical structure.

Based on these observations, we assume two things;

- the keywords of novelties tend to exist in the elements that the dependent claims depend on.

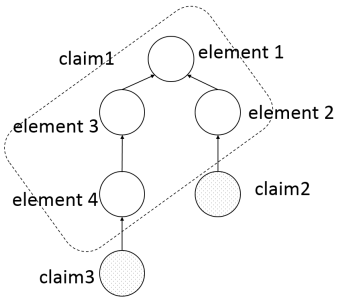

Figure 1: Example of Claim Structure

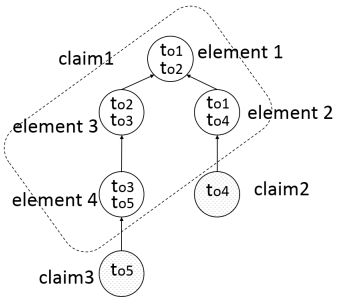

Figure 2: with Overlapping terms

- the keywords of novelties tend to exist in a lower level of the element hierarchical structure.

3.2 Outline of New Approach to Extract Keywords

In this subsection, we describe the outline of our proposed approach to extract keywords of novelties in the first claim using patent claim structures under the assumptions in the previous section. (The extension from the first claim to all independent claims is straightforward.) The notation is listed in Table 1.

Notation	Description
$e(w)$	the first element in $\{e_i\}$ where term w appears
$d(e_i)$	the depth of the element e_i
t_o	overlapping term that connects element-element dependency or element-dependent claim dependency
$ET(e_i)$	map from child element e_i to t_o
$DT(c_i)$	map from dependent claim c_i to t_o
$parent(e_i)$	the parent element of e_i
T_o	the set of all t_o
$ncl(t_o)$	the number of dependent claims $DT^{-1}(t_o)$
$Mod(k)$	map to $\{t_o\}$ that k modifies

Table 1: Notation

Algorithm 1 extracting element dependency structure

$d(e_1) \leftarrow 0$
for $i = 2$ **to** $i = |\{e_i\}|$ **do**
  search $e(w)$ in $\{e_j | j \leq i\}$ for $\forall w \in e_i$
  $d(e_i) \leftarrow -1$
  $d(e_i) \leftarrow \max_{w \in e_i} d(e(w)) + 1$
  if $d(e_i) \neq 0$ **then**
    $t_o \leftarrow \arg\max_{w \in e_i} d(e(w))$
    $parent(e_i) \leftarrow e(t_o)$
    $ET(e_i) \leftarrow t_o$
  end if
end for

Step1:extracting element structure: The first claim of a patent is parsed so that each structural element is decomposed, and dependencies within the elements are extracted. Dependencies between the elements are extracted in the following way. First, the decomposition of each element is done by using cue phrases (Shinmori et al., 2003) or using line breaks. Then, the depth for each element is calculated by following the procedure in Algorithm 1. Note that $\{e_i\}$ is a set of elements sequentially derived from the first claim. Those terms that appear in the subject matter are removed from this analysis. Figure 2 represents the example of dependencies using overlapping terms t_o. The term t_{o3} first appears in e_3, then in e_4. Therefore $parent(e_4) = e_3$, and $ET(e_4) = t_{o3}$. Other types of structure extraction is also applicable.

Step2:extracting claim dependency structure: The claims that depend on the first claim are parsed. The procedure to attach depth for all dependent claims is the same as that of step 1. This means that overlapping term t_o is attached for each dependent claim c_i, i.e. $DT(c_i) \leftarrow t_o$. In figure 2, t_{o5} first appeared in e_4. t_{o5} also appears in the claim 3, then $DT(c_3) = t_{o5}$.

Step3:calculating the score of the representative keywords: For every overlapping term t_o stored in the set T_o, the score s_o is calculated using the depth of element $e(t_o)$ and the number of dependent claims $ncl(t_o)$ attached to t_o. The definition of score s_o is explained in the next subsection 3.3.

Step4:calculating the score of the keywords of novelties: Keywords k modifying each t_o are searched in the first claim. Modification of t_o by k is defined by satisfing at least one of the following conditions;

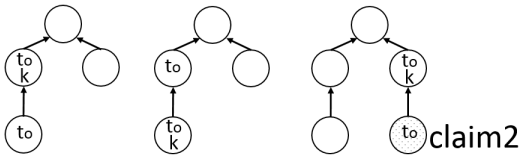

Figure 3: Examples of Modification: k modifying t_o

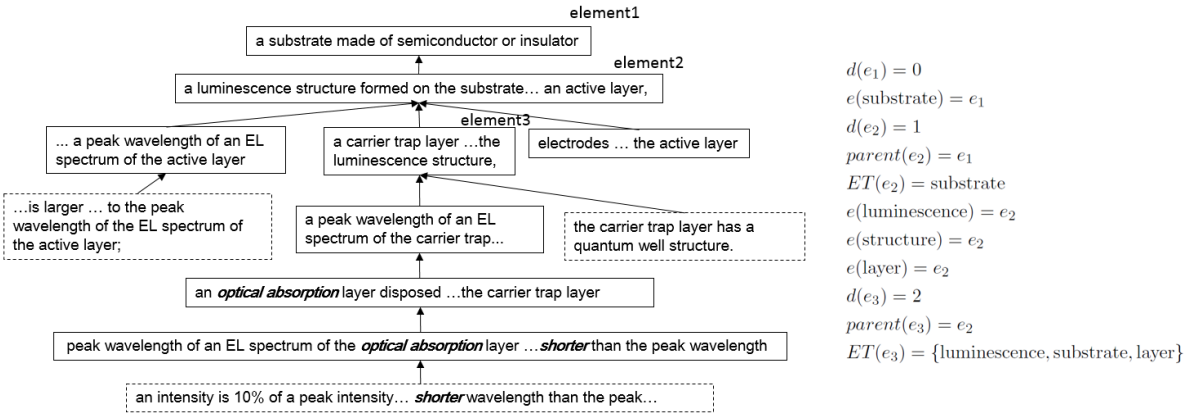

Figure 4: Actual Example of Claim Structure

1. k appears in the element $ET^{-1}(t_o)$.
2. k appears in the element $e(t_o)$.

t_o can be also regarded as k. A keyword k modifying t_o is represented as $t_o \in Mod(k)$ and $k \in Mod^{-1}(t_o)$. Note that the mapping function Mod and Mod^{-1} is many-to-many mapping. Figure 3 shows examples of modifications. In every example in figure 3, k modifies t_o. Then the score $S(k)$ for each $k \in \{k| \cup_{t_o \in T_o} Mod^{-1}(t_o)\}$ is calculated using the definition in the next subsection 3.3.

The actual example of claim structures is shown in figure 4. The boxes enclosed by solid line represent elements in the first claim and those of dashed line represent dependent claims. The bold italic keywords are the keywords of novelties annotated automatically in the framework introduced in the section 4. The right side of figure 4 shows the actual procedure of Algorithm 1 for the first 3 elements.

3.3 Definition of Scores

During the whole process, the locality score for each term w is calculated by

$$loc(w) = \frac{|\{e_i\}|}{|\{e_i | e_i \ni w\}|}, \tag{1}$$

that is, locality represents how much w is localized among all elements.

The score for overlapping terms is defined as

$$s_{o1}(t_o) = d(e(t_o)) * (ncl(t_o) + 1) \tag{2}$$

$$s_{o2}(t_o) = d(e(t_o)) * (log(ncl(t_o) + 1) + 1), \tag{3}$$

and using the score of overlapping terms t_o, the score of k that modifies t_o is defined in the equation

$$S_l(k) = \max_{t_o \in Mod(k)} loc(k) * s_{ol}(t_o) \tag{4}$$

with $l = 1, 2$ and s_{ol} represents eq.(2) or eq.(3), respectively. Note that $S_l(k) = 0$ if $Mod(k) = \emptyset$.

4 Evaluation Method Using Rejected and Granted Patents

In the previous section, we proposed a new approach of how to calculate the scores for each term k. This score $S_l(k)$ represents the degree of novelties of term k in each patent. But the evaluation of this approach is another difficult task. To evaluate the performance of extracting such keywords, we need annotated data. But manual annotation needs domain knowledge of each technical field and expertise in reading patent claims. Therefore, preparing large amount of manual annotations for various technical fields is quite difficult. Since extracting the keywords of novelties is not a conventional task in patent analysis, there is no commonly available shared task set for evaluation. In this section, we propose a general framework to obtain annotated data automatically from the examination result of Patent Offices.

4.1 Process of Patent Examination

Patent Offices in some countries publish all examination processes of each patent. Basically, a submitted patent follows a process like this; **1**. A patent is examined and if an insufficient part exists, the examiner reject the patent. **2**. The applicant may withdraw submission, or modify the claim to overcome the reason of the rejection. **3**. After repeated examination and possible rejection/modification, a patent is decided to be granted or rejected.

One of the major and critical reasons of the rejection is the existence of prior art that invalidates the submitted patent. In other words, if this type of rejection is overcome by modifications of the claims, this modified part must contain the keywords of novelties.

4.2 Framework of Evaluation

Based on the assumption, we build a framework to evaluate the extraction of keywords of novelties for each patent. Each patent document used in this framework must be rejected only by the reason of existence of prior art and then be granted after modifications. For each patent satisfying the above condition, two types of claims are extracted for each patent; the claims before the patent is examined and the claims after the patent is granted. Then those keywords, which appear in the granted first claim but not in the rejected first claim, are extracted. Such keywords are regarded as the positive-labeled set of keywords of novelties. The reason of extracting keywords only from the first claim is, the correspondence between the two types is clear. (For example, the third claim in the rejected patent corresponds to the second claim in the granted patent, which is difficult to guess. But usually, the first claim of the rejected patent is corrected by adding keywords from the proceeding dependent claims or from the description in the application.)

In order to examine the extracted set of keywords are truly positive, we randomly pickup and check some of the granted first claims manually by referencing the arguments in response to the notices of reasons for rejection (i.e. Office Actions). In the arguments, applicants explain how the corrected claims differ from the prior art. In this preliminary analysis, the average f-measure of 26 patents becomes 0.8339. This result ensures that our proposed framework is adequate for preparing positive-labeled set of keywords of novelties at least as an approximation.

The positive-labeled set is compared to those keywords extracted by various approaches for evaluation.

5 Experiments

In this section, we evaluate our approach proposed in section 3 using the framework proposed in section 4.

5.1 Corpus

The Japanese patents submitted during Jun 1 to March 31 in 2005 are used in the evaluation. We selected patents for each technical field corresponding to International Patent Classification (IPC) from A to H. The IPC Section title and the definition list is shown in table 2 (More detailed explanation can be found in (WIPO Guide, 2016)). For calculating document frequency in BM25 (one of the baseline approaches we applied), we use other corpus containing the patent data submitted before Jun 1, 2005. This corpus contains around 3 million patents.

Section	Definition
A	HUMAN NECESSITIES
B	PERFORMING OPERATIONS; TRANSPORTIN
C	CHEMISTRY; METALLURG
D	TEXTILES; PAPER
E	FIXED CONSTRUCTIONS
F	MECHANICAL ENGINEERING; LIGHTING; HEATING; WEAPONS; BLASTING
G	PHYSICS
H	ELECTRICITY

Table 2: IPC Section Title

Approach	Definition
Proposed1	$S_1(k)$ in eq.(4)
Proposed2	$S_2(k)$ in eq.(4)
BM25	BM25 score $BM(w)$
BM25perEle	$S_{base2}(w)$ in eq.(7)
Locality	$loc(w)$ in eq.(1)
Loc*Ele1	$\sum_{e_i \ni w} loc(w) * \tilde{S}_{e1}(e_i)$
Loc*Ele2	$\sum_{e_i \ni w} loc(w) * \tilde{S}_{e2}(e_i)$

Table 3: Definition of Approaches

5.2 Approaches to be Evaluated

As a baseline, we try BM25, the traditional keyword extraction approach. Besides, we also try several naive approaches that are easily conceivable from the related work in section 2. One is using locality as a score defined in eq.(1). This is similar to Takaki(2004)'s approach while they also used element-wise score as well. Here we prepare two types of element-wise score referring to Takaki's approach.

$$\tilde{S}_{e1}(e_i) = \frac{1}{|e_i|} \sum_{w \in e_i} loc(w) \tag{5}$$

$$\tilde{S}_{e2}(e_i) = \frac{1}{log(|e_i|+1)} \sum_{w \in e_i} loc(w) \tag{6}$$

Moreover we prepare one simple extension of BM25:

$$S_{base2}(w) = \max_{e_i \ni w} \tilde{S}_{e2}(e_i) * BM_i(w) \tag{7}$$

where $BM_i(w)$ represents the value of BM25 of w regarding the element e_i as a document.

The table 3 shows the definition of scores of tested approaches. **Proposed1** and **Proposed2** are our new proposed approaches introduced in section 3. **BM25** is the baseline approach. **BM25perEle**, **Loc*Ele1** and **Loc*Ele2** are the approaches easily conceivable from the related work.

5.3 Evaluation Results

We evaluate the performance of keyword extraction using each score by Mean Average Precision (MAP) which is often used to evaluate the performance of information retrieval. Since several types of scores like our proposed approaches or locality tend to have the same value for multiple terms, we calculate all the orders for those tie ranks and averaged the MAP value of each order.

The result is in the table 4. This shows that in every technical field our proposed approaches **Proposed1**, **Proposed2** outperform the baselines using BM25 or those approaches that are easily conceivable from the relate work. Especially the approach **Proposed2** significantly outperforms the baselines in most of the tehcnical fields except for IPC=C (chemistry). One reason for relatively low performance of our proposed approach in the field of chemistry is, that patent claims in the field are often the type of Markush Claim which doesn't fit our current structure parsing method in step1 of subsection 3.2 (The current method fits Jepson Claim better).

6 Conclusion

We propose a new approach to extract keywords of novelties from patent claims. It is a challenging task partly because the problem setting itself is rather unique, and partly because there has been no framework to evaluate the performance directly. We show that the existing keyword extraction techniques don't work well when analyzing patent claims, since patent claims have a specific format that a non-expert finds difficult. Although analyzing patent claims is quite important in many industries, understanding the contents of claims using NLP techniques is still in a developing phase.

number of documents	356	501	278	198	370	351	338	501

Table 4: MAP result

While there are works on extracting novelties from trend analysis of news, SNS or other documents, these are mainly aiming to extract only keywords from those documents with brand new contents. But in patent claims, novelties are often represented in general expressions. This is one main reason that we focus on extracting what inventors think as novel for every patent using the structures of patent claims.

In this paper we apply only preliminary approaches, but additional attempts such as using key phrases, using dependencies between terms, or using other fields in patent specifications will surely increase the performance. Moreover, since annotated data is available using our proposed framework, supervised approaches are applicable. Combining features like eq.(4) with other features derived from patent claim structures, supervised approaches may give us some knowledges on what kind of structure may be effective for extracting keywords of novelties.

A simple expansion of the method in step 1 of subsection 3.2 to Markush Claim will also increase the performance in the field of chemistry.

Future work also includes applying our approach to patent retrieval, patent summarization, or detecting important technologies.

Leveraging Multilingual Training for Limited Resource Event Extraction

Andrew Hsi **Yiming Yang** **Jaime Carbonell** **Ruochen Xu**

Abstract

Event extraction has become one of the most important topics in information extraction, but to date, there is very limited work on leveraging cross-lingual training to boost performance. We propose a new event extraction approach that trains on multiple languages using a combination of both language-dependent and language-independent features, with particular focus on the case where target domain training data is of very limited size. We show empirically that multilingual training can boost performance for the tasks of event trigger extraction and event argument extraction on the Chinese ACE 2005 dataset.

1 Introduction

Traditionally, event extraction has focused on monolingual training – typically English (Grishman et al., 2005; Ji and Grishman, 2008; Gupta and Ji, 2009; Liao and Grishman, 2010; Liao and Grishman, 2011; Li et al., 2013; Bronstein et al., 2015), and occasionally Chinese or other languages (Chen and Ji, 2009b; Piskorski et al., 2011; Li et al., 2012; Chen and Ng, 2012; Chen and Ng, 2014). However, apart from a few isolated studies (Chen and Ji, 2009a; Piskorski et al., 2011), to date there is very little work leveraging cross-lingual information for event extraction. Cross-lingual approaches have proven useful for many other tasks in natural language processing (NLP), including part-of-speech (POS) tagging (Snyder et al., 2009; Cohen et al., 2011), dependency parsing (Zeman and Resnik, 2008; Cohen et al., 2011; McDonald et al., 2011; Ammar et al., 2016), and named entity recognition (Richman and Schone, 2008).

An important issue in event extraction is that the amount of available training data is often insufficient or unbalanced across domains and/or languages. Event extraction training datasets typically contain merely a few hundreds of documents, owing to the complexity and high costs of human annotation. This issue is even more severe for new event types in new languages. This provides strong motivation to leverage existing language resources for event extraction in new languages. This problem is closely related to low-resource NLP, which has been gathering increased interest among researchers (Garrette et al., 2013; Miao et al., 2013; Duong et al., 2014; Duong et al., 2015).

In this paper, we propose a novel approach for cross-lingual event extraction, which trains on multiple languages and leverages both language-dependent and language-independent features in order to boost performance. Using such a system we aim to jointly leverage available multilingual resources (annotated data and induced features) to overcome the annotation-scarcity issue in the target language of interest. Empirically we show that our approach can substantially improve the performance of monolingual systems for the task of Chinese event argument extraction. Our approach is novel compared to existing work in that we have no reliance on using either high quality machine translation or manually aligned documents, which may be unavailable for a given target language.

The rest of the paper is organized as follows. Section 2 introduces relevant terminology used in the event extraction field. Section 3 describes some related work on event extraction and cross-lingual NLP. Section 4 details our event extraction system and the types of features we use. In Section 5, we describe

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1201–1210, Osaka, Japan, December 11-17 2016.

our experimental setup and discuss results for both cross-lingual event trigger extraction and cross-lingual event argument extraction. We conclude in Section 6 with some ideas for future work.

2 Terminology and Task Definitions

We will begin by briefly introducing the basic terminology used in the event extraction field and the task definitions by the Automatic Content Extraction (ACE) Evaluation program[1] conducted by the National Institute of Science and Technology (NIST). The ACE program focused on entity detection, relation detection, and event detection – among these, we focus in this paper specifically on the event detection task, which consists of event trigger extraction and event argument extraction.

- An *event* is something that happens at a particular time and place, often involving one or more people. Examples include births, attacks, and arrests.
- An *event mention* is a particular textual occurrence of an event. A text may contain several different mentions that all refer to the same physical event.
- An *event trigger* is the specific word in a sentence that indicates the existence of an event.
- An *event argument* is an entity fulfilling a specific role within the event. The set of permissible roles depends on the event type. For example, the Attacker role would be valid for a Conflict.Attack event, while the same role would be invalid for an event of type Business.Declare-Bankruptcy. Additionally, all event types in ACE include roles for Time and Place.
- Lastly, an *event argument mention* is a particular textual occurrence of an event argument.

The *event trigger extraction task* is to identify all of the event triggers contained within a set of documents. The *event argument extraction* task is to identify all of the event arguments contained within a set of documents. In most cases, the event trigger extraction step is conducted first to identify the event mentions, and then event argument extraction is performed on top of this to identify the particular entities fulfilling argument roles for these event mentions.

3 Related Work

A variety of machine learning methods have been used for event extraction in the past, including pipelines of classifiers (Grishman et al., 2005; Ji and Grishman, 2008; Liao and Grishman, 2011), joint inference models (Li et al., 2013; Li and Ji, 2014; Yang and Mitchell, 2016), and neural networks (Nguyen and Grishman, 2015; Chen et al., 2015) – the vast majority of which focus solely on the English monolingual training scenario. A subset of the event extraction literature has considered the study of Chinese event extraction (Chen and Ji, 2009b; Li et al., 2012; Chen and Ng, 2012; Chen and Ng, 2014). However, most of these works also focus solely on the monolingual case, and do not leverage any additional training data from other languages.

The most related work to our approach is that of Chen and Ji (2009a). In their model, they designed a co-training approach to augment a small Chinese training corpus with additional examples from an unlabeled corpus. Given a parallel corpus of English-Chinese documents and a monolingual English event extraction system (trained on annotated English documents), they used the system to predict the event labels on the English part of the parallel documents and project the predicted labels to the Chinese part of the parallel corpus based on gold standard alignments. The Chinese system is then trained using a combination of the originally annotated Chinese document and the parallel texts with the projected labels. This approach offered slight improvements in the event trigger extraction task and the event argument extraction task (see Section 2 for definitions), but relies on having in-domain parallel texts either aligned by humans or by high quality machine translation models between the source and target languages. In contrast, our proposed approach has no such limitation, and hence is easier to apply to any target language of interest.

[1] http://www.itl.nist.gov/iad/mig/tests/ace/

Another related work is that of Piskorski et al. (2011), who use cross-lingual information to refine the results of event extraction. In particular, they run several monolingual event extraction systems independently, translate the extracted argument fillers into English, and merge together argument fillers across documents. Using this cross-document information fusion, they find improved performance over monolingual systems. However, this work relies on having documents across multiple languages that describe the exact same event, which is an unrealistic case in practice. Additionally, they also rely on having high quality machine translation in order to translate the argument output of each monolingual system into English.

There does exist some prior work on the broader field of cross-lingual information extraction. Riloff et al. (2002) start with English annotated source texts, create a parallel corpus via machine translation, and project the annotations via alignments. The projected annotations are then used to conduct training in the target language. Sudo et al. (2004) presents an approach for extracted patterns in a source language and translating these patterns for use on a target language. However, these works are limited to entity extraction, whereas our focus is on event extraction. Furthermore, both works rely on having high-quality machine translation output.

Beyond information extraction, cross-lingual training has offered benefits for a variety of tasks. McDonald et al. (2011) use a delexicalized English parser to seed a lexicalized parser in the target language, and then iteratively improve upon this model via constraint driven learning. Duong et al. (2014) develop a POS tagger for low resource languages by first projecting predicted English POS tags across parallel data to obtain target language training data, and then further augment this with a small amount of annotated data in the target language. Ammar et al. (2016) developed a language universal dependency parser by using language-independent features to create a general model, and fine-tuning the resulting model with language-specific features and embeddings. Similarly to our model, this method has no requirement about the availability of alignments and parallel text.

4 System Description

To date, there exist only a handful of languages that have ACE-style event annotations, yet this leaves a vast number of languages in which people have no capacity to conduct event extraction. This problem is compounded by the difficulty of event extraction annotation. Annotation of documents for event extraction is a very labor-intensive, costly task – even the standard benchmark dataset of ACE 2005 only contains several hundred annotated English documents. It is inconceivable to believe that we will ever have similar datasets for every language of interest.

A natural effort therefore, is to leverage as much information as we can from existing "high-resource" event-extraction languages, along with whatever limited training data we may have for the target language. To accomplish this, we create a standard pipeline-of-classifiers approach to event extraction, and then augment this model with multilingual features.

The overall system architecture may be seen in Figure 1. We begin by preprocessing the data to obtain tokenizations, POS tags, and dependency parses. We then extract our trigger features, and run a multi-class classifier to predict the trigger labels. We subsequently extract our argument features using the original preprocessed data in combination with the system predicted trigger labels, and run a second multi-class classifier to make predictions on the argument roles.

4.1 Trigger Prediction

We begin by describing our trigger prediction component. For the task of event trigger prediction, we train a multi-class logistic regression classifier using LIBLINEAR (Fan et al., 2008). For each word, we make a prediction on the event trigger type – one of 33 given types from the ACE ontology, or the NONE category to represent when a word does not trigger an ACE event.

The trigger system uses a variety of monolingual features, seen in Table 1. For the majority of the features, we use binary indicator functions to represent whether the feature is either active or inactive for the particular data instance. For the word embedding features, we use the real-valued vectors directly for representing each word.

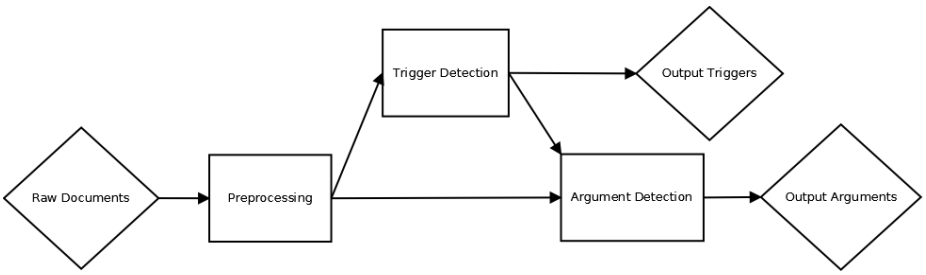

Figure 1: Architecture for our event extraction system. The argument component relies on the predictions from the trigger component.

Event Trigger Extraction Features
Lexical features (e.g. words and lemmas within a context window)
Length of the current word
Language-specific POS tags within a context window
Universal POS tags within a context window
Word embedding vector for current word
Dependent/Governor information from dependency parsing
Bilingual dictionary word pairs

Table 1: Features used in the Event Trigger Extraction component

Multilingual training is leveraged via the use of four types of features: 1.) Universal POS Tags (Petrov et al., 2012), 2.) Universal Dependencies (McDonald et al., 2013), 3.) limited bilingual dictionaries, and 4.) aligned multilingual word embeddings. The Universal POS tags and Universal Dependencies allow us to use a single set of tags for both languages, which thereby enables the use of English training data directly in our model. The bilingual dictionary provides a limited number of translations between words, and may be used both directly in the model and for aligning word embeddings. The aligned word embeddings similarly allow us to directly use English training data, as each component in the vector is aligned to semantically match those of the target word embeddings.

To obtain aligned word embeddings, we first start with monolingual word embeddings. We obtain monolingual texts for both English and the target language from Wikipedia, and independently train word embeddings for each language using word2vec (Mikolov et al., 2013). These monolingual embeddings are then aligned by solving a regression problem.

Let $D = (x_i, z_i)_{i=1}^{n}$ represent a limited bilingual dictionary between the two languages, where $x_i \in \mathbb{R}^{d_1}$ is the word embedding of word i in English and $z_i \in \mathbb{R}^{d_2}$ is the word embedding of its translation in the target language. Our regression problem is to find a transformation matrix W minimizing the following objective function:

$$\min_{W \in \mathbb{R}^{d2 \times d1}} \sum_{i=1}^{n} \|Wx_i - z_i\|^2 + \lambda \|W\|_F^2 \tag{1}$$

The first term of the objective function serves to ensure that the projected vectors in English closely match those of their translations in the target language. The second term is a regularization term to avoid overfitting. This problem has a closed form solution, which is given by:

$$W^* = ZX^T(XX^T + \lambda I)^{-1} \tag{2}$$

where $X = [x_1, x_2, ..., x_n] \in \mathbb{R}^{d_1 \times n}$ and $Z = [z_1, z_2, ..., z_n] \in \mathbb{R}^{d_2 \times n}$

The resulting aligned embeddings may then be used in our feature set. Using these aligned embeddings is preferable over just using the direct dictionary translations, as many words in both the source and target language may not appear in the bilingual dictionary. In our approach, once a mapping is found between two embedded spaces, we may project any word into this shared space.

4.2 Argument Prediction

We now describe the argument prediction component of our system. For this component, we require a few additional fields of information: 1.) event trigger words, and 2.) entity mentions. Event trigger words and entity mentions may be provided either as gold information or extracted automatically using machine learning approaches.

In each sentence, for each (trigger word, entity mention) pair, we make a prediction on the argument role (if any) between the trigger and the entity. The ACE ontology contains 35 different argument types, and we also include the NONE label to indicate when there is no relationship between the trigger and the entity. As in the previous case of trigger extraction, we once again accomplish this by training a multi-class logistic regression classifier using LIBLINEAR.

Event Argument Extraction Features
Lexical features about the entity phrase
Lexical features for individual words in the entity phrase
Entity type, subtype
Event type and subtype of trigger word
Existence of any other candidate entities in the same sentence
Distance between the trigger and entity
Dependent/Governor information from dependency parsing
Bilingual dictionary word pairs

Table 2: Features used in the Event Trigger Extraction component

Features for the event argument extraction component may be seen in Table 2. Multilingual information is leveraged in a similar way to the trigger prediction component, using Universal POS tags, Universal Dependencies, and any available bilingual dictionaries to learn from English training data.

5 Experimental Setup

To test our approach, we conduct experiments on two separate tasks: event trigger extraction and event argument extraction. We begin by describing our experimental setup and metrics, and subsequently show empirical results on the two tasks.

5.1 Dataset

We conduct experiments on the ACE 2005 dataset, the most dominating benchmark dataset for event trigger extraction and event argument extraction. The English and Chinese portions of ACE each contain several hundred documents annotated with gold standard entity and event information. We preprocess the raw text of each document using Stanford CoreNLP (Manning et al., 2014). We split the Chinese portion into 10 folds, and perform cross-validation. In the ACE collection, the number of labeled Chinese documents is approximately the same as the number of English documents, so to simulate a low resource scenario, we select just one training fold for each round of cross-validation. We use another fold for parameter tuning, and use the remaining folds in each round for testing. We use CC-CEDICT[2] as our bilingual dictionary between English and Chinese.

For our baseline system, we use just the Chinese data for training, and only the monolingual features. Our cross-lingual system uses the entire set of features, and additionally incorporates the entire English portion of ACE 2005 for training.

5.2 Metrics

We report both micro-averaged and macro-averaged precision, recall, and F1. Typically the event extraction community reports micro-averaged results, which give the overall performance after pooling all the labels together. However, we argue that only presenting this single perspective provides a skewed

view of the system performance, as this type of measure is highly favorable to the majority class labels. This is particularly an issue for the ACE 2005 collection, as the distribution over both trigger types and argument roles is highly skewed, as seen in Figures 2 and 3.

Table 3 shows the specific counts for each trigger type in the English portion of ACE 2005. The trigger type "Conflict.Attack" occurs far more frequently in the texts than any of the others – more than twice that of the second most common type. On the other extreme, the highly infrequent types only occur very rarely in the text. Analysis of the argument counts (Table 4) shows a similar situation. While not as badly skewed as in the trigger case, there is still noticeable disparity between the most frequent and least frequent classes. Some of this may be attributed to the fact that ACE includes several argument types that correspond to different varieties of "Time", but even if we ignore the "Time"-type arguments, there are still nine argument classes with less than 100 examples each.

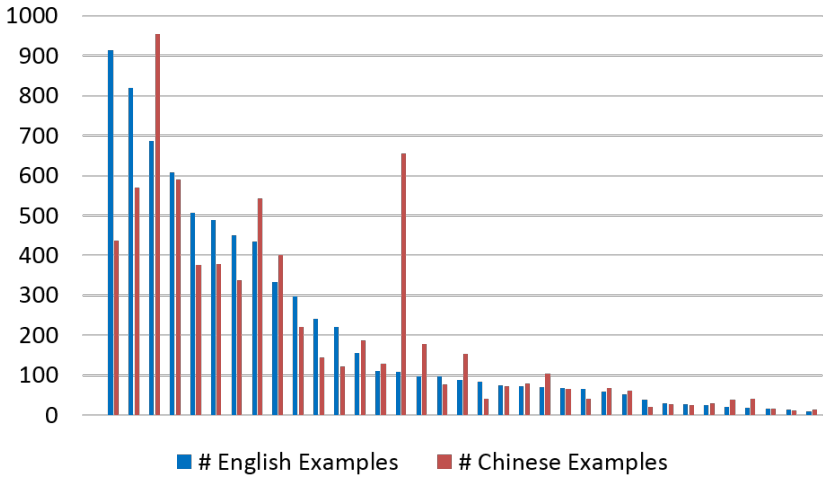

Figure 3: Distribution of Argument Roles in ACE 2005. Each bar represents one of the argument roles found in ACE 2005, and the height of the bar represents the number of argument mentions for said class.

Argument Roles (frequency)		
Person (1064)	Place (891)	Time-Within (699)
Entity (685)	Attacker (564)	Target (535)
Victim (529)	Destination (462)	Agent (368)
Defendant (359)	Crime (245)	Instrument (244)
Origin (160)	Artifact (131)	Position (111)

5.3 Event Trigger Extraction results

Results for trigger extraction may be seen in Table 5. The cross-lingual approach shows improved performance on both the micro-averaged and macro-averaged F1 metrics, demonstrating the success of incorporating multilingual training. On the macro-averaged metric, we see an improvement of 10.7%, and on the micro-averaged metric, an improvement of 3.9%. We find these improvements on F1 to be significant under a t-test with α=0.01.

As one would expect, the macro-averaged scores are noticeably lower than the micro-averaged scores, which suggests that the rare classes for event triggers suffer from worse performance than the frequent classes. Note that the difference in performance between the two approaches is larger on the macro-average metric. This suggests that the addition of multilingual training is playing a key role to improve performance on these particular rare classes.

	Macro-Average			Micro-Average		
	Precision	Recall	F1	Precision	Recall	F1
Monolingual approach	0.421	0.183	0.233	**0.646**	0.271	0.381
Cross-lingual approach	**0.443**	**0.209**	**0.258**	0.635	**0.288**	**0.396**

Table 5: Results of Trigger Extraction Task on Chinese ACE 2005

5.4 Event Argument Extraction results

Results for argument extraction may be seen in Tables 6 and 7. Table 6 shows the optimal performance obtained by using the gold event triggers as input, and Table 7 shows the more realistic scenario of using the system predicted triggers as input. In both cases, we utilize the existing gold entity information provided by the ACE collection.

We see even larger boosts in macro-average performance from the argument extraction component than from the trigger extraction component – using gold triggers we get a 34.8% improvement on macro F1, and using system predicted triggers we get a 28.2% improvement on macro F1. On micro-average metrics, we find a smaller, but still meaningful boost in performance: 3.2% improvement on micro F1 when using gold triggers as input, and 5.7% improvement on micro F1 when using the system predicted triggers. We find all of our argument results to show significant improvements on F1 over the monolingual equivalents under a t-test with α=0.01.

We suspect that the noticeably larger gains in argument macro-average performance compared to trigger performance may be due to the more semantic nature of the task. Trigger words are primarily dependent on lexical information, whereas arguments rely more heavily on deeper semantic information such as that provided by dependency parsing. Information leveraged from sources like Universal Dependencies is therefore likely to have a greater effect in the argument extraction setting, and in particular on the rare classes that do not have enough data to perform well under monolingual training.

	Macro-Average			Micro-Average		
	Precision	Recall	F1	Precision	Recall	F1
Monolingual approach	0.510	0.189	0.250	**0.744**	0.336	0.462
Cross-lingual approach	**0.556**	**0.267**	**0.337**	0.731	**0.355**	**0.477**

	Macro-Average			Micro-Average		
	Precision	Recall	F1	Precision	Recall	F1
Monolingual approach	0.400	0.080	0.124	**0.651**	0.140	0.230
Cross-lingual approach	**0.422**	**0.105**	**0.159**	**0.651**	**0.150**	**0.243**

Table 7: Results of Argument Extraction Task on Chinese ACE 2005, using system predicted trigger labels as input

6 Conclusion

In this paper, we proposed a cross-lingual approach to event extraction that leverages both language-dependent and language-independent features to train with multiple languages. Motivated by the necessity of developing new techniques for expansion of event extraction to new languages, and inspired by the recent success stories of cross-lingual NLP, we developed an approach which allows us to incorporate any additional training data from other languages, while also maximally utilizing whatever monolingual data we have available. Our experimental results show improved performance for event trigger extraction and event argument extraction with multilingual training, under both the macro-averaged and micro-averaged metrics. These are very encouraging numbers, and we believe this indicates event extraction to be a promising direction for future cross-lingual researchers to explore.

There are several natural extensions to this work. One interesting direction of research would be to explore an actual (rather than simulated) low-resource language, where the target language may not only have little (or no) training data, but may not even have available tools for preprocessing tasks (POS tagging, entity recognition, parsing, etc.). This is an important area of research, as the majority of the world's languages do not have such tools available. A second direction of promising research is consider the case of not just leveraging a single source language, but to rather include multiple source languages.

A final interesting direction is to adapt recent neural methods for cross-lingual NLP, such as those by Ammar et al. (2016). By using a more sophisticated machine learning approach, we may be able to improve our multilingual efforts even further than our current approach.

LILI: A Simple Language Independent Approach for Language Identification

Mohamed Al-Badrashiny and Mona Diab
Department of Computer Science, The George Washington University
{badrashiny,mtdiab}@gwu.edu

Abstract

We introduce a generic Language Independent Framework for Linguistic Code Switch Point Detection. The system uses the word length, character level (1, 2, 3, 4, and 5)-grams and word level unigram language models to train a conditional random fields (CRF) model for classifying input words into various languages. We test our proposed framework and compare it to the state-of-the-art published systems on standard data sets from several language pairs: English-Spanish, Nepali-English, English-Hindi, Arabizi (Refers to Arabic written using the Latin/Roman script)-English, Arabic-Engari (Refers to English written using Arabic script), Modern Standard Arabic(MSA)-Egyptian, Levantine-MSA, Gulf-MSA, one more English-Spanish, and one more MSA-EGY. The overall weighted average F-score of each language pair are 96.4%, 97.3%, 98.0%, 97.0%, 98.9%, 86.3%, 88.2%, 90.6%, 95.2%, and 85.0% respectively. The results show that our approach despite its simplicity, either outperforms or performs at comparable levels to state-of-the-art published systems.

1 Introduction

Linguistic Code Switching (LCS) is a common practice among multilingual speakers in which they switch between their common languages in written and spoken communication. In Spanish-English for example: "She told me that mi esposo looks like un buen hombre." ("She told me that my husband looks like a good man"). In this work we care about detecting LCS points as they occur intra-sententially where words from more than one language are mixed in the same utterance. LCS is observed on all levels of linguistic representation, and especially pervasive in social media. LCS poses a significant challenge to NLP, hence detecting LCS points is a very important task for many downstream applications. In this paper we address this challenge using a generic simple language independent approach. We illustrate our approach on several language pairs utilizing publicly available data sets and comparing our performance against state-of-the-art sophisticated systems tailored to the problem of LCS point detection (LCSPD). Furthermore, we show the robustness of our approach on the most challenging problem of language variety code switching where the code switching is happening between a standard and dialect, namely we illustrate our performance on Modern Standard Arabic (MSA) mixed with Egyptian Dialectal Arabic data (EGY).

2 Related Work

Several systems have recently addressed the problem of LCSPD in written text both within language varieties and across different language pairs. Relevant work on the problem of LCSPD among different language pairs can be summarized in the following works.

3ARRIB (Al-Badrashiny et al., 2014; Eskander et al., 2014) addresses the challenge of how to distinguish between Arabic words written using Roman script (Arabizi) and actual English words in the same context/utterance. The assumption in this framework is that the script is Latin for all words. It trains a finite state transducer (FST) to learn the mapping between the Roman form of the Arabizi words and

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1211–1219, Osaka, Japan, December 11-17 2016.

their Arabic form. It uses the resulting FST to find all possible Arabic candidates for each word in the input text. These candidates are filtered using MADAMIRA (Pasha et al., 2014), a state-of-the-art morphological analyzer and POS disambiguation tool, to filter out non-Arabic solutions. Finally, it leverages a decision tree that is trained on language model probabilities of both the Arabic and Romanized forms to render the final decision for each word in context as either being Arabic or English.

Bar and Dershowitz (2014) addresses the challenge for Spanish-English LCSPD. The authors use several features to train a sequential Support Vector Machines (SVM) classifier. The used features include previous and following two words, substrings of 1-3 character ngrams from the beginning and end of each word thereby modeling prefix and suffix information, a boolean feature indicating whether the first letter is capitalized or not, and 3-gram character and word ngram language models trained over large corpora of English and Spanish, respectively.

Barman et al. (2014) present systems for both Nepali-English and Spanish-English LCSPD. The script for both language pairs is Latin based, i.e. Nepali-English is written in Latin script, and Spanish-English is written in Latin script. The authors carry out several experiments using different approaches including dictionary-based methods, linear kernel SVMs, and a k-nearest neighbor approach. The best setup they found is the SVM-based one that uses character n-gram, binary features indicate whether the word is in a language specific dictionary of the most frequent 5000 words they have constructed, length of the word, previous and next words, 3 boolean features for capitalization to check if the first letter is capitalized, if any letter is capitalized, or if all the letters are capitalized.

The approach presented by King et al. (2014) utilizes character n-gram probabilities, lexical probabilities, word label transition probabilities and existing named entity recognition tools within a Markov model framework.

Jain and Bhat (2014) use a CRF based token level language identification system that uses a set of easily computable features (Ex. isNum, isPunc, etc.). Their analysis showed that the most important features are the word n-gram posterior probabilities and word morphology.

Lin et al. (2014) use a CRF model that relies on character n-grams probabilities (tri and quad grams), prefixes, suffixes, unicode page of the first character, capitalization case, alphanumeric case, and tweet-level language ID predictions from two off-the-shelf language identifiers: cld2[1] and ldig.[2] They increase the size of the training data using a semi supervised CRF autoencoder approach (Ammar et al., 2014) coupled with unsupervised word embeddings.

MSR-India (Chittaranjan et al., 2014) uses character n-grams to train a maximum entropy classifier that identifies whether a word is language1 or language2. The resultant labels are then used together with word length, existence of special characters in the word, current, previous and next words to train a CRF model that predicts the token level classes of words in a given sentence/tweet.

On the other hand, for within language varieties, AIDA (Elfardy et al., 2014) and AIDA2 (Al-Badrashiny et al., 2015) are the best published systems attacking this problem in Arabic. In this context, the problem of LCSPD is more complicated than mixing two very different languages since in the case of varieties of the same language, the two varieties typically share a common space of cognates and often faux amis, where there are homographs but the words have very different semantic meanings, hence adding another layer of complexity to the problem. In this set up the assumed script is Arabic script. AIDA (Elfardy et al., 2014) uses a weakly supervised rule based approach that relies on a language model to tag each word in the given sentence. Then it uses the LM decision for each word in the given sentence/tweet and combine it with other morphological information to decide upon the final class of each word. AIDA2 (Al-Badrashiny et al., 2015) uses a complex system that is based on a mix of language dependent and machine learning components to detect the linguistic code switch between the modern standard Arabic (MSA) and Egyptian dialect (EGY) that are both written using Arabic script. It uses MADAMIRA (Pasha et al., 2014) to find the POS tag, prefix, lemma, suffix, for each word in the input text. Then it models these features together with other features including word level language model probabilities in a series of classifiers where it combines them in a classifier ensemble approach to

[1] https://code.google.com/p/cld2/

[2] https://github.com/shuyo/ldig

find the best tag for each word.

We compare our system to all of the above systems in addition to some other baselines.

3 Approach

In this paper, we present a very simple language independent framework called LILI to address the challenge of linguistic code switch point detection (LCSPD) when it occurs using the same script for the mixed languages in the utterance. Our framework is mainly based on the assumption that each language has its own character pattern behaviors and combinations relating to the underlying phonology, phonetics, and morphology of each language independently. Accordingly, the manner of articulation constrains the possible phonemic/morphemic combinations in a language. For example in Arabic, it is hard to find a word that have the "th" sound followed by an "s" sound, while it is possible in English as in the word "thus". Historically, the famous Arab lexicographer Al-Farahidi (718 - 786 CE) noticed this phenomenon (where certain sound sequences are allowed while others are not in the language) and devised a method by which he can distinguish Arabic words from foreign ones on the basis of the possible sequences of letters in Arabic (Ahmad, 2003). Though having closed set of impossible sequences of letters in each language could help in distinguishing between languages within an utterance, but in reality it is hard to find such sets for all languages. Hence, we believe that building a character level n-gram language model for the target language to maximize the probabilities of the possible patterns and suppress the probabilities of the impossible ones should provide an approximation to such a closed set rule-based list. Not to mention that producing such a list by hand is quite laborious and error prone as a process.

Accordingly, we propose a supervised learning framework to address the challenge of LCSPD. We assume the presence of annotated code switched training data where each token is annotated as either Lang1 or Lang2. We create a sequence model using Conditional Random Fields (CRF++) tool (Sha and Pereira, 2003). For each word in the training data, we create a feature vector comprising word length, character sequence level probabilities, and unigram word level probabilities. Once we derive the learning model, we apply to input text to identify Lang1 tokens vs. Lang2 tokens in context. For the character sequence level probabilities, we build (1, 2, 3, 4, and 5)-gram character language models (CLMs) using the SRILM tool (Stolcke, 2002) for each of the two languages presented in the training data using the annotated words. For example, if the training data contains the two languages "lang1" and "lang2", we use all words that have the "lang1" tags to build (1, 2, 3, 4, and 5)-grams CLMs for "lang1" and the same for "lang2". We apply all of the created CLMs to each word in the training data to find their character sequence probabilities in each language in the training data. To increase the difference between the feature vectors of the words related to "lang1" and those related to "lang2", we use a word level unigram LM for each of the two languages in the training data. Then we apply the unigram LMs to each word in the training data to find their word level probabilities in each language in the training data, i.e. checking whether it pertains to the language or not by virtue of having a higher probability in the corresponding LM than words not in the language.

4 Experimental Setup

4.1 Data

We evaluate our proposed framework on different language pairs exhibiting code switching. We use the training and test data sets provided by the shared task for "Language Identification in Code-Switched Data" [ShTk] in 2014 and 2016 (Solorio et al., 2014; Molina et al., 2016). The ShTk-2014 datasets includes English-Spanish, English-Nepali, Modern standard Arabic (MSA)-Egyptian Arabic (EGY), and English-Mandarin[3], while the ShTk-2016 datasets includes English-Spanish, and, MSA-EGY. In addition to these languages, we evaluate our system on MSA-Levantine (LEV), MSA-Gulf, Arabizi-English, Arabic-Engari, and English-Hindi datasets[4].

[3]Unfortunately, we did not manage to get English-Mandarin datasets from the organizers but we got the rest of them.

[4]Nepali, Arabizi, and Hindi are written using Roman script. Engari is written using Arabic script

- MSA-LEV and MSA-Gulf: These datasets are collected from online newspaper commentary and Twitter by Cotterell and Callison-Burch (2014). The datasets are annotated for sentence level. We re-annotated the data for token level using the guidelines provided by Diab et al. (2016). We then split the data into training and test (80% for training and 20% for testing);

- Arabizi-English: We use the same training and test sets used by 3ARRIB. The data sets are created by the Linguistic Data Consortium from SMS/Chat corpus (Bies et al., 2014; LDC, 2014a; LDC, 2014b; LDC, 2014c);

- Arabic-Engari: Same as the MSA-EGY data sets. But we re-annotated the data to tag all English words that are written in Arabic script. MSA and EGY words are both tagged as Arabic words;

- English-Hindi: It consists of 728 and 376 sentences for training and test sets, respectively, collected from Twitter and Facebook. This dataset is part of a corpus that is used for POS-tagging experiment in code-switched data (Jamatia et al., 2015).

Table 1 shows the distribution of each language in the training and test sets. The lang1, lang2 labels refer to the two languages addressed in the dataset name, for example for the language pair English-Spanish, lang1 is English and lang2 is Spanish, in that order[5].

All Language-Pairs	Training-Set		Test-Set	
	lang1	lang2	lang1	lang2
English-Spanish-2014	77,101	33,099	7,424	5,278
Nepali-English-2014	60,493	44,111	12,286	17,216
MSA-EGY-2014	79,059	16,291	57,740	21,871
Arabizi-English-2014	93,402	11,122	27,308	1,903
Arabic-Engari	439,875	1,282	79,611	433
English-Hindi	6,562	5,526	8,676	378
LEV-MSA	44,694	11,522	11,524	2,265
Gulf-MSA	57,718	8,655	15,400	1,409
English-Spanish-2016	77,101	33,099	32,442	123,973
MSA-EGY-2016	79,059	16,291	5,804	9,630

Table 1: Language distribution (words/language) in the training and test data sets for all language-pairs

In addition to the training data described in table 1, we used the following datasets to improve the word level LMs of the English, Spanish and Arabic langauges:

- English Gigaword (LDC, 2003b): To build the unigram word level LM for the English part in English-Spanish, English-Nepali, and English-Hindi language-pairs;

- Spanish Gigaword (LDC, 2009): To build the unigram word level LM for the Spanish part in English-Spanish language-pair;

- Arabic Gigaword (LDC, 2003a): To build the unigram word level LM for the MSA part in MSA-EGY, LEV-MSA, and Gulf-MSA language-pairs;

- Egyptian discussion forums (LDC, 2012): To build the unigram word level LM for the EGY part in MSA-EGY language-pairs. It is also used in addition to the Arabic Gigaword to build the LM for the Arabic part in the Arabic-Engari language pair.

4.2 Baselines

We evaluate our approach against the best published results using the same training and test sets. The baselines include:

[5]The ShTk-2014 has a different naming convention for the Nepali-English, however we opt for changing the naming to indicate the majority class is Nepali as in lang1 and English is the minority class language lang2

- Majority: In this baseline, for each word in the test set, we check the most frequent tag for that word in the training set and assign it to that word. If the word is not in the training set, we give it the most frequent language tag observed overall in the training data;
- TAU: The results on the English-Spanish dataset obtained by Bar and Dershowitz (2014);
- DCU-UVT: The results on the English-Spanish and English-Nepali datasets obtained by Barman et al. (2014);
- CMU: The results on the English-Spanish, English-Nepali, and MSA-EGY datasets obtained by Lin et al. (2014);
- IUCL: The results on the English-Spanish, English-Nepali, and MSA-EGY datasets obtained by King et al. (2014);
- IIIT: The results on the English-Spanish, English-Nepali, and MSA-EGY datasets obtained by Jain and Bhat (2014);
- MSR-India: The results on the English-Spanish, English-Nepali, and MSA-EGY datasets obtained by Chittaranjan et al. (2014);
- AIDA: The results on the MSA-EGY dataset obtained by our contribution in the ShTk-2014 (Elfardy et al., 2014);
- AIDA2: The results on the MSA-EGY dataset obtained by our previous publication about AIDA2 system (Al-Badrashiny et al., 2015);
- 3ARRIB: The results on the Arabizi-English dataset obtained by Eskander et al. (2014);
- IIIT Hyderabad and HHU-UH-G: The best results on the English-Spanish-2016 and MSA-EGY-2016 respectively[6].

5 Evaluation

Table 2 summarizes the published results by all baselines systems on the English-Spanish-2014, English-Nepali-2014, Arabizi-English, and MSA-EGY-2014 datasets. The table shows that TAU is the best published system on the English-Spanish-2014 data, DCU-UVT is the best published system on the English-Nepali-2014 data, 3ARRIB is the best published system on the Arabizi-English, and AIDA2 is the best published system on the MSA-EGY-2014 data.

Table 3 shows the results of our system on all language-pairs compared to the best published results from table 2 and the majority baseline. Lang1 indicates the majority class as per the training data, while lang2 indicates the minority class in the training data. The results show that LILI yields competitive results compared to all published state-of-the-art systems. The overall weighted average F-score for LILI is higher than all the majority baselines. It is also either higher than the published state-of-the-art systems except in the MSA-EGY compared to AIDA2 and HHU-UH-G, or very close to the best published results as in the English-Spanish-2016 dataset (LILI got 95.2% compared to 96% of IIIT Hyderabad with only 0.8% difference). Arabic language pairs; MSA-EGY, Gulf-MSA, and LEV-MSA are the most challenging ones. Because unlike the other languages, the words in each of these pairs do not create disjoint sets, as mentioned earlier, there is significant overlap hence they share significant character and word patterns. This issue is even worse because the native Arabic speakers do not write the short vowels (also know as diacritics) while they are able to reconstruct them while reading without any problem. The MSA shares many words with the other Arabic dialects but with different diacritics. For example, the words (yalEabuwn) in MSA and (yilEabuwn) in Gulf (Both mean they are playing)

[6]We are unaware of the citations of these 2 papers since they are not published yet while writing this paper. We got the systems names and their results from the shared task website `http://care4lang1.seas.gwu.edu/cs2/call.html`

Language-Pairs	System	lang1	lang2	Avg-F

Table 3: Summary results of our system performance on all language-pairs compared to the best published results and Majority baselines. For each group, the F-score is presented for lang1 and lang2 followed by the weighted average F-score for both languages. There are no published systems for English Hindi, Arabic-Engari, LEV-MSA, and Gulf-MSA hence the NA (not available).

become the same after removing the short vowels (ylEbwn). Hence, modeling more nuanced features is needed such as POS tags and morphological information, which is the case in the AIDA2 system. But despite the simplicity of the presented approach in this paper, in the MSA-EGY-2014 and MSA-EGY-2016 datasets, our yielded weighted average F-scores (87.2% and 85.0%) are not far from the AIDA2 (90.15%) and HHU-UH-G (88.5%) scores. Furthermore, It worth mentioning that running AIDA2 on the MSA-EGY-2016 gives 85.2% weighted average F-score; which is lower than LILI.

In a supervised framework, minority class detection is the more challenging task. We compare our performance to the published systems where available as well as the majority baseline. Our results are comparable to the published state-of-the-art systems, even significantly better in the MSA-EGY-2014 dataset. Moreover, our results outperform the majority baseline in all language pairs.

We can notice from table 2 that neither of the baselines published systems achieve the best results across the different language pairs. For example the DCU-UVT system achieved best result on Nepali-EN-2014 but it did not even achieve the second best on Spanish-EN-2014. Although the MSR-India has higher result than the DCU-UVT on the Spanish-EN-2014, it has lower results than it on the Nepali-EN-2014 data. This shows that despite the simplicity of our approach, it is generic and outperforms the states of the art systems or competitively compared to them across all the language pairs.

The above results show that the proposed approach is working well on the binary problems when we know beforehand the word is either lang1 or lang2. However, in real code switching scenario we do not know what the other language variety could be in the data. To see how robust our approach is, we tested our approach on a multi-class model. We trained a single multi-class CRF model using a combined data from our different training sets and tested it on the corresponding combined test sets. Unfortunately, we didn't manage to create a CRF model using all our training data. The datasets we managed to use are the English-Spanish-2014, Nepali-English-2014, English-Hindi, Arabizi-English, and MSA-EGY-2014. Table 4 shows the F-score results of our system on all languages using the multi-class model. We didn't find any published systems that conducted the same experiment to compare our results to. Therefore, table 4 only compares our results to the majority baseline and the binary model in table 3. The results show that LILI outperforms the majority baseline on all languages. The F-scores on all languages are comparable to the F-scores from the binary-classes case except on Hindi, where the multi-class model is much lower than the binary one. However, the overall weighted average F-score is high (91.0%). This shows that LILI is able to perform in a good way on the real code switching problem.

Language	LILI-Multi-Class-Model	LILI-Binary-Model	Majority Baseline
Nepali	97.4%	97.6%	90.0%
Hindi	62.3%	80.4%	30.7%
Arabizi	95.6%	98.3%	80.7%
English	96.2%	96.4%	93.4%
MSA	85.5%	86.0%	70.0%
Spanish	94.3%	95.3%	79.1%
Engari	64.0%	64.2%	56.5%
EGY	87.7%	87.2%	63.0%
Avg-F	91.0%	91.2%	77.8%

Table 4: The F-score of our system compared to the majority baseline on all languages using a single multi-class model. The last row shows the weighted average F-score for all languages.The number in the English row of LILI-Multi-Class-Model is the weighted average F-score of the English label obtained by LILI in table 3 on English-Spanish-2014, Nepali-English-2014, English-Hindi, and Arabizi-English datasets.

Finally, the simplicity of our system made it very fast. It can process up to 20,000 words/sec; which renders it very efficient and amenable to large scale processing. We compare our system's speed to our previously published tools; AIDA2 and 3ARRIB. AIDA2 processes 1000 words/sec and 3ARRIB processes 49 words/sec. Hence LILI is orders of magnitude faster than both systems with a relatively minor drop in performance compared to AIDA2 if we consider overall F1-score, or better performance if we care about detecting the minority class, and better performance than 3ARRIB overall.

6 Conclusion

In this paper, we introduced a simple yet powerful framework for the linguistic code switch point detection problem. The solution is language independent, thus it can work with any language-pair. The framework is based on the idea that each language has its own phonological system that control which set of sounds can occur together. Our assumption was that this is sufficient to distinguish between languages used in the same utterance. The results show that our simple approach outperforms or at least performs competitively compared to state-of-the-art complex machinery systems when evaluated against standard data sets with the added advantage of speeds that could be scaled up to big data levels.

Abstract

We present in this paper a purely rule-based system for Question Classification which we divide into two parts: The first is the extraction of relevant words from a question by use of its structure, and the second is the classification of questions based on rules that associate these words to Concepts. We achieve an accuracy of *97.2%*, close to a 6 point improvement over the previous State of the Art of 91.6%. Additionally, we believe that machine learning algorithms can be applied on top of this method to further improve accuracy.

1 Introduction and Motivation

Question Answering (QA) is a task in Natural Language Processing (NLP) that requires the system to provide concise answers to Natural Language questions. Interest in QA has grown dramatically over the past couple of years, in part due to advances in NLP and Machine Learning, that have allowed for significant improvements in QA systems, and in part due to its increased accessibility to the general public via smart-phone applications such as Siri and Google Now.

An important element of QA is Question Classification (QC), which is the task of classifying a question based on the expected answer. As an example, the question "Who is the prime minister?" could be assigned the class "person", whereas the question "Where is the prime minister?" could belong to the class "location". Since the task involves identifying the type of answer, it is sometimes referred to as Answer Type Classification. While there do exist QA Systems that do not make use of QC, QC has been shown to significantly improve the performance of QA systems (Hovy et al., 2001).

A priori knowledge of the kind of information that a QA system is required to extract allows for the exploitation of predefined patterns and improved feature selection. For example, consider a QA system provided with the information that the question "How long is the term of office of the Prime Minister?" requires, as an answer, a "number that represents a duration". Such a system could dramatically reduce its search space, in that it could focus on numbers. The design of a QA system's search and information extraction components determines the classes that a QC should use. Despite this dependence on how question classes are used, there are some common question classes that are widely accepted as useful. The rules that govern and classes contained in a given question classification are based on the specific *Question Taxonomy* chosen.

2 Related Work

Work on QC, as in most NLP tasks, can be broadly divided into three categories: **a)** those that make use of machine learning, **b)** those that rely purely on rules, and **c)** those that are a hybrid of the two. With the increased popularity and success of machine learning techniques, most recent work on QC has been limited to methods that make use of machine learning. While there continues to be some exploration into semantic information contained in sentences, such information is often converted into features.

While there are several Question Taxonomies that are available for use in training and testing QC systems, the most popular is the one introduced by Li and Roth (2002). This is because of the 5,500

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1220–1230, Osaka, Japan, December 11-17 2016.

training questions and corresponding classification they provide, in addition to the classification of the 500 TREC 10 (Voorhees, 2001) questions. Their classification is a two level system which contains a coarse and a fine level of classification for each question. Table 1 lists the classification introduced by them. In this paper, we refer to a specific classes in the following format: coarse:fine. For example, the class animal, contained in the coarse class ENTY, will be referred to as enty:animal.

Coarse	Fine
ABBR	abbreviation, expansion
DESC	definition, description, manner, reason
ENTY	animal, body, color, creation, currency, disease, event, food, instrument, language, letter, other, plant, product, religion, sport, substance, symbol, technique, term, vehicle, word
HUM	description, group, individual, title
LOC	city, country, mountain, other, state
NUM	code, count, date, distance, money, order, other, percent, percent, period, speed, temperature, size, weight

Table 1: Question Taxonomy introduced by Li and Roth (2002).

The original method proposed by Li and Roth (2002), relies on machine learning and first classifies questions into coarse classes, before then using the coarse class as a feature in fine grained classification. They also report their results for both the coarse and fine classes. We, however, focus our efforts on fine grained classification.

Metzler and Croft (2005) provide a detailed analysis of statistical methods of QC prior to 2005, while dismissing rule-based systems as "cumbersome and inflexible", and a more recent survey by Loni (2011) details QC methods using more recent Machine Learning techniques. Work on QC over the last couple of years has involved either reducing the number of features (Pota et al., 2016; Pota et al., 2015), focusing on specific domains (Feng et al., 2015) or using new methods in machine learning such as Convolutional Neural Networks (Kim, 2014) and Skip-Thought Vectors (Kiros et al., 2015).

The previous State of the Art in fine grained classification of Li and Roth (2002)'s data is 91.6% and was achieved by Van-Tu and Anh-Cuong (2016), who base their work on using semantic features in a linear SVM. Of specific relevance to our work is the work by Silva et al. (2011), who first extract headwords, before then mapping these headwords into various categories using WordNet (Miller, 1995) to achieve an accuracy of 90.8%. Previous work by (Huang et al., 2008), which also makes use of both headwords and WordNet, while using slightly different methods, achieves an accuracy of 89.2%.

3 Concepts as a Theoretical Framework for Question Classification

Concepts are generalisations or abstractions that allow the use of previous experience in new situations. For example, questions such as "Who is the actor who ...?", of the form "Who $auxiliary\_verb$ $(determiner)^*$ *Concept:Occupation* who ...?", can be classified under the class hum:person, if we had information about the Concept "occupation", because this would enable us to map all questions that use any occupation in this particular pattern to this QC. Similarly, information about the Concept "meaning" would enable us to create a rule to classify questions such as "What is the meaning of the word ...?", and "What does the word ... mean?" to the question class desc:definition. As can be seen from the latter example, Concepts need not always be associated with nouns.

3.1 Implementing Concepts using Types

As described in the previous section, it is useful to define Concepts as sets of words and to this end, we require a method of generating a large number of words that belong to a particular Concept. To achieve this, we make use of Types (Tayyar Madabushi et al., 2016), which provide a way of defining sections of an ontology to belong to a given *Type*. While the authors use Types to identify classes of nouns that can be compared when measuring the semantic similarity between two sentences, we use Types to define Concepts. In this work, we modify the definition of types by making use of WordNet hyponyms: W_1 is considered a hyponym of W_2 if $\forall e \in W_1$, e is an instance of W_2.

A Type consists of a set of WordNet synsets or words S, and represents the set of words whose lemmas belongs to the union of the set S, and in the case of synsets, the set containing the hyponym closure of the synsets in S, and in the case of words, those words. As an example, all words whose lemmas belong to the hyponym closure of the synset 'occupation.n.01', such as bookkeeping, acting, and ministry belong to the the Type 'occupation.n.01'. It is interesting to note that this one definition provides us conceptual information on 283 lemmas (the size of the hyponym closure of occupation.n.01).

We use types to create a rough approximation of Concepts. We achieve this by manually picking specific synsets within WordNet and associating them and all their hyponyms to a particular QC based on where in a question they appear. Revisiting the first example in Section 3, the Concept "occupation" is defined by creating a Type that includes the word occupation and all hyponyms of the synset 'occupation.n.01'. Similarly, the synsets 'people.n.01', 'organization.n.01', 'university.n.01', 'company.n.04', 'social_group.n.01', and all of their hyponyms are assigned to the Question Class "Human Group". Some words, such as the word "mean" discussed in the second example in Section 3, belong to a particular Type while their hyponyms do not (in the case of "mean", "aim", "drive", and "spell" are hyponyms, which do not imply that a question belongs to the definition class the same way the word "mean" does), and in such cases, we add just the word and not its hyponyms.

The manual process of creating Types is done by looking at all hyponyms of the synset entity.n.01 and assigning them to a Type *iff* that synset and all its hyponyms represent the same Concept. This sometimes leads to instances wherein the same word is part of different Types because of its different word sense. In such cases, Types are redefined using less general synsets.

Not all of the Types we define are directly associated with a Question Class. For example, we define the Type $people\_from$, consisting of 'inhabitant.n.01' and all its hyponyms which enables us to identify the class enty:termeq (i.e. equivalent term). We do this by checking to see if the question asks us what people from a particular place call something, by use of the rule "What $auxiliary\_verb$ $people\_from$ call $word$?". As an example, the question "What do Italians call Noodles?" matches this rule and belongs to the QC enty:termeq. We also define groups of verbs as belonging to certain Types, such as the Type of verbs that can only be performed by a person (e.g. sing, invent) and the Type of words that require us to perform a possessive or a prepositional *roll* (Section 6.1).

4 System Overview

The system presented in this work consists of three parts: **a)** extracting a Question's Syntactic Map (defined in Section 5.1), **b)** identifying the headword, of the noun phrase in the question, while handling Entity Identification and phrase detection, and **c)** using rules to map words at different positions in the Syntactic Map to identify the QC. These are further broken down into the following steps (programmatically, methods):

Syntactic Map Extraction	*Question Rewrite*	Rewrites questions that are in non-standard form.
	Parse Tree Analysis	Extract structure information from the question using Constituency-based parse trees
Word, Phrase and Entity Extraction	*Headword Extraction*	Extract headwords from noun phrases in the question using **a)** Possessive Unrolling **b)** Preposition Rolling **c)** Entity Identification
	Verb, Wh-word and Adjective Extraction	Extract the Auxiliary and Major Verbs, the Wh-word and all adjectives from the question.
Rule-based Classification	*Match Rules based on the Question Syntax and Word Type*	Using a hierarchy of syntactic positions in a question, iteratively check to see if there exists a rule for mapping the word at that position to a QC.

For example, given the question "Name of actress from England in the movie 'The Titanic' is what?", our system identifies its QC as follows: We first identify that this question is not in a form that we can analyse to extract the Syntactic Map and rewrite it as "What is the name of the actress from England in the movie 'The Titanic'?" (Section 5.2). The question's parse tree is then analysed to generate the Question's Syntactic Map (Section 5.1). We then identify the headword to be the noun *actress* using prepositional

rolling (Section 6.1). At this stage, we have established that the question's wh-word is "What", auxiliary verb is "is", and headword is "actress". We check for the existence of a rule that classifies this question by iterating through these elements in a predefined order (Section 7.2). This results in the word "actress" matching the rule : *'occupation.n.01' and its hyponyms in SQ-NNP when the wh-word is 'what' indicate that the question class is* ***hum:ind***, so enabling us to classify the question as hum:ind.

4.1 Methodology

To avoid bias, we use the 5,500 questions and their respective question classes provided as training data by Li and Roth (2002) for exploration and rule discovery, and ensure that the 500 TREC questions, which consist of the test set, are not observed during the creation of rules (although the system is, at regular intervals, tested on this set to ensure progress). Once we complete the analysis of a question's parse tree, not all words in the question are of further relevance to the task of QC. However, so as to maximise the number of words that we have rules for, we try to create rules for all words that appear in training set.

5 Syntactic Maps

Previous work that has made use of parse trees includes that by Silva et al. (2011), who used Collin's Rules (Collins, 1999) to extract headwords and work by Shen and Lapata (2007) who made use of FrameNet (Baker et al., 1998). Unlike these works, we first extract, what we call, a Question's *Syntactic Map*, before creating rules that depend on the position of words in this Map.

A Syntactic Map (SM), unlike a parse tree, is a *fixed* structure that we fill in with information from a question's parse tree and can contain empty or "None" elements. It is a generic template for all the different kinds of questions that we can classify, and any question that we cannot convert to a Syntactic Map, cannot be classified using our system. Crucially, the SM contains the following five elements of a question: **a)** the question's wh-word **b)** the noun phrase (if any) contained in the WHNP sub-tree and its internal phrase structure, and from the SQ sub-tree of the parse tree: **c)** the Auxiliary Verb (AVP) **d)** the noun phrase (if any) and its internal phrase structure, and **e)** the Main Verb (MVP) (if any). Noun phrases including possessives, and prepositional phrases are extracted into similar fixed structures. Programmatically, a SM is a class (object-oriented programming), as are the constituent noun phrases, prepositional phrases, and verbs. The generic structure of a SM, along with the structure of its constituents is shown in Table 2.

Syntactic Map		
WH Word		What/Name/Who/...
WHNP		
	NNP	Noun Phrase in WHNP
SQ		
	AVP	Axillary Verb of SQ
	NNP	Noun Phrase in SQ
	MVP	First Main Verb of SQ

Constituent Noun Phrase		Constituent Prepositional Phrase		Constituent Verb	
JJ	Adjective	PP	Prepositional word		
NN	Noun	NN	Attached Noun Phrase		
PRP	Preposition	VP	Attached Verb Phrase	VB	Verb
POS	Possessive	CPP	Attached Prepositional Phrase		
TJJ	Trailing Adjective				

Table 2: The fixed structure of a Syntactic Map (left), and the constituent phrase structures (right).

In the question "How much does the President get paid ?", it is the adverb "much" that allows us to infer that the expected answer is a number and additionally, the word "paid" allows us to infer that the number, in fact, represents money hence resulting in the question class num:money.

In the questions "What is a golf ball made of ?" and "What does gringo mean ?" the verbs after the noun (the first Main Verb or MVP) provide us with important clues on which question class these questions belong to (in this case enty:substance and desc:def). It is for this reason that we move beyond conventional headword extraction and focus on populating Syntactic Maps, which capture more information about the question. Although Silva et al. (2011) consider words other than nouns, they do so only when the questions contain certain exact phrases.

5.1 Syntactic Map Extraction

The first step in SM extraction is the extraction of the "WHNP" and "SQ" sections of a question from its constituent parse tree, which we generating using the Stanford CoreNLP toolkit Manning et al. (2014).

The WHNP sub-tree represents the Wh-noun Phrase and the SQ sub-tree the main clause of a wh-question. In cases where there is neither (e.g. Name the highest mountain.), we use the first noun phrase as the SQ sub-tree. From the WHNP and the SQ sections of the parse tree, we extract the various elements of the SM as shown in Table 2. This requires the parsing of noun, prepositional, possessive and verb phrases. Due to space constraints, we only provide an overview of each of these below. Additionally, extracting each of these elements is done recursively as sentences often contain possessive phrases or prepositional phrases within one another. Table 3 illustrates one such scenario in which a question has two recursive possessive phrases.

Parse Tree	Extracted Structure
	WH Word: What WHNP NNP: None SQ AVP: ['is'] NNP: (Possessive)Dudley Do-Right (Possessive)horse name MVP

Table 3: The Parse Tree and Extracted SM of a Question Consisting of a Nested Structure.

We make the conscious decision of stopping the SM extraction process after reaching the first main verb. This is because we observed that there were very few questions that require structural information beyond this point.

Our method of analysing noun phrases handles the extraction of adjectives, possessive phrases, prepositions and trailing adjectives but ignores all determiners. Prior to analysing parse trees of noun phrases, we first modify certain parse tree patterns that noun phrases occur in. The resultant Constituency-based parse trees are not always valid but greatly simplify the analysis of noun phrases. Two examples of the modifications we perform to noun phrase sub-trees are illustrated in Table 4

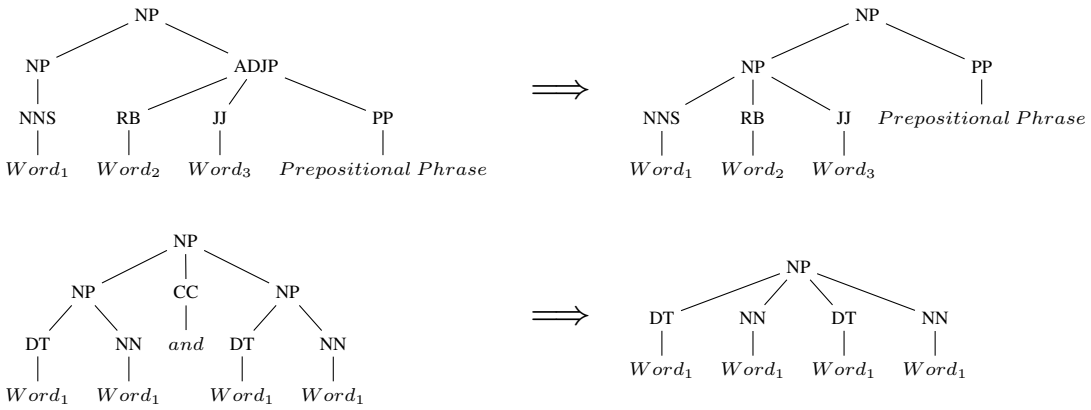

Table 4: Some of the Parse Tree Modifications that are Performed on Noun Phrases.

This simplification process leaves us with the task of extracting information from noun phrases that belong to a much smaller set of sub-tree patterns. Some of the more common noun phrase patterns are illustrated in Table 5. Possessive phrases are treated as nouns that must have, attached to them, yet another noun. When we identify a preposition phrase or a verb phrase, that sub-tree is passed to either the preposition or verb analysis method respectively.

Similarly, we extract information from prepositional sub-trees based on their structure, which nearly

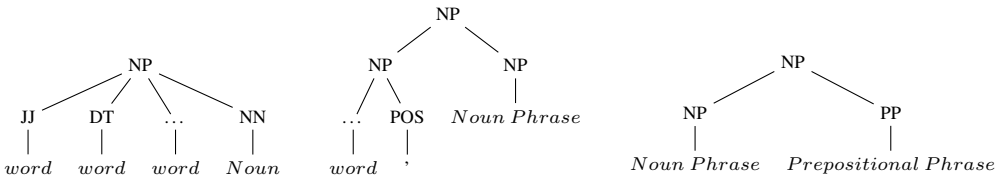

Table 5: Some Common Sub-tree Patterns that Noun Phrases occur in.

always belong to one of the following three patterns: A preposition phrase with one child that is the preposition and the other that is one of either a noun phrase, verb phrase or another prepositional phrase (e.g. "name of the prime minister of U.K."). These patterns are illustrated in Table 6. Just as in the case of noun phrases, we pass on any sub-trees of phrases that are of a different kind to the appropriate analysis module, which enables us to generate a recursive SM.

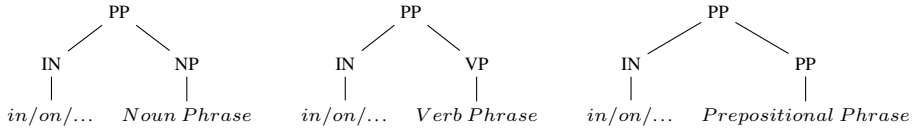

Table 6: Some Common Sub-Tree Patterns that Prepositional Phrases occur in.

5.2 Question Rewrites

There are some questions that do not belong to the standard structure of questions such as "A corgi is a kind of what?" and "In 139 the papal court was forced to move from Rome to where?". We identify several of these structures and create rewrite rules (e.g *x is/was y in/of what z?*) to rewrite these questions to a form that we can parse. We use regular expressions instead of parse tree analysis as these structures are very easy to identify and so the overhead of parsing is not justified. Using these rules the above two questions will be rewritten as "What is a corgi a kind of?" and "To where was the papal court forced to move from Rome in 139?".

6 Concept Identification

In this section, we provide details on methods we use for identifying relevant Concepts, which we extract by analysing the SM.

6.1 Preposition Rolling and Possessive Unrolling

Rolling and Unrolling refer to the selective moving forward through a preposition, or backwards through a possessive noun. Consider the question "What is the quantity of American soldiers still unaccounted for from the Vietnam war?" from which we extract *quantity(PP) of PP-NN:(JJ)American soldiers*, and the question "What are the different types of plastic?" from which we extract *(JJ)different types(PP) of PP-NN: plastic*. In the second instance, we must *roll* through the preposition to reach the relevant word "plastic", whereas, in the first instance, we must not, so identifying "quantity'.

Similarly, consider the question "What game's board shows the territories of Irkutsk, Yakutsk and Kamchatka?" from which we extract the noun phrase *(Possessive)game board*, and the question "Name Alvin's brothers." from which we extract *(Possessive)Alvin brothers*. In the first instance we need to *unroll* through the possessive to reach the relevant word "game", whereas in the second case we must not. We call this selective process of moving forward through a preposition "Rolling", and the process of selectively moving backwards through a possessive "Unrolling". Rolling and Unrolling are achieved through a list of rules that depend on the Type of the target and source of the Roll or Unroll.

6.2 Headword and Phrase Extraction

Consider the question "What mystery writer penned '...the glory that was Greece, and the grandeur that was Rome'?". The relevant noun phrase that we extract from the SM is "mystery writer" and the head of

this noun phrase is "writer", the last noun in the noun phrase. This is often the case, and some previous works have used only this to identify the head of a noun phrase (Metzler and Croft, 2005). Unfortunately, this is not always the case, and does not always provide the word that is most useful for QC. For example, the noun phrase extracted from "What crop failure caused the Irish Famine?" is "crop failure" and the relevant noun is "crop". Although it can be argued that the head noun in this phrase is "failure", qualified by "crop", this would not aid us in classification, as "crops" are a form of food and the expected Question Class is enty:food, while "failure" is a very different Concept.

We automatically identifying the head noun by identifying *Verb Nouns* and *Descriptive Nouns* starting at the right of the noun phrase and ignoring such nouns. We define Verb Nouns as nouns that have a more common verb form (e.g. fail) or verbs that are "acts", which we identify by parsing the definition of the verb. Similarly, we define Descriptive Nouns as nouns that belong to a Type we define as descriptive which includes, for example, hyponyms of the synyset 'digit.n.01'.

6.3 Entity Identification

Let us now consider the question "What is bipolar disorder?". The correct Question Class for this question is desc:definition, however, it is easy to miss-classify this question as belonging to the class enty:dismed (entity, disease or medicine), because the word "bipolar" is tagged as an adjective. To get around this we require a method of identifying that "bipolar disorder" must be considered as a single entity.

Even in instances wherein it is relatively easy to identify an entity, as in the case of phrases that consist of consecutive nouns, it is important to be able to convert these phrases to a form that appears in WordNet. For example, the phrase "equity securities" can be identified as a single entity, however, it is listed in WordNet under the entry "Shares".

We identify these phrases using a method called Wikification (Mihalcea and Csomai, 2007), which is the process of linking words and phrases in a piece of text to titles of Wikipedia entries. The intuition behind this is that a phrase that appears as a Wikipedia Article title must be important enough to be considered as a single Entity. We base our method of Wikification on the original, while replacing the process of keyword identification with SM and that of Word Sense Disambiguation with the method detailed in Section 7.1. For example, there is an article on Wikipedia titled "Bipolar Disorder" on Wikipedia and the Wikified term for "equity securities" is "Shares".

7 Question Classification using Syntactic Maps

Once we have the SM of a question, we use rules to identify the relevant QC. However, before we can match appropriate words, we require a way of identifying the correct sense of a word.

7.1 Word Sense Disambiguation

SMs often provide us with a single word that represents the object that the question expects as an answer. The question "What album put The Beatles on the cover of Time in 1967 ?", for example, requires that the answer consists of an "album". However, it is unclear whether album refers to "one or more recordings issued together" or "a book of blank pages with pockets or envelopes". Huang et al. (2008) address this problem by use of the Lesk Algorithm (Lesk, 1986).

Our use of SM allows for implicit Word Sense Disambiguation as it is rare for the same word to appear at the same syntactic location but in different senses. When this does happen however, we identify the sense of a word based on the Types of the surrounding elements of the SM. For example, "How much does it cost to fly to Japan?" and "How much does a plane weigh?" both have the word "much" at the same position and so require us to identify the Types of associated words (i.e. "cost" and "weigh") to be able to disambiguate the relevant Concept.

7.2 Mapping Question Classes

The intuition behind the mapping process is that words or phrases at certain positions in the SM trigger certain Concepts, which gives away the question class. To this end, we use Types defined for each different position in the SM to map questions to question classes. For example, the word "do" appearing as the

Algorithm 1: A Simplified Algorithm showing the Mapping of the Syntactic Map to Question Classes

auxiliary verb is handled differently from when it appears as the main verb in the SM. The order in which different sections of the SM are considered determines which word is finally used during classification.

There are some special words, such as "much", "do", "name" and "call", that require more complex classification rules. The adjective "much" for example could indicate the class num:money or num:weight depending on whether the other sections of the SM contain the Type "money" or the Type "weight". As in the case of WSD, we define disambiguation rules for each such word.

Algorithm 1, while not exhaustive in listing the mapping rules (due to space constraints), provides a simplified overview of the mapping of Semantic Maps to Question Classes. It takes as input the SM,

the Type definitions and associated Question Classes and returns a tuple consisting of the Major and Minor question classes. Just over 230 Type definitions and 10 special Word Sense Disambiguation definitions cover the entire test set, and at the time of writing, these have been expanded to around 600 Type definitions and 70 WSD definitions.

8 Results

We achieve an accuracy of 97.2% on the TREC 10 dataset which translates to an incorrect tagging of 14 of the 500 questions in the dataset. This is close to a 6 point improvement over the previous state of the art of 91.6% (Van-Tu and Anh-Cuong, 2016). We list our accuracy against that of various other works that have reported results on the TREC 10 dataset in Table 7.

Study	Classifier	Accuracy	
		Coarse	Fine
This Work	**None**	**-**	**97.2%**
Van-Tu and Anh-Cuong (2016)	Linear SVM	95.2%	91.6%
Pota et al. (2016; Pota et al. (2015)	Linear SVM	89.6%	82.0%
Kim (2014)	Convolutional Neural Networks	93.6%	-
Kiros et al. (2015)	Skip-Thought Vectors	91.8%	-

Table 7: Results Achieved by this Work alongside some other Works that use the same Dataset.

8.1 Error Analysis

Table 8 provides a list of some of the questions that we misclassify along with the reason for this. One of the advantages of a purely rule-based system is the ability to pinpoint the exact reason for an incorrect classification.

Question	**Correct Class**	**Classified As**	**Reason**
What are the twin cities?	LOC city	DESC def	We classify both these as definitions because we (correctly) identify "twin cities" and "speed of light" as entities. The presence of the word "the" however requires information about the entity instead of a definition for the entity - a rule that requires to be added.
What is the speed of light?	NUM speed	DESC def	
What is compounded interest?	DESC def	DESC desc	Our Wikification system fails to identify "compounded interest" to be the same as the entity "compound interest".
What is the spirometer test?	DESC def	ENTY instru	The word "test", has a natural verb form so forcing the system to identify "spirometer" as the head noun. Some modifications to the function identifying Verb Nouns are required to rectify this.

Table 8: An analysis of some of the questions that we fail to classify correctly.

9 Conclusion and Future Work

We presented a purely rule-based system for QC which exploits decades of research into the structure of language and Concepts. Although this method has focused on a particular type of questions, we believe that a similar method can be applied to classifying questions of a different type, and we intend to extend our work to include those datasets. We also note that these are a common and important kind of questions, which are similar to those handled by most modern smartphone interactive systems such as Google Now (Ristovski, 2016).

Finally, we intend to implement a QA system that leverages QC to explore the true impact of high-accuracy question classification. We also intend to make this system available through a simple Application Programming Interface (API) [1] so other QA systems can benefit from this work.

Abstract

In community question answering (cQA), the quality of answers are determined by the matching degree between question-answer pairs and the correlation among the answers. In this paper, we show that the dependency between the answer quality labels also plays a pivotal role. To validate the effectiveness of label dependency, we propose two neural network-based models, with different combination modes of Convolutional Neural Networks, Long Short Term Memory and Conditional Random Fields. Extensive experiments are taken on the dataset released by the SemEval-2015 cQA shared task. The first model is a stacked ensemble of the networks. It achieves 58.96% on macro averaged F_1, which improves the state-of-the-art neural network-based method by 2.82% and outperforms the Top-1 system in the shared task by 1.77%. The second is a simple attention-based model whose input is the connection of the question and its corresponding answers. It produces promising results with 58.29% on overall F_1 and gains the best performance on the *Good* and *Bad* categories.

1 Introduction

Community question answering (cQA) provide abundant human-to-human questions and answers, behaving as a good resource for building automatic question answering systems. For example, many users ask about "How to build your body like a model?" in Yahoo Answers[3] and also there are many answerers who are willing to share their experiences. Answer quality tagging refers to automatically identifying whether an answer is good, so as to collect high quality question answer pairs.

The task is challenging in that one should develop useful features that can effectively bridge the semantic gap between the question and answer (QA) pair. The matching degree on content is the primary factor that determines how good an answer is. It can be measured through a series of syntactic and semantic features such as overlapped linguistic elements (Berger et al., 2000; Agichtein et al., 2008; Punyakanok et al., 2004). For example, if the question and answer have several words shared, the answer is likely to be good. However, the content similarity performs well only when both the question and answer are well-structured and overlapped, which are rare to see in cQA sentences.

Many previous studies discover specific features based on the characteristics of cQA systems. For instance, opinion leader or experts would probably contribute more good answers than bad, and the number of thumbs-up towards an answer may reflect how much the users accept it (Agichtein et al.,

[1] The first two authors have equal contributions.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1231–1241, Osaka, Japan, December 11-17 2016.

2008). The inefficiency of textual similarity can be partly complemented with the help of these specific features (Hu et al., 2013; Tran et al., 2015). But the definition and validation of them need too much laborious cost and might not be appropriate when transferring to newly built systems.

In this paper, we focus on a novel concept of contextual feature, the *label dependency*, which we think plays a pivotal role when predicting the answer quality in cQA. Intuitively, being a rational answerer, when we decide to answer a question, we face the following situations:

- If it is a new question (without an answer), just answer it.
- If it has been answered but all the existed answers are bad, we provide our good answer.
- If it has been answered and some of the existed answers have already satisfied the asker's information needs, we can choose to answer it from a distinct perspective.
- Other actions.

A typical example for cQA is shown in Figure 1 in which A4 and A5 follow several bad or potentially good comments. Although A4 and A5 are both good answers, they provide alternative useful information. Based on the above assumptions, we say that there are possible soft constraints between the quality tags of the answers (i.e. a good answer follows several bad ones). The contextual dependency relation can be affected by the relations among the answer contents as well as the interactions between answer quality tags.

> **A5**: ... available at designated retail outlets in the Philippines. u would easily find it while processing some of ur papers at POEA Ortigas. (Good)

Figure 1: Example for cQA thread.

To efficiently model the contextual information, we propose two neural network-based models with different combination modes of Convolutional Neural Networks (CNN), Long Short Term Memory (LSTM) and Conditional Random Fields (CRF). The first model (ARC-I) is a stacked ensemble of the above networks, which can be seen as a combination of RCNN (Zhou et al., 2015) and LSTM-CRF (Huang et al., 2015). In ARC-I, LSTM is applied on the sequence of encoded QA matching pairs, with CRF on the final layer to memorize transition probabilities over the tag sequence. The main improvement from Zhou et al. (2015) is the addition of backward LSTM and CRF. And the difference from Huang et al. (2015) is that we adopt the LSTM-CRF model in comment-level (actually sentence-level within this paper) sequence tagging, with the help of CNN sentence modelling (Kim, 2014).

ARC-II is a novel and much simpler model, with the integration of the attention mechanism. In ARC-II, the question and its answers are linearly connected in a sequence and encoded by CNN. An attention-based LSTM is then applied on the encoded sequence. Through attention, the model learns how much the question and the context affect the predicting of the current answer. And similar to ARC-I, a CRF layer is appended at last. Using a simple attention function (described in Section 3), ARC-II reduces the size of the parameter space and trains faster than ARC-I.

We carried out extensive experiments on the dataset released by the SemEval-2015 cQA shared task. By adding bidirectional LSTM (Bi-LSTM) and CRF, we achieve 58.96% on macro averaged F_1 (by ARC-I) for answer quality tagging, which improves the state-of-the-art neural network-based method by 2.82% and outperforms the task winner by 1.77%. ARC-II produces promising results with 58.29% on overall F_1 and gains the best performance on the *Good* and *Bad* categories. The contributions of this

work can be summarized as: 1) experiments show that encoding the label dependency is powerful in answer quality tagging; 2) the proposed models achieve state-of-the-art result and considerable improvements on individual categories; 3) as far as we know, this is the first work using the LSTM-CRF architecture on sentence-level sequence tagging.

The roadmap of this paper is: in Section 2 we briefly introduce the literature. The proposed models are detailedly described in Section 3. Experiments are arranged in Section 4. Discussion and conclusion are at last.

2 Related Work

2.1 Answer Quality Tagging

In the literature, methods for answer quality tagging in cQA can be roughly divided into the following four groups: sparse feature-based methods, translation models, parsing trees, and deep CNNs. Sparse feature-based methods are the mostly widely applied and have the longest research duration. Early studies such as Agichtein et al. (2008) and Suryanoto et al. (2009), and later studies such as Yih et al. (2013) and Hou et al. (2015) all achieved not bad results using simple classifiers with manually constructed sparse features. However, feature engineering is time consuming and has low extensibility to other domains. Translation models relied on large-scale of training pairs and can effectively bridge the semantic gap in many cases (Berger et al., 2000; Riezler et al., 2007; Surdeanu et al., 2008). One difficulty is that large parallel training dataset is hard to obtain. The similarity computed from parsing trees is a direct criterion to measure the semantic correlation between two sentences. Typical works are tree edit distance (Punyakanok et al., 2004; Yao et al., 2013) and convolutional tree kernels (Severyn and Moschitti, 2013). But one of the drawbacks of parsing tree-based methods is that most existed parsers perform badly in low-quality sentences (i.e. spoken style language in cQA or daily dialogues).

In the research field of deep learning, Deep Belief Networks (DBN) can also be classified into sparse feature-based methods since they mainly incorporated sparse encodings for multiple features (Wang et al., 2010). The issue of discontinuous word features are later tackled by CNN (Kim, 2014; Hu et al., 2014), following some applications for answer selection in cQA (Yu et al., 2014; Qiu and Huang, 2015; Shen et al., 2015). Zhou et al. (2015)'s work modelled the content correlations using LSTM along QA sequences but they ignored the constraints among quality tags. Their method is insufficient in context learning also due to the neglect of sequence-level dependency modelling. Joty et al. (2015) proposed a graph-cut approach on the judgement of good or bad answers and gains improvement from the baselines. Joty et al. (2016) is an improved version of Joty et al. (2015) in which the authors introduced jointly learning approaches to capture global dependency. The above two works validated the importance of label dependency but they divided the tagging task into two subtasks and built their models in a distinct way.

2.2 Combining Deep Neural Networks and Graphical Models

Wöllmer et al. (2011) was one of the earliest studies that combine neural networks and graphical models. They appended an LSTM layer on top of a Hidden Markov Model in automatic speech recognition. However, the LSTM they applied was only a shallow architecture. Only in recent two or three years did some researchers begin to explore the combination of deep neural networks and graphical models. Huang et al. (2015) proposed the LSTM-CRF model for POS, chunking and NER, and produced state-of-the-art (or close to) accuracies. Lample et al. (2016) applied character and word embeddings in LSTM-CRF and generated good results on NER for four languages. Ma et al. (2016) added a CNN layer on word and character embedding and outperformed previous works in POS tagging and NER.

As far as we know, all the related studies were settled on word-level tasks. In most cases, sentence-level sequence labelling is quite distinct from the word-level in that the dependencies between adjacent sentences are not hard. So that the constraints for tags are weak than word-level tasks, demanding additional information to reinforce the constraints (i.e. sentence meanings).

3 Approach

3.1 ARC-I

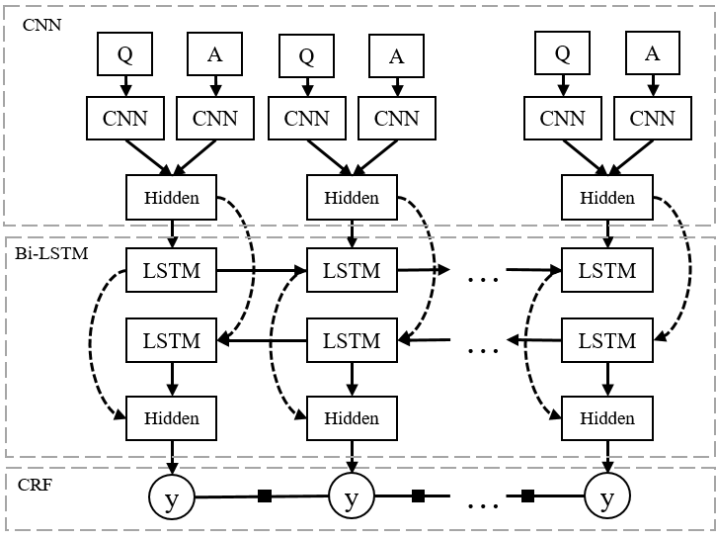

Figure 2: The overview of ARC-I.

The overview of ARC-I is shown in Figure 2. From input to output, the stack of networks are CNN, Bi-LSTM, and CRF. In more detail, in the CNN layer, each QA pair is encoded into a fixed length vector by parallel CNNs together with a following fully connected layer (denoted as *Hidden* in the figures). A Bi-LSTM layer is put next to learn the correlations along the encoded sequence. A fully connected layer and softmax are appended later to generated the predicted tags for the neural network. And at last the cost of the whole network is adjusted using the transition probabilities by a CRF layer over the generated tags.

We incorporate forward linear chain CRF. It jointly models the generative probability (from the output of Bi-LSTM) and the transition probability between adjacent tags from a global perspective, and thus automatically learns the content correlation and constraints among labels.

3.2 ARC-II

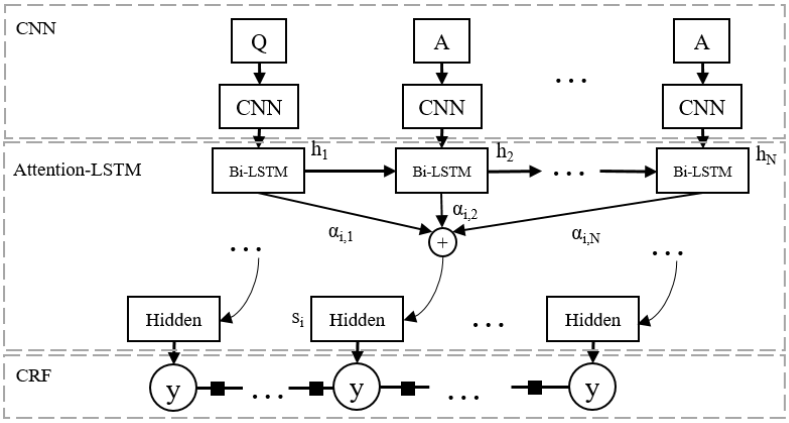

Figure 3: The overview of ARC-II. $\alpha_{i,j}$ stands for the attention weight of the *i*th unit focused on the *j*th encoded element.

Encoding the sequence of QA pairs may introduce extra parameters, the optimization of which can cause much training time. A concise way is to directly learn from the sequence composed of the question and its answers. The model is depicted in Figure 3. In the CNN layer, each question/answer is encoded using a single CNN. In the LSTM layer, an attention based Bi-LSTM is applied to learn the context information along the sequence. Attention mechanism can tackle the bias problem of RNNs (i.e. LSTM/GRU) through computing a weighted distribution of the encoded elements at each time step (Bahdanau et al.,

2015). The distribution reflects the correlations between the current answer and its context. Similar to ARC-I, we also put a CRF layer at last to learn the transitions. To simplify the network, we used a simple form of attention: the attention vector is compromised by the similarities between the current answer and the contextual sentences (the question and the answers).

There are also some variants based on the proposed architectures. By removing backward LSTM or CRF, we validated the contribution of each module to the final result. By replacing CRF with the previously predicted label (denoted as *LP* in the experiment), we tested the superiority of modelling the tag sequence softly over hard encoding. In the following subsections, we explain each applied module in detail.

3.3 CNN

We did not explore deep on sentence modelling such as tuning the depth or dimensions of the nodes, instead we simply adopt the architecture from Kim (2014). The input for CNN is the distributed representation of a sentence, by mapping each word index into its embeddings which were pre-trained in an unsupervised way. Each question or answer is taken as a sentence but not a paragraph due to its length limit (<100 words) in the dataset. To simplify calculation, each sentence is padded to the same length *n* with zero vectors.

We denote the *k*-dimensional embedding for word *j* in a sentence as $z_j \in \mathbb{R}^k$, and thus the sentence can be represented by:

$$z_{1:n} = z_1 \oplus z_2 \oplus ... \oplus z_n \quad (1)$$

where $\oplus$ is the concatenation operator and $z_{i:h}$ stands for $\{z_i, z_{i+1}, \ldots, z_{i+h-1}\}$, i=0,1,…,*n*-*h*+1. The basic CNN operations for sentence modelling include convolution and max-pooling. Convolution is achieved by applying a fixed length sliding window (filter) $w^m \in \mathbb{R}^{h \times k}$ on each word position *i*, such that *n*-*h*+1 convolutional units are generated by:

$$c_i^m = \sigma(w^m \cdot z_{i:i+h} + b^m),\ i = 0,1,...,n-h+1 \quad (2)$$

where σ is the activation function such as Sigmoid or ReLU (Dahl et al., 2013) and b^m is the bias factor for the *m*th layer.

Max-pooling is more popular than mean-pooling in sentence modelling due to the characteristics of natural language. A *d*-max-pooling is to select the maximum unit in every adjacent *d* convolutional units.

$$c_i^m = max(c_j^m, c_{j+1}^m, ..., c_{j+d-1}^m),\ j = 0, d, 2d, ... \quad (3)$$

Following Kim (2014), we applied three convolution filters with lengths *3*, *4* and *5* (with the embedding dimension as the width of the filter), each of which is followed by a max pooling layer to select the most effective structures. Feature maps of size 100 are applied to learn the representations from multiple perspectives.The flattened output vectors for each filter are concatenated as the output of the CNN layer.

3.4 LSTM

LSTM can learn long-distance dependencies through the additions of the *input gate*, *forget gate*, *output gate* and *memory cell* into each recurrent unit. The architecture employed in this paper is analogous to the one introduced by Graves et al. (2013). The input to each LSTM unit is x_t and the output is h_t. The output can be computed through Equations 4-8.

$$i_t = \sigma(W_{xi}x_t + W_{hi}h_{t-1} + b_i) \quad (4)$$

$$f_t = \sigma(W_{xf}x_t + W_{hf}h_{t-1} + b_f) \quad (5)$$

$$c_t = f_t c_{t-1} + i_t \tau(W_{xc}x_t + W_{hc}h_{t-1} + b_c) \quad (6)$$

$$o_t = \sigma(W_{xo}x_t + W_{ho}h_{t-1} + b_o) \quad (7)$$

$$h_t = o_t \theta(c_t) \quad (8)$$

where τ and θ are usually set as the *tanh* function. *W*s and *b*s are weights and biases for each gate. The gate functions can decide what should be passed or retained, thus control whether certain information can be propagated or overwritten across the recurrent network.

In our models, LSTM is applied over the sequence generated by CNN. To bidirectional sequence dependencies, a backward LSTM is arranged over the reverse sequence. We denote the encoded result by forward LSTM as $\vec{h}_{enc}$, backward LSTM as $\overleftarrow{h}_{enc}$ and the concatenation of them as $h_{enc} = [\vec{h}_{enc}, \overleftarrow{h}_{enc}]$.

3.5 Attention-LSTM

Attention mechanism is firstly introduced by Bahdanau et al. (2015) in machine translation. By applying attention in an encoder-decoder framework, the model can figure out the contributions of the encoded elements to the generation of the current unit, using an automatic alignment model. Attention is later popularized in other tasks, such as QA (Hermann et al., 2015) and relation extraction (Liu et al., 2016).

Assume the encoded sequence (question+answers) by LSTM is $h_{enc} \in \mathbb{R}^{(n+1)\times d}$ where d is the output dimension of LSTM. For the ith answer (encoded as s_i), the context vector c_i is computed as a weighted sum of the annotations $\{h_j\}$ (h_j stands for the jth element in h_{enc}):

$$c_i = \sum_{j=1}^{n+1} \alpha_{ij} h_j \tag{9}$$

and the weight α_{ij} is computed by

$$\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{k=1}^{n+1} \exp(e_{ik})} \tag{10}$$

where

$$e_{ij} = s_i^T \cdot h_j \tag{11}$$

In ARC-II, we degenerate Eq. 11 into simply computing the similarity between sentences, that is $e_{ij} = h_i^T \cdot h_j$. Thus, the attention context for an answer derives from the similarity with the question as well as the associations with other answers. The correlation with previous answers reflect the information of dependency while the correlation with later answers perhaps convey the information of comments.

3.6 CRF

CRF has been shown superior in many sequence labelling tasks (Lafferty et al., 2001;Sha and Pereira, 2003; Quattoni et al.,2004). Given an observation sequence $X=\{x_1, x_2, \ldots, x_n\}$, CRF jointly models the probability of the entire sequence of labels $Y=\{ y_1, y_2, \ldots, y_n \}$ by using the discriminative probability to y_i given x_i and the transition probability between adjacent labels. The original probability model of CRF is written as:

$$p(Y \mid X; W, b) = \frac{\prod_{i=1}^{n} \psi_i(y_{i-1}, y_i, X)}{\sum_{y' \in \mathcal{Y}(X)} \prod_{i=1}^{n} \psi_i(y'_{i-1}, y'_i, X)} \tag{12}$$

where $\psi_i(y', y, x_i) = \exp(W^T_{y',y} x_i + b_{y',y})$ are potential functions, and $\mathcal{Y}(X)$ denotes the set of possible label sequences given X.

In this work, the observed variable is the encoded sequence (QA sequence) generated by Bi-LSTM. A CRF layer is followed to capture the dependencies between adjacent labels via a state transition matrix. Therefore, Equation 12 is transformed into a simpler form by replacing the potential functions by the outputs of Bi-LSTM. Formally, we denote the outputs of Bi-LSTM as $M=\{m_1, m_2, \ldots, m_n\}$ so as to differentiate from the input of the whole network X (the original word ids). By applying softmax, we obtain the predicted score for each answer on each category.

$$P(y_i = j \mid m_i) = \frac{e^{m_i^T w_j + b_j}}{\sum_k e^{m_i^T w_k + b_k}}, \; j,k = 0,1,2 \tag{13}$$

By adding the transition probability from state y_{i-1} to y_i, the probability of the sequence M is:

$$S(M, Y) = \sum_{i=1}^{n} P(y_i = j \mid m_i) + \sum_{i=1}^{n} T(y_i = j \mid y_{i-1} = k) \tag{14}$$

So the probability for the sequence Y can be yielded by applying a softmax over all possible tag sequences:

$$p(Y \mid M) = \frac{e^{s(M,Y)}}{\sum_{y' \in \mathcal{Y}(M)} e^{s(M,y')}} \tag{15}$$

3.7 Training

We pre-trained the word embeddings with word2vec (Miklov et al., 2013) using the continuous bag-of-words model and the embedding dimension is 100. To achieve fixed length sentence representations (100 in this work), we padded each sentence with zero vectors. The embeddings were not fine-tuned during training because of performance decline in the experiments. We add a dropout layer after CNN with the dropout rate 0.1. The parameters are optimized using AdaDelta (Zeiler, 2012) and the learning rate is initialized as 0.01. The settings for CNN are the same as those by Kim (2014). Following Zhou et al. (2015), we set the dimension of the gates as 360. However, we did not follow the settings of CNN in Zhou et al. (2015)'s work since we found that the settings by Kim (2014) can produce better results when adding Bi-LSTM and CRF. We train the network using a complete end-to-end process. The implementation is under the help of Theano (Al-Rfou et al., 2016) and the tagger codebase[4].

4 Experiments

4.1 Experimental Settings

We carried out the experiments on the dataset released by SemEval-2015 cQA shared task (Nakov et al., 2015). The statistics of the dataset are listed in Table 1. The questions and answers are crawled from Qatar Living Forum. The word embeddings are pre-trained on the untagged cQA data[5]. Each answer is manually tagged as *Good*, *Bad* or *Potential* according to its quality in which *Potential* means the answer is potentially useful to the questioner.

The evaluation metrics include macro averaged precision, recall and F_1 over the target categories, denote as *Prec.*, *Recall*, and F_1 in this section. We also reported the F_1s on individual categories to see whether the models work well on certain labels. The models are trained on the training set, tuned on the development set and tested on the testing set.

	No. of Threads (Q)	No. of Answers (A)	Avg. Length
Train	2600	16541	6.36
Dev	300	1645	5.48
Test	329	1976	6.01

Table 1. Statistical data for SemEval-2015 cQA dataset.

We compare our models with five baselines: 1) The Top-1 system in the shared task which includes almost all the previous popular features, such as translation models and word-based topic models (Tran et al., 2015). This is the state-of-the-art work in the literature. 2) The Top-2 system in the shared task which employs multiple syntactic and semantic features, with ensemble learning as its classification schema (Hou et al., 2015). 3) The state-of-the-art neural network-based system that has an analogous architecture as the proposed models, differing in an insufficient modelling of answer correlation and label dependency (Zhou et al., 2015). 4) A global inference model using graph-cut algorithm but only on binary classification (*Good* or *Bad*) (Joty et al., 2015). 5) An improved version of (Joty et al., 2015) which jointly models the dependencies between tags and learns comment-level classifiers. The main idea of the latter two methods is to divide the tagging task into two subtasks: comment-level tagging and pairwise similarity measuring. However, they still depend on laborious feature engineering.

Further, to validate the role of each component, we compare several sub-networks based on the proposed architectures. The sub-networks are denoted as CNN+LSTM (without backward LSTM and CRF), CNN+LSTM+CRF (without backward LSTM), CNN+Bi-LSTM (without CRF), and CNN+Bi-LSTM+CRF (with all components). To test the importance of CRF in modelling label dependency, we

[4] https://github.com/glample/tagger
[5] http://alt.qcri.org/semeval2015/task3/index.php?id=data-and-tools

replace CRF with the previously predicted label (LP) which is encoded using one-hot format and initialized with zero vectors. The naming rule for LP-based models is similar to those for CRF. The parameters were trained on the training set, and tuned on the development set. Finally, the optimal set of parameters were tested on the testing set.

4.2 Multiclass Tagging

ARC-I The results for multiclass (*Good*, *Bad* and *Potential*) tagging are shown in Table 2[6]. From the fourth column, we see that the best F_1 value is achieved by ARC-I with CNN+Bi-LSTM+CRF, which outperforms the state-of-the-art (Tran et al., 2015) by 1.77% and the best neural network-based method on this dataset (Zhou et al. 2015) by 2.82%. Meanwhile, the optimal values on precision and recall are also generated by this setting. The results imply the importance of both Bi-LSTM (for content dependency) and CRF (for label dependency).

We also notice that the addition of LP gains improvement for both the two variants (LSTM vs. Bi-LSTM), but in varying degrees. Without backward LSTM, LP enhance the baseline by 1.63%, while on the other side, the improvement is about 0.2%.One possible explanation is that backward LSTM plays a more important part than the constraint from the previous label. The F_1 values by both the settings with CRF outperform the baselines heavily, and are also better than other settings without label dependency, indicating the effectiveness of applying CRF. It is also remarkable that the optimal overall precision overpasses 60%, which is a significant improvement over the baselines (2.5%). A good precision is helpful in many real world applications such as QA knowledge base building.

Methods	**Prec.**	**Recall**	**F_1**	**F-Good**	**F-Bad**	**F-Pot.**
Baselines						
(Tran et al., 2015)	57.31	57.20	57.19	78.96	78.24	14.36
(Hou et al., 2015)	57.83	56.82	56.41	76.52	74.32	18.41
(Zhou et al., 2015)	56.41	56.16	56.14	77.31	75.88	15.22
ARC-I						
CNN+LSTM	55.74	55.86	55.75	78.29	77.66	11.30
CNN+LSTM+LP	57.26	57.72	57.32	76.37	77.32	18.28
CNN+LSTM+CRF	58.97	58.41	58.61	78.91	77.06	**19.87**
CNN+Bi-LSTM	57.61	56.98	56.75	79.13	78.44	12.70
CNN+Bi-LSTM+LP	57.22	56.84	56.96	78.23	76.11	16.17
CNN+Bi-LSTM+CRF	**60.33**	**58.86**	**58.96**	79.80	78.63	18.46
ARC-II						
CNN+LSTM	58.45	57.07	56.48	79.84	78.84	10.76
CNN+LSTM+LP	56.34	56.67	55.23	**81.71**	**79.95**	4.04
CNN+LSTM+CRF	59.62	57.98	57.92	81.29	79.07	13.39
CNN+Bi-LSTM	56.47	56.06	55.43	80.63	77.68	7.96
CNN+Bi-LSTM+LP	56.89	56.73	56.39	80.78	78.11	10.28
CNN+Bi-LSTM+CRF	59.83	58.41	58.29	81.22	79.60	14.05

Table 2: Experiment results by the proposed models and baselines. The optimal value for each column is marked bold. F-Pot stands for the F_1 value for the *Potential* category.

ARC-II ARC-II has considerable improvement from the baselines. We notice that with the full network components, it outperforms (Zhou et al., 2015) by 2.15% and (Tran et al. 2015) by 1.10%. Similar trends in the addition of LP or CRF also indicate the importance of label dependency and the superiority of CRF to LP. We also test the model without the attention part, but got very bad results, regardless of

[6] The result files can be downloaded from https://github.com/o0laika0o/CNN-LSTM-CRF-for-cQA-answer-tagging

the addition of backward LSTM. It is mainly due to the loss of the question information from the sequence. We think using attention over the post sequence is a neat way to capture relations from both the question and the context.

A statistical test (*t*-test) is further conducted to evaluate the significance of the improvements by the CRF-based methods (compared with the existed state-of-the-art by Tran et al. (2015)). The results show that the improvement of ARC-I with Bi-LSTM and CRF is mildly significant (p<0.08), and all the other three CRF-based results are statistically significant (p<0.05).

4.3 Binary Classification

Methods	Prec.	Recall	F_1	Acc
(Joty et al., 2015)	78.30	82.93	80.55	79.80
(Joty et al., 2016)	77.3	**86.2**	81.5	80.5
ARC-I	81.54	81.29	81.28	81.33
ARC-II	**82.29**	82.22	**82.22**	**82.24**

Table 3: Results for binary classification.

The last two competitors' methods are binary classification, which removes the *Potential* class from the original target category set. Determining *Good* or *Bad* is a more direct way for the answer selection task and is much closer to real world applications. Joty et al. (2015) and Joty et al. (2016) gain improvements from baselines and the latter one is the state-of-the-art work on binary classification.

We carried out experiments on binary classification and show the results in Table 3. It is notable that we have much better precision and accuracy than their methods. And ARC-II gets the best F_1, which outperforms (Joty et al., 2016) by 0.72%. We may say that ARC-II is more appropriate for binary classification albeit it is inferior in predicting the *Potential* class (seen from Table 2, even 4.04% in F_1 for *Potential* while around 80% for *Good* and *Bad*). From this perspective, although the overall F_1 for multiclass tagging is not the best, ARC-II has its unique advantage.

5 Discussion

We can draw a conclusion that backward LSTM and CRF are both good contributors and complement each other in determining the quality tags and CRF plays a more important part. The backward LSTM intends to capture the comments to the previous answers (i.e. a negative comment perhaps follows a bad answer) and we notice that it improves the original model by 1% in ARC-I. However, in ARC-II, the improvement is not as obvious as the former, mainly due to that the attention mechanism already takes the future steps into account. The employment of CRF brings over 2% promotion from the baselines and can be seen as the most vital factor (the role of LSTM is not so significant which can be drawn from Zhou et al. (2015)). For ARC-II, we also tried other forms of attention such as using more parameters to replace the element-wise dot in this work, but failed to get better results. We think a possible explanation is that the explosive parameters cannot be effectively trained given the current size of the training corpus.

From Table 2, we also recognize that the addition of LP is helpful in some cases but in other cases the improvement is not obvious or even LP does bad to the result (CNN+LSTM+LP for ARC-II). The comparisons between methods with LP and CRF prove that soft constraints are more powerful than hard constraints. Moreover, it is noticed that in most cases, label dependency can boost the performance on *Potential*, which indicates that this class rely more on the contextual information.

6 Conclusion

This paper introduces two models for answer quality tagging in cQA, one with a hierarchical architecture from input to output, and the other with attention mechanism integrated. Through the combination of CNN, Bi-LSTM and CRF, we focus on the modelling of context information, including content correlation and label dependency. Experiments show that we achieve the state-of-the-art overall precision, recall, F_1, as well as the best performance on individual classes. Through the comparisons on label dependency, we discover that CRF is superior to others by learning global constraints. Future development may rise from the import of extra features, such as the user metadata, and a thorough pre-processing

towards the noisy input. With adjustment to the architectural elements or training procedures, we believe the models can be incrementally improved further.

Abstract

Identification of Multi-Word Expressions (MWEs) lies at the heart of many natural language processing applications. In this research, we deal with a particular type of Hebrew MWEs, Verb-Noun MWEs (VN-MWEs), which combine a verb and a noun with or without other words. Most prior work on MWEs classification focused on linguistic and statistical information. In this paper, we claim that it is essential to utilize semantic information. To this end, we propose a semantically motivated indicator for classifying VN-MWE and define features that are related to various semantic spaces and combine them as features in a supervised classification framework. We empirically demonstrate that our semantic feature set yields better performance than the common linguistic and statistical feature sets and that combining semantic features contributes to the VN-MWEs identification task.

1 introduction

Multi-word expressions (MWE) were defined by Sag et al. (2002) as "idiosyncratic interpretations that cross word boundaries (or spaces)" while Bouamor et al. (2012) defined a MWE as "a combination of words for which syntactic or semantic properties of the whole expression can not be obtained from its parts".

Jackendoff (1997) claimed that that the frequency of MWEs in a speaker's lexicon is of the same order of single words. Due to their relative high frequency and complexity, MWEs require high-quality treatment in many applications in natural language processing (NLP) such as data mining, machine translation (MT), information retrieval, natural language understanding, natural language generation, question answering (QA), text summarization, and word sense disambiguation (WSD).

The aim of this work is to explore Hebrew Verb-Noun MWEs (VN-MWEs). VN-MWEs are MWEs whose constitutents include a verb and a noun. The motivation of this research is to enable automatic identification of VN-MWEs for various NLP tasks such as MT, QA, and WSD, and to classify collocations that include verbs as VN-MWEs or non-VN-MWEs.

Most prior efforts to automatically classify MWEs focused on three approaches: (1) Statistical approaches, either frequency-based or co-occurrence-based (Dias et al., 1999; Deane, 2005; Pecina and Schlesinger, 2006). (2) Linguistic approaches that are based on NLP tools, such as taggers and parsers (Al-Haj, 2009; Bejcek et al., 2013; Green et al., 2013). (3) Hybrid approaches which combine statistical and linguistic approaches (Baldwin, 2005; Boulaknadel et al., 2008; Farahmand and Nivre, 2015).

In this paper, we claim that on top of standard linguistic and statistical metrics, MWE identification methods can greatly benefit from exploiting semantically motivated cues. For example, when a VN-MWE is highly idiomatic, the semantics of the verb and the noun are not likely to overlap.

The contribution of this paper is, in a first step, to combine semantic features in the framework of supervised MWE classification. We suggest a simple semantically-motivated indicator that helps to

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1242–1253, Osaka, Japan, December 11-17 2016.

detect VN-MWEs. Then, we define semantic features that implement our indicator in various semantic spaces and integrate them within our Machine Learning (ML) classification algorithm.

We show that combining semantic features improves the accuracy and F-score results of VN-MWE classification. Moreover, our analysis reveals that the semantic feature set yields better results than each one of the two other approaches, the statistical and the linguistic.

The rest of this paper is organized as follows: Section 2 introduces relevant background about MWEs in Hebrew and identification of MWEs using semantic features. Section 3 presents the linguistic, statistical, and semantic feature sets that were applied for the supervised VN-MWEs classification task. Section 4 introduces the experimental setting, the experimental results for nine ML methods, and their analysis. Finally, Section 5 summarizes the main findings and suggests future directions.

2 Background

2.1 MWEs in Hebrew

Al-Haj (2009) presented an architecture for lexical representation of MWEs written in Hebrew and a specification of the integration of MWEs into a morphological processor of Hebrew. He also introduced a system that extracts noun compounds from Hebrew raw text based on their idiosyncratic morphological and syntactic features. A support vector machine (SVM) classifier using these features identified noun-noun constructs with an accuracy of over 80%.

Al-Haj and Wintner (2010) created for each noun-noun construction, a vector of the 16 features: 12 linguistically-motivated features and 4 collocation measures. Their dataset includes 463 instances, of which 205 are noun compounds (positive examples) and 258 negative. They applied LIBSVM classifier (Chang and Lin, 2001) with a radial basis function kernel. The best combination of features yielded an accuracy of 80.77% and F-score of 78.85, representing a reduction of over one third in classification error rate compared with the baseline.

Tsvetkov and Wintner (2012) proposed a methodology for extracting MWEs in Hebrew-English corpora. MWEs of various types are extracted along with their translations, from small, word-aligned parallel corpora. They focused on misalignments, which typically indicate expressions in the source language that are translated to the target in a non-compositional way. They implemented a simple algorithm that proposes MWE candidates based on such misalignments, relying on 1:1 alignments as anchors that delimit the search space. Evaluation of the algorithm's quality demonstrates significant improvements over Naive alignment-based methods.

Tsvetkov and Wintner (2014) proposed a framework for identifying MWEs in texts using multiple sources of linguistic information. Their system enables identification of MWEs of various types and multiple syntactic constructions. Their methodology is unsupervised and language-independent; it requires relatively few language resources and is thus suitable for a large number of languages. They applied four ML methods. The system was tested on three languages: Hebrew, French, and English. Applying the Bayesian Network ML method on a combination of linguistically motivated features and feature interdependencies reflecting domain knowledge yielded the best results (Hebrew: accuracy of 76.82% and F-score of 0.77; French: accuracy of 79.04% F-score of 0.778; and English: accuracy of 83.52% and F-score of 0.835).

Sheinfux et al. (2015) introduced different types of verbal MWEs in Modern Hebrew. In addition, they proposed an analysis of these MWEs in the framework of HPSG, and they incorporated this analysis into HeGram, a deep linguistic processing grammar of Modern Hebrew. Their analysis covers various MWE types, including challenging phenomena such as (possessive) co-indexation and internal modification. The HeGram grammar produced two analyses for most MWEs, corresponding to their idiomatic and literal readings.

Liebeskind and HaCohen-Kerner (2016) presented a lexical resource containing 505 Verb-Noun MWEs (VN-MWEs) in Hebrew. These VN-MWEs (247 bigrams and 258 trigrams) were manually collected from five web resources and annotated. Following Al-Haj (2009), the authors classified the linguistic properties of these VN-MWEs along 3 dimensions: morphological, syntactic, and semantic. The major findings are: (1) the main characteristic properties of VN-MWEs are the semantic properties

of non-compositionality and lexical fixedness; (2) High degrees of idiomaticity (92%) and lexical fixedness (94%) were found for the VN-MWEs; (3) 82% of the VN-MWEs do not allow any changes in the constituent order; and (4) 87% have a non-compositional syntax.

2.2 Identification of MWEs using Semantic Features

Katz and Giesbrecht (2006) applied latent semantic analysis (LSA) vectors to distinguish compositional from non-compositional uses of German expressions. The LSA vectors of compositional and non-compositional meaning were constructed from a training set of example sentences. Afterwards, a simple nearest neighbor algorithm was applied on the LSA vectors of the tested MWEs. The LSA-based classifier obtained an average accuracy of 72%, which outperformed the simple maximum-likelihood baseline with accuracy of 58%.

Sporleder and Li (2009) proposed supervised and unsupervised methods to distinguish literal from non-literal usages of idiomatic expressions by measuring the semantic relatedness of an expression's component words to nearby words in the text. Their assumption was that if an expression is used literally, but not idiomatically, its component words will be related semantically to a few words in the surrounding discourse. If one or more of the expression's components were sufficiently related to enough surrounding words, the usage was classified as literal, otherwise as idiomatic. The supervised classifier method (90% F-score on literal uses) was better than the lexical chain classifier methods (60% F-score).

Biemann and Giesbrecht (2011) provided an overview of the shared task at the ACL-HLT 2011 DiSCo (Distributional Semantics and Compositionality) workshop. The authors described the motivation for the shared task, the acquisition of datasets, the evaluation methodology, and the results of participating systems. The evaluation shows that most systems outperformed simple baselines, yet have difficulties in reliably assigning a compositionality score that closely matches the gold standard. Generally, approaches based on word space models performed slightly better than approaches relying merely on statistical association measures.

Guevara (2011) proposed and evaluates a framework that models the semantic compositionality in computational linguistics based on the combination of distributional semantics and supervised ML. The applied method, Partial Least Squares (PLS) Regression, outperformed all the competing models in the reported experiments with Adjective-Noun (AN) pairs extracted from the BNC.

Salehi et al. (2015) introduced the first attempt to use word embeddings to predict the compositionality of MWEs. They considered both single- and multi-prototype word embeddings. Experimental results showed that, in combination with a back-off method based on string similarity, word embeddings are superior to, or competitive with state-of-the-art methods over 3 standard compositionality datasets ((1) English noun compounds ("ENCs"); (2) English verb particle constructions ("EVPCs"); and (3) German noun compounds ("GNCs")).

3 Supervised VN-MWEs Classification

In the previous section, we discussed linguistic properties of Hebrew VN-MWEs that may help in distinguishing coincidental word combinations from collocations. We next define them and describe how to incorporate these properties as features within a ML framework for classifying candidate VN-MWEs.

3.1 Feature Sets

We next detail how the semantic properties of VN-MWEs, as well as the linguistic and statistical properties found useful in prior work, are encoded as features. Then, in Section 4, we describe the supervised ML model and our feature analysis procedure. There are 206 features in our model, divided into 3 sets: linguistic, statistical and semantic. We defined the sets as Al-Haj and Wintner (2010) and Liebeskind and HaCohen-Kerner (2016) did. However, we note that semantic information is often defined as a sub-type of linguistic information and it might be more accurate to contrast morpho-syntactic information (i.e., parts-of-speech and syntactic parses) with semantic information.

3.1.1 Linguistic features

Most of our linguistic features are based on information extracted from a Part-Of-Speech (POS) tagger for the Hebrew language (Adler, 2007). Our linguistic features encode both morphological and syntactical properties of VN-MWEs. For each candidate VN-MWE, we compute counts that reflect the reasonableness of the candidate to represent at least one of its linguistic properties. We focus on the linguistic properties that Liebeskind and HaCohen-Kerner (2016) recognized as notable. Our linguistic properties include two families of properties: morphological and syntactical.

Partial Inflection Following Al-Haj and Wintner (2010), for each VN-MWE candidate, the following 8 features are defined: the number of occurrences of the candidate in which both constituents are in singular, the number of occurrences in which both constituents are in plural, the number of occurrences in which the verb is in singular and the noun is in plural, the number of occurrences in which the noun is in singular and the verb is in plural, the number of occurrences of the verb in plural, the number of occurrences of the verb in singular, the number of occurrences of the noun in plural and the number of occurrences of the noun in singular. Two additional features that we calculate are the number of verb suffixes, which indicate a conjugation of grammatical tense, possession or direct objects, as well as the number of noun suffixes, which indicate nouns number and gender (*ildi*[1] (my child), *ild**inw*** (our children), *ild**h*** (a girl)).

Syntactic Fixedness VN-MWEs are expected to appear in restricted syntactic forms. Fazly and Stevenson (2006) suggested that to quantify the syntactic fixedness of a VN-MWE candidate, we need to: (i) identify relevant syntactic patterns and (ii) translate the frequency distribution of the candidate in the identified patterns into a measure of syntactic fixedness. Following this approach, we define syntactic patterns and clues as features in our supervised framework.

We use the most frequent POS patterns found in Liebeskind and HaCohen-Kerner (2016)'s VN-MWEs lexical resource as relevant syntactic patterns and count the number of occurrences of the candidate in each of these patterns (7 features).

Since prepositions and definite articles frequently appear in these patterns, we counted the number of occurrences of the candidate in which it includes an article, a pronoun, a particle, a conjunction, an auxiliary or a negation (6 features). Then, considering the fact that some of these POS are often Hebrew prefixes, we also encoded prefixes' occurrences. The features that we calculate are the number of occurrences of verb and noun prefixes (2 features), the number of occurrences of prefixes which start with a certain frequent *formative letter* (7 features for each POS, verb and noun), the number of occurrences of a certain frequent prefix (36 features for each POS). Our Hebrew stopword list also include some particles. Therefore, we calculated an additional feature of the number of stopwords in the candidate VN-MWE (1 feature).

The syntactic property of compositionality is encoded by the difference between the number of occurrences of the candidate constituents with and without a *slot* (1 feature). The syntactic property of a number of syntactic structures that permit a change in the order of constituents is encoded by the difference between the number of occurrences of the candidate constituents in their original order and the number of occurrences of the candidate constituent in a reversed order (1 feature).

3.1.2 Statistical features

We define some statistical features based on frequency and co-occurrence affinity. Each of these features is separately calculated for two candidate representations: surface and lemmatized. First, we compute the raw frequency of the VN-MWE candidate and the raw frequency of its verb and noun constituents (6 features). Then, we utilize features that represent known association measures: Log-likelihood, Total mutual information, Pointwise mutual information and Poisson-Stirling measure. We calculate them for bigrams and trigrams separately (16 features). Finally, we define four statistical features based on two non-parametric methods, which does not make the independence assumption and allows scores to be

[1]To facilitate readability we use a transliteration of Hebrew using Roman characters; the letters used, in Hebrew lexicographic order, are abgdhwzxTiklmns`pcqršt.

compared across n-grams of different length: Mutual Expectation (ME) (Dias et al., 1999) and Mutual Rank Ratio (MRR) (Deane, 2005) (4 features).

In addition, we calculate the number of words, number of characters and the average number of characters per word (3 features) for each candidate in its base form.

3.1.3 Semantic features

Liebeskind and HaCohen-Kerner (2016) observed that the most characteristic properties of VN-MWEs are the semantic properties of compositionality and lexical fixedness. To encode this property, we represent the meaning of the candidate's constituents by vectors in the same semantic space. Due to the idiomaticity of VN-MWEs, we expect the similarity of vectors of words in a non-VN-MWE to be greater than the similarity of vectors of words in a VN-MWE. For example, the VN-MWE *to eat one's hat* vs. the non-VN-MWE *to eat an apple*. We expect the vectors of *eat* and *apple*, which share a common context, to be closer than the vectors of *eat* and *hat* in a representative semantic space.

We construct semantic features from the following five different semantic spaces:

(1) Hyperspace Analogue to Language (HAL) (Lund and Burgess, 1996): The algorithm computes a word-by-word matrix, using a 10-word reading frame that moves incrementally through a corpus of text. The algorithm considers context only as the words that immediately surround a given word. Any time two words are simultaneously in the frame, the association between them is increased, that is, the corresponding cell in the matrix is incremented. The amount by which the association is incremented varies inversely with the distance between the two words in the frame; closer neighboring words are thought to reflect more of the focus word's semantics and so are weighted higher. The algorithm also records word-ordering information by treating the co-occurrence differently based on whether the neighboring words appeared before or after the focus word.

(2) Correlated Occurrence Analogue to Lexical Semantics (COALS) (Rohde et al., 2006): The algorithm constructs a word-by-word matrix where each element in the matrix represents how frequently word_i occurs with word_j in a certain window. The matrix is then normalized by correlation, and any negative values are set to zero and all other values are replaced by its square root. Then, optionally, the Singular Value Decomposition (SVD) is used to reduce the word co-occurrence matrix.

(3) Random Indexing (RI) (Sahlgren, 2005): The algorithm uses statistical approximations of the full word co-occurrence data to achieve dimensionality reduction. RI represents co-occurrence through index vectors. Each word is assigned a high-dimensional, random vector that is known as its index vector. These index vectors are very sparse, which ensures that the chance of any two arbitrary index vectors having an overlapping meaning is very low. Word semantics are calculated for each word by keeping a running sum of all of the index vectors for the words that co-occur.

(4) Reflective Random Indexing (RRI) (Cohen et al., 2010): The algorithm is a second-order iterative extension to the RI method. Reflective random indexing adds another cycle by restarting the construction of the term vectors using the basis of document vectors, and then creating the document vectors again using the term vectors. Such retraining has been found to improve the ability of RI to make indirect inferences, drawing meaningful associations between terms that do not occur together in any document.

(5) Word Embeddings (Mikolov et al., 2013): Word embedding is the collective name for neural-network based approaches in which words are embedded into a low dimensional space. In word embedding models, the contexts of each word are modeled by a d-dimensional vector of real numbers. The vector are meaningless on their own, but semantically similar words have similar vectors, and vector similarities are easy to compute.

Each of these five semantic spaces is generated for two word representations: surface and lemmatized. We use different measures to compute the similarity between two vectors. For the first four semantic spaces[2], we calculate Cosine similarity, Lin similarity, Euclidean distance, Pearson correlation, average common feature rank, Jaccard index, Tanimoto coefficient, and Spearman rank correlation. For the fifth semantic space[3], we calculate cosine similarity, euclidean distance, and manhattan distance.

[2]implemented by the S-Space Package `https://github.com/fozziethebeat/S-Space`

[3]implemented by the deeplearning4j word2vec package `http://deeplearning4j.org/word2vec`

Some of the measures did not yield a valid score for all the examples in our dataset. As a result, the total number of semantic features is 62.

An additional semantic feature, which measures lexical fixedness, counts the number of occurrences of the VN-MWE candidate in the Bible. MWEs from the Bible are citations that tend to be fixed, replacing any of their constituents by a semantically similar word generally results in an invalid or a literal expression.

We note that corpus-based statistics are used to calculate some of the linguistic features (e.g., the features which encode the Partial Inflection property). Additionally, some of the statistical features, such as Mutual Expectation (ME) and Mutual Rank Ratio (MRR), capture the semantic behavior of VN-MWEs.

4 Evaluation and Analysis

4.1 Experimental setting

Following Al-Haj and Wintner (2010), we used four of the MILA knowledge center[4]corpora: the Knesset corpus, which contains the Israeli parliament proceedings from 2004-2005; the Haaretz corpus that contains articles from the Haaretz newspaper from 1991; TheMarker corpus, which contains financial articles from the TheMarker newspaper from 2002; and the Arutz 7 corpus, which contains newswire articles from 2001-2006. From the morphologically disambiguated version of the corpora (Itai and Wintner, 2008; Yona and Wintner, 2008; Bar-haim et al., 2008), we extracted all word bigrams and trigrams that include a verb and a noun.

To evaluate our proposed supervised model, we constructed a labeled dataset. We selected all the word bigrams and trigrams that occur at least 25 times in the corpora. These candidates were annotated by two annotators, who were asked to classify them as a VN-MWE or a non-VN-MWE. We evaluated the inter-annotator agreement and observed a Kappa (Cohen, 1960) value of 0.59, which is considered as moderate (Landis and Koch, 1977). Thus, we considered a candidate as a VN-MWE or not only if both annotators agreed on its classification. This reduced the labeled data to 553 instances, of which 306 are VN-MWEs (256 bigrams and 50 trigrams) and 247 are non-VN-MWEs (157 bigrams and 90 trigrams).

4.2 Application of nine Machine Learning methods

We combined the features in a supervised classification framework using nine ML methods: Random Forest, Decision Tree, Bagging, Adaboost, Bayes Network, Supported Vector Machine (SVM), Logistic Regression and Multilayered Perceptron. The accuracy rate of each ML method was estimated by a 10-fold cross-validation test. We ran these ML methods by the WEKA platform (Witten and Frank, 2005; Hall et al., 2009) using the default parameters. Table 1 shows the performances of the different ML methods on the full feature set of 206 features, as described above. The best ML method was Random Forest. Therefore, we have performed further experiments using only this method. These experiments are presented in the next sub-section.

4.3 Further experimental results using the random forest method

In this research, we defined three types of feature sets (Section 3): linguistic, statistic and semantic. The classification results of the Random Forest algorithm (the best ML method in Table 1) on each of the sets are presented in the left side of Table 2. The semantic feature set yielded the best accuracy result (77.4%). The advantage of the semantic feature set over the linguistic and statistical feature sets is notable (3.5% and 5% respectively) and is statistically significant according to the McNamar test (McNemar, 1947) for the statistical feature set (p=0.017). The advantage is also almost statistically significant at level 0.05 for the linguistic feature set (p=0.056).

A hybrid approach, which combines the linguistic and statistical information, is commonly used in MWE extraction. Therefore, we investigated different combinations of feature sets. The results of our exploration are presented in the right side of Table 2. The best results were obtained using all the three sub-feature sets. However, the contribution of the linguistic feature set was negligible (80.47% vs.

80.29%). As was found in previous studies (Justeson and Katz, 1995; Pecina, 2010), the approach of combining linguistic and statistical features works efficiently. Yet, combining linguistic and semantic features did not yield any improvement over using only the semantic feature set.

For each of the above feature set configurations, we tried to filter out non-relevant features using two well-known feature selection methods: Information gain (InfoGain, IG) (Hunt et al., 1966) and Correlation-based Feature Subset (CFS) (Hall, 1998). The use of these two feature selection methods did not improve the accuracy of any configuration. However, we used the information obtained by the IG selection method to better understand which features have more influence on the classification accuracy. Table 3 presents the features, which were selected by the IG method for the three feature sets (the number in parentheses is the feature rank). The linguistic properties of partial inflection and constituent order were found as important properties for distinguishing MWEs from non-MWEs. The two non-parametric statistical features, Mutual Expectation (ME) and Mutual Rank Ratio (MRR), outperformed other baseline association measures. The good performance of the algorithm using the semantic features is due to the combination of various semantic spaces and vector comparison measures.

Table 4 shows the features that were selected by the IG method for the different combinations of feature sets. For each feature sub-set of a combined configuration, Table 4 details how many and which of its selected features were also selected by the IG measure when each set was tested as a standalone feature set (see Table 3). While the same semantic features were selected for the standalone (Semantic) and combined configurations (Linguistic & Semantic and Semantic & Statistical), different linguistic and statistical features were selected by each of the configurations that include them.

We further analyze our suggested semantic feature set by comparing the performance of the different semantic spaces. Table 5 shows the classification results of the Random Forest algorithm on the various sub-sets of the semantic features. The semantic features that were constructed by the HAL semantic space outperformed the other semantic representations. The advantage of the HAL semantic space might be due to its sensitivity to word-ordering. This sensitivity enables the representation to model the important constituent order linguistic property of VN-MWE. The low performance of the word embedding space could be explained either by its low number of features or by the fact that these vector were constructed without any task-depended training.

Finally, we investigated the False Positive (FP) and False Negative (FN) classifications of our suggested semantic feature set. We found that some of the FPs were due to light verbs, such as ***lqbl*** *mid`* (to

get information) and ***`wšh*** *`bwdh* (to make a work). The general meaning of the light verbs decreased the vectors comparison score and candidates with light verbs were wrongly classified as VN-MWEs. This might be because light verbs have little semantic content of their own and they are used in combination with various nouns. Thus, the semantic similarity between the light verb and a specific noun was relatively low. A possible solution to the light verb issue is to use a directional inclusion-based measure to compute the similarity between two vectors (Weeds and Weir, 2003; Clarke, 2009; Kotlerman et al., 2010).

Another interesting finding is that domain-specific VN-MWEs were often misclassified as FNs. VN-MWEs like *lhqim mmšlh* (to establish a government) and *lgbš `mdh* (to form an opinion) were wrongly classified as non-MWEs since they frequently co-occur in our political domain, so their semantic vectors are rather close.

5 Conclusions and Future Work

We presented a supervised classification model for identification of Hebrew VN-MWEs. Our semantic feature set yields better performance than the common linguistic and statistical feature sets and that combining semantic features contributes to the Hebrew VN-MWEs identification task.

Most previous related studies apply only one ML method. An exception was the study of Tsvetkov and Wintner (2014), which applied 4 ML methods. In this research, we applied 9 ML methods. Moreover, we have performed further experiments using only the Random Forest method, which has been found as the best ML method for our task. Our experiment over a manually labeled dataset showed that the semantic feature set outperforms the statistical and linguistic feature sets and that combining semantic features with the two other feature sets further improved the performance (especially with the statistical set).

In future work, we would like to investigate more sophisticated models for representing the semantic meaning of VN-MWEs. For example, we plan to extend the single-word vector representation to learn larger semantic composition representations (Baroni and Zamparelli, 2010; Grefenstette and Sadrzadeh, 2011; Socher et al., 2012). We also plan to investigate directional inclusion-based similarity measures for computing vector similarity.

In addition, we plan to adopt our model to under-resourced languages, many of them are found in the developing world where we lack the linguistic information.

xiaomg@mail2.sysu.edu.cn, liucong3@mail.sysu.edu.cn

Abstract

Semantic relation classification remains a challenge in natural language processing. In this paper, we introduce a hierarchical recurrent neural network that is capable of extracting information from raw sentences for relation classification. Our model has several distinctive features: (1) Each sentence is divided into three context subsequences according to two annotated nominals, which allows the model to encode each context subsequence independently so as to selectively focus as on the important context information; (2) The hierarchical model consists of two recurrent neural networks (RNNs): the first one learns context representations of the three context subsequences respectively, and the second one computes semantic composition of these three representations and produces a sentence representation for the relationship classification of the two nominals. (3) The attention mechanism is adopted in both RNNs to encourage the model to concentrate on the important information when learning the sentence representations. Experimental results on the SemEval-2010 Task 8 dataset demonstrate that our model is comparable to the state-of-the-art without using any hand-crafted features.

1 Introduction

Semantic relation classification is an important task in natural language processing, which has attracted great attention in recent years. The goal is to identify the semantic relationship between a pair of nominals marked in a sentence. For instance, in the sentence "The software $[\text{company}]_{e_1}$ addressed the problem with the $[\text{publication}]_{e_2}$ of a fix on Saturday", the marked nominals of *company* and *publication* are of relationship *Product-Producer(e_2, e_1)*. Most conventional models focus on machine learning and feature design, which have been shown to obtain performance improvements (Kambhatla, 2004; Tratz and Hovy, 2010; Rink and Harabagiu, 2010).

Recently, neural network approaches have been widely used for relation classification, which aim at reducing the need of hand-crafted features. These approaches are broadly divided into two categories: one explores the effectiveness of using dependency paths and its attached subtrees between two nominals, and various neural networks are adopted to model the shortest dependency paths and dependency subtrees (Xu et al., 2015a; Xu et al., 2015b; Liu et al., 2015); the other exploits deep neural networks to learn syntactic and semantic features from raw sentences (Zeng et al., 2014; Dos Santos et al., 2015; Zhang et al., 2015), which has been proved effective, but inevitably suffers from irrelevant parts. Our paper introduces an attentive neural network that selectively focuses on useful information on raw sentences.

Context information of the annotated nominals has been widely believed to be useful for relation classification (Zhang et al., 2015; Thang Vu et al., 2016). In this work, we further explore the effectiveness of context information around the annotated nominals in a sentence. In our model, a sentence with two marked nominals is divided into three context subsequences according to two marked nominals: the left context subsequence, the middle context subsequence and the right context subsequence. This method is similar to Pei et al. (2015) and Thang Vu et al. (2016), which have showed that contextual information is effectively obtained by deep learning techniques. Instead of combining the middle context

*Cong Liu is the corresponding author.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1254–1263, Osaka, Japan, December 11-17 2016.

subsequence with the left and right context subsequences, respectively, as in (Thang Vu et al., 2016), we propose to learn context representations via recurrent neural networks that work on each context subsequence independently. For example, the sentence "The software $[\text{company}]_{e_1}$ addressed the problem with the $[\text{publication}]_{e_2}$ of a fix on Saturday" is split into three subsequences: " The software", "addressed the problem with the" and "of a fix on Saturday". And the marked nominals of $[\text{company}]_{e_1}$ and $[\text{publication}]_{e_2}$ are not included in any context subsequence. As a result, the sentence is divided into five parts: three context subsequences and two annotated nominals. Our sentence representations are leant hierarchically from context subsequences to sentences using a hierarchical recurrent neural network, which firstly learns the context representation of each context subsequence independently, and then encodes the semantics of context subsequences into a sentence representation for the relation classification. Furthermore, we introduce the attention mechanism (Bahdanau, 2014; Rush, 2015; Rocktäschel et al., 2016) that encourages the model to focus on the important information. Experimental results demonstrate that our model is comparable to the state-of-the-art with a single model that works on the raw sentences.

In the rest of this paper, we review recurrent neural networks in Section 2. We provide details about our model in Section 3. Section 4 presents our experiments and their results. Finally, we make a conclusion in Section 5.

2 Recurrent Neural Networks

Recurrent neural networks (RNNs) (Elman, 1990; Mikolov et al., 2010) project a sequence of inputs $x_1, \ldots, x_T$ to a sequence of outputs $y_1, \ldots, y_T$ via an affine transformation followed by a non-linear function. At timestep *t*, a standard RNN computes the new hidden vector as

$$h_t = f(Wx_t + Uh_{t-1} + b) \tag{1}$$

where *W* is trained matrix transforming the current input x_t into the current state linearly, *U* is also trained matrix connecting the previous state h_{t-1} with the current state, and *b* is a bias term, and *f* is a non-linear function (e.g., tanh).

However, RNNs with the above form may suffer from gradient *exploding* or *vanishing* problem (Bengio et al., 1994; Hochreiter, 1997) during training when it is trained with the backpropagation through time algorithm (Rumelhart et al., 1986; Werbos, 1990; Williams and Zipser, 1995). To address this problem, long short-term memory network (LSTM) was proposed in (Hochreiter and Schmidhuber, 1997) where the architecture of a standard RNN was modified to avoid vanishing or exploding gradients. Many LSTM variants have been proposed, and here we adopt the version of Zaremba and Sutskever (2014a).

The LSTM model comprises a memory cell that can store information over a long period of time, and three gates that allow it to control the flow of information into and out of the cell: input gate, forget gate, and output gate. Concretely, the LSTM unit at time step *t* encompasses a collection of vectors: an input gate i_t, a forget gate f_t, an output gate o_t, a memory cell c_t, and a hidden state h_t. The unit accepts an input vector x_t, the previous hidden state h_{t-1}, and the memory cell c_{t-1} and computes the new vectors using the following equations:

$$\begin{aligned}
i_t &= \sigma(W^{(i)}x_t + U^{(i)}h_{t-1} + b^{(i)}) \\
f_t &= \sigma(W^{(f)}x_t + U^{(f)}h_{t-1} + b^{(f)}) \\
o_t &= \sigma(W^{(o)}x_t + U^{(o)}h_{t-1} + b^{(o)}) \\
u_t &= tanh(W^{(u)}x_t + U^{(u)}h_{t-1} + b^{(u)}) \\
c_t &= i_t \odot u_t + f_t \odot c_{t-1} \\
h_t &= o_t \odot tanh(c_t)
\end{aligned} \tag{2}$$

where σ denotes the element-wise application of the logistic function, $\odot$ denotes the element-wise multiplication of two vectors, *W* and *U* are weight matrices, and *b* are bias vectors.

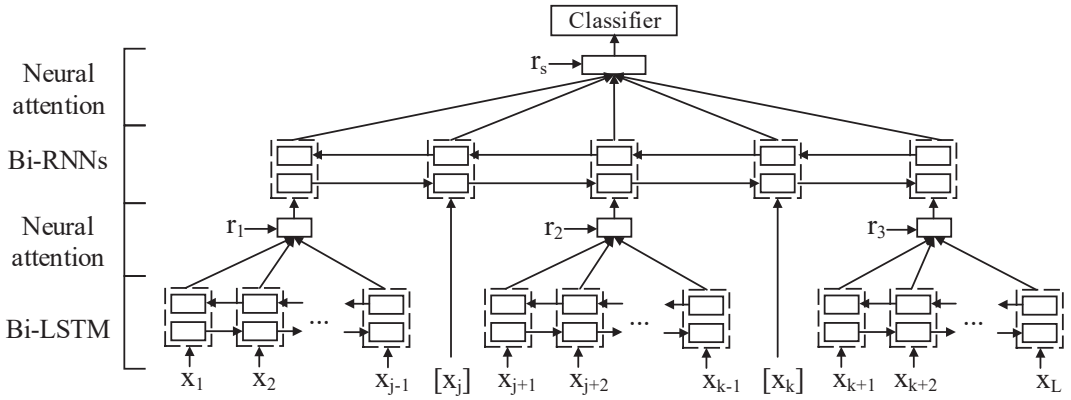

Figure 1: The architecture of our model. Given a sentence consisting of *L* words, it is divided into the left context subsequence $[x_1, \ldots, x_{j-1}]$, the middle context subsequence $[x_{j+1}, \ldots, x_{k-1}]$ and the right context subsequence $[x_{k+1}, \ldots, x_L]$. $[x_j]$ and $[x_k]$ represent the marked nominals e_1 and e_2 respectively.

3 Model

In this section, we introduce the proposed neural model that learns distributed representations from raw sentences. These representations serving as features are further used for relation classification. An overview of our model is shown in Figure 1.

Given a sentence with two annotated nominals, the sentence is firstly divided into five parts (three context subsequences and two annotated nominals) based on the two marked nominals (Section 3.1). Next, the model computes the distributed representations for the context subsequences using a bidirectional LSTM that works on word vectors (Section 3.2). Lastly, these distributed context representations are further encoded into a sentence representation via a bidirectional RNN (Section 3.3). Furthermore, we extend this model with a neural attention that encourages the model to focus on important information.

3.1 Context Subsequences

In most cases different contexts have different functions for the meaning of sentences. Some recent work fell into the idea that the middle context contains the most relevant information for relation classification, combining the middle context with the left and right context respectively (Zhang et al., 2015; Thang Vu et al., 2016). We instead model each context part independently, which allows the model to automatically identify contexts that contain useful information.

Given a sentence *s* and its annotated nominals e_1 and e_2, the sentence first is split into five parts according to the two annotated nominals: the left context subsequence, entity e_1, the middle context subsequence, entity e_2 and the right context subsequence. Preprocessing the sentence in such a way allows the model to encode each context subsequence independently.

3.2 Context Subsequence Composition

3.2.1 Word Encoder

A bidirectional LSTM (Bi-LSTM) (Graves and Schmidhuber, 2005; Graves et al., 2013) is applied to independently encoding each of the three context subsequences. A bidirectional LSTM consists of two LSTMs: the forward and backward LSTMs. They are run in parallel: the forward LSTM inputs the words from x_1 to x_T, and the backward LSTM inputs in an reverse order from x_T back to x_1. At time step *t*, we obtain the hidden state (denoted as h_t) of the bidirectional LSTM by concatenating the forward hidden state (denoted as $\overrightarrow{h_t}$) and the backward one (denoted as $\overleftarrow{h_t}$), i.e., $h_t = [\overrightarrow{h_t}, \overleftarrow{h_t}]$. Bi-LSTM can summarize the information from the whole context subsequence centered around words, which let the model understand the meaning of words comprehensively.

Given a sentence *s* divided into the left context subsequence c_1, the middle context subsequence c_2 and the right context subsequence c_3, we assume that the sentence *s* contains *L* words and the context subsequence c_i has T_i words, where *i* $\in [1, 3]$. The input to Bi-LSTM is a context subsequence c_i: [x_{i1}, ..., x_{iT_i}] where x_{it} is the word vector for word w_{it}. At time step *t*, the encoder produces a hidden state h_{it} which gathers the information of the whole context subsequence c_i centered around w_{it}. The equations are following:

$$\overrightarrow{h_{it}} = \overrightarrow{LSTM}(x_{it}) \tag{3}$$

$$\overleftarrow{h_{it}} = \overleftarrow{LSTM}(x_{it}) \tag{4}$$

$$h_{it} = concat(\overrightarrow{h_{it}}, \overleftarrow{h_{it}}) \tag{5}$$

where *concat* is concatenation function, i.e., h_{it} = [$\overrightarrow{h_{it}}$; $\overleftarrow{h_{it}}$].

Note that our model encodes the left, middle and right context subsequence independently but with one Bi-LSTM. [1]

3.2.2 Word-level Attention

Due to the fact that raw sentences contain more information than the shortest dependency paths, there may be some irrelevant information in raw sentences. For concentrating on these words that are important to predict the relationship of entities, it can be a good strategy to pay more attention on these words. To encourage such behavior, this paper introduces a word-level attention mechanism. The attention mechanism enables the model to differently attend over the hidden vectors of Bi-LSTM along a context subsequence, and produces a weighted representation m_i of them as follows:

$$\begin{aligned} z_{it} &= tanh(W^{(w)} h_{it} + W^{(c)} r_i + b) \\ \alpha_{it} &= \frac{exp(v_z^\top z_{it})}{\sum_{j=1}^{T_i} exp(v_z^\top z_{ij})} \\ m_i &= \sum_{t=1}^{T_i} \alpha_{it} h_{it} \end{aligned} \tag{6}$$

where $W^{(w)}$ and $W^{(c)}$ are weight matrices, *b* is a bias vector, v_z is a weight vector and $v_z^\top$ is its transformation, and r_i is an external context vector that is randomly initialized and jointly optimized during training.

The attention representation z_{it} corresponding to the *t*-th word w_{it} in the context subsequence c_i is computed via a non-linear combination of the hidden state h_{it} and the external context vector r_i. The attention weight α_{it} for the *t*-th word w_{it} in the context subsequence c_i is a probability that is the normalized weight of z_{it} (parameterized by v_z) through a softmax layer, reflecting the importance of the *t*-th word w_{it} with respect to the meaning of the context subsequence c_i in classifying the relationship of two entities. The external context vector r_i not only represents the high-level meaning of the context subsequence c_i, but also allows the model to identify that the word w_{it} is in the context subsequence c_i.

3.3 Sentence Composition

After establishing an attention-based Bi-LSTM (Section 3.2) to capture the meaning of three context subsequences, resulting in three context representations, there is one difficulty that how to further obtain the semantic composition of these context representations plus two representations of marked nominals. Note that there are five semantic representations. The most common approach is that a multilayer perceptron (MLP) is adopted to take these representations as input and compute semantic compositionality

[1] We adopt Bi-LSTM to encode each context subsequence separately even if it contains few words, such as one word.

for them. In this work, we adopt a Bi-RNN to integrate syntactics and semantics of three context subsequences and two annotated nominals into sentence representation *s*, which is further fed into a classifier for relation classification. We propose to learn sentence representations via Bi-RNNs for two reasons: (1) a sentence containing two annotated nominals divided into three context subsequences that are ordered as in the sentence, can be treated as a short sequence that consists of five tokens; (2) recurrent neural networks are competent enough to model the semantics of these context subsequences and their inherent relations, which is important to obtain the semantic meaning of the sentence. The experimental results demonstrate that Bi-RNNs significantly outperform MLP.

Let Y be a matrix containing five column vectors [m_1, m_{e_1}, m_2, m_{e_2}, m_3], where m_i ($i \in [1, 3]$) is the representation of the context subsequence c_i, and m_{e_1} and m_{e_2} are the representations of annotated nominals e_1 and e_2. [2] To obtain compositional vector representations for sentences, we iterate the following sequence of equations:

$$\overrightarrow{h_j} = \overrightarrow{RNN}(y_j) \tag{7}$$

$$\overleftarrow{h_j} = \overleftarrow{RNN}(y_j) \tag{8}$$

$$h_j = concat(\overrightarrow{h_j}, \overleftarrow{h_j}) \tag{9}$$

where $y_j \in Y$ (j $\in [1, 5]$) is the *j*-th column vector in Y.

Note that the sentence only contains five elements, our model do not make any assumptions about the type of RNNs used in this subsection. But as far as comparison goes, LSTMs performs better than the standard RNNs.

To selectively focus on the important context subsequences, it is an alternative solution to applying neural attention to the hidden vectors of the above Bi-RNNs, similar to Subsection 3.2.2. We also make further extensions such as average pooling and max pooling.

3.4 Training

A fully connected softmax layer is used as classifier for classification. It produces the probability distribution *p* over relation types conditioned on the sentence representation *s*:

$$p = softmax(W^{(s)}s + b^{(s)}) \tag{10}$$

The training objective is to minimize the cross-entropy error between the ground truth and predicted label. The parameters of our model are optimized using AdaGrad (Duchi et al., 2011) with a learning rate of 0.01, a mini-batch size of 5 and a L_2 regularization coefficient of 10^{-6}. The details are described further in Section 4.2.

4 Experiments and Evaluation

4.1 Dataset

In our experiments, we evaluate our model on the SemEval-2010 Task 8 dataset (Hendrickx et al., 2010), which is one of the most widely used benchmarks for relation classification. The dataset contains 10,717 annotated sentences divided into 8,000 sentences for training and 2717 for testing. Each sentence is annotated with each of nine different relationship and an artificial relation *Other*, and each relationship has two direction except for the undirected relation *Other*. The nine directed relations are *Cause-Effect, Instrument-Agency, Product-Producer, Content-Container, Entity-Origin, Entity-Destination, Component-Whole, Member-Collection, and Message-Topic*.

The official evaluation metric is the macro-averaged F1-score (excluding *Other*), and takes into consideration the directionality. We use the official scorer to test the model performance.

[2] We use an additional *tanh* layer to map the word vectors of annotated nominals e_1 and e_2 to the dimensionality of the hidden size of the Bi-LSTM.

4.2 Implementation

We tune the hyperparameters for our model using 5-fold cross-validation. We pretrain 200-dimensional word embeddings using *word2vec* (Mikolov et al., 2013) on the English Wikipedia corpus, and randomly initialize other hyperparameters. We set the LSTM dimension to be 200. We apply dropout only on the word embeddings and outputs of LSTM as in (Zaremba et al., 2014b), and the dropout rate is 0.2.

To enable a direct comparison with the previous work, we use the same features: position features, WordNet hypernyms and NER. WordNet hypernyms and NER were obtained using the tool of Ciaramita and Al-tun (2006). [3]

4.3.1 The Effect of Different Components

The effect of neural network architectures We first analyze the effect of different neural network architectures of the combinations of Bi-LSTM with MLP, a standard Bi-RNN and Bi-LSTM separately. Here we apply neural attention to the hidden states of RNNs (Bi-LSTM and Bi-RNN). To ensure the number of parameters comparable, we adopt a two-layer full-connected neural network with the hidden size of 600 dimension and a non-linear function of *tanh* to serve as MLP. And the hidden size of the standard RNN is 350-dimensional. From Table 1a, we find that both the combinations of Bi-LSTM with Bi-RNN and Bi-LSTM outperform the combination of Bi-LSTM and MLP without any features. In particular, the combination of Bi-LSTM and Bi-LSTM achieves the best result 83.90% without any feature, and its F1-score is about 1.5% higher than the model of Bi-LSTM+MLP. The results indicate that the neural architecture of two Bi-LSTMs effectively captures semantic meanings of these context subsequences and their inherent relations, and obtains more robust sentence representations for relation classification. In this paper, we tackle the relation classification task using the combination of two Bi-LSTMs.

The comparison of different methods Table 1b shows experiments for our model with various methods for the hidden vectors of Bi-LSTMs. We begin with the model using the concatenation of the final state of forward and backward LSTMs. And then we replace concatenation operation with average pooling, max-pooling and neural attention respectively. Not surprisingly, processing the hidden vectors of Bi-LSTMs via neural attention achieves the best result, which gives an improvement of 2.23 percentage points in F1-score over max-pooling. We suspect that this is due to the attention model being run in a more focused way that makes it easier to capture large important information from contexts. We also consider the impact of features for these methods. Results in Table 1b show that by adding features the F1-scores of all methods improve, which hints that three features are useful for relation classification.

4.3.2 Comparison with State-of-the-art Models

Table 2 compares our model with several start-of-art models. The SVM model (Rink and Harabagiu, 2010) is used for relation classification by combining lexical and semantic features. It extracts these hand-crafted features from sentences with the use of many external resources. Socher et al. (2012) extend the recursive neural networks with matrix-vector spaces (MV-RNN), and use MV-RNN to learn representations along the constituency tree for relation classification. Yu et al. (2014) propose factor-based compositional embedding models (FCM) for relation classification. It learns representations for the substructures of an annotated sentence, which are further used for classification. Zeng et al. (2014) exploit a convolutional neural network (CNN) to extract lexical and sentence level features for relation classification. And they design position features to specify the target nouns in the sentence, which leads to better performance for their model. CR-CNN outperforms the state-of-art by using a new ranking loss function and omitting the representation of the *Other* class for diminishing its effect, as proposed by (Dos Santos et al., 2015). Zhang et al. (2015) utilized bidirectional LSTMs (BLSTM) to capture the sentence level features and concatenated them and lexical level features to form the finally feature vector for relation classification. Liu et al. (2015) design a dependency-based framework (DepNN) to learn semantic representations of the augmented dependency paths that are the combination of the shortest dependency paths and their dependency subtrees. Xu et al. (2015a) build multiple LSTMs to model the different channels of word vectors, POS, grammatical relations, and WordNet along the shortest dependency paths and achieves an F1-score of 83.7 (SDP-LSTM). Xu et al. (2015b) propose to learn a robust representation using a convolutional neural network that works on the dependency path between subjects and objects, and propose a negative sampling strategy (NS) to address the relation directionality (DepLCNN). Thang Vu et al. (2016) design extended middle context and present a new context representation for convolutional neural networks for relation classification (ER-CNN). And they also propose connectionist bi-directional recurrent neural networks (R-RNN) that adds a connection to the hidden states of bi-directional recurrent neural networks.

We observe in Table 2 that our model is comparable to the state-of-the-art (previous best result is 84.0% obtained by depLCNN + NS) without any features, whereas depLCNN works on the shortest dependency

Model	Feature Set	F1
CR-CNN	-	82.8
	+position features	84.1
R-RNN	+position features, position indicators, entity flag	83.4
ER-CNN	+position features, extended middle context	84.2
ER-CNN + R-RNN	+all features, voting scheme	84.9
Our model	-	84.1
	+position features	84.5

Table 3: Comparison of ranking models (no lexical features).

paths, which consist of most relevant information and avoid negative effect from irrelevant parts in the sentences. This result suggests that our model automatically focuses on important information related to determining the relationship of two entities. The F1-score is improved by adding three features but not as obvious as in (Zeng et al., 2014; Xu et al., 2015b) (CNN, depLCNN). We argue that this is due to Bi-LSTMs being able to learn position information on sequences and lexical features leading to overfitting as in (Yu et al., 2014; Liu et al., 2015).

4.3.3 Comparison of ranking models

For fair comparison, we also replace the softmax layer with a ranking layer to train our model, as proposed in (Dos Santos et al., 2015). We use training settings following Thang Vu et al. (2016). More details about ranking layer are described in (Dos Santos et al., 2015; Thang Vu et al., 2016).

From Table 3, we observe that our model outperform the state-of-the-art without any feature, whereas previous work's best reported performance is 83.9% in ER-CNN using word embeddings of size 400. Combining ER-CNN and R-RNN using a voting scheme achieves a state-of-the-art result of 84.9 in F1-score, which is presented by (Thang Vu et al., 2016). But our model reaches a new state-of-the-art result with a single model when position features are added, and outperforms the model of ER-CNN that learns context representations for two contexts of the combinations of the middle context with the left and right context respectively.

5 Conclusion

In this work, we introduce a hierarchical recurrent neural network model that learns useful features from raw sentences for relation classification. We further extend the model with neural attention at two different levels that provides significant improvements over the concatenation, average pooling and max-pooling. Our model shows comparable performance to the state-of-the-art on the SemEval-2010 Task 8 dataset without using any costly hand-crafted features. In addition, the models presented here are general hierarchical models, and are therefore suitable for hierarchical structures, such as paragraphs and documents.

Abstract

This paper describes a unified neural architecture for identifying and classifying multi-typed semantic relations between words in a sentence. We investigate two typical and well-studied tasks: *semantic role labeling* (SRL) which identifies the relations between predicates and arguments, and *relation classification* (RC) which focuses on the relation between two entities or nominals. While mostly studied separately in prior work, we show that the two tasks can be effectively connected and modeled using a general architecture. Experiments on CoNLL-2009 benchmark datasets show that our SRL models significantly outperform state-of-the-art approaches. Our RC models also yield competitive performance with the best published records. Furthermore, we show that the two tasks can be trained jointly with multi-task learning, resulting in additive significant improvements for SRL.

1 Introduction

Semantic relation identification and classification are important problems towards the understanding of natural language sentences. Multi-typed semantic relations have been defined between two terms in a sentence in natural language processing (NLP) to promote various applications. For instance, the task of *Semantic Role Labeling* (SRL) defines shallow semantic dependencies between arguments and predicates, identifying the semantic roles, e.g., *who did what to whom, where, when, and how*. SRL has been a long-standing and challenging problem in NLP, primarily because it is strongly dependent on rich contextual and syntactical features used by the underlying classifiers (Gildea and Jurafsky, 2002). Another instance is *Relation Classification* (RC) which assigns sentences with two marked entities (or nominals) to a predefined set of relations (Hendrickx et al., 2010). Compared with SRL, relations defined in RC express much deeper semantics. Figure 1 shows example annotations of SRL and RC respectively.

These two problems are typically studied separately in different communities. Hence the connections between them are neglected, both in data resources and approaches. In this paper, we show that SRL and RC have a lot of common ground and can be modeled with a unified model. We start by looking into the key features which have been proven dominant in both SRL and RC.

- Contextual features. Words within a proper window size of the target words are important for most statistical models of various NLP tasks, such as Part-of-Speech tagging, Named Entity Recognition and Parsing. They are also important for identifying the semantic relatedness between two terms in a sentence. Consider the RC example in Figure 1(b), the context word "*moved*" is a strong indicator for classifying the relation of ⟨**People**, **downtown**⟩ as *Entity-Destination*. However, most of the conventional approaches in SRL and RC only considers local context features through feature engineering, which might be incomplete.

- Syntactical features. Both state-of-the-art SRL and RC systems employ the syntactic path between the two target terms as an important feature. Figure 1 shows the dependency parses for

(a) Semantic Role Labeling. (b) Relation Classification.

Figure 1: Examples of *semantic role labeling* (a) and *relation classification* (b).

the two sentences. For example, the dependency path between "meetings" and the predicate "**holding**" ("holdings" $\xrightarrow{OBJ}$ "meetings") strongly indicates an A1 relation (*patient* role). Early approaches built in discrete feature space are not capable of utilizing the *word path* features which are extremely sparse. Fortunately, recent progress in distributed representations and deep neural networks provides a promising solution for this problem.

- Lexical semantic features. Lexical properties of a word (e.g., the identity of a word, its lemma, its morphological features) are important for semantic tasks. Particularly in tasks like relation classification, it is often impossible to determine the relation without the semantic ground of the target words. Therefore, previous approaches have been using lexical features like word embeddings, lemmas, WordNet, etc.

This paper describes a unified neural model for SRL and RC that effectively utilizes the three kinds of features above. Our model captures global contextual features and syntactic path features by using bidirectional long short-term memory (LSTM)-based recurrent neural networks. We especially focus on SRL which, in our opinion, is more complicated and difficult. SRL is a structure prediction task with certain structural constraints. To this end, an additional post-inference procedure based on integer linear programming (ILP) is applied to SRL, in order to meet the constraints. Furthermore, our unified model successfully connects SRL and RC, presenting the possibility of *multi-task learning*. We show that the SRL performance can be significantly improved through knowledge transfer from RC.

We conduct experiments on the CoNLL-2009 shared task datasets for SRL, and the SemEval-2010 Task 8 dataset for RC. On SRL, our models significantly outperform previous approaches in various languages. On RC, our model also obtains performance competitive to the state-of-the-art.[1]

Our primary original contributions include:

- We propose a unified model for SRL and RC, which effectively captures global contextual features, syntactical features and lexical semantic features.
- We show that SRL can be significantly improved by jointly training with RC, reaching new state-of-the-art performance.

2 Related Work

The present work ties together several strands of previous studies.

Semantic Role Labeling A great deal of previous SRL research has been dedicated to designing rich and expressive features, pioneered by Gildea and Jurafsky (2002). For instance, the top performing system on the CoNLL-2009 shared task employs over 50 language-specific feature templates (Che et al., 2009). These features mostly involve the predicate, the candidate argument, their contexts and the syntactic path between them (Surdeanu et al., 2003; Xue and Palmer, 2004; Pradhan et al., 2005). Besides, higher-order features involving several arguments or multiple predicates have also been explored (Toutanova et al., 2008; Martins and Almeida, 2014; Yang and Zong, 2014).

[1]Our code is available at: `https://github.com/jiangfeng1124/nnsrl-rc`.

Several approaches have been studied to alleviate the intensive feature engineering in SRL and get better generalization. Moschitti et al. (2008) introduce different kinds of tree kernels for capturing the structural similarity of syntactic trees. While attractive in automatic feature learning, the kernel-based approaches typically suffer from high computational cost. Lei et al. (2015) instead use low-rank tensors for automatic feature composition based on four kinds of basic feature sets. However, tensor-based approaches cannot well generalize the high-sparsity structural features like syntactic path. Besides, they still need a relatively small amount of feature engineering to make use of the local contexts. Another line of research focuses on neural models (Collobert et al., 2011; Zhou and Xu, 2015; FitzGerald et al., 2015), which have shown great effectiveness in automatic feature learning on a variety of NLP tasks. Most recently, Roth and Lapata (2016) employ LSTM-based recurrent neural networks to obtain the representations of syntactic path features, which is similar to our work. Aside from the distributed path features, they also use a set of binary input feature sets from Anders et al. (2010). In contrast to these prior work, our model jointly leverages both global contexts and syntactic path features using bidirectional LSTMs.

Relation Classification Early research on RC has also been relying heavily on human-engineered features (Rink and Harabagiu, 2010). Recent years have seen a great deal of work on using neural networks to alleviate the intensive engineering on contextual and syntactic features. For example, Socher et al. (2012) propose recursive neural networks for modeling the syntactic paths between the two entities whose relation is to be determined. Zeng et al. (2014) use convolutional neural network for learning sentence-level features of contexts and obtain good performance even without using syntactic features. Later approaches have used more sophisticated models for better handling long-term dependencies, such as sequential LSTMs and tree LSTMs (Liu et al., 2015; Xu et al., 2015b; Miwa and Bansal, 2016). In addition, Yu et al. (2014) and (2015) investigate tensor-based approaches for learning the combination of embedding features and lexicalized sparse features.

Therefore, despite that relation classification has mostly been studied separately from SRL, they have a substantial amount of commonalities. It inspires us to develop a potentially unified architecture to take advantage of the progress in each research direction.

Multi-task Learning There has been a line of research on joint modeling pipelined NLP tasks, such as word segmentation, POS tagging, parsing and semantic role labeling (Hatori et al., 2012; Li et al., 2011; Bohnet and Nivre, 2012; Henderson et al., 2013; Lluís et al., 2013). Most multi-task learning or joint training frameworks can be summarized as parameter sharing approaches proposed by Ando and Zhang (2005). In the context of neural modeling for NLP, the most notable work was proposed by Collobert and Weston (2008), which aims at solving multiple NLP tasks within one framework by sharing common word embeddings. This work also inspires us in this study to develop a unified architecture for SRL and RC in prior to joint training.

Recently, the idea of neural multi-task learning was applied to sequence-to-sequence problems with recurrent neural networks. Dong et al. (2015) use multiple decoders in neural machine translation systems that allows translating one source language to many target languages. Luong et al. (2015) study the ensemble of a wide range of tasks (e.g., syntactic parsing, machine translation, image caption, etc.) with multi-task sequence-to-sequence models. Liu et al. (2016) incorporate different kinds of corpus for implicit discourse relation classification using multi-task neural networks. More recently, multi-task learning has also been applied to sentence compression (Klerke et al., 2016) and machine translation quality estimation (Shah and Specia, 2016).

3 Problem Definition

This section gives formal definitions of the two tasks to be investigated: SRL and RC.

3.1 Semantic Role Labeling

We follow the setup of the CoNLL-2009 shared task. Given a sentence $\mathbf{s}$, each token is annotated with a predicated POS tag and predicted word lemma. Some tokens are also marked as predicates. Besides,

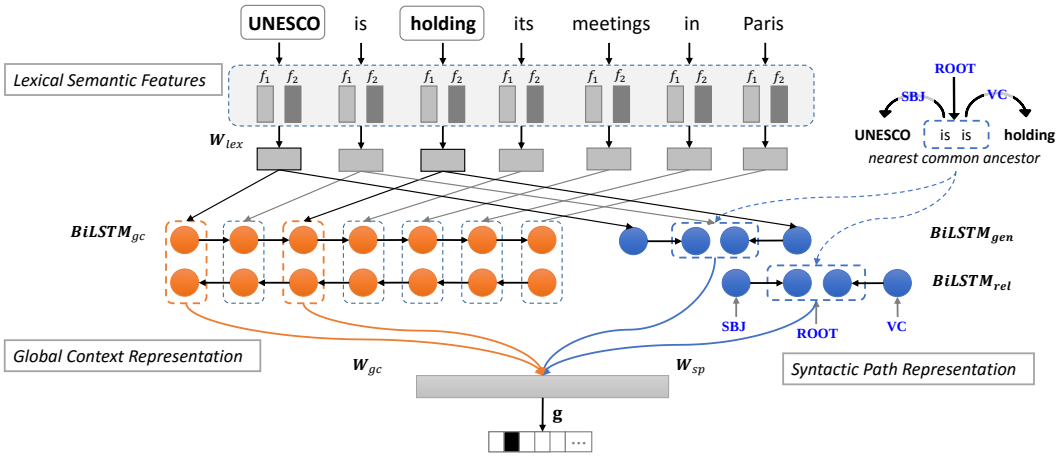

Figure 2: The unified architecture for SRL and RC.

a predicted syntactic dependency tree y_{syn} is also provided (cf. below part of Figure 1(a)). The goal is to determine the semantic dependencies for each predicate p_i (cf. upper part of Figure 1(a)). These dependencies identify the arguments of each predicate and the role labels.

In this work, we focus on the identification and classification of the arguments associated with given predicates. More formally, for each predicate p_i in $\mathbf{s}$, we loop over all the tokens in $\mathbf{s}$ except p_i: $\{w \in \mathbf{s} | w \neq p_i\}$, and determine their role labels. It can be considered as a classification problem with each instance as a word pair $\langle p_i, w \rangle$. We include an additional *NULL* label indicating that a token is not an argument of p_i. To guarantee the resulting semantic dependencies meet certain constraints, we further apply ILP over the output probabilities in each position for post-inference (Section 4.4).

3.2 Relation Classification

As demonstrated in Figure 1, the semantic relations specified in relation classification are totally different from SRL. SRL is more close to the syntactic dependencies while RC is totally semantic. Our setup follows the SemEval-2010 Task 8. Each sentence $\mathbf{s}$ is annotated with a pair of nominals e_1 and e_2, and our goal is to identify the relation between e_1 and e_2. Nine relations are defined in the task, and the directionality of relation between e_1 and e_2 is considered in the evaluation. Relations that do not belong to the nine relations are marked as *Other*.

4 Unified Neural Architecture

As described above, both SRL and RC can be formalized as a classification problem over instances of word pairs within a sentence. We propose a unified neural architecture, as illustrated in Figure 2, for modeling these two tasks. Our architecture includes the following three primary components.

4.1 Lexical Feature Representation

We extract basic lexical features for each token in a sentence. Typical lexical features for SRL and RC include word (or *lemma* when available) and POS tag. For RC, additional features can be used, such as *named entity type* (NE) and WordNet. All these features are then represented as low-dimensional real-valued vectors, i.e., feature embeddings. Word embeddings can be readily pretrained using *word2vec* on a large unlabeled corpus, which have proved helpful in many applications. Next, various feature embeddings are composed through a nonlinear transformation, and thus a token can be represented as:

$$\begin{aligned} &\mathbf{x}_i = \texttt{ReLU}(\mathbf{W}_{lex}\mathbf{\Phi}_i + \mathbf{b}_{lex}), where \\ &\mathbf{\Phi}_i = [\mathbf{w}_i; \mathbf{p}_i] \ \ for \ \ \textbf{SRL}, \ \ \mathbf{\Phi}_i = [\mathbf{w}_i; \mathbf{p}_i; \mathbf{ne}_i; \mathbf{wn}_i] \ \ for \ \ \textbf{RC} \end{aligned} \tag{1}$$

$\mathbf{w}_i$ represents the word or lemma (when available), $\mathbf{p}_i$ represents the POS tag, $\mathbf{ne}_i$ is the named entity, and $\mathbf{wn}_i$ is the WordNet hypernym.

4.2 Global Context Representation

We obtain global context representations of the target words by using bidirectional LSTM-based RNNs. For more computation details of LSTM, we refer the readers to Hochreiter and Schmidhuber (1997). The LSTMs take as input the token representation $\mathbf{x}_i$ in each position. The hidden state vectors of the two directions' LSTM units corresponding to each target word are then concatenated as its global context representation:

$$\mathbf{R}^{gc}_{e_1} = [\overrightarrow{\mathbf{h}}_{e_1}; \overleftarrow{\mathbf{h}}_{e_1}]; \quad \mathbf{R}^{gc}_{e_2} = [\overrightarrow{\mathbf{h}}_{e_2}; \overleftarrow{\mathbf{h}}_{e_2}] \tag{2}$$

Note that an important difference between our model and previous neural models is that we utilize the hidden state vectors of e_1 and e_2 instead of the representation of the whole sentence, which frees us from using position-related features (Zeng et al., 2014; Collobert et al., 2011; dos Santos et al., 2015).

4.3 Syntactic Path Representation

We define the *nearest common ancestor* token of e_1 and e_2 as $nca(e_1, e_2)$. Then the path from e_1, e_2 to $nca(e_1, e_2)$, i.e., $e_1 \rightarrow \ldots \rightarrow nca(e_1, e_2)$ and $nca(e_1, e_2) \leftarrow \ldots \leftarrow e_2$, are also modeled with bidirectional LSTMs, as shown in Figure 2 (right panel). We use two kinds of syntactic paths, including a *generic path* that takes the token representation $\mathbf{x}_i$ as input, and a *relation path* that takes the dependency relations along the path as input (Figure 2). These two paths are modeled with $\mathbf{BiLSTM}_{gen}$ and $\mathbf{BiLSTM}_{rel}$ respectively. The hidden state vectors of the two directions' LSTM units of $nca(e_1, e_2)$ are then concatenated as the syntactic path representation of (e_1, e_2):

$$\mathbf{R}^{gen}_{(e_1,e_2)} = [\overrightarrow{\mathbf{h}}^{gen}_{nca(e_1,e_2)}; \overleftarrow{\mathbf{h}}^{gen}_{nca(e_1,e_2)}]; \quad \mathbf{R}^{rel}_{(e_1,e_2)} = [\overrightarrow{\mathbf{h}}^{rel}_{nca(e_1,e_2)}; \overleftarrow{\mathbf{h}}^{rel}_{nca(e_1,e_2)}] \tag{3}$$

The global context representations and syntactic path representation are then composed through a non-linear layer, resulting in the representation used for final classification.

$$\mathbf{p} = \texttt{ReLU}(\mathbf{W}_{gc}\underbrace{[\mathbf{R}^{gc}_{e_1}; \mathbf{R}^{gc}_{e_2}]}_{\text{Global Context}} + \mathbf{W}_{sp}\underbrace{[\mathbf{R}^{gen}_{(e_1,e_2)}; \mathbf{R}^{rel}_{(e_1,e_2)}]}_{\text{Syntactic Path}} + \mathbf{b}) \tag{4}$$

$$p(c|\mathbf{p}) = \texttt{softmax}(\mathbf{g}_c^\top \mathbf{p} + \mathbf{q}_c) \tag{5}$$

Our model is trained by minimizing the cross-entropy loss: $\mathcal{L}(\theta) = -\sum_{i=0}^{N} \log p(c_i|\mathbf{p}_i)$, where N is number of training instances.

4.4 Post-Inference with Integer Linear Programming for SRL

SRL is a structure prediction problem and the predicted results should satisfy some structural constraints. For instance, some roles only appear once for a predicate in a sentence. Following Punyakanok et al. (2004) and Che et al. (2008), we apply ILP on the probability distributions at each token generated by our model to get the global optimization. We use the three constraints defined in Che et al. (2008):

- C1: Each word should be labeled with one and only one label (including *NULL*).
- C2: Roles with a small probability (smaller than 0.3) should never be labeled (except for *NULL*).
- C3: Some roles (except for *NULL*) usually appear once for a predicate in a sentence. Hence a non-duplicate-roles list is utilized for each language.

5 Multi-task Learning

The commonalities between SRL and RC inspire us to explore their potential mutual benefits. According to the *Shortest Path Hypothesis* (Bunescu and Mooney, 2005), if e_1 and e_2 are two entities mentioned in the same sentence such that they are observed to be in a certain relationship R, they often indicate two arguments of the same predicate or a sequence of predicates. To gain more insights, let's look at the following example in RC:

"The **author**$_{[e_1]}$ of a keygen uses a **disassembler**$_{[e_2]}$ to look at the raw assembly code."

Here, the "Instrument-Agency" relation provides significant evidences that **author** and **disassembler** are two arguments of a certain predicate, most likely with semantic roles A0 (agent) and A1 (patient). Furthermore, given the dependency parse tree, it's easy to find out that their associated predicate is "uses". Therefore, RC is expected to benefit both the identification and classification of semantic roles. Analogously, SRL results of a sentence also have positive impacts to the *identification* of semantic relations between e_1 and e_2, i.e. whether or not a relation exists between e_1 and e_2.

However, the roles defined in SRL can hardly contribute to the *classification* of much more fine-grained relation types in RC. For example, the roles A0, A1 can hardly help us to distinguish between the relation types like *Instrument-Agency*, *Product-Producer*, *Cause-Effect*, etc. Given this intuition, we will mainly focus on improving SRL with RC in this work.

Our proposed unified model allows knowledge transfer across SRL and RC in a natural way through parameter sharing. In this work, we consider two ways of knowledge transfer.

- Cascaded Learning (CAS). Models are trained in a cascaded manner. Specifically, a RC model is trained first, and then the parameters (e.g., word embeddings, network weights) are used to initialize the neural network for training SRL in the second stage.
- Multi-task Learning (MTL). Models are trained jointly in a stochastic manner:
  1. Select a task according to a certain probability distribution (explained below).
  2. Sample a batch of instances from the task, and feed-forward the neural network.
  3. Update the corresponding parameters by back-propagation w.r.t. the instances.
  4. Go to 1.

In multi-task learning, two important factors are taken into account. First, we typically expect the two tasks to converge at a similar rate (Caruana, 1997). We approximately achieve this by using a **weighted task sampling** strategy in step 1. More specifically, we observe that SRL converges about 4 times slower than RC by running them separately, hence we sample from SRL 4 times often than RC during training. Despite the lack of theoretical guarantee, we found it working well in practice. Second, the key for multi-task learning to work is **parameter sharing**. Given the unified architecture, we can share most of the network parameters for knowledge transfer. Note that different dependency parses might be used for SRL and RC in practice. In this work, we use the officially provided predicted parses from CoNLL-2009 shared task in SRL, but adopt Stanford parser (Manning et al., 2014) to obtain parses for sentences in RC. These kinds of parses are quite different in terms of both the head-finding rules and the dependency relations. Therefore, we set the parameters involving dependency path modeling as *task-specific*, i.e., $\mathbf{BiLSTM}_{gen}, \mathbf{BiLSTM}_{rel}$ and $\mathbf{W}_{sp}$ (Figure 2). The output weights ($\mathbf{g}$) are *task-specific* as standard of multi-task learning, in order to handle different set of relations to be classified in SRL and RC.

6 Experiment

In this section, we first describe data and our experimental settings, then the results and analysis.

6.1 Data and Settings

For SRL, we evaluate on the English dataset and other 4 languages (Chinese, Catalan, German and Spanish) in the CoNLL-2009 shared task. We use the official split for training, development and testing. In addition, a subset of the Brown corpus is used as the out-of-domain test set. We use the officially provided predicted POS tags, lemmas and dependency parses as our input. All predicates are given for each sentence during both training and testing. Besides, we neither predict nor use the sense for each predicate, and thus exclude the predicate senses in most of the evaluation. We follow Lei et al. (2015) and combine the predicate sense output of Anders et al. (2010) with our SRL output, to provide results directly comparable to previous published results.

We compare our model to several state-of-the-art systems, primarily including the best performing system in CoNLL-2009 shared task, the most recently proposed PathLSTM model of Roth and Lapata (2016), the neural network model of FitzGerald et al. (2015), and the low-rank tensor model of Lei et al. (2015). We also consider some variants of the above models that use reranking or model ensemble.

For RC, we use the relation classification dataset of the SemEval 2010 task 8. The dataset contains 10,717 annotated sentences, including 8,000 for training and 2,717 for testing. We conduct 5-fold cross-validation to determine the best training iterations, and use the official scoring script for evaluation.

Several competitive models are to be compared, including the top performed system in SemEval 2010 (Rink and Harabagiu, 2010), the Matrix-Vector Recursive Neural Network (MV-RNN) model of Socher et al. (2012), the CNN model of Zeng et al. (2014), the tensor-based model of Yu et al. (2014), the CNN model using ranking loss (dos Santos et al., 2015), and the dependency-based neural network models (Liu et al., 2015; Xu et al., 2015b).

Word embeddings are pretrained using *word2vec* on large-scale unlabeled data. For English, Catalan, German and Spanish, we use the latest Wikipedia data. For Chinese, we obtain the raw text from Xinhua news section (2000–2010) of the fifth edition of Chinese Gigaword (LDC2011T13). The LTP toolkit (Che et al., 2010) is applied to segment Chinese text into words.

We adopt *predicate-wise* training for SRL and *sentence-wise* training for RC, and use stochastic gradient descent for optimization. Initial learning rate is set to $\eta_0 = 0.1$ and updated as $\eta_t = \eta_0/(1+0.1t)$ on each epoch t. Our hyperparameters for the unified model are listed in Table 1. When training RC-only models, the LSTM input/hidden dimension is set to 200, and the dimension of hidden layer is 400.

Dimension of embeddings				Dimension of layers		
word	*POS*	*NE*	*WordNet*	*LSTM input*	*LSTM hidden*	*hidden*
200	25	25	25	100	100	200

Table 1: Hyperparameters settings.

6.2 SRL Results

Table 2 reports the SRL performance on the English dataset. Our supervised models (SUP) outperform the six top performing systems on both in-domain and out-of-domain datasets (the second block), and is comparable to two top systems that use reranking or model ensemble (the third block).

Effect of transfer learning By comparing the cascaded training system (CAS), the multi-task learning system (MTL) with SUP, we can find that the task of RC is significantly helpful for improving SRL models. In particular, MTL consistently works better than CAS. Our best models (MTL) outperform all of the previous systems, and achieve new state-of-the-art SRL results.

Figure 3 shows the learning curves of SUP, CAS and MTL on development data. At early training iterations, CAS is very close to MTL, and improves faster than SUP, indicating that the RC parameters indeed serve as a good initialization for SRL. MTL gradually outperforms CAS as the training converges, which further verifies the advantage of joint training over cascaded training.

Effect of post-inference We further investigate the effect of post-inference with ILP. As shown in Table 3, ILP has a considerable impact on the final SRL performance consistently for all of our models.

Multilingual Results Table 4 shows the results of our SRL-only system (SUP) on other languages in the CoNLL-2009 shared task. Our model outperforms the best performing system on all the four languages we considered, with particularly large gains on Chinese (+6.3 absolute F1-score). Note that our model is also unified for each language, without language-specific tuning of features or hyperparameters.

6.3 RC Results

The only difference of our RC model from the SRL model is at the input layer, where we use two additional features: NE and WordNet. Table 5 shows the RC results on the SemEval 2010 task 8. Our model achieves an F1-score of 83.9%, which is comparable to the top performing systems in previous work. dos Santos et al. (2015) obtain an F1-score of 84.1% by using ranking loss, with special treatment

to the artificial relation (*Other*). Such task-specific strategy can also be potentially used in our model for further improvements. As discussed in Section 5, to our intuition, knowledge contained in SRL is not supposed to benefit RC. To verify this, we further test on RC with cascaded learning and multi-task learning. We obtain a small degradation in RC performance in both cases (-0.9 for CAS and -0.7 for MTL). Nevertheless, we still expect improvements on joint learning of SRL and *relation extraction* (rather than *classification*), which we leave to future exploration.

7 Conclusion

In this paper, we propose a unified architecture for the task of SRL and RC. We effectively capture the global contextual representation and syntactic path representations using bidirectional LSTM-based recurrent neural networks. By evaluating on benchmark datasets for both SRL and RC, we show that our models outperform or get competitive results with the state-of-the-art systems. Furthermore, we take advantage of our unified model to transfer knowledge across the two tasks using multi-task learning with parameter sharing. Our models obtain new state-of-the-art results for SRL.

Abstract

We present a successful collaboration of word embeddings and co-training to tackle in the most difficult test case of semantic role labeling: predicting out-of-domain and unseen semantic frames. Despite the fact that co-training is a successful traditional semi-supervised method, its application in SRL is very limited. In this work, co-training is used together with word embeddings to improve the performance of a system trained on CoNLL 2009 training dataset. We also introduce a semantic role labeling system with a simple learning architecture and effective inference that is easily adaptable to semi-supervised settings with new training data and/or new features. On the out-of-domain testing set of the standard benchmark CoNLL 2009 data our simple approach achieves high performance and improves state-of-the-art results.

1 Introduction

Semantic role labeling (SRL) is an essential natural language processing (NLP) task that identifies the relations between a predicate and its arguments in a given sentence. Intuitively, it aims at answering the questions of "Who did What to Whom, and How, When and Where?" in text. For example, the processing of the sentence "He bought tons of roses yesterday" should result in the identification of a "buying" event corresponding to the predicate "bought" with three arguments including "he" as the *Agent (A0)*, "tons of roses" as the *Thing being bought (A1)*, and "yesterday" as the *Time (AM-TMP)* arguments. Traditional SRL systems have concentrated on supervised learning from several manually-built semantic corpora, (e.g., FrameNet (Baker et al., 1998) and PropBank (Palmer et al., 2005)). One important limitation of supervised approaches is that they depend heavily on the accuracy, coverage and labeling scheme of the labeled corpus. When the training and the testing data are in different domains, the linguistic patterns and their distributions in the testing domain are different from the ones observed in the training data, resulting in a considerable performance drop. Developing more manually-built semantic corpora is expensive and requires huge human efforts. Thus, exploiting large unlabeled datasets by semi-supervised or unsupervised approaches is a promising solution.

Our contribution in this paper is two-fold: First, we introduce a SRL system with a simple learning architecture and effective inference that is easily adaptable to new training data or new features in semi-supervised settings. Second, we present a semi-supervised approach that is a combination of using word embeddings as extra features and using a variant of a co-training algorithm to create new training data facing the most difficult cases of SRL: improving the SRL system trained on a relatively large training dataset (CoNLL 2009) when working with the "out-of-domain" and especially "unseen" semantic frames. Although co-training is a successful traditional semi-supervised method, its application to SRL is very limited. To our knowledge, there has been no successful case of co-training applied to a large amount of training data in the literature.

In this work, we first enrich a traditional feature set of SRL by the distributional word representations induced from a large unlabeled corpus. Then, we divide the feature set into two different sets with one referring to the semantic or meaning information of the argument candidate and one referring to its

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1275–1284, Osaka, Japan, December 11-17 2016.

syntactic information based on the dependency structure. Two local classifiers are then trained, one on each of the two feature sets. Next, we label unannotated data from the same domain as the target data with these classifiers. Finally, a global classifier is trained with selected newly labeled instances and the joint feature set of the two local classifiers. Our experiments show that the combination of using distributional word representations and a co-training strategy effectively improves SRL in the challenging out-of-domain scenario. It outperforms using only word embeddings or co-training especially in unseen frames.

The rest of the paper is structured as follows. Section 2 discusses related works. We describe our SRL system and our methodology in Section 3 and Section 4 respectively. Our experiment is presented in Section 5 and Section 6 and finally we conclude in Section 7.

2 Related Work

In traditional supervised approaches, SRL is modeled as a pipeline of predicate identification, predicate disambiguation, argument identification, and argument classification steps. Hand-engineered linguistically-motivated feature templates represent the semantic structure employed to train classifiers for each step. It is common among the state-of-the-art systems to train a global reranker on top of the local classifiers to improve performance (Toutanova et al., 2005; Björkelund et al., 2010; Roth and Lapata, 2016). SRL models have also been trained using graphical models (Täckström et al., 2015) and neural networks (Collobert et al., 2011; FitzGerald et al., 2015). Some systems have applied a set of structural constraints to the argument classification sub-task, such as avoiding overlapping arguments and repeated core roles, and enforced these constraints with integer linear programming (ILP) (Punyakanok et al., 2008) or a dynamic program (Täckström et al., 2015).

Regarding leveraging unlabeled data, semi-supervised methods have been proposed to reduce human annotation efforts. He and Gildea (2006) investigate the possibility of a weakly supervised approach by using self-training and co-training for unseen frames of SRL. They separate the headword and path as the two views for co-training, but could not show a clear performance improvement. The sources of the problem appeared to be the big gap in performance between the headword and path feature sets and the complexity of the task. Some other works show slight improvements of using co-training for SRL when there is a limited number of labeled data (Lee et al., 2007; Samad Zadeh Kaljahi and Baba, 2011). Fürstenau and Lapata (2012) find novel instances for classifier training based on their similarity to manually labeled seed instances. This strategy is formalized via a graph alignment problem.

Recently, there has been interest in distributional word representations for natural language processing. Such representations are typically learned from a large corpus using neural networks (e.g., Weston et al. (2008)), probabilistic graphical models (e.g., Deschacht et al. (2012)) or term-cooccurrence statistics (e.g., Turney and Pantel (2010)) by capturing the contexts in which the words appear. Often words from the vocabulary or phrases are mapped to vectors of real numbers in a low dimensional continuous space resulting in so-called word embeddings. Deschacht et al. (2012) employ distributed representations for each argument candidate as extra features when training a supervised SRL. Roth and Woodsend (2014) propose to use the compositional representations such as interaction of predicate and argument, dependency path and the full argument span to improve a state-of-the-art SRL system.

3 A Semantic Role Labeling System for Semi-Supervised Approaches

In this section, we introduce a semantic role labeling system designed for semi-supervised settings. The system has a simple training strategy with local classifiers for different steps in SRL pipeline. Instead of training a global reranker on top of the local classifiers to improve performance as in other common pipeline-based state-of-the-art systems like (Toutanova et al., 2005; Björkelund et al., 2010; Roth and Lapata, 2016), we propose a novel joint inference technique that works across the argument identification and argument classification steps. That makes the SRL training simple (no reranker, only local classifiers) and therefore easily adaptable to new training examples or new features. We will show later in the experiment that the joint inference gives us comparable results to a reranker.

Following prior work (Toutanova et al., 2005; Björkelund et al., 2010; Roth and Lapata, 2016), our system consists of four modules: (1) A predicate identification (PI) module which detects whether a

word is a predicate. (2) A predicate disambiguation (PD) module which labels a predicate with a sense, where we train a local classifier for each predicate lemma. (3) An argument identification (AI) module that recognizes argument words, where given a predicate p, each word w_i in p's sentence is assigned a probability $P^{AI}(p, w_i)$ of being p's argument. (4) An argument classification (AC) module that assigns labels to argument words, where given a predicate p and a set of labels $\mathbf{L}$ – PropBank semantic role label set in this work, each word w_i is assigned probabilities $P^{AC}(p, w_i, L_j)$ to receive $L_j \in \mathbf{L}$ as semantic label.

We employ the features proposed by Björkelund et al. (2010) as the basic feature set. All of the local classifiers are trained using L2-regularized logistic regression. For multiclass problems, we use the one-vs-rest strategy.

At inference time, the local classifier predictions are merged using integer linear programming (ILP). In most of the prior work, ILP was only used for AC inference. However, this approach limits the interaction of AI and AC when making decisions. In another approach, Srikumar and Roth (2011) introduce a simple approach to joint inference over AI and AC allowing the two argument sub-tasks to support each other. Their local AC classifier has an empty label which indicates that the candidate is, in fact, not an argument. This forces AC module to learn also the argument identification and is in contrast with our approach in which the tasks of AI and AC classifiers are completely separated leading to a simpler AC learning. Their inference is formularized as an ILP problem that mazimizes the sum of local prediction scores over AI and AC. The authors then enforce consistency constraints between the identifier and the argument classifier predictions – the identifier should predict that a candidate is an argument if and only if the argument classifier does not predict the empty label. In this paper, we propose a novel ILP inference formulation in which the interaction of AI and AC is exploited and emphasized not only in the consistency constraint but also in the objective function.

Joint Argument Inference For each predicate, we perform joint inference over the AI and AC steps for all the words in the sentence. Given a predicate p and set of words in the sentence $w_1, w_2, ..., w_n$, each word is determined as either non-argument or as one of the semantic roles via an ILP formulation. Let $\mathbf{U}$ be the set of binary indicator variables corresponding to the decision whether w_i is a non-argument. Specifically, $u_i = 1$ if w_i is not an argument and $u_i = 0$ otherwise. Let $\mathbf{V}$ be the set of binary indicator variables corresponding to the decision whether w_i is a certain semantic role. Specifically, $v_{ij} = 1$ if w_i is assigned label L_j and $v_{ij} = 0$ otherwise.

A simple joint inference to maximize the sum of local prediction scores over AI and AC (see Srikumar and Roth (2011)) would be[1]:

$$\sum_{i=1}^{n} \left[(1 - P^{AI}(p, w_i)) * u_i + P^{AI}(p, w_i) * (1 - u_i) + \sum_{j=1}^{|\mathbf{L}|} \left(v_{ij} * P^{AC}(p, w_i, L_j) + (1 - v_{ij}) * (1 - P^{AC}(p, w_i, L_j)) \right) \right]$$

In this paper, to exploit more effectively the interaction between AI and AC, we propose to maximize the objective function:

$$\sum_{i=1}^{n} \left\{ (1 - P^{AI}(p, w_i)) * u_i * \lambda + P^{AI}(p, w_i) * \left[\sum_{j=1}^{|\mathbf{L}|} \left(v_{ij} * P^{AC}(p, w_i, L_j) + (1 - v_{ij}) * (1 - P^{AC}(p, w_i, L_j)) \right) \right] \right\}$$

Subject to:

$$\forall i : u_i + \sum_{j=1}^{|L|} v_{ij} = 1 \tag{1}$$

$$\forall j : if\ L_j\ is\ core\ role : \sum_{i=1}^{n} v_{ij} \leq 1 \tag{2}$$

[1]Note that we can not use exactly the same objective function as in Srikumar and Roth (2011) because our AC module does not produce the empty label.

λ is a parameter between 0 and 1 controlling the balance of recall and precision. If λ is small, the importance of predicting correct non-argument words is lowered, so more words are considered as argument candidates leading to the increase of recall and decrease of precision. In contrast, if λ is large, precision goes up and recall goes down.

Constraint 1 forces the system to assign either only one semantic role or a non-argument label to each word. Meanwhile, constraint 2 restricts the core roles (A0, A1, A2, A3, A4, A5, AA) to appear no more than once.

In the experiment, we will compare the performance of our proposed inference to the approaches using a reranker as in Björkelund et al. (2010) and the above simple joint inference of AI and AC.

4 Semi-supervised approach

4.1 Problem

In SRL, classifiers need linguistic clues to make a correct prediction. Two different types of clues are frequently distinguished: (1) Semantic or meaning clues. For example, when classifying arguments for the predicate "sleep", if the classifier sees the word "bed", assigning the role "AM-LOC" to the word seems reasonable. (2) Syntactic or word order clues. In the above example, if the classifier sees a candidate that is a child of the predicate in the dependency tree and has "SUBJECT" as deprel or "NNP" as part of speech (POS) tag, it is likely to be the role "A0". These clues are often helpful, but they often are not specific enough to predict the exact semantic role. For example, given the sentences "we cut the cake on Monday" and "we cut the cake on the table", the words "on" in both sentences have the same POS path to the predicate "cut", but they are two different roles ("AM-TMP" and "AM-LOC" respectively). Traditional approaches for SRL encode linguistic clues as indicator features such as the observed POS tag of a word and the syntactic path to its head. However, their occurrence is often sparse in the training data and in combination with being ambigous signals for semantic roles they do not generalize well across domains. When the target data is in a different domain, its vocabulary differs from the training data, and the classifier may fail to recognize semantic or meaning clues. If the predicate is observed in the training data, then the syntactic patterns may still be useful. However, in the worst case, if the predicate is unseen, both of the clues become weak leading to the most difficult case for SRL.

4.2 Method Description

Motivated by the successes of distributional word representations in capturing word similarity and of co-training in boosting the performance of classification by using two different views which naturally fit the two types of clues discussed above, we propose a combination of these approaches to tackle the problem. Our method, shown in Algorithm 1 and described in detail in Section 4.4, leverages unlabeled data to improve the performance of SRL. We first extend the feature set with distributional representations induced from a large unlabeled corpus. The two modules PI and PD are trained and used to label the predicate and predicate senses in the unlabeled texts. We then divide the feature sets of AI and AC into two intuitive sets, one for the semantic information of the argument candidate, and one for the syntactic information. A co-training strategy is applied twice, once to AI and once to AC. In each process, local classifiers are trained on the labeled data using the two divided feature sets. Then, we label a set of unlabeled data from the target domain using these classifiers. At the final step, selected newly labeled instances are used to train a global classifier with the joint feature set of the two local classifiers.

4.3 Word Embeddings

Instead of using the compositional representations proposed in (Roth and Woodsend, 2014), we follow a simple and natural approach to employ word embeddings: For each *word feature* (e.g., argument word, predicate word, right child word), we map its value to a distributed representation and concatenate the new representation to the original feature vector. For each *word set feature* (e.g., child word set), we sum up the distributional representations of the set elements, and concatenate the obtained vector to the original feature vector. Under this approach, word embeddings can be easily applied to any step of SRL which contains word or word set features. We will show later in the experiments that this simple approach

Table 1: The feature division for Co-training. -,N,V indicates that the feature is not used, used for nominal frames, and used for verbal frames respectively. Note that we omit distributional representation features and feature bigrams.

gives us comparable results to other state-of-the-art systems. Word embeddings also help to improve the semantic or meaning clues, and can therefore boost the performance of the co-training strategy.

4.4 Co-training

The *co-training* semi-supervised learning paradigm was first proposed by Blum and Mitchell (1998), aiming at exploiting unlabeled data to improve performance given limited training data. The classical algorithm applies when the data can be represented by two or more separate, but redundant "views" such as two disjoint feature subsets. For example, web pages can be described by either the text on the web page or the text from hyperlinks pointing to the web page. The two classifiers trained on two "views" of the data can help each other, by adding one's most confident examples into the other one's training set.

In this work, we apply a variant of co-training to the two argument steps. We propose to divide the SRL feature sets into two views based on the dependency tree. The Sem_View, which emphasizes the semantic or meaning clues (and is related to the headword view of He and Gildea (2006)), consists of all features based on the argument candidate itself and all the words that are lower than the argument candidate on the dependency tree (e.g., left child word, right child word, children word set). The Syn_View, which emphasizes syntactic clues (and is related to the path view of He and Gildea (2006)), consists of all features based on the path from the argument to the predicate and all the words that are equal or higher than the argument candidate on the dependency tree (e.g., left sibling word, right sibling word, parent word). The features referring to the predicate itself are included in both views. More details of the feature division can be found in Table 1.

The details of the co-training method are shown in Algorithm 1. First of all, we extend our feature sets with word embeddings as proposed in Section 4.3. The two predicate modules PI and PD are trained on the original training data, then used to label the unannotated data. After that, we start the co-training process. For each of AI and AC[2], we loop for a number of iterations: the two views are trained on the labeled data using their corresponding feature sets with logistic regression. Both of the two views are used to label the unannotated data. We then select informative examples from the unlabeled dataset to be used as extra training data. Our selection strategy is to select the examples that cause a disagreement between the two views: one view is confident that the example belongs to class c (labeling score is higher than a certain threshold) while the other view is uncertain about this (labeling score is between a lower and upper threshold). This strategy differs from a classical co-training set up where we select the examples where the two local classifiers confidently agree (Blum and Mitchell, 1998). This is motivated by the

[2]Note that the co-training is applied to AI and AC separately. That means the two views of AI interact with each other, and the two views of AC interact with each other, but views from AI do not interact with views from AC.

Algorithm 1: The SRL Co-training Algorithm.

Input : A large collection of labeled sentences $\mathbf{L}$ and one of unlabeled sentences $\mathbf{U}$
Output : A full SRL

Enrich feature sets with word embeddings.
Train PI and PD on $\mathbf{L}$.
Label $\mathbf{U}$ by PI and PD.
Divide the feature sets of AI and AC into semantic/meaning clues (Sem_View) and syntactic/word-order clues (Syn_View).
for *each of the two argument sub-tasks (AI or AC)* **do**
    $\mathbf{V} = \mathbf{U}$
    $n = 0$
    while $\mathbf{V} \neq \emptyset \wedge n < |\mathbf{L}|$ **do**
        Build local classifier A on $\mathbf{L}$ using Sem_View features
        Build local classifier B on $\mathbf{L}$ using Syn_View features
        $n = |\mathbf{L}|$
        for *x in* $\mathbf{V}$ **do**
            Use A and B to label x.
            if *A or B is confident (labeling score* $> t_1$*) that* x *belongs to class* c *and the other is uncertain (*$t_3 <$ *labeling score* $< t_2$*)* **then**
                Add (x, c) to $\mathbf{L}$
            end
            Remove x from $\mathbf{V}$
            if $|\mathbf{L}| \geq n + k$ **then**
                Break the for loop
            end
        end
    end
    Build the global classifier for AI (or AC) on $\mathbf{L}$ using the joint feature set.
end

fact that the training data in SRL is sufficiently large to build a good system, so we only select the most informative new instances: the ones that make a disagreement between the two views. That means we are helping the classifiers to overcome the cases when one of the two clue types is weak which is common in out-of-domain prediction. Intuitively, when one clue type is strong and the other is not good, the strong one can help the other.

To ensure the balance between different classes, for AI, we added the same number of positive and negative examples to the labeled data. For main roles (e.g., A0, A1) in AC, we skip adding an instance to class c if the ratio of the number of instances in c to the rest is increased more than a certain number of times (2.0 in our experiments) since main roles are already the majority in the original training data. The maximum number of instances that could be added to the training data in each iteration is k[3]. The iterations will finish when there is no instance satisfying our selection criteria or there is no unlabeled data left. At the end of the process, a global classifier for each of the argument sub-task modules (AI or AC) is trained on the final labeled training set using the joint feature set of the two views.

Although co-training has reported success in many real-world applications (Blum and Mitchell, 1998; Kiritchenko and Matwin, 2001; Mihalcea, 2004; Javed et al., 2005), its application in SRL is still very limited. It is common in NLP that the two assumptions of co-training do not strictly hold. He and Gildea (2006) discovered that their two co-training views, headword and path, were not balanced. The headword view was more sensitive to new data, and led to a significant drop in precision. The path view was a more accurate and stable indicator for semantic role labeling. By adding distributional word representations to

[3] k is fixed to 50% of the size of the original training data in our experiment.

Table 2: Information about datasets.

	Section	Corpus	Type
Train	02-21	TreeBank	financial news
Dev	24	TreeBank	financial news
Ood	ck01-03	Brown	fiction
UB	ck04-29,cl,cm,cp	Brown	fiction
UW	01	TreeBank	financial news

the feature set, we expect to improve the performance of the headword view when faced with new data, and thereby produce a successful co-training strategy. Also, since it is difficult to make a good prediction with just one of the two different clue types, we build a global classifier for each of AI and AC with a joint feature set at the end of the process.

5 Experiments

We evaluate the performance of our method when training on a large training set and testing on an out-of-domain test set using a collection of unlabeled data. We expect that from the unlabeled data, which is mostly in the same domain as the target data, we can create a number of new training instances that improve system performance on the target domain.

5.1 Settings

We use the same training, development and out-of-domain test set as provided in the CoNLL 2009 shared task (Hajič et al., 2009). We also collect two sets of unlabeled data which are mostly texts in the same domain as the CoNLL 2009 out-of-domain test set. Table 2 shows some information about our datasets. We call the training set Train, development set Dev, out-of-domain test set Ood, unlabeled data from Brown corpus UB and unlabeled data from TreeBank UW. The training data has 39,279 financial sentences with 12,036 predicate words. In the out-of-domain test set, there are 788 different predicate words and 114 of them have never been observed in the training data. The collection of unlabeled data (UB and UW) contains 12,462 fictional and 1,828 financial news sentences.

The prepreprocessing modules including POS tagger, lemmatizer and dependency parser of (Björkelund et al., 2010) are used in our experiments. All the modules are retrained on the CoNLL 2009 training set. We use Word2Vec[4] (**?**) to learn 300-dimensional word representations from unlabeled corpora including Wikipedia[5], Reuters[6], TreeBank[7].

Following the standard setting of the CoNLL 2009 shared task, we skip the predicate identification step when evaluating our models. It is only used to annotate unlabeled data in the co-training experiments. All the methods are evaluated using the official CoNNL 2009 evaluation software.

We set λ, the parameter controlling the balance between precision and recall, to 0.3 in all of our experiments based on tuning that parameter on the Dev set.

We use as a baseline our system trained on the feature sets proposed by Björkelund et al. (2010) (Baseline).

To evaluate the effectiveness of our proposed inference, we replace the inference of the above Baseline model by a simple joint inference maximizing the local prediction scores over AI and AC (see Section 3). We call this model Simple. Furthermore, we also implement NoJoint model, which has the same settings as Baseline, but the joint inference is replaced by the classical predictions of the local modules.

Our three different proposed approaches are evaluated: using only word embeddings as in Section 4.3 (WE), using co-training strategy as in Section 4.4 (CO) but without word embeddings, and using the combination of word embeddings and co-training as in Section 4.4 (WECO). We also compare our

Simple	73.3	75.3	74.3
Baseline	79.5	72.3	75.7
WE	80.1	73.1	76.4
CO	80.3	71.9	75.9
WECO	80.5	73.2	**76.7**

results with the current state-of-the-art systems. We tune the thresholds t_1, t_2, and t_3 in Algorithm 1 by measuring performance on Dev set resulting in $(t_1, t_2, t_3) = (0.8, 0.5, 0.3)$.

5.2 Results

From Table 3, we can see that including word embeddings with the capacity of better capturing word similarity already improves the out-of-domain prediction. Using co-training seems to be more useful when working with unseen frames. It can be seen that CO gives high precision which has possibly benefited from the enforced agreement between the two views. Meanwhile, WE appears to be better in improving recall because of the good capacity to capture word similarity. Interestingly, the combination of these two approaches WECO brings us high scores in both precision and recall. It obtains the best results especially for unseen semantic frames which are the most difficult cases for SRL. WECO improves the prediction for unseen frames over the baseline, WE and CO 2.5, 1.4 and 1.1 F1 points respectively.

As can be seen from Table 4, with a simple learning architecture (local learning, no reranker) and an effective inference, our Baseline model already obtains results comparable to those of state-of-the-art systems. It reaches the F1 score of 75.7% which is the same as Björkelund et al. (2010) using a reranker on top of local classifiers with the same feature set as our baseline model. Our Baseline model surpasses both Simple and NoILP models by 1.4 F1 points proving the effectiveness of our ILP objective function. With our best model, WECO, the official CoNLL 2009 F1 score obtained on the out-of-domain test set outperforms a much more complicated system using reranker and neural network proposed in (Roth and Lapata, 2016) by 0.2 F1 points.

Selection strategy To evaluate our selection strategy in the co-training, we also perform an experiment with a classical selection strategy in which we select examples on which the two views agree with high confidence (i.e. larger than t_1 in both views), resulting in a reduction of 0.2 F1 points on the out-of-domain

test set.

6 Discussion

Semi-supervised setting The experiments show the promising application of semi-supervised methods in out-of-domain scenarios. We present the first successful case of using co-training for SRL when using all available training data (and not an artificially limited small subset). These successes encourage us to develop more advanced techniques digging into the collaboration of the two views in SRL. Semi-supervised techniques have the capacity to exploit a huge amount of unlabeled data, which is cheaper than manually-built annotated data. However, the success of these techniques depends on the quality of unlabeled data. If the unlabeled data itself does not contain informative knowledge, then semi-supervised methods will not help in improving the performance.

System architecture As shown before, even with a simple learning technique we still can obtain very strong results with an effective inference. This architecture is beneficial in semi-supervised settings which often require dealing with new training examples and new features. The inference might increase the computational complexity of the prediction, but given the current progress in efficient software and hardware solutions this will not pose serious problems.

7 Conclusion

We have presented a semi-supervised SRL system facing the most difficult case of SRL: predicting out-of-domain and unseen semantic frames. Our system, with a simple learning architecture and effective joint inference, obtains very strong results on the standard benchmark SRL data from the CoNLL 2009 shared task. We propose using a collaboration of word embeddings and a variant of co-training to exploit unlabeled data. Our method leverages the collaborative relationship of the two signal types in SRL (semantic and syntactic clues) to create informative new training examples that help out-of-domain prediction. An experiment exploiting unlabeled data which includes mostly fictional texts from the Brown corpus achieves better performance than state-of-the-art models on the out-of-domain test set of the CoNLL 2009 shared task.

Last but not least, our SRL system is made publicly available at http://liir.cs.kuleuven.be/software.php.

Abstract

Compositional distributional semantic models (CDSMs) have successfully been applied to the task of predicting the meaning of a range of linguistic constructions. Their performance on semi-compositional word formation process of (morphological) derivation, however, has been extremely variable, with no large-scale empirical investigation to date. This paper fills that gap, performing an analysis of CDSM predictions on a large dataset (over 30,000 German derivationally related word pairs). We use linear regression models to analyze CDSM performance and obtain insights into the linguistic factors that influence how predictable the distributional context of a derived word is going to be. We identify various such factors, notably part of speech, argument structure, and semantic regularity.

1 Introduction

Compositional models of distributional semantics, or CDSMs (Mitchell and Lapata, 2010; Erk and Padó, 2008; Baroni et al., 2014; Coecke et al., 2010), have established themselves as a standard tool in computational semantics. Building on traditional distributional semantic models for individual words (Turney and Pantel, 2010), they are generally applied to *compositionally compute phrase meaning* by defining combination operations on the meaning of the phrase's constituents. CDSMs have also been co-opted by the deep learning community for tasks including sentiment analysis (Socher et al., 2013) and machine translation (Hermann and Blunsom, 2014). A more recent development is the use of CDSMs to model meaning-related phenomena above and below syntactic structure; here, the term "composition" is used more generally to apply to processes of meaning combination from multiple linguistic units, e.g., above and below syntactic structure. Above the sentence level, such models attempt to predict the unfolding of discourse (Kiros et al., 2015). Below the word level, CDSMs have been applied to model word formation processes like compounding (*church* + *tower* → *church tower*) and (morphological) derivation (Lazaridou et al., 2013) (*favor* + *able* → *favorable*). More concretely, given a distributional representation of a basis and a derivation *pattern* (typically an affix), the task of the CDSM is to predict a distributional representation of the derived word, without being provided with any additional information. Interest in the use of CDSMs in this context comes from the observation that derived words are often less frequent than their bases (Hay, 2003), and in the extreme case even completely novel; consequently, distributional evidence is often unreliable and sometimes unavailable. This is confirmed by Luong et al. (2013) who compare the performance of different types of word embeddings on a word similarity task and achieve poorer performance on data sets containing rarer and more complex words. Due to the Zipfian distribution there are many more rare than frequent word types in a corpus, which increases the need for methods being able to model derived words.

In this paper, we ask to what extent the application of CDSMs to model derivation is a success story. The record is unclear on this point: Lazaridou et al. (2013), after applying a range of CDSMs to an English derivation dataset, report success, while Kisselew et al. (2015) found very mixed results on German derivation and generally high variance across words and derivation patterns. The analyses in both studies

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1285–1296, Osaka, Japan, December 11-17 2016.

POS + ID	Pattern	Sample word pair	English translation
A → N 16	*+ität*	produktiv → Produktivität	productive → productivity

V → N 09	*(null)*	aufatmen → Aufatmen	to breathe → sigh of relief
V → V 14	*auf+*	holen → aufholen	to fetch → to catch up

Table 1: Examples of derivation patterns from DErivBase

were also limited in scope (cf. Section 2.2). Furthermore, from a linguistic point of view, it is not at all obvious that it is reasonable to model derivation as a fully compositional process, as CDSMs do. Indeed, the classic linguistic definition of derivation distinguishes it from inflection by appealing to its *semantic irregularity*: the meaning changes that accompany derivation are not supposed to be completely predictable (Plank, 1981; Laca, 2001; Plag, 2003; Dressler, 2005).

More specifically, our goal is to gain a more precise understanding of the linguistic factors that govern the success or failure of CDSMs to predict distributional vectors for derived words. To this end, we conduct a broad-coverage analysis of the performance of CDSMs on more than 30,000 German derivationally related word pairs instantiating 74 derivation patterns. As a first step, we build *CDSM prediction models* for each of these patterns. The second step is a linear regression analysis with linguistic properties of patterns and word pairs as predictors and the models' performances as dependent variables. We formulate and test a number of hypotheses about the linguistic properties and establish that, notably, derivations that create new argument structure are generally hard to predict – although the difficulty is mediated by the regularity of the semantic shift involved. Subsequently, we exploit the regression results to combine several state-of-the-art CDSMs into an ensemble. Unfortunately, we do not see improvements over the individual models, which we trace back to a lack of complementarity among the CDSMs.

2 Background: Modeling Morphological Derivation

2.1 Derivational Lexicons

Morphological derivation is a word formation process that produces new words and which, at the word surface-level, can be described by means of an orthographic *pattern* applied to basis words. Table 1 shows that in the simplest case (row 1) this means attaching an affix (*+ität*). The other rows show that the pattern can be more complex, involving stem alternation (row 2; note that the infinitive suffix *+en* is inflectional), deletion of previous affixes (row 3), circumfixation (row 4), or no overt changes, i.e., conversion (row 5).[1] Derivation can take place both within parts of speech (row 6) and across parts of speech.

Derivation is a very productive process in many languages, notably Slavic languages. Thus, natural language processing (NLP) for these languages can profit from knowledge about derivational relationships (Green et al., 2004; Szpektor and Dagan, 2008; Padó et al., 2013). Nevertheless, derivation is a relatively understudied phenomenon in NLP, and few lexicons contain derivational information. For English, there are two main resources. CatVar (Habash and Dorr, 2003) is a database that groups 100K words of all parts of speech into 60K *derivational families*, i.e., derivationally related sets of words. The other is CELEX (Baayen et al., 1996), a multi-level lexical database for English, German, and Dutch, which covers about 50K English words and contains derivational information in its morphological annotation. For German, DErivBase (Zeller et al., 2013) is a resource focused on derivation that groups 280K lemmas into 17K derivational families. As opposed to CatVar and CELEX, it also provides explicit information about the applicable derivation pattern at the level of word pairs. The examples in Table 1 are from DErivBase.

[1] We write patterns as sequences of orthographic operations, using '+' for addition and '-' for deletion, and place the operator before or after the affix to distinguish prefixation and suffixation.

2.2 Modeling the Semantics of Derivation with CDSMs

Lazaridou et al. (2013) were the first to predict distributional vectors for derived words using CDSMs and experimented with a range of established CDSMs. In their paper, all models are supervised, i.e., some word pairs for each pattern are used as training instances, and others serve for evaluation. Also, all models assume that the base word (input) $\mathbf{b}$ and derived word (output) $\mathbf{d}$ are represented as vectors in some underlying distributional space. The *simple additive model* predicts the derived word from the base word as $\mathbf{d} = \mathbf{b} + \mathbf{p}$ where $\mathbf{p}$ is a vector representing the semantic shift accompanying the derivation pattern. The *simple multiplicative model*, $\mathbf{d} = \mathbf{b} \odot \mathbf{p}$ is very similar, but uses component-wise multiplication ($\odot$) instead of addition to combine the base and pattern vectors (Mitchell and Lapata, 2010). The third model, the *weighted additive model*, enables a simple reweighting of the contributions of basis and pattern ($\mathbf{d} = \alpha\mathbf{b} + \beta\mathbf{p}$). Finally, the *lexical function model* (Baroni and Zamparelli, 2010) represents the pattern as a matrix P that is multiplied with the basis vector: $\mathbf{d} = \mathrm{P}\mathbf{b}$, essentially modelling derivation as linear mapping. This model is considerably more powerful than the others, however its number of parameters is quadratic in the number of dimensions of the underlying space, whereas the additive and multiplicative models only use a linear number of parameters.

For their empirical evaluation, Lazaridou et al. (2013) considered a dataset of 18 English patterns defined as simple affixes – 4 within-POS (such as *un-*) and 14 across-POS (such as *+ment*) – and found that the lexical function model is among the top performers, followed by the weighted additive and multiplicative models, all substantially better than baseline. From our perspective, their evaluation has a number of limitations, though: they only included "high-quality" vectors (using human judgments of nearest neighbors to determine quality), thereby focusing on a relatively well-behaved subset of the vocabulary and potentially missing out on highly polysemous words. Furthermore, they evaluated mainly by computing mean cosine similarities between predicted and corpus-observed ("gold") vectors for the derived words – this is not highly informative, as the closeness of the prediction to the actual vector is also dependent on the density of the target's neighborhood.[2] A follow-up study on German (Kisselew et al., 2015) attempted to address these limitations by including all word pairs without prefiltering, and introducing a new evaluation metric that measured how often the predicted vector $\mathbf{d}$ was among the five nearest neighbors of the corpus-observed ("gold") vector $\mathbf{d}$. Kisselew et al.'s evaluation obtained fairly different results: the lexical function model performed worse than the simple additive model, and both CDSMs often had problems outperforming the baseline. This study had its own limitations, though, since it considered only 6 derivation patterns, all within-POS. Thus, it remains unclear to what extent the differences between the two studies are due to (a) the language difference, (b) prefiltering word pairs, or (c) the choice of derivation patterns under consideration.

3 Analyzing Models of Morphological Derivation

Given these conflicting results, we propose to empirically investigate the factors that influence how well CDSMs can predict the semantics of derived words. Note that when we talk about 'predictability' of a derived form, we refer to the ability to model an otherwise already established term, for which a distributional analysis can be performed. That is, we investigate to which extent a one-off compositional procedure can capture the meaning of a word, as in a situation where a speaker encounters an existing term for the first time. Further, we assume that the individual items in the observed data will naturally have different frequencies (from rare to highly frequent) and that this will affect both the learning process and the certainty we can have about the meaning of a test vector. We believe this is a realistic setup in terms of modelling first encounters with established derivations, and we therefore make no attempt to control for the frequency of individual word vectors, either at training or test time.

3.1 Overall Workflow

We follow a two-step workflow depicted on the left-hand side of Figure 1. The workflow involves *prediction models* (cf. Section 3.2), i.e., CDSMs that predict a vector for the derived word given the vector for the base word, as well as *analysis models* (cf. Section 3.3), i.e., linear regression models that predict

[2] They also performed a manual judgment study, but only as an additional experiment on "low-quality" word pairs.

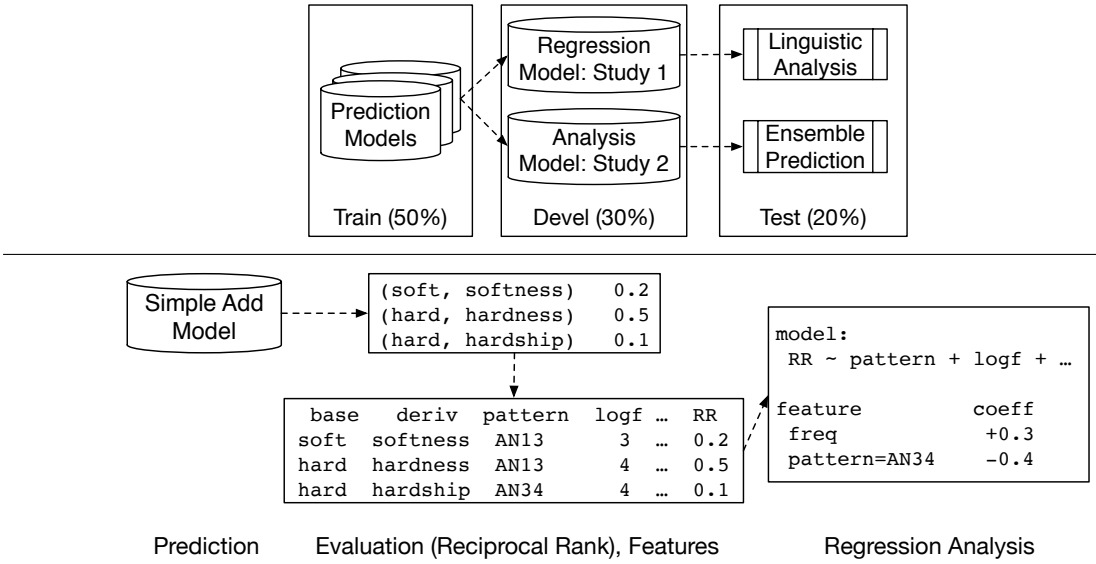

Figure 1: Top: Overall workflow. Below: Toy example

the performance of the CDSMs based on a rich set of linguistic predictors. We build two analysis models, one for linguistic analysis (Experiment 1, Section 4) and one for NLP (Experiment 2, Section 5).

The workflow uses a large set of derivationally related word pairs split into training, development, and test sets (50%, 30%, and 20%, respectively). The splits are stratified by derivation pattern, i.e., each pattern occurs in approximately these ratios in each split. This is a reasonable strategy, assuming that our set of patterns is fairly complete (Zeller et al., 2013) and we can disregard the problem of unseen patterns.

The three sets play different roles. The training set is used to train prediction models. The development set is then used to measure the performance of prediction models on unseen data. These performance numbers are those that the regression model is then trained to predict. Finally, the analysis model itself is evaluated on the test set, that is, on another previously unseen dataset. In this manner, we guarantee that all results we obtain are measured on unseen data and generalize well to novel instances.

We note that the task of the prediction models (constructing the vector for the derived word) incorporates our general assumption that we do not have any information about the derived word. While this is not a reasonable assumption from an NLP point of view, where we would know at least the frequency of the derived word, and may also have a (typically less reliable) distributional vector for it, this "no-knowledge" setup represents, in our opinion, the cleanest setup for an analysis of linguistic factors.

3.2 Prediction (CDSM) Models

Derivationally Related Word Pairs. We draw our derivationally related word pairs from DErivBase[3] (Zeller et al., 2013). As stated above, each word pair is labeled with a derivation pattern, representing the orthographic transformation of the basis word. Since our predictive models are trained for each pattern separately, we ensure that each model will have enough training instances by discarding all patterns with less than 80 word pairs. Out of the 158 patterns in DErivBase, we retain 74 patterns, of which 49 are cross-POS patterns. The 74 patterns cover 30,757 word pairs. Patterns have a median of 194.5 word pairs (min. 83, max. 3028).

Corpus. We derive the frequency counts and the distributional vectors for our analysis from the German web corpus SdeWaC (Faaß and Eckart, 2013), POS-tagged and lemmatized using TreeTagger (Schmid, 1994). Following Kisselew et al. (2015), to mitigate sparsity, for out-of-vocabulary words we back off to the lemmas produced by MATE Tools (Bohnet, 2010), which have higher recall but lower precision than TreeTagger. We also use the MATE dependency analysis to reconstruct lemmas for separated prefix verbs.

[3] http://goo.gl/tiRJy0

Prediction Models. To obtain the vector representations on which we can train our prediction models, we use CBOW, a state-of-the-art predictive distributional semantics space which been shown particularly effective for modelling word similarity and relational knowledge (Mikolov et al., 2013).[4] (Considering the type of semantic space as a parameter is outside the scope of our study.)

As both target and context elements, we use all 280K unique POS-disambiguated lemmas (nouns, adjectives, and verbs) from DErivBase. We use a within-sentence context window of size ± 2 to either side of the target word, 300 context dimensions, negative sampling set to 15, and no hierarchical softmax. On these vector representations, we train four prediction models (cf. Section 2): the simple additive model, the simple multiplicative model, the weighted additive model, and the lexical function model. Each model is trained on each of the 74 patterns separately by minimizing the expected square loss between the predicted and the observed derived vector.[5] For additive models, the shift vector $\mathbf{p}$ is computed as the average of the shift vectors across all word pairs from a single pattern, while the weighted additive model additionally optimizes α and β in a subsequent step. Since the lexical function model is more prone to overfitting due to its many parameters, we train it using ridge regression, employing generalized cross-validation to tune the regularization parameter on the training set. As a fifth, baseline model, we use the identity mapping, which simply predicts the basis vector as the vector of the derived word. Our implementation is based on the DISSECT toolkit (Dinu et al., 2013).

Evaluation. The performance of the CDSMs is measured by how well the predicted vector aligns with the corpus-observed vector for the derived word. More concretely, we quantify the performance on each word pair by *Reciprocal rank (RR)*, that is, 1 divided by the position of the predicted vector in the similarity-ranked list of the observed vector's neighbors. Besides being a well-established evaluation measure in Information Retrieval, RR is also more sensitive than the "Recall out of n" measure used previously (Kisselew et al., 2015), which measures the 0–1 loss and also requires fixing a threshold n. RR also has the advantage of being easily interpretable: a mean reciprocal rank (MRR) of 0.33, e.g., indicates that the correct predicted vector is on average the third-nearest neighbor of the observed vector. The neighbor list for each derived word is POS-specific, that is, it consists of all words in the space that match its part of speech.

3.3 Analysis (Linear Regression) Models

The task of our analysis models is to predict the performance of the CDSM models (measured as reciprocal rank, cf. Section 3.2) at the word pair level, i.e., individual pairs of base and derived words. The goal is to assess which factors have a substantial influence on the prediction of the semantics of derived words. To this end, we use linear regression, which is a well-established analysis method in linguistics and psycholinguistics (Baayen, 2008). Linear regression predicts a dependent variable v as a linear combination of weighted predictors p_i, i.e., $v = \alpha_1 p_1 + \cdots + \alpha_n p_n$. A coefficient α_i can be interpreted as the change in v resulting from a change in the predictor p_i. We use the R statistical environment.

The right-hand side of Figure 1 shows a toy example for a single prediction model (simple additive). We first run the prediction model, then evaluate its reciprocal ranks at the word pair level, then compute features (such as the pattern and the logarithmized frequency of the base). Finally, we perform a regression analysis. It yields the information that higher frequency has a positive impact on performance, while the pattern AN34 has a negative impact.

Our complete set of predictors comprises three classes:

- **Base word level predictors** describe properties of the base word. They include `base_productivity`, the number of derived words known for the base, `base_polysemy`, the number of WordNet synsets, and `base_freq`, its lemma frequency in the SDeWaC corpus.[6] Predictor `base_typicality` is the cosine similarity between the base and the centroid of all bases for the present pattern, as a measure of how semantically typical the base is for the pattern;

[4] `https://code.google.com/p/word2vec/`

[5] For the simple additive and multiplicative models, there are analytical solutions.

[6] All numeric variables (predictors and dependent variable) are z-scaled; frequency variables are logarithmized.

	Baseline	Simple Add	Weighted Add	Mult	LexFun
Mean Reciprocal Rank	0.271	0.309	**0.316**	0.272	0.150
# Predictions used by Oracle (Experiment 2)	2139	954	1613	532	913
# Predictions used by Regression-based Ensemble (Experiment 2)	51	2306	3528	190	76

Table 2: Results for individual prediction models on test set

- **Prediction level predictors** describe properties of the vector that the CDSM outputs. Following work on assessing the plausibility of compositionally constructed vectors by Vecchi et al. (2011), we compute the length of the vector (`deriv_norm`) and the similarity of the vector to its nearest neighbors (`deriv_density`), and the similarity between base vector and derived vector (`base_deriv_sim`);
- **Pattern level predictors**. We represent the identity of the pattern, which is admissible since we can assume that the DErivBase patterns cover the (vast) majority of German derivation patterns (Clark, 1973). Unfortunately, this excludes a range of other predictors, such as the parts of speech of the base and derived words, due to their perfect collinearity with the pattern predictor.

The rest of the paper is concerned with performing a regression analysis based on these features. We perform two separate analyses to satisfy two fairly different motivations. The first one is linguistic, namely to understand which *properties of the base and the pattern* make the prediction easy or difficult. This analysis concentrates on one single CDSM, namely the best individual one: if it included multiple CDSMs, the regression model would spend part of its power on predicting the behavior of the (arguably irrelevant) worse CDSMs. Further, this regression model should include only pattern-level and base-level features, since prediction-level features are arguably not linguistic properties. For this approach, see Section 4.

The second motivation comes from NLP and concerns the possibility to define an *ensemble* over several CDSMs that works better than individual CDSMs by employing a regression model to select the best CDSM at the word pair level. This analysis must by definition include the output of multiple prediction models. Furthermore, it should also include the features at the prediction level since they may help distinguish reasonable from unreasonable predictions. We will pursue this approach in Section 5.

4 Experiment 1: Linguistic Analysis

As outlined above, the first task in the linguistic analysis is to select the best individual prediction model for evaluation. The test set evaluation results are shown in the first row of Table 2. As the numbers show, the weighted additive model is the best model, and our analysis will focus on it. We estimate the following linear regression model to predict reciprocal rank (RR) on the development set:

```
RR ~ pattern + base_productivity + base_typicality + base_polysemy + base_freq
```

Applied to the test set, the model achieves a highly significant fit with the data (F=58.32, $p<10^{-12}$, R^2=0.324). Performance is highly variable across patterns and words pairs: results for word pairs span almost the full range of reciprocal ranks between 0 and 1, and the pattern level results range between 0.03 (pattern VV01, *zucken → zuckeln / twitch → saunter*), i.e., predictions are no good, and 0.69 (pattern AN10, *präsent → Präsenz / present → presence*), i.e., most predictions are ranked first or second. Predicted values are not correlated with the residuals ($r < 10^{-6}$). Our further discussion of this regression model is structured along a set of hypotheses we made regarding the influence of particular factors, or more specifically how they translate into distributional behavior.

Training Data and Polysemy. We start by considering the "usual suspects" in data-driven computational linguistics regarding performance, which leads us to three hypotheses. First, *low-frequency bases are hard* due to the limited reliability of the distributional evidence. Second, *atypical bases are hard*, that is,

Predictor	Estimate	LMG score
pattern	(see Table 4)	87.2%
base_productivity	−0.13***	7.6%
base_freq	0.21***	4.1%
base_polysemy	−0.03**	0.8%
base_typicality	0.04***	0.2%

Table 3: Experiment 1: Coefficients, significances, and effect sizes for the predictors

derivations of instances unlike those seen in the training data are difficult to predict. Third, derivation models must account for the selection of individual word senses in derivation: e.g., the verbal base *absetzen* variously means *depose (an official), drop (a load), deduct (an amount)*, but the derived adjective *absetzbar* is only used in the meaning of *deductable*. Since typical distributional models, including ours, do not disambiguate bases by sense, *highly polysemous bases are hard*.

Consider now Table 3, which lists coefficients, significance, and effect sizes for these predictors. Recall that we predict reciprocal rank (RR), that is, positive coefficients indicate better whereas negative coefficients indicate worse performance.[7] The data bears out our hypotheses fairly well: we find positive effects of frequency and of typicality, and negative effects of base productivity and polysemy. The relative importances of these effects is however only weakly indicated by the sizes of the coefficients. Thus, the column LMG provides normalized Lindeman-Merenda-Gold (LMG) scores (Lindeman et al., 1980), a measure of effect size (Grömping, 2012), applied, e.g., by Marelli et al. (2015) in a similar context. These scores indicate what percentage of the variance explained by the model is due to the individual predictor groups. As we see, most variance is accounted for by the `pattern` predictor. `Productivity` and `frequency` account for respectable amounts of variance, while `polysemy` and `typicality` contribute surprisingly little. This finding needs however to be interpreted taking into account that the `pattern` predictor is categorical, and as such "soaks up" all properties at the level of individual patterns, including polysemy. As a matter of fact, the correlation between RR and polysemy at the level of individual word pairs is only weak (ρ=−0.03), while MRR and average polysemy are strongly correlated at the level of derivational patterns (ρ=−0.30).

Since the bulk of the variance is accounted for by the `pattern` predictor, we now turn to formulating hypotheses about derivation patterns.

Within-POS Derivations. We first start out by considering within-POS derivations. While cross-POS derivations are at least partially motivated by the need to change the base's syntactic category, within-POS derivations primarily reflect proper semantic processes, such as polarity and gradation prefixes (*un+*, *über+* for adjectives) or prefix verbs (*hören → aufhören / hear → stop*), which are particularly prominent in German. Such affixes are known to be highly polysemous and hard to characterize both linguistically and computationally (Lechler and Roßdeutscher, 2009; Lehrer, 2009). Thus, we expect that *within-POS derivation is hard to model*.

Table 4 lists all levels of the factor `pattern` that are statistically significant from the grand mean (using contrast coding in the regression model), adopting a threshold of α=0.01. The columns correspond to the parts of speech of the base word, and the rows to the parts of speech of the derived word. Recall that negative coefficients indicate worse performance than average, and positive coefficients better-than-average performance.

The table strongly confirms our hypothesis: all five significant adjective → adjective and all seven verb → verb derivation patterns come with large negative coefficients.

Argument Structure. For cross-POS derivation, we hypothesize that *argument structure* (Grimshaw, 1990) is a major factor, connected to the largest difference to existing applications of CDSMs for phrase meaning: while in phrasal composition the resulting phrase usually shows the same semantic behavior as

[7] We use standard notation for significance (*: $p < 0.05$, **:$p < 0.01$, ***:$p < 0.001$).

Table 4: Experiment 1: Derivation patterns with significant regression model coefficients (α=0.01), cross-classified by base and derived part of speech (*null*: morphologically null derivation; *stem*: anticausative stem change, as in *legen* → *liegen, put* → *lie*)

its head component (an adjective-noun phrase behaves largely like a noun), this is not always the case in derivation. For example, the agentive nominalization pattern *-er* (*laufen* → *Läufer / run* → *runner*) incorporates the agent noun of the verb, which therefore drops out of the context of the derived word. We hypothesize that *argument structure changes are difficult to learn* for the CDSMs we consider.

Looking at Table 4, we see a mixed picture, with easy and difficult patterns. Adjective → noun derivations, which predominantly generate abstract nouns without argument structure (like AN02, *taub* → *Taubheit / deaf* → *deafness*), are overwhelmingly easy to generate. We hypothesize that the deletion of the adjective's argument is not problematic to learn. For verb → noun patterns, the default event nominalization suffix *+ung* (*umleiten* → *Umleitung / redirect* → *redirection*) and stem nominalizations (*fahren* → *Fahren / drive* → *driving*), both of which preserve argument structure, are easy to model. So are the verb → adjective patterns that form present participles (*+end*) and past participles (*+t*). In contrast, the agentive/instrumental nominalization pattern *+er* (*fahren* → *Fahrer / drive* → *driver*), where argument structure changes, is associated with a loss in performance.

We noted that those verb → adjective patterns that form property adjectives (*beachten* → *beachtlich / notice* → *noticeable*) are more challenging to model. This made us aware that difficulties associated with argument structure are mediated by an another important factor, namely *semantic regularity*. The difficulty of such patterns is related to how uniform the semantic shift is among the instances of the pattern, and how well it can be picked up by distributional analysis. As an example of semantically regular shifts, consider the significant adjective → verb patterns (AV01, AV04) which can be paraphrased as "to cause to have property X" (*anonym* → *anonymisieren / anonymous* → *anonymize*). Since there is a direct mapping from the modified head noun of the adjective onto the direct object of the verb, the distributional mapping is relatively easy, even though the shift even involves the creation of new argument structure. In contrast, some verb → adjective patterns like VA11 (*+lich*) involve the introduction of modality, a complex semantic change whose distributional consequences are hard to grasp and which is similar in nature to within-POS derivations (see above).

At the far end of the difficulty scale, we find bad performance for the noun → verb derivations, because these patterns face challenges on both the argument structure and regularity fronts: they generate verbs

from nouns that are only loosely semantically related (Clark and Clark, 1979). An example is NV22 with instances like *Zweig → abzweigen / (tree) branch → branch off*. The only easy noun → verb pattern, NV09, comes with a particularly regular semantic shift, paraphrasable as "to use X as instrument" (*Hammer → hämmern / (a) hammer → (to) hammer*).

Argument structure being a complex phenomenon, we would require additional work to exactly identify which factors play a role in derivational processes, and how those factors interact with distributional models. For instance, certain types of argument deletion/addition can result in shifting lexical items to other sentence constituents (e.g., *X developed Y over ten years* vs. *Y underwent ten years of development*). This kind of effect can, at least in principle, be captured using variable window sizes in a CDSM. Whilst we leave such questions for further research, the present results seem to support the idea that argument structure is a worthwhile aspect to investigate.

5 Experiment 2: Ensemble Prediction

In our second study, we investigate the use of linear regression models to construct an *ensemble* of CDSMs for derivation prediction. Ensemble learning is well established in NLP to capture phenomena that exceed the power of individual models (Dietterich, 2000). In our case, we want to select one vector from among the predictions of multiple CDSMs. We consider two strategies to perform this selection: The *oracle model* compares all prediction models, and simply picks the one with the highest RR. The oracle thus establishes an upper bound that assesses the theoretical benefit of model combination. It achieves an MRR of 0.362 – a modest, but substantial improvement of four and a half points over the best individual model (weighted additive, MRR=0.316, cf. Table 2).

The second strategy is the *regression model* which predicts the CDSMs' expected performances at the word pair level with a linear regression model trained on the development set (cf. Figure 1). As discussed in Section 3.3, our regression model for this purpose differs in two respects from the first study: it includes features for the prediction, and it is trained on the evaluations of all five CDSMs. The provenance of each evaluation result is coded in a new predictor, `cdsm`, with the values `baseline, simple_add, weighted_add, mult, lexfun`. We introduce interactions between `cdsm` and all base-level features to enable the regression model to learn, e.g., that some CDSMs can deal better with low-frequency bases. We estimate the following model on the development set:

```
RR ~ deriv_density + base_deriv_sim + deriv_norm + pattern +
     (base_productivity + base_typicality + base_freq + base_polysemy) * cdsm
```

On the test set, the model achieves a highly significant fit with the data (F=193.5, p$< 10^{-12}$, R^2=0.305), that is, it achieves a similar model fit to the first study.

Unfortunately, the use of this regression model to define an ensemble does not work particularly well: the ensemble yields an MRR of just 0.321, only half a point above the best-performing individual model, weighted additive, with an MRR of 0.316. This is a negative result: our regression models do not directly translate into better predictions for derived word vectors. To understand the reasons for this failure, we perform two analyses. The first one compares how many predictions of each CDSM the oracle and the ensemble selected, as shown in the lower part of Table 2. The oracle selects substantially from all models, while the regression-based ensemble chooses strictly in proportion to the CDSMs' overall performance: The best model (weighted additive) is selected for over 60% of all cases while the lexical function model is almost ignored. This indicates that the regression model is overly dependent on the `cdsm` predictor, while the base-level and pattern-level predictors are not powerful enough to reverse the bias towards higher-MRR models.

Our second analysis follows Surdeanu and Manning (2010), who found that the complementarity between participating models in an ensemble is more important than the exact combination method. To test the amount of complementarity, we computed rank correlations (Spearman's ρ) between the CDSMs' predictions at the word pair level. The results in Table 5 show that the baseline, additive, and multiplicative models are highly correlated (all pairwise ρs larger than 0.84). Only the lexical function model behaves substantially differently (pairwise ρ less than 0.34). This would make it a good candidate

	Baseline	Simple add	Weighted add	Multiplicative
Simple add	0.923			
Weighted add	0.840	0.930		
Multiplicative	0.967	0.929	0.853	
Lexical function	0.281	0.310	0.333	0.304

Table 5: Experiment 2: Correlations among CDSMs at the word level (Spearman's ρ)

for complementary predictions (as its selection by the oracle also witnesses) – however, its overall bad performance (MRR=0.150) drastically reduces its chance to be picked by the ensemble.

6 Conclusions

In this paper, we presented the first analysis of CDSMs on derivational phenomena that is both detailed and broad-coverage. Our main premise was that the linguistic features of individual lexical items, as well as the nature of the derivation pattern, would affect the extent to which the derived form could be predicted. This led us to establish relationships between linguistic properties and distributional behavior of words, a central topic in distributional semantics that seems to have received very little attention.

To quantify these relationships, we built a linear regression model with CDSM performance as dependent variable and linguistic features as predictors. An effect size analysis showed that the base term's productivity and frequency influence difficulty, but that the derivation pattern has a much larger effect. By analyzing patterns, we found that the three main factors for bad performance were: modifications of argument structure, semantic irregularity, and within-POS derivations.

Regarding the apparent contradictions among previous studies, our analysis can resolve them to some degree. We can attribute the overall bad CDSM results of Kisselew et al. (2015) to an unfortunate choice of hard within-POS derivations. At the same time, we replicate their particularly disappointing results for the lexical function, which contrasts with Lazaridou et al.'s reported performance for that model. To test whether these differences are due to Lazaridou et al.'s prefiltering, we re-evaluated all CDSMs on a "high-quality" subset of our data by throwing away the quartile with the lowest base word frequency (corresponding to a threshold of 420). The results for all models improve by 1–2%, but the lexical function model remains at 15% below the baseline. Obvious remaining differences are the language and the type of the distributional model used. However, these factors were outside the scope of the current study, so we leave them for future work.

We also built an ensemble model over the different CDSMs but did not substantially outperform the best single CDSM. We draw two conclusions from this failure: (a), despite the array of available CDSMs, it makes sense to continue developing new CDSMs to increase complementarity; and (b), the limiting factor in difficult prediction is the idiosyncratic behaviour of base words that our current distributional features capture only imperfectly.

To encourage further research, we make available our dataset with derivationally related word pairs and CDSM performance predictors.[8]

Abstract

In recent years linguistic typology, which classifies the world's languages according to their functional and structural properties, has been widely used to support multilingual NLP. While the growing importance of typological information in supporting multilingual tasks has been recognised, no systematic survey of existing typological resources and their use in NLP has been published. This paper provides such a survey as well as discussion which we hope will both inform and inspire future work in the area.

1 Introduction

One of the biggest research challenges in NLP is the huge global and linguistic disparity in the availability of NLP technology. Still, after decades of research, high quality NLP is only available for a small number of the thousands of languages in the world. Theoretically, we have two solutions to this problem: i) development of universal, language-independent models which are equally applicable to all natural language, regardless of language-specific variation; ii) comprehensive systematisation of all possible variation in different languages.

The field of linguistic typology offers valuable resources for nearing both of these theoretical ideals: it studies and classifies world's languages according to their structural and functional features, with the aim of explaining both the common properties and the structural diversity of languages. Many of the current popular solutions to multilingual NLP: transfer of information from resource-rich to resource-poor languages (Padó and Lapata, 2005; Khapra et al., 2011; Das and Petrov, 2011; Täckström et al., 2012, inter alia), joint multilingual learning (Snyder, 2010; Cohen et al., 2011; Navigli and Ponzetto, 2012, inter alia), and development of universal models (de Marneffe et al., 2014; Nivre et al., 2016, inter alia), either assume or explicitly make use of information related to linguistic typology.

While previous work has recognised the role of linguistic typology (Bender, 2011), no systematic survey of typological information resources and their use in NLP to date has been published. Given the growing need for multilingual NLP and the increased use of typological information in recent work, such a survey would be highly valuable in guiding further development. This paper provides such a survey for *structural* typology, the areas of typological theory that consider morphosyntactic and phonological features[1], which has been the main focus of typology research in both linguistics and NLP.

We begin by introducing the field of linguistic typology and the main databases currently available (§ 2). We then discuss the role and potential of typological information in guiding multilingual NLP (§ 3). In § 4 we survey existing NLP work in terms of how typological information has been developed (4.1) and integrated in multilingual application tasks (4.2). § 5 discusses future research avenues, and § 6 concludes.

*These authors contributed equally to this work.

[1]Whilst outside of the scope of this paper, other areas of linguistic typology (e.g., lexico-semantic classifications) are also of significance for the NLP community and should be addressed in future work.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1297–1308, Osaka, Japan, December 11-17 2016.

Name	Type	Coverage	Notes
World Atlas of Language Structures (WALS)	Phonology Morphosyntax Lexicosemantics	2,676 languages; 192 features; 17% of features have values	Defines language features and provides values for a large set of languages; originally intended for study of areal distribution of features
Syntactic Structures of the World's Languages (SSWL)	Morphosyntax	262 languages; 148 features; 45% of features have values	Similar to WALS, but differs in being fully open to public editing (Wikipedia-style), and by the addition of numerous example sentences for each feature
Atlas of Pidgin and Creole Language Structures (APiCS)	Phonology Morphosyntax Lexicosemantics	76 languages; 130 features; 18,526 examples	Designed to allow comparison with WALS
PHOIBLE Online	Phonology	1,672 languages; 2,160 segments	Collates and standardises several phonological segmentation databases, in addition to new data
Lyon-Albuquerque Phonological Systems Database (LAPSyD)	Phonology	422 languages	Documents a broader range of features than PHOIBLE, including syllable structures and tone systems; provides bibliographic information and links to recorded samples
URIEL Typological Compendium	Phonology Morphosyntax Lexicosemantics	8,070 languages and dialects; 284 features; approximately 439,000 feature values	Collates features from WALS, SSWL, PHOIBLE, and 'geodata'(e.g. language names, ISO codes, etc.) from sources such as Glottolog and Ethnologue; includes cross-lingual distance measures based on typological features; provides estimates for empty feature values

Table 1: An overview of major publicly accessible databases of typological information.

2 Overview of Linguistic Typology

Languages may share universal features on a deep, abstract level, but the structures found in real-world, surface-level natural language vary significantly. This variation is conventionally characterised into 'languages' (e.g. French, Hindi, Korean)[2], and linguistic typology describes how these languages resemble or differ from one another. The field comprises three pursuits: the definition of language features and their capacity for variance, the measurement and analysis of feature variance across empirical data, and the explanation of patterns observed in this data analysis. Bickel (2007) terms these three pursuits qualitative, quantitative and theoretical typology, respectively.

Typological classifications of languages have strict empirical foundations. These classifications do often support theories of causation, such as historical, areal or phylogenetic relations, but importantly, these hypotheses come second to quantitative data (Bickel, 2007). Indeed, patterns of variance may even run contrary to established theories of relations between languages based on geographical or historical proximity. For instance, Turkish and Korean are typically considered to be highly divergent in lexical features, yet their shared syntactic features make the two languages structurally quite similar. Such indications of similarity are of value for NLP which primarily seeks to model (rather than explain) cross-linguistic variation.

Typologists define and measure features according to the task at hand. Early studies, focused on word order, simply classified languages as SVO (Subject, Verb, Object), VSO, SOV, and so forth (Greenberg, 1963). There are now more various and fine-grained studies based on a wide range of features, including phonological, semantic, lexical and morphosyntactic properties (see (Bickel, 2007; Daniel, 2011) for an overview and further references). While a lot of valuable information is contained in these linguistic studies, this information is often not readily usable by NLP due to factors such as information overlap and differing definitions across studies. However, there is also a current trend towards systematically collecting typological information from individual studies in publicly-accessible databases, which are suitable for direct application in NLP (e.g., for defining features and their values).

[2]Note that there is a lacking consensus on how to define a 'language' (as opposed to a dialect, for instance) and the divisions themselves are often arbitrary and/or political. Nonetheless, the divisions are relevant insofar as they are observed in multilingual NLP.

Table 1 presents a selection of current major databases, including the Syntactic Structures of the World's Languages (SSWL) (Collins and Kayne, 2009), the World Atlas of Language Structures (WALS) (Dryer and Haspelmath, 2013), the Phonetics Information Base and Lexicon (PHOIBLE) (Moran et al., 2014), the URIEL Typological Compendium (Littel et al., 2016), the Atlas of Pidgin and Creole Language Structures (APiCS) (Michaelis et al., 2013), and the Lyon-Albuquerque Phonological Systems Database (LAPSyD) (Maddieson et al., 2013). The table provides some basic information about these databases, including type, coverage, and additional notes. From these databases, WALS is currently by far the most commonly-used typological resource in NLP due to its broad coverage of features and languages.

We next discuss the potential of typological information to guide multilingual NLP and the means by which this can be done.

3 Multilingual NLP and the Role of Typologies

The recent explosion of language diversity in electronic texts has made it possible for NLP to move increasingly towards multilingualism. The biggest challenge in this pursuit has been resource scarcity. In order to achieve high quality performance, NLP algorithms have relied heavily on manually crafted resources such as large linguistically-annotated datasets (treebanks, parallel corpora, etc.) and rich lexical databases (terminologies, dictionaries, etc.). While such resources are available for key NLP tasks (POS tagging, parsing, etc.) in well-researched languages (e.g. English, German, and Chinese), for the majority of other languages they are lacking altogether. Since resource creation is expensive and cannot be realistically carried out for all tasks in all languages, much recent research in multilingual NLP has investigated ways of overcoming the resource problem.

One avenue of research that aims to solve this problem has been unsupervised learning, which exploits unlabelled data that is now available in multiple languages. Over the past two decades increasingly sophisticated unsupervised methods have been developed and applied to a variety of tasks and in some cases also to multiple languages (Cohen and Smith, 2009; Reichart and Rappoport, 2010; Snyder, 2010; Spitkovsky et al., 2011; Goldwasser et al., 2011; Baker et al., 2014, inter alia). However, while purely unsupervised approaches are appealing in side-stepping the resource problem, their relatively low performance has limited their practical usefulness (Täckström et al., 2013). More success has been gained with solutions that use some form of supervision or guidance to enable NLP for less-resourced languages (Naseem et al., 2010; Zhang et al., 2012; Täckström et al., 2013, inter alia). In what follows, we consider three such solutions: language transfer, joint multilingual learning, and the development of universal models. We discuss the guidance employed in each, paying particular attention to typological guidance.

Language Transfer This very common approach exploits the fact that rich linguistic resources do exist for some languages. The idea is to use them for less-resourced languages via data (i.e. parallel corpora) and/or model transfer. This approach has been explored widely in NLP (Hwa et al., 2005; McDonald et al., 2011; Petrov et al., 2012; Zhang and Barzilay, 2015). It has been particularly popular in recent research on dependency parsing, where a variety of methods have been explored. For example, most work for resource-poor languages has combined delexicalised parsing with cross-lingual transfer (e.g. (Zeman and Resnik, 2008; McDonald et al., 2011; Søgaard, 2011; Rosa and Zabokrtsky, 2015)). Here, a delexicalised parser is first trained on a resource-rich source language, with both languages POS-tagged using the same tagset, and then applied directly to a resource-poor target language.

While such a transfer approach outperforms unsupervised learning, it does not achieve optimal performance. One potential reason for this is that the tagset used by a POS tagger may not fit a target language which exhibits significantly different morphological features to a source language for which the tagset was initially developed (Petrov et al., 2012). Although parallel data can be used to give additional guidance which improves transfer (McDonald et al., 2011), such data are only available for some language pairs and cannot be used in truly resource-poor situations.

An alternative direction that has recently emerged uses typological information as a form of non-parallel guidance in transfer. This direction capitalises on the fact that languages do exhibit systematic cross-lingual connections at various levels of linguistic description (e.g. similarities in language structure), despite their great diversity. Captured in typological classifications at the level of generalisation useful

for NLP, such information can be used to support multilingual NLP in a variety of ways (Bender, 2011). For example, it can be used to define the similarity between two languages with respect to the linguistic information one hopes to transfer; it can also help to define the optimal degree, level and method of transfer. For example, direct transfer of POS tagging is more likely to succeed when languages are sufficiently similar in terms of morphology in particular (Hana et al., 2004; Wisniewski et al., 2014).

Typological information has been used to guide language transfer mostly in the areas of part-of-speech tagging and parsing, e.g. (Cohen and Smith, 2009; McDonald et al., 2011; Berg-Kirkpatrick and Klein, 2010; Naseem et al., 2012; Täckström et al., 2013). Section 4 surveys such works in more detail.

Multilingual Joint Learning Another approach involves learning information for multiple languages simultaneously, with the idea that the languages will be able to support each other (Snyder, 2010; Navigli and Ponzetto, 2012). This can help in the challenging but common scenario where none of the languages involved has adequate resources. This applies even with English, where annotations needed for training basic tools are primarily available only for newspaper texts and a handful of other domains. In some areas of NLP, e.g. word sense disambiguation (Navigli and Ponzetto, 2012), multilingual learning has outperformed independent learning even for resource-rich languages, with larger gains achieved by increasing the number of languages.

Success has also been achieved on morphosyntactic tasks. For example, Snyder (2010) observes that cross-lingual variations in linguistic structure correspond to systematic variations in ambiguity, so that what one language leaves implicit, another one will not. For instance, a given word may be tagged as either a verb or a noun, yet its equivalent in other languages may not present such ambiguity. Together with his colleagues, Snyder exploited this variation to improve morphological segmentation, POS tagging, and syntactic parsing for multiple languages. Naseem et al. (2012) introduced a selective sharing approach to improve multilingual dependency parsing where the model first chooses syntactic dependents from all the training languages and then selects their language-specific ordering to tie model parameters across related languages. Because the ordering decisions are influenced by languages with similar properties, this cross-lingual sharing is modelled using typological features. In such works, typological information has been used to facilitate the matching of structural features across languages, as well as in the selection of languages between which linguistic information should be shared.

Development of Universal Models A long-standing goal that has gained renewed interest recently is the development of language-independent (i.e. *universal*) models for NLP (Bender, 2011; Petrov et al., 2012). Much of the recent interest has been driven by the Universal Dependencies (UD) initiative. It aims to develop cross-linguistically consistent treebank annotation for many languages for the purposes of facilitating multilingual parser development and cross-lingual learning (Nivre et al., 2016). The annotation scheme is largely based on universal Stanford dependencies (de Marneffe et al., 2014) and universal POS tags (Petrov et al., 2012). UD treebanks have been developed for 40 languages to date. Whilst still biased towards contemporary Indo-European languages, the collection developed by this initiative is gradually expanding to include additional language families.

The development of a truly universal resource will require taking into account typological variation for optimal coverage. For example, while the current UD scheme allows for language-specific tailoring, in the future, language type-specific tailoring may offer a useful alternative, aligned with the idea of universal modeling (Bender, 2011).

4 Development and Uses of Typological Information in NLP

Given the outlined landscape of multilingual NLP and its relation to structural typology, we now survey existing approaches for obtaining (4.1) and utilizing (4.2) typological information to support various NLP tasks.

4.1 Development of Typological Information for NLP

Typological information has been obtained using two main approaches: i) extraction from manually constructed linguistic resources, such as the databases reviewed in §2; and ii) automatic learning. The two

methods have been used independently and in combination, and both are based on the assumption (be it explicit or implicit) that typological relations may be fruitfully used in NLP.

Manual Extraction from Linguistic Resources Manually crafted linguistic resources – in particular the WALS database – have been the most commonly used sources of typological information in NLP. To date, syntactic parsing (Naseem et al., 2012; Täckström et al., 2013; Zhang and Barzilay, 2015; Ammar et al., 2016) and POS tagging (Zhang et al., 2012; Zhang et al., 2016) were the predominant areas for integration of structural information from such databases. In the context of these tasks, the most frequently used features related to word ordering according to coarse syntactic categories. Additional areas with emerging research which leverages externally-extracted typological features are phonological modeling (Tsvetkov et al., 2016; Deri and Knight, 2016) and language learning (Berzak et al., 2015).

While information obtained from typological databases has been successfully integrated in several NLP tasks, a number of challenges remain. Perhaps the most crucial challenge is the partial nature of the documentation available in manually-constructed resources. For example, WALS currently covers about 17% of its possible feature values (Dryer and Haspelmath, 2013) (see Table 1 for feature coverage of other typological databases). The integration of information from different databases is challenging due to differences in feature taxonomies as well as information overlap across repositories. Furthermore, available typological classifications contain different feature types, including nominal, ordinal and interval variables, and features that mix several types of values. This property hinders systematic and efficient encoding of such features in NLP models – a problem which thus far has only received a partial solution in the form of feature binarisation (Georgi et al., 2010). Further, typological databases are constructed manually using limited resources, and do not contain information on the distribution of feature values within a given language. This results in incomplete feature characterisations, as well as inaccurate generalisations. For example, WALS encodes only the dominant noun-adjective ordering for French, although in some cases this language also permits the adjective-noun ordering.

Other aspects of typological databases may require feature pruning and preprocessing prior to use. For example, some features in WALS, such as feature 81B "Languages with two Dominant Orders of Subject, Object, and Verb" are applicable only to a subset of the world's languages. Currently, no explicit specification for feature applicability is present in WALS or other typological resources. Furthermore, distinct features may encode overlapping information, as in the case of WALS features 81A "Order of Subject Verb and Object" and 83A "Order of Verb and Object", where the latter can be deduced from the former. Although many of these issues have been noted in previous research (Östling, 2015), there are currently no standard procedures for preprocessing typological databases for NLP use.

Despite the caveats presented above, typological resources do offer an abundance of valuable structural information which can be integrated in many NLP tasks. This information is currently substantially underutilised. Out of 192 available features in WALS, only a handful of word order features are typically used to enhance multilingual NLP. Meanwhile, the complementary information on additional languages and feature types offered by other repositories has, to our knowledge, rarely been exploited in NLP. This readily-available information could be used more extensively in tasks such as POS tagging and syntactic parsing, which have already gained from typological knowledge, and it could also be used to support additional areas of NLP.

Automatic Learning of Typological Information The partial coverage of existing typological resources, stemming from the difficulty of obtaining such information manually, have sparked a line of work on automatic acquisition of typological information. Here too, WALS has been the most common reference for defining the features to be learned.

Several approaches were introduced for automatic induction of typological information through multilingual word alignments in parallel texts. Mayer and Cysouw (2012) use alignments to induce language similarities, and use this approach to support learning of fine-grained features, such as the typology of person interrogatives (e.g., English "who"). In Östling (2015) multilingual word alignments are used to project POS tags and syntactic trees for translations of the New Testament, and subsequently learn typological information relating to word order. The predicted typological features, when evaluated against

WALS, achieve high accuracy. This method not only extends WALS word order documentation to hundreds of new languages, but also quantifies the frequency of different word orders across languages – information that is not available in manually crafted typological repositories.

Typological information can also be extracted from Interlinear Glossed Text (IGT). Such resources contain morphological segmentation, glosses and English translations of example sentences collected by field linguists. Lewis and Xia (2008) and Bender et al. (2013) demonstrate that IGT can be used to extract typological information relating to word order, case systems and determiners for a variety of languages.

Another line of work seeks to increase the coverage of typological information using existing information in typological databases. Daumé III and Campbell (2007) and Bakker (2008) use existing WALS features to learn typological implications of the kind pioneered by Greenberg (1963). Such rules can then be used to predict unknown feature values for new languages. Georgi et al. (2010) use documented WALS features to cluster languages, and subsequently predict new feature values using nearest-neighbour projection. A classifier-based approach for predicting new feature values from documented WALS information is presented in (Takamura et al., 2016). Coke et al. (2016) predict word order typological features by combining documented typological and genealogical features with the multilingual alignment approach discussed above.

An alternative approach for learning typological information uses English as a Second Language (ESL) texts (Berzak et al., 2014). This work demonstrates that morphosyntactic typological similarities between languages are largely preserved in second language structural usage. It leverages this observation to approximate typological similarities between languages directly from ESL usage patterns and further utilise these similarities for nearest neighbor prediction of typological features. The method evaluates competitively compared to baselines in the spirit of (Georgi et al., 2010) which rely on existing typological documentation of the target language for determining its nearest neighbors.

In addition, a number of studies learned typological information tailored to the particular task and data at hand (i.e. *task-based development*). For example, Song and Xia (2014) process Ancient Chinese using Modern Chinese parsing resources. They manually identify and address statistical patterns in variation between monolingual corpora in each language, and ultimately optimise the model performance by selectively using only the Modern Chinese features which correspond to Ancient Chinese features.

Although automatically-learned typological classifications have not been used frequently to date, they hold great promise for extending the use of typological information in NLP. Furthermore, such work offers an additional axis of interaction between linguistic typology and NLP, namely using computational modeling in general and NLP in particular to assist linguistic documentation and analysis of typological information. We discuss the future prospects of these research directions in § 6.

4.2 Uses of Typological Information in NLP

Multilingual Syntactic Parsing As mentioned in § 4.1, the main area of NLP in which information from structural typology has been exploited thus far is multilingual dependency parsing. In this task, a priori information about the predominant orderings of syntactic categories across languages are used to guide models when parsing a resource-poor language and using training data from other languages. This information is available in typological resources (e.g., WALS) which, among a variety of other syntactic features, list the dominant word orderings for many languages (see Table 1).

A seminal work that integrates typological word order information in multilingual dependency parsing (Naseem et al., 2012) presents the idea of "selective sharing" between source and target languages. In brief, while the identity of possible dependents for a given syntactic category is (hypothesised to be) language-universal, their ordering is language-specific. The work then presents a generative multilingual parsing model in which dependent ordering parameters are conditioned on word order typology, obtained from WALS. Specifically, the paper utilises the following word order features (henceforth WALS Basic word Order, WBO): 81A (Subject Verb and Object), 85A (Adposition and Noun), 86A (Genitive and Noun), 87A (Adjective and Noun), 88A (Demonstrative and Noun) and 89A (Numeral and Noun). This information enables the model to take into account dependent orderings only when the source language has a similar word order typology to the target language. In a similar vain, Täckström et al. (2013) present

an instance of the typologically guided selective sharing idea within a discriminative parsing framework. They group the model features into features that encode arc directionality and word order, and those that do not. The former group is then coupled with the same WBO features used by Naseem et al. (2012) via feature templates that match the WALS properties with their corresponding POS tags. Additional features that group languages according to combinations of WALS features as well as coarse language groups (Indo-European versus Altaic), result in further improvements in parsing performance.

Zhang and Barzilay (2015) extended the selective sharing approach for discriminative parsing to tensor-based models using the same WBO features as in (Naseem et al., 2012) and (Täckström et al., 2013). While traditional tensor-based parsers represent and assign non-zero weights to all possible combinations of atomic features, this work presents a hierarchical architecture that enables discarding chosen feature combinations. This allows the model to integrate prior typological knowledge, while ignoring uninformative combinations of typological and dependency features. At the same time, it capitalises on the automatisation of feature construction inherent to tensor models to generate combinations of informative typology-based features, further enhancing the added value of typological priors.

Another successful integration of externally-defined typological information in parsing is the work of Ammar et al. (2016). They present a multilingual parser trained on a concatenation of syntactic treebanks of multiple languages. To reduce the adverse impact of contradicting syntactic information in treebanks of typologically distinct languages, while still maintaining the benefits of additional training data for cross-linguistically consistent syntactic patterns, the parser encodes a language-specific bias for each given input language. This bias is based on the identity of the language and its WBO features as used in (Naseem et al., 2012; Täckström et al., 2013; Zhang and Barzilay, 2015). Differently from prior work, their parsing model also encodes all other features in the WALS profile of the relevant language. Overall, this strategy leads to improved parsing performance compared to monolingually trained baseline parsers.

While the papers surveyed above use prior information about word order typology extracted from WALS, word order information for guiding multilingual parsing can also be extracted in a bottom-up, data-driven fashion, without explicit reference to typological taxonomies. For example, in Søgaard (2011), training sentences in a source language are selected based on the perplexity of their coarse POS tag sequence under a target language POS language model. This approach essentially chooses sentences that exhibit similar word orderings in both source and target languages, thus realizing a bottom-up variant of the typology-based selective sharing methods discussed above.

There are also several methods which have made use of less explicit typological information. For instance, Berg-Kirkpatrick and Klein (2010) selectively combine languages in their method for cross-lingual dependency grammar induction using a phylogeny tree, which has been constructed from external (unspecified) knowledge of language families. Zeman and Resnik (2008) demonstrate improved performance of cross-lingually transferred dependency parsers within sets of typologically similar languages (e.g. Swedish-Danish, Hindi-Urdu); they do not explain how languages may be determined as "closely-related", though presumably this decision was based on the intuition of the researchers or on widely-acknowledged generalisations.

POS Tagging, Phonological Modeling and Language Learning Besides dependency parsing, several other areas have started integrating typological information in various forms. A number of such works revolve around the task of POS tagging. For example, in Zhang et al. (2012), the previously discussed WBO features were used to inform mappings from language-specific to a universal POS tagset. In (Zhang et al., 2016), WBO feature values are used to evaluate the quality of a multilingual POS tagger.

Another application area which benefited from integration of typological knowledge are phonological models of text. In (Tsvetkov et al., 2016) a multilingual neural phoneme-based language model is trained on several languages using a shared phonological inventory. The model is conditioned on the identity of the language at hand, as well as its phonological features obtained from a concatenation of phonological features from WALS, PHOIBLE and Ethnologue, extracted from URIEL. The resulting model subsumes and outperforms monolingually trained models for phone sequence prediction. Deri and Knight (2016) use URIEL to obtain phone and language similarity metrics, which are used for adjusting Grapheme to Phoneme (G2P) models from resource rich to resource poor languages.

Berzak et al. (2015) use typological classifications to study language learning. Formalizing the theory of "Contrastive Analysis" which aims to analyse learning difficulties in a foreign language by comparing native and foreign language structures, they build a regression model that predicts language-specific grammatical error distributions by comparing typological features in the native and foreign languages.

5 Typological Information and NLP: What's Next?

§ 4.2 surveyed the current uses of typological information in NLP. Here we discuss several future research avenues that might benefit from tighter integration of linguistic typologies and multilingual NLP.

Encoding Typological Information in Traditional Machine Learning-based NLP One of the major open challenges for typologically-driven NLP is the construction of principled mechanisms for the integration of typological knowledge in machine learning-based algorithms. Here, we briefly discuss a few traditional machine learning frameworks which support encoding of expert information, and as such hold promise for integrating typological information in NLP.

Encoding typological knowledge into machine learning requires mechanisms that can bias *learning (parameter estimation)* and *inference (prediction)* of the model towards predefined knowledge. Algorithms such as the structured perceptron (Collins, 2002) and structured SVM (Taskar et al., 2004) iterate between an inference step and a parameter update step with respect to gold training labels. The inference step is a natural place for encoding external knowledge through constraints. It biases the prediction of the model to agree with external knowledge, which, in turn, affects both the training process and the final model prediction. As typological information often reflects tendencies rather than strict rules, *soft constraints* are helpful. Ultimately, an efficient mechanism for encoding soft constraints into the inference step is needed. Indeed, several modeling approaches have been proposed that do exactly this: constraint-driven learning (CODL) (Chang et al., 2007), posterior regularisation (PR) (Ganchev et al., 2010), generalized expectation (GE) (Mann and McCallum, 2008), and dual decomposition (Globerson and Jaakkola, 2007), among others. Such approaches have been applied successfully to various NLP tasks where external knowledge is available. Examples include POS tagging and parsing (Rush et al., 2010; Rush et al., 2012), information extraction (Riedel and McCallum, 2011; Reichart and Barzilay, 2012), and discourse analysis (Guo et al., 2013), among others. In addition to further extensions to the modeling approaches surveyed in §4.2, these type of frameworks could expedite principled integration of typological information in NLP.

Typologies and Multilingual Representation Learning While the traditional models surveyed above assume a predefined feature representation and focus on generating the best prediction of the output labels, a large body of recent NLP research has focused on learning dense real-valued vector representations —- i.e., word embeddings (WEs). WEs serve as pivotal features in a range of downstream NLP tasks such as parsing, named entity recognition, and POS tagging (Turian et al., 2010; Collobert et al., 2011; Chen and Manning, 2014). The extensions of WE models in bilingual and multilingual settings (Klementiev et al., 2012; Hermann and Blunsom, 2014; Coulmance et al., 2015; Vulić and Moens, 2016, inter alia) abstract over language-specific features and attempt to represent words from several languages in a language-agnostic manner such that similar words (regardless of the actual language) obtain similar representations. Such multilingual WEs facilitate cross-lingual learning, information retrieval and knowledge transfer. The extent to which multilingual WEs capture word meaning across languages has been recently evaluated in (Leviant and Reichart, 2015) with the conclusion that multilingual training usually improves the alignment between the induced WEs and the meaning of the participating words in each of the involved languages.

Naturally, as these models become more established and better understood, the challenge of external knowledge encoding becomes more prominent. Recent work has examined the ability to map from word embeddings to interpretable typological representations (Qian et al., 2016). Furthermore, a number of works (Faruqui et al., 2015; Rothe and Schütze, 2015; Osborne et al., 2016; Mrkšić et al., 2016) proposed means through which external knowledge from structured knowledge bases and specialised linguistic resources can be encoded in these models. The success of these works suggests that more extensive integration of external linguistic knowledge in general, and typological knowledge in particular, is likely to play a key role in the future development of WE representations.

Can NLP Support Typology Construction? As discussed in §4, typological resources are commonly constructed manually by linguists. Despite the progress made in recent years in the digitisation and collection of typological knowledge in centralised repositories, their coverage remains limited. Following the work surveyed in §4.1 on automatic learning of typological information, we believe that NLP could play a much larger role in the study of linguistic typology and the expansion of such resources. Future work in these directions will not only assist in the global efforts for language documentation, but also substentially extend the usability of such resources for NLP purposes.

6 Commentary; conclusion

This paper has provided a survey of linguistic typologies and the many recent works in multilingual NLP that have benefited from such resources. We have shown how combined knowledge of linguistic universals and typological variation has been used to improve NLP by enabling the use of cross-linguistic data in the development and application of resources. Promising examples of both explicit and implicit typological awareness in NLP have been presented. We have concluded with a discussion on how typological information could be used to inform improved experimental and conceptual practice in NLP. We hope that this survey will be useful in both informing and inspiring future work on linguistic typologies and multilingual NLP.

From phonemes to images: levels of representation in a recurrent neural model of visually-grounded language learning

g.chrupala@uvt.nl

Abstract

We present a model of visually-grounded language learning based on stacked gated recurrent neural networks which learns to predict visual features given an image description in the form of a sequence of phonemes. The learning task resembles that faced by human language learners who need to discover both structure and meaning from noisy and ambiguous data across modalities. We show that our model indeed learns to predict features of the visual context given phonetically transcribed image descriptions, and show that it represents linguistic information in a hierarchy of levels: lower layers in the stack are comparatively more sensitive to form, whereas higher layers are more sensitive to meaning.

1 Introduction

Children acquire their native language with little and weak supervision, exploiting noisy correlations between speech, visual, and other sensory signals, as well as via feedback from interaction with their peers and parents. Understanding this process is an important scientific challenge in its own right, but it also has potential to generate insights useful in engineering efforts to design conversational agents or robots. Computationally modeling the ability to learn linguistic form–meaning pairings has been the focus of much research, under scenarios simplified in a variety of ways, for example:

- distributional learning from pure word-word co-occurrences with no perceptual grounding (Landauer et al., 1998; Kiros et al., 2015);
- cross-situational learning with word sequences and sets of symbols representing sensory input (Siskind, 1996; Fazly et al., 2010);
- cross-situational learning using sensory audio and visual input, but with extremely limited sets of words and objects (Roy and Pentland, 2002; Iwahashi, 2003).

Some recent models have used more naturalistic, larger-scale inputs, for example in cross-modal distributional semantics (Lazaridou et al., 2015) or in implementations of the acquisition process trained on images paired with their descriptions (Chrupała et al., 2015). While in these works the representation of the *visual scene* consists of pixel-level perceptual data, the *linguistic* input consists of sentences segmented into discrete word symbols. In this paper we take a step towards addressing this major limitation, by using the phonetic transcription of input utterances. While this type of input is symbolic rather than perceptual, it goes a long way toward making the setting more naturalistic, and the acquisition problem more challenging: the learner may need to discover structure corresponding to morphemes, words and phrases in an unsegmented string of phonemes, and the length of the dependencies that need to be detected grows substantially when compared to word-level models.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1309–1319, Osaka, Japan, December 11-17 2016.

Our contributions We design and implement a simple architecture based on stacked recurrent neural networks with Gated Recurrent Units (Chung et al., 2014): our model processes the utterance phoneme by phoneme while building a distributed low-dimensional semantic representation through a series of recurrent layers. The model learns by projecting its sentence representation to image space and comparing it to the features of the corresponding visual scene.

We train this model on a phonetically transcribed version of MS-COCO (Lin et al., 2014) and show that it is able to successfully learn to understand aspects of sentence meaning from the visual signal, and exploits temporal structure in the input. In a number of experiments we show that different levels in the stack of recurrent layers represent different aspects of linguistic structure. Low levels focus on local, short-time-scale spans of the input sequence, and are comparatively more sensitive to form. The top level encodes global aspects of the input sequence and is sensitive to visually salient elements of its meaning.

2 Related work

A major part of learning language consists in learning its structure, but in order to be able to communicate it is also of crucial importance to learn the relation of words to entities in the world. Grounded lexical acquisition is often modeled as cross-situational learning, a process of rule-based (Siskind, 1996) or statistical (Fazly et al., 2010; Frank et al., 2007) inference of word-to-referent mappings. Cross-situational models typically work on word-level language input and symbolic representations of the context. However, infants have to learn from continuous perceptual input. Lazaridou et al. (2016) partially remedy this shortcoming and propose a model of learning word meanings from text paired with continuous image representations; the limitation of their work is the toy evaluation dataset.

Recent experimental and computational studies have found that co-occurring visual information may help to learn word forms (Thiessen, 2010; Cunillera et al., 2010; Glicksohn and Cohen, 2013; Yurovsky et al., 2012). This suggests that acquisition of word form and meaning are interactive, rather than separate.

The Cross-channel Early Lexical Learning (CELL) model of Roy and Pentland (2002) and the more recent work of Räsänen and Rasilo (2015) take into account the continuous nature of the speech signal, and incorporate visual information as well. The CELL model learns to discover words in continuous speech through co-occurence with their visual referent, but the visual input only consists of the shape of single objects, effectively bypassing referential uncertainty. Räsänen and Rasilo (2015) propose a probabilistic joint model of word segmentation and meaning acquisition from raw speech and a set of possible referents that appear in the context. In both Roy and Pentland (2002) and Räsänen and Rasilo (2015) the visual context is considerably less noisy and ambiguous than that available to children.

There is an extensive line of research on image captioning (see Bernardi et al. (2016) for a recent overview). Typically, captioning models learn to recognize high-level image features and associate them with words. Inspired by both image captioning research and cross-situational human language acquisition, two recent automatic speech recognition models learn to recognize word forms from visual data. In Synnaeve et al. (2014), language input consists of single spoken words and visual data consists of image fragments, which the model learns to associate. Harwath and Glass (2015) employ two convolutional neural networks, a visual object recognition model and a word recognition model, and an embedding alignment model that learns to map recognized words and objects into the same high-dimensional space. Although the object recognition works on the raw visual input, the speech signal is segmented into words before presenting it to the word recognition model. As both Harwath and Glass (2015) and Synnaeve et al. (2014) work with word-sized chunks of speech, they bypass the segmentation problem that human language learners face.

Character-level input representations have recently gained attention in NLP. Ling et al. (2015) and Plank et al. (2016) use bidirectional LSTMs to compose characters into word embeddings, while Chung et al. (2016) propose machine translation model with character level output. These approaches exploit character-level information but crucially they assume that word boundaries are available in the input.

Character-level neural NLP *without* explicit word boundaries in the input is studied in cases where fixed vocabularies are inherently problematic, e.g. with combined natural and programming language

input (Chrupała, 2013) or when specifically dealing with misspelled words in automatic writing feedback (Xie et al., 2016).

Character-level language models are analyzed in Hermans and Schrauwen (2013) and Karpathy et al. (2015). Both studies show that character-level recurrent neural networks are sensitive to long-range dependencies: for example by keeping track of opening and closing parentheses over stretches of text. Hermans and Schrauwen (2013) describe the hierarchical organization that emerges during training, with higher layers processing information over longer timescales. In our work we show related effects in a model of visually-grounded language learning from unsegmented phonemic strings.

We use phonetic transcription of full sentences as a first step towards large-scale multimodal language learning from speech co-occurring with visual scenes. The use of phonetic transcription rather than raw speech signal simplifies learning and allows us to perform experiments on the encoding of linguistic knowledge as reported in section 4 without additional annotation. Our goal is to model a multi-modal language learning process that includes the segmentation problem faced by human language learners. In contrast to character-level NLP and language modeling approaches, our input data therefore does not contain word boundaries or strong cues such as whitespace and punctuation.

In contrast to Roy and Pentland (2002) and Räsänen and Rasilo (2015), the visual input to our model consists of high-level visual features, which means it contains ambiguity and noise. In contrast to Synnaeve et al. (2014) and Harwath and Glass (2015), we consider full utterances rather than separate words.

To our knowledge, there is no work yet on multimodal phoneme or character-level language modeling with visual input. Although the language input in this study is low-level-symbolic rather than perceptual, the learning problem is similar to that of a human language learner: discover language structure as well as meaning, based on ambiguous and noisy data from another modality.

Chrupała et al. (2015) simulate visually grounded human language learning in face of noise and ambiguity in the visual domain. Their model predicts visual context given a sequence of words. While the visual input consists of a continuous representation, the language input consists of a sequence of words. The aim of this study is to take their approach one step further towards multimodal language learning from raw perceptual input. Kádár et al. (2016) develop techniques for understanding and interpretation of the representations of linguistic form and meaning in recurrent neural networks, and apply these to word-level models. In our work we share the goal of revealing the nature of emerging representations, but we do not assume words as their basic unit. Also, we are especially concerned with the emergence of a hierarchy of levels of representations in stacked recurrent networks.

3 Models

Consider a learner who sees a person pointing at a scene and uttering the unfamiliar phrase *Look, the monkeys're playing*. We may suppose that the learner will update her language understanding model such that the subsequent utterance of this phrase will evoke in her mind something close to the impression of this visual scene. Our model is a particular instantiation of this simple idea.

3.1 Phon GRU

The architecture of our main model of interest, PHON GRU is schematically depicted in Figure 1 and consists of a phoneme encoding layer, followed by a stack of K Gated Recurrent Neural nets, followed by a densely connected layer which maps the last hidden state of the top recurrent layer to a vector of visual features.

Gated Recurrent Units (GRU) were introduced in Cho et al. (2014) and Chung et al. (2014) as an attempt to alleviate the problem of vanishing gradient in standard simple recurrent nets as known since the work of Elman (1990). GRUs have a linear shortcut through timesteps which bypasses the nonlinearity and thus promotes gradient flow. Specifically, a GRU computes the hidden state at current time step, $\mathbf{h}_t$, as the linear combination of previous activation $\mathbf{h_{t-1}}$, and a new *candidate* activation $\tilde{\mathbf{h}}_t$:

$$\mathrm{gru}(\mathbf{x}_t, \mathbf{h}_{t-1}) = (1 - \mathbf{z}_t) \odot \mathbf{h}_{t-1} + \mathbf{z}_t \odot \tilde{\mathbf{h}}_t \quad (1)$$

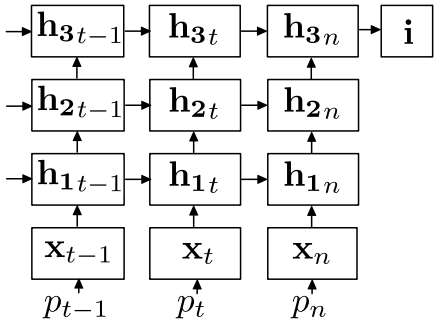

Figure 1: A three-timestep slice of the stacked recurrent architecture with three hidden layers.

ɐjʌŋwʊmənɹaɪdɪŋəhɔːshəʊldɪŋəflag

A young woman riding a horse holding a flag

Figure 2: (Top) Example of a postprocessed phonetic transcription from eSpeak used as input to the PHON GRU model. (Bottom) Corresponding image.

where $\odot$ is elementwise multiplication, and the update gate activation $\mathbf{z_t}$ determines the amount of new information mixed in the current state:

$$\mathbf{z}_t = \sigma_s(\mathbf{W}_z\mathbf{x}_t + \mathbf{U}_z\mathbf{h}_{t-1}) \tag{2}$$

The candidate activation is computed as:

$$\tilde{\mathbf{h}}_t = \sigma(\mathbf{W}\mathbf{x}_t + \mathbf{U}(\mathbf{r}_t \odot \mathbf{h}_{t-1})) \tag{3}$$

The reset gate $\mathbf{r_t}$ determines how much of the current input $\mathbf{x_t}$ is mixed in the previous state $\mathbf{h}_{t-1}$ to form the candidate activation:

$$\mathbf{r}_t = \sigma_s(\mathbf{W}_r\mathbf{x}_t + \mathbf{U}_r\mathbf{h}_{t-1}) \tag{4}$$

By applying the gru function repeatedly a GRU layer maps a sequence of inputs to a sequence of states:

$$\mathrm{GRU}(\mathbf{X}, \mathbf{h}_0) = \mathrm{gru}(\mathbf{x}_n, \ldots, \mathrm{gru}(\mathbf{x}_2, \mathrm{gru}(\mathbf{x}_1, \mathbf{h}_0))) \tag{5}$$

where $\mathbf{X}$ stands for the matrix composed of input column vectors $\mathbf{x}_1, \ldots, \mathbf{x}_n$. Two or more GRU layers can be composed into a stack:

$$\mathrm{GRU}_2(\mathrm{GRU}_1(\mathbf{X}, \mathbf{h_{1}}_0), \mathbf{h_{2}}_0). \tag{6}$$

In our version of the Stacked GRU architecture we use *residualized* layers:

$$\mathrm{GRU}_{\mathrm{res}}(\mathbf{X}, \mathbf{h}_0) = \mathrm{GRU}(\mathbf{X}, \mathbf{h}_0) + \mathbf{X} \tag{7}$$

Residual convolutional networks were introduced by He et al. (2015), while Oord et al. (2016) showed their applicability to recurrent architectures. We adopt residualized layers here as we observed they speed up learning in stacks of several GRU layers.

Our gated recurrent units use steep sigmoids for gate activations:

$$\sigma_s(z) = \frac{1}{1 + \exp(-3.75z)}$$

and rectified linear units clipped between 0 and 5 for the unit activations:

$$\sigma(z) = \mathrm{clip}(0.5(\mathrm{z} + \mathrm{abs}(\mathrm{z})), 0, 5)$$

There are two more components of our PHON GRU model: the phoneme encoding layer, and mapping from the final state of the top GRU layer to the image feature vector. The phoneme encoding layer is a simply a lookup table $\mathbf{E}$ whose columns correspond to one-hot-encoded phoneme vectors. The input

phoneme p_t of utterance p at each step t indexes into the encoding matrix and produces the input column vector:

$$\mathbf{x}_t = \mathbf{E}[:, p_t]. \tag{8}$$

Finally, we map the final state of the top GRU layer $\mathbf{h}_{\mathbf{K}n}$ to the vector of image features using a fully connected layer:

$$\hat{\mathbf{i}} = \mathbf{I}\mathbf{h}_{\mathbf{K}n} \tag{9}$$

Our main interest lies in recurrent phoneme-level modeling. However, in order to put the performance of the phoneme-level PHON GRU into perspective, we compare it to two word-level models. Importantly, the word models should **not** be seen as baselines, as they have access to word boundary and word identity information not available to PHON GRU.

3.2 Word GRU

The architecture of this model is the same as PHON GRU with the difference that we use words instead of phonemes as input symbols, use learnable word embeddings instead of fixed one-hot phoneme encodings, and reduce the number of layers in the GRU stack. See Section 4 for details.

3.3 Word Sum

The second model we use for comparison is a word-based non-sequential model, consisting of a word embedding matrix, a vector sum operator, and a mapping to the image feature vector:

$$\hat{\mathbf{i}} = \mathbf{I}\sum_{t=1}^{n}\mathbf{E}[:, w_t] \tag{10}$$

where w_t is the word at position t in the input utterance. This model simply learns word embeddings which are then summed into a single vector and projected to the target image vector. Thus this model does not have access to word sequence information, and is a distributed analog of a bag-of-words model.

4 Experiments

For all experiments, the models were trained on the training set of MS-COCO. MS-COCO contains over 163,000 images accompanied by at least five captions by human annotators. With an average of 7.7 labeled object instances per image, images typically contain more objects than the captions mention, making reference to the scene ambiguous. Textual input for the PHON GRU models was transcribed automatically using the grapheme-to-phoneme functionality with the default English voice of the eSpeak speech synthesis toolkit.[1] Stress and pause markers were removed, as well as word boundaries (after storing their position for use in experiments), leaving only phoneme symbols. See Figure 2 for an example transcription.

Visual input for all models was obtained by forwarding images through the 16-layer convolutional neural network described in Simonyan and Zisserman (2014) pre-trained on Imagenet (Russakovsky et al., 2014), and recording the activation vectors of the pre-softmax layer. The z-score transformation was applied to these features to ease optimization.

Most of the details of the three model types and training hyperparameters were adopted from related work, and adapted via a limited amount of exploratory experimentation. Exhaustive exploration of the search space was not feasible due to the large number of adjustable settings in these models and their long running time. Given the importance of depth for our purposes, we did systematically explore the number of layers in the PHON GRU and WORD GRU models. A single layer is optimal for WORD GRU. For PHON GRU, see Section 4.1 below. Other important settings were as follows:

- All models: Implemented in Theano (Bastien et al., 2012), optimized with Adam (Kingma and Ba, 2014), initial learning rate of 0.0002, minibatch size of 64, gradient norm clipped to 5.0.

[1] Available at `http://espeak.sourceforge.net`

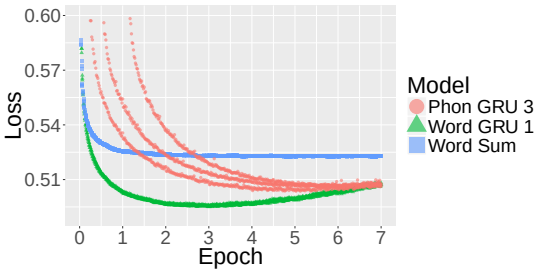

Figure 3: Value of the loss function on validation data during training. Three random initialization of each model are shown.

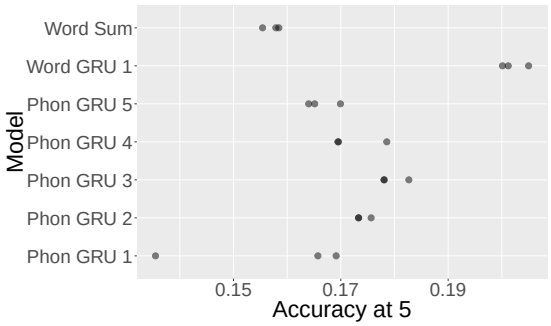

Figure 4: Validation accuracy at 5 on the image retrieval task.

- WORD SUM: 1024-dimensional word embeddings, words with frequencies below 10 replaced by UNK token.
- WORD GRU: 1024-dimensional word embeddings, a single 1024 dimensional hidden layer, words with frequencies below 10 replaced by UNK token.
- PHON GRU: 1024-dimensional hidden layers.

4.1 Prediction of visual features

The models are trained and evaluated on the prediction of visual feature vectors from captions. While our goal is not to develop an image retrieval method, we use this task as it reflects the ability to extract visually salient semantic information from language. For the experiments on the prediction of visual features all models were trained on the training set of MS-COCO. As validation and test data we used a random sample of 5000 images each from the MS-COCO validation set.

Figure 3 shows the value of the validation average cosine distance between the predicted visual vector and the target vector for three random initializations of each of the model types.

The Phonetic GRU model is more sensitive to the initialization: one can clearly distinguish three separate trajectories. The word-level models are much less affected by random initialization. In terms of the overall performance, the PHON GRU model falls between the WORD SUM model and the WORD GRU model.

We also evaluated the models on how well they perform when used to search images: for each validation sentence the model was used to predict the visual vector. The image vectors in the validation data were then ranked by cosine similarity to the predicted vector, and the proportion of times the correct image was among the top 5 was reported. By *correct* image we mean the one which the sentence was used to describe (even though often many other images are also good matches to the sentence).

In Figure 4 we report the validation accuracies on this task for the two word-level models, as well as for the Phon GRU model with different number of hidden layers. We trained each model version with three random initializations for each model setting, and evaluate after each epoch. We report the score of the best epoch for each initialization. The overall ranking of the models matches the direct evaluation of the loss function above: the phoneme-level models are in between the two word-level models. PHON GRU with three hidden layers is the best of the phoneme-level models.

In Table 1 we show the accuracies of the best version of each of the models types on the test images; these are also the model versions used in all subsequent experiments. The scores for the WORD GRU are comparable to what Chrupała et al. (2015) report for their multitask IMAGINET model, whose visual pathway has the same structure, and who use the same data. More recently, Vendrov et al. (2016) report

substantially higher scores for image search with a word-level GRU model, with the following main differences from our setting: better image features, larger training set, and a loss function optimized for the ranking task.[2]

4.2 Word boundary prediction

To explore the sensitivity of the PHON GRU model to linguistic structure at the sub-word level, we investigated the encoding of information about word-boundaries in the hidden layers. Logistic regression models were trained on activation patterns of the hidden layers at all timesteps, with the objective of identifying phonemes that preceded a word boundary. For comparison, we also trained logistic regression models on *n*-gram data to perform the same tasks, with positional phoneme *n*-grams in the range 1-*n*. The location of the word boundaries was taken from the eSpeak transcriptions, which mostly matches the location of word boundaries according to conventional English spelling. However, eSpeak models some coarticulation effects which sometimes leads to word boundaries disappearing from the transcription. For example, *bank of a river* is transcribed as [baŋk əvə ɪɪvə].

All models were implemented using the `LogisticRegression` implementation from Scikit-learn (Pedregosa et al., 2011) with L2-regularization. The random samples of 5,000 images each that served as validation and test sets in the visual feature prediction task were used as training and test sets. For the models based on the activation patterns of the hidden layers, the z-score transformation was applied to the activation values to ease optimization. The optimal value of regularization parameter *C* was determined using `GridSearchCV` with 5-fold cross validation on the training set, after which the model with the optimal settings was trained on the full training sample.

Table 2 reports the scores on the test set. The proportion of phonemes preceding a word boundary is 0.29, meaning that predicting *no word boundary* by default would be correct in 0.71 of cases. At the highest hidden layer, enough information about the word form is available for correct prediction in 0.82 of cases – substantially above the majority baseline. The lower levels allow for more accurate prediction of word boundaries: 0.86 at the middle hidden layer, and 0.88 at the bottom level. Prediction scores of the logistic regression model based on the activation patterns of the lowest hidden layer are comparable to those of a bigram logistic regression model.

These results indicate that information on sub-word structure is only partially encoded by PHON GRU, and is mostly absent by the time the signal from the input propagates to the top layer. The bottom layer does learn to encode a fair amount of word boundary information, but the prediction score substantially below 100% indicates that it is rather selective.

Model	Acc @ 5	Acc @ 10
WORD SUM	0.158	0.243
WORD GRU	0.205	0.306
PHON GRU	0.180	0.276

Table 1: Image retrieval accuracy at 5 and at 10 on test data for the versions of WORD SUM, WORD GRU and PHON GRU chosen by validation.

Model		**Acc**	**Prec**	**Rec**
Majority		0.71		
Phon GRU	Layer 1	0.88	0.82	0.78
	Layer 2	0.86	0.79	0.71
	Layer 3	0.82	0.74	0.60
n-gram	$n = 1$	0.80	0.79	0.41
	$n = 2$	0.87	0.79	0.78
	$n = 3$	0.93	0.86	0.90
	$n = 4$	0.95	0.90	0.93

Table 2: Prediction scores of logistic regression models based on activation vectors of PHON GRU and on positional *n*-grams

4.3 Word similarity

To understand the encoding of semantic information in PHON GRU, we analyzed the cosine similarity of activation vectors for word pairs from the MEN Test Collection (Bruni et al., 2014). The MEN

[2]We have preliminary results indicating that most of the analyses in the rest of Section 4 show the same general pattern for phoneme models trained following the setting of Vendrov et al. (2016).

dataset contains 3,000 pairs of English words with semantic similarity judgements on a 50-point scale, which were obtained through crowd-sourcing.[3] For each word pair in the MEN dataset, the words were transcribed phonetically using eSpeak and then fed to PHON GRU individually. For comparison, the words were also fed to WORD GRU and WORD SUM. Word pair similarity was quantified as the cosine similarity between the activation patterns of the hidden layers at the end-of-sentence symbol. In contrast to WORD GRU and WORD SUM, PHON GRU has access to the sub-word structure. To explore the role of phonemic form in word similarity, a measure of phonemic difference was included: the Levenshtein distance between the phonetic transcriptions of the two words, normalized by the length of the longer transcription.

Table 3 shows Spearman's rank correlation coefficient between human similarity ratings from the MEN dataset and cosine similarity at the last timestep for all hidden layers. In all layers, the cosine similarities between the activation vectors for two words are significantly correlated with human similarity judgements. The strength of the correlation differs considerably between the layers, ranging from 0.09 in the first layer to 0.28 in the highest hidden layer. The second column in Table 3 shows the correlations when only taking into account the 1283 word pairs of which both words appear at least 100 times in the training set of MS-COCO. Correlations for both WORD GRU and WORD SUM are considerably higher than for PHON GRU. This is expected given that these are word level models with explicit word-embeddings, while PHON GRU builds word representations by forwarding phoneme-level input through several layers of processing.

	All words	Frequent words
PHON GRU Layer 1	0.09	0.12
Layer 2	0.21	0.33
Layer 3	0.28	0.45
WORD GRU	0.48	0.60
WORD SUM	0.42	0.56

Table 3: Spearman's correlation coefficient between word-word cosine similarity and human similarity judgements. All correlations significant at $p < 1e{-}4$. Frequent words appear at least 100 times in the training data.

Layer	ρ
1	-0.30
2	-0.24
3	-0.15

Table 4: Spearman's rank correlation coefficient between PHON GRU cosine similarity and phoneme-level edit distance. All correlations significant at $p < 1e{-}15$.

Table 4 shows Spearman's rank correlation coefficient between the edit distance and the cosine similarity of activation vectors at the hidden layers of PHON GRU. As expected, edit distance and cosine similarity of the activation vectors are negatively correlated: words which are more similar in form are also more similar according to the model.[4]

The negative correlation between edit distances and cosine similarities is strongest at the lowest hidden layer and weakest, though still present and stronger than for human judgements, at the third hidden layer.

The correlations of cosine similarities with edit distance on the one hand, and human similarity rating on the other hand, indicate that the different hidden layers reflect increasing levels of representation: whereas at the lowest level mostly encodes information about form, the highest layer mostly encodes semantic information.

4.4 Position of shared substrings

Here we quantify the time-scale at which information is retained in the different layers of PHON GRU. We looked at the location of phoneme strings shared by sentences and their nearest neighbors in the 5,000-image validation sample. We determined each sentence's nearest neighbor for each hidden layer in PHON GRU. The nearest neighbour is the sentence for which the activation vector at the end of sentence symbol has the smallest cosine distance to the activation vector of the original sentence. The

[3]The MEN dataset is available at `http://clic.cimec.unitn.it/~elia.bruni/MEN`

[4]Note that in the MEN dataset, meaning and word form are also (weakly) correlated: human similarity judgements and edit distance are correlated at -0.08 ($p < 1e{-}5$).

position of matching substrings is the average position in the original sentence of symbols in substrings that are shared by the neighbor sentences, counted from the end of the sentence. A high mean average substring position thus means that the shared substring(s) appear early in the sentence. This gives an indirect measure of the timescale at which the different layers operate. Table 5 shows an example.

As can be seen in Table 6, the average position of shared substrings in neighbor sentences is closest to the end for the first hidden layer and moves towards the beginning of the sentence for the second and third hidden layer. This indicates a difference between the layers with regards to the timescale they represent. Whereas in the lowest layer only information from the latest timesteps is present, the higher layers retain the input signal over longer timescales.

Layer 1
A metallic bench **on a path in** the **park**
A man riding a bicycle **on a path** in a **park**
Layer 3
A metallic **bench** on a path in the **park**
A stone park **bench** sitting in an empty green **park**

Table 5: An illustrative sentence with its nearest neighbour at layer 1 and layer 3. For readability, sentences are displayed in conventional spelling, and only highlight matching substrings of length $\geq$ 3. In reality we used phonetic transcriptions to compute shared substring positions, and substrings of all lengths.

Layer	Mean position
1	12.1
2	14.9
3	16.8

Table 6: Average position of phonemes in shared substrings between nearest neighbour sentences according to PHON GRU representations at the different layers. Positions are indexed from end of string.

5 Future work

Although our analyses show a clear pattern of short-timescale information in the lower layers and larger dependencies in the higher layers, the third layer still encodes information about the phonetic form: its activation patterns were predictive of word boundaries, and similarities between word pairs at this level were more strongly correlated with edit distance than human similarity judgements are. It would be interesting to investigate exactly what information that is, and to what extent it is analogous to language representation in the mind of human speakers. In humans both word phonological form and word meaning can act as primes, which is somewhat reminiscent of the behavior of our model.

Finally, we would like to take the next step towards grounded learning of language from raw perceptual input, and apply models similar to the one described here to acoustic speech signal coupled with visual input. We expect this to be a challenging but essential endeavor.

Abstract

Light verb constructions (LVC) in Hindi are highly productive. If we can distinguish a case such as *nirnay lenaa* 'decision take; decide' from an ordinary verb-argument combination *kaagaz lenaa* 'paper take; take (a) paper', it has been shown to aid NLP applications such as parsing (Begum et al., 2011) and machine translation (Pal et al., 2011). In this paper, we propose an LVC identification system using language specific features for Hindi which shows an improvement over previous work (Begum et al., 2011). To build our system, we carry out a linguistic analysis of Hindi LVCs using Hindi Treebank annotations and propose two new features that are aimed at capturing the diversity of Hindi LVCs in the corpus. We find that our model performs robustly across a diverse range of LVCs and our results underscore the importance of semantic features, which is in keeping with the findings for English. Our error analysis also demonstrates that our classifier can be used to further refine LVC annotations in the Hindi Treebank and make them more consistent across the board.

1 Introduction

Light verb constructions (LVC) are found across languages e.g. Japanese, Korean, Persian as well as English. An LVC consists of a predicating element (usually a noun) and a verb, which is also known as a *light* verb. For instance, *take a walk* or *give a sigh* are LVCs consisting of light verbs *take* and *give* and their corresponding predicating nouns *walk* and *sigh*. The nouns in an LVC contribute to the event semantics and the light verb supplies additional meaning e.g. agentivity, completeness, or permission. In Hindi, LVCs are productive and are also sometimes termed as 'support verb' or 'conjunct verb' constructions. Examples 1 and 2 contrast the use of a simple predicate *de* 'give' with its light verb usage.

(1) Simple predicate

raam=ne mohan=ko kit̪ab d̪-ii
Ram.M.Sg=Erg Mohan.M.Sg=Dat book.F.Sg give-Perf.F.Sg

'Ram gave Mohan a book'

(2) Noun-Verb complex predicate

raam=ne us baat̪=par **zor** **d̪i-yaa**
Ram.M.Sg=Erg that topic=loc pressure.M.Sg give-Perf.M.Sg

'Ram put an emphasis on that topic'

LVCs form a large part of the lexicon in Hindi. In the Hindi treebank (Palmer et al., 2009) (400,000 words), there are nearly 47,163 predicates, of which 37% have been annotated as LVCs. LVCs consist of predicate types that are far more numerous than simple verbs. Hindi has approximately 700 simple verbs, but potentially many more unique LVCs. This makes them a highly productive phenomenon in Hindi.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1320–1329, Osaka, Japan, December 11-17 2016.

Butt (2010) notes that light verbs in Hindi LVCs act as a verbalizers in order to create new predicates and incorporate borrowed items into the language e.g. *email kar* 'email do; email'. Therefore, LVCs are sometimes described as "a preferred way of augmenting the creative potential of the language" (Kachru, 2006, pp 93).

The identification of LVCs in Hindi (as well as other South Asian languages) is an important NLP task, which has been shown to improve parsing accuracy (Begum et al., 2011) as well as machine translation performance (Pal et al., 2011). The detection of multi-words such as LVCs has been widely studied and association measures, linguistic knowledge and parallel corpora have been used.

As LVCs are a type of multiword, a commonly used method is 'N-gram classification' (Green et al., 2013). This strategy extracts n-grams from the corpus, filters them and assigns some values based on a bigram measures such as log-likelihood or mutual information. A classifier is then used to make a LVC/non-LVC decision. However, previous work has shown that LVCs benefit from the use of linguistic features for identification. Vincze et al. (2011) used bigram association measures for English noun-noun compounds and LVCs. They found that LVC detection improves when linguistic features are used in addition to n-gram information. Tu and Roth (2011) showed that linguistic and statistical features perform at par for English LVC detection.

For Hindi, we expect that linguistic features will be useful for automatic detection. At the same time, the productivity and range of LVC constructions in Hindi result in some specific challenges. In the next section, we carry out a linguistic analysis of LVCs based on the annotations in the Hindi Treebank. We use these insights to propose two new features to identify LVCs. Following this, we describe our experimental setup and then discuss the results.

2 Linguistic challenges for Hindi

The linguistic notion of an LVC differs across languages. While annotating an English corpus with LVC information, Tu and Roth (2011) make use of a 'replacing' principle for their annotators, where if a candidate light verb like *take* in *take a walk* can be replaced by *walk* without (too much) of a change in meaning, then a combination like *take a walk* is considered an LVC.

In Hindi, such a 'replacing' principle is not available as the nouns that participate in LVCs are not necessarily deverbal in nature i.e. the majority do not have a direct verbal counterpart. In fact, LVCs are a preferred method of introducing new predicates into the language via borrowed nouns. Bhattacharyya et al. (2007) have described a number of diagnostic criteria for Hindi LVCs, but these are not completely robust–and can only be applied to LVCs that are transitive. In fact, most linguistic diagnostics mentioned in Mohanan (1994) and Bhattacharyya et al. (2007) are appropriate for transitive LVCs that occur with light verb *kar*. Such cases are the most frequently occurring LVCs in Hindi, but do not represent all LVCs.

Consequently, the application of diagnostic tests for LVCs for a large corpus can be challenging. The Hindi Treebank (Palmer et al., 2009) is a relatively large resource that is annotated with LVC information using the `pof` label. We use this data to examine the behaviour of Hindi LVCs, focusing on each component: the light verb and the predicating nominal.

2.1 Light verbs

Jespersen (1965) coined the term 'light' verb to refer to verbs that do not behave like standard verbal predicates as they have a depleted semantic contribution to the event described by the LVC. These light verbs tend to be similar cross-linguistically e.g. *take*, *make* and *give* can be found in English, Persian and Hindi. At the same time, these verbs are distributed differently across languages.

In the Hindi Treebank, the distribution of light verbs reflects some interesting facts about LVC formation in Hindi. Figure 1 shows the 20 most frequently occurring light verbs in the Training and Development sections of the Hindi Treebank (approx. 21,000 sentences). These light verbs include the following: *kar* 'do', *ho* 'be/happen', *de* 'give', *hE* 'be', *raha* 'stay', *aa* 'come', *karaa/karvaa* 'cause to do', *lagaa* 'touch/feel', *jataa* 'convey', *le* 'take', *banaa* 'make', *rakh* 'keep', *chal* 'go', *uthaa* 'rise', *daala* 'put', *laDa* 'fight', *lag* 'seem', *ban* 'become', *maar* 'hit'. Each of these light verbs also appear as 'full' verbs

i.e. they can also appear without a nominal predicate, as a non-LVC.

The bar plot in Figure 1 shows that the frequency of *kar* 'do' is the greatest, followed by *ho*, 'be' and *de* 'give'. The light verb *kar* 'do' has many more positive cases of LVCs as compared to non-LVCs.For other light verbs such as *de*, the distribution is more even and with other light verbs, there are far more non-light usages of these verbs as compared to light.

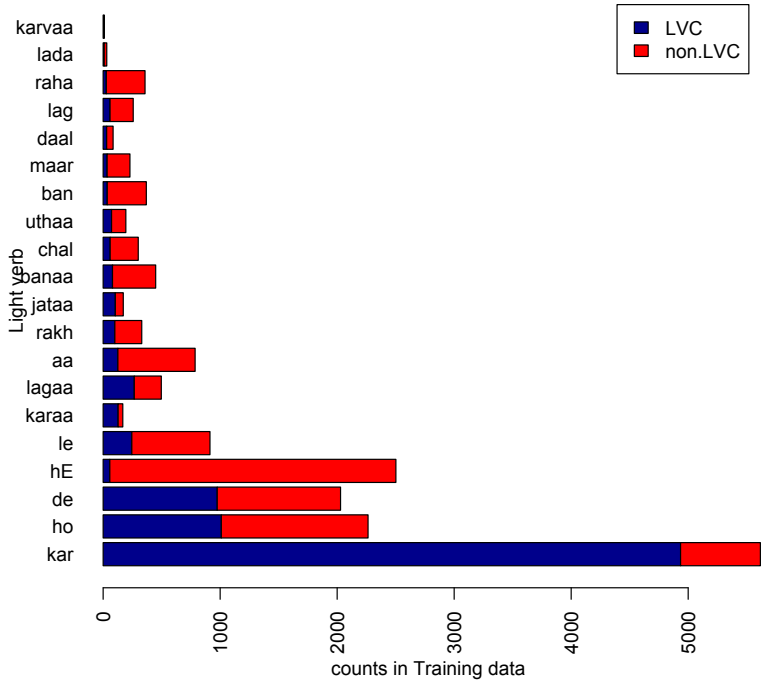

Figure 1: Light verb distribution in the Training and Development section of the Treebank

If we were to divide the training data by light verb and use the majority class to predict the light or non-light case, we would still get reasonably good results. This is because the light *kar* cases far outnumber the others, and one can expect the majority class baseline to be as high as 0.8. Conversely, a light verb like *aa* 'come' has more non-light usages than light, hence the majority class prediction would also be quite high.

Begum et al. (2011) describe a classifier for Hindi LVCs but do not mention the distribution of LVCs in the data. Therefore, it is difficult to know whether the results are applicable to all LVCs or just the light verb 'kar'. In contrast, Butt et al. (2012) focus on light verbs *kar* 'do' and *ho* 'be' alone. In this paper, we make use of the Hindi Treebank LVC annotations to evaluate our 'combined' system, but provide evaluation across individual light verbs in the corpus. This also implies that we must incorporate features that are specific not only to 'kar', but across all light verbs in the data.

2.2 Nominal predicates

The Hindi Treebank consists of more than 3000 unique nominals that can occur as part of an LVC. At the same time, some of these nouns can combine with more than one light verb to form an LVC e.g. *ishaara kar* 'signal do; make a sign' and *ishaara de* 'signal give; give a sign', with some subtle differences in meaning. It is possible that one of these combinations is more frequent than the other- or they may be equiprobable. There are also certain nouns where only one light verb is possible e.g. *maut ho* 'death be; die'.

We carried out a corpus study, examining 1853 unique nouns from the Training and Development sections of the Hindi Treebank and extracted the number of light verbs that occurred with them. Although,

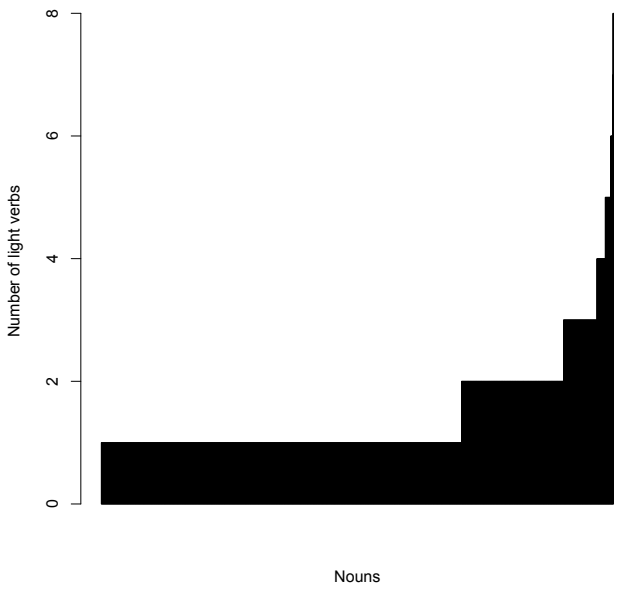

Figure 2: Number of light verbs that occur with a unique noun. (t=1853)

Figure 2 shows a 'long tail', where a large number of nouns occur with just one light verb, about 1/4th of the data consists of nouns that alternate with more than one light verb.

These alternations show that a collocational measure that only looks at the bigram occurrences may not be able to capture a noun-light verb alternation that is relatively infrequent. Therefore, linguistic information would be required to identify a predicating nominal that appears in a number of contexts. In the following section, we propose new features that could help capture this information.

3 Linguistic features used for LVCs

English LVC identification focuses on extracting linguistic features for LVCs (Tan et al., 2006; Grefenstette and Teufel, 1995; Stevenson et al., 2004). For example, the morpho-syntactic similarity between nominal predicates and their verbal counterparts (e.g. *walk* and *take a walk*) is often exploited. Other cues include the presence of indefinite determiners (such as *a*) before the nominal predicate.

Tu and Roth (2011) look at both statistical and linguistic contexts to detect English complex predicates. Among their local linguistic features, they utilize bigram information about the nominal head and light verb, the nouns themselves and the Levin verb class members of deverbal nouns. In a more recent study, Chen et al. (2015) have described an improvement over Tu and Roth (2011)'s performance by using lexical features from WordNet, as well as word sense information. Using the Tu and Roth (2011) testset, they report a 0.89 F-score for English LVCs.

Author/Feature	**Tan et al'06** (Eng)	**Tu and Roth'11** (Eng)	**Begum et al'11** (Hin)
Deverbal noun	Y	Y	
Noun semantics	Y	Y	Y
Light verb list	Y	Y	Y
Presence post-posn			Y
Presence determiner	Y	Y	
Collocational measure		Y	Y

Table 1: Commonly used linguistic features for English and Hindi LVC detection.

The work for Hindi LVC detection makes use of a similar set of linguistic features. Begum et al. (2011) look for the presence of postpositions and demonstratives, which preferentially do not occur with a noun that is a part of an LVC. Like Tu and Roth (2011), they use the verb-object bigram and the noun class information from Hindi WordNet (Narayan et al., 2002). They have achieved an accuracy of around 0.85 for identification of Hindi complex predicates. More recently, Singh et al. (2015) have compared word embeddings and WordNet-based measures to detect Hindi noun compounds and LVCs. While word embeddings are effective for compounds, they perform poorly for LVCs, suggesting the importance of more precise linguistic features.

3.1 Linguistic features for Hindi

Our linguistic analysis of LVCs indicates that the properties of both noun and light verb are crucial as features for identifying LVCs. In the previous section, we described some of the commonly used features for LVC identification. Table 1 shows some of these: the presence of post-positions after the predicating noun, collocational features and lexical features.

In this section, we introduce two new features that are based on our study of Hindi LVCs. The first is based on the idea that there are semantic constraints on the combination of a particular noun and light verb. Sulger and Vaidya (2014) examined the combinatorial properties of noun and light verb based on relative frequency of occurrence. They found that a light verb such as *de* 'give' is likelier to combine with nouns that have a 'transfer' property, whereas nouns that occur with *kar* 'do' will occur with nouns that describe actions with animate agents. Light verb *ho* 'be' often appears with stative nouns or those that indicate mental states.

In order to capture these properties, we used a feature that associated a light verb with the ontological property of the noun that is likely to occur with it. For example *kar* was associated with *Physical_Action_Abstract_Inanimate* and *de* 'give' with *Communication_Action_Abstract_Inanimate*. These ontological properties were extracted from Hindi WordNet (Bhattacharyya, 2010). If a noun occurred with the ontological property that was associated with a particular light verb, it was marked positively for this feature.

The second feature was based on the idea that predicating nominals usually introduce arguments of their own. These usually occur with the postpositions *par* 'on', *se* 'with', *ko* 'to' or *kii* 'of'. These indicate that a nominal has introduced an argument of its own–and is likely to be a predicating nominal rather than an ordinary argument of the verb. Examples 3-5 illustrate the cases where a nominal introduced an argument with *par*, *se* or *kii*.

(3) pulis=ne **logon=par** hamlaa ki-yaa
police=Erg people=loc attack.M.Sg do-Perf.M.Sg
'(The) Police attacked the people'

(4) samir=ne **mohan=se** nafrat k-ii
samir.M.Sg=Erg Mohan.M.Sg=instr hatred.F do-perf.F.Sg
'Samir hated Mohan'

(5) samir=ne **ghadii=kii** chorii k-ii
Samir.M.Sg-Erg watch.F.Sg-gen theft.F do-Perf.F
'Samir stole the watch'

This feature was introduced to overcome some of the shortcomings of the 'presence of post-position' feature on the noun (Table 1). The post-position only looks at the presence or absence of post-positions on the predicating noun, whereas the proposed feature looks at the postpositions on the nominal's *arguments*. The former feature is restricted to agentive nominals, whereas this feature is applicable to all predicating nominals that license arguments.

4 Experimental setup

We make use of the Hindi Treebank data to train our LVC identification system. The Hindi Treebank annotation guidelines describe the use of the label `pof` to identify Hindi LVCs. They make use of

	Train	**Development**	**Test** (Treebank)	**Test** (ICON)
News	14282	3500	1708	2757
LVC	6739	1665	790	1056
non-LVC	7543	1835	918	1701

Table 2: Training, Development and Test instances, with the number of light and non-light verbs

annotators' linguistic intuition to identify **pof** cases with a "full understanding that it may lead to some inconsistency in the data" (Bharati et al., 2012, p41). This is probably because of the lack of reliable linguistic diagnostics mentioned earlier in section 2. As a result, we can think of the Hindi Treebank annotation of LVCs as reflecting a fairly generous conceptualization of LVCs.

In order to reduce any errors and inconsistencies, in this work we take into consideration only the top 20 most frequently occurring light verbs in the corpus[1]. These account for 90% of the LVCs in the Treebank. The remaining light verbs occur only less than 10 times in the corpus and we assume that low frequency might indicate an annotation error. Although this may leave out some valid cases of LVCs, we make the assumption that LVCs represented by these 20 light verbs give us a fairly good representation of the LVC construction. Begum et al. (2011) also make use of the 20 most frequently occurring light verbs in their model. However, they do not provide a list of these light verbs in their paper. Although we may not be able to make a very exact comparison with their model, we would imagine that the differences will be minor, with respect to the low frequency light verbs.

In order to select candidates, we identified positive and negative instances of LVCs in the Hindi parse trees. In the Hindi dependency parse tree, the predicative noun is a dependent of the light verb and in the majority of the cases, both noun and light verb occur next to each other in the sentence. The noun and light verb can be scrambled away from each other, but we found this to be fairly rare in the Treebank LVC examples. Therefore, we chose candidates based on proximity; e.g. if a phrase annotated as an NP occurred next to a verb phrase containing a light verb, this was taken to be a candidate for LVC identification. Apart from NP phrases, we also accepted phrases annotated as 'BLK', which indicated that the noun was borrowed from English. Such nouns often occur as part of LVCs, as complex predication is used to introduce new words into the language.

Our training data made use of the splits provided by the Hindi Treebank, to which we added a small sub-part of the Treebank consisting of conversational data, taken from fiction. The rest of the Hindi Treebank is news text. We made use of the training and test splits given by the Treebank, but kept a small portion of the training set as a development set. Table 2 shows the division between the training, development and test sets and the distribution of positive and negative classes. Across the board, we find that the number of non-LVCs is higher than the LVC instances.

The two test sets are drawn from different genres. The Treebank test set is from the testing split provided by the Hindi Treebank and is news text. The second test set consists of sentences taken from literary criticism. This data is not from the Treebank, but taken from the ICON 2009 Shared task for Hindi parsing (Husain, 2009) and we will refer to this test set as 'ICON'. We included this test set to compare the performance of our model with Begum et al. (2011).

4.1 Features

The features used for identification of LVCs can be grouped into roughly four categories viz. lexical, morphosyntactic, collocational and semantic. We used features that are similar to those included in Begum et al. (2011) as well as Tu and Roth (2011), and additionally introduced two new features (section 3.1). Table 3 shows the set of features used for identifying LVC cases in the Treebank. The other features have been used in previous work to identify English or Hindi LVCs. For the collocational features, the values were obtained from a large corpus (Hindi Wikipedia) and then converted to binary features. For log-likelihood, this was done using a table of critical values to decide whether the ratio was significant.

[1]These verbs are listed in section 2.1

Accordingly, it got the binary feature 0 or 1. In the case of PMI, we checked whether its value was greater than or less than 0 for a given noun and verb candidate. If it was greater, then the noun-verb pair was likely to be a better collocation.

Type	No	Feature
Lexical	1	Verb lemma (Baseline)
	2	Noun lemma
Morpho-syntactic	3	Postposition after noun
	4	Arguments of eventive noun (eventive nouns have an 'extra' argument)
Collocational	5	Log-likelihood value
	6	Pointwise Mutual Information value
Semantic	7	Ontological category of noun
	8	Acceptability of noun with a given light verb

Table 3: Features used for LVC detection

4.2 Model

We experimented with two types of models: a linear model (Logistic Regression) and SVM with an RBF kernel. The eight feature types described earlier generated 3278 features, over which we performed feature selection to choose 1638 (roughly half) of the features based on their individual f-scores. The motivation to carry out feature selection was because of the large number of lexical features, some of which may not have been significantly useful for the classifier. We made use of the *fselect.py* tool for feature selection (Chen and Lin, 2006).

We used the Scikit-learn package (Pedregosa et al., 2011) to train our model. Scikit-learn uses the LIBSVM implementation of support vector machines (Chang and Lin, 2011) and the LIBLINEAR implementation for logistic regression (Fan et al., 2008). We made use of 10-fold cross validation to find the best value of C and gamma for the RBF kernel (C=1, gamma=0.05).

5 Evaluation

We trained our two models using the features described in section 4.1 and evaluated them against the two test sets that we described earlier. We used the verb lemma as our baseline feature. Table 4 shows the performance of our system in comparison to the verb lemma baseline and the system described in Begum et al. (2011).

	Logistic Regression			**SVM with RBF**		
ICON	**Precision**	**Recall**	**F1**	**Precision**	**Recall**	**F1**
LVC	87.77	76.13	81.54	88.42	76.7	82.15
Non-LVC	86.31	93.41	89.72	86.63	93.76	90.06
Accuracy	86.79			**87.23**		
Begum et. al. (2011)	85.28					
Verb lemma Baseline	75.87			75.66		
News	**Precision**	**Recall**	**F1**	**Precision**	**Recall**	**F1**
LVC	86.36	91.39	88.80	85.8	90.25	87.97
Non-LVC	92.20	87.58	89.83	91.22	87.14	89.13
Accuracy	89.34			88.58		
Verb lemma Baseline	80.97			80.91		

Table 4: Precision, recall and F1 scores for the ICON and News test sets

Both our models perform better than Begum et al. (2011) on the same test set. Additionally, we also evaluated our system on the news test set from the Hindi Treebank. The performance on the news dataset is better, most probably because of the smaller number of unseen nouns in news (180) as compared to ICON (612).

The diversity of the LVCs in Hindi implies that we would like to check the performance of our system across all light verbs. As the light verb *kar* is the most frequently occurring light verb, we expect that it will give us the best results. We carried out two types of experiments for light verbs: first we

ran individual classifiers across light verbs using the same feature set and compared its micro-averaged performance with that of the combined model. We found that this result was almost exactly similar to the combined model. As a second experiment, we also looked at the performance for individual light verbs within the combined model itself.

Table 5 describes the performance for individual light verbs *kar*, *ho*, *de* and *le*. The other light verbs are fairly infrequent, hence they are grouped into *LF-TR* for transitive light verbs and *LF-INTR* for intransitive light verbs. We find that LVCs with *kar* are identified with high accuracy because of their high frequency. The performance is slightly less accurate for other light verbs, notably *ho* 'be'. However, they still perform above the baseline, indicating that the features are robust enough to identify a wide range of LVCs. The *LF-INT* cases have a poor recall because the number of negative examples far outnumber the positive. The baseline accuracy for *LF-INT* also reflects this imbalance. We see a similar performance for individual light verbs in the news test set.

Individual LVs	LVs in test data	Precision	Recall	F1	Baseline	Accuracy
kar 'do'	650	96.54	95.07	95.80	81.23	93.23
ho 'be'	454	72.26	83.49	77.47	54.62	77.97
de 'give'	216	85.36	70.00	76.92	53.7	80.5
le 'take'	110	91.66	52.38	66.66	61.81	80
LF-TR	263	85.71	42.85	57.14	73.0	86.31
LF-INT	1064	83.33	16.12	27.02	88.34	89.84

Table 5: Precision, Recall and F1 for individual light verbs in the ICON test set, using Logistic Regression. The baseline accuracy uses the verb lemma as the feature.

5.1 Discussion

In order to understand the most informative features for our model, we examined the top 25 best performing features for the SVM model. We found that the best features for the positive class included the light verb lemma *kar* and a high-frequency noun lemma *shuru* 'begin'. Both log-likelihood and PMI were highly predictive of the positive class as well as the new feature using nominal argument postpositions. Semantic features such as 'Artifact,Object,Inanimate,Noun' were predictive of the negative class. This shows us that the linguistically motivated features are indeed effective for identification. From the analysis, it also appeared that semantic features overall can be more discriminative than lexical features for Hindi. This result is congruent with the results from English in Chen et al. (2015), who also use WordNet and sense annotated data as features.

We also made use of the probability scores for each class to understand the confidence of the classifier in assigning an instance to a positive or negative class. We found that in general, both classifiers were more confident in predicting the negative class label as their probabilities formed a distribution that was grouped closer to 1. The scores given to the positive class on the other hand were more distributed, with several instances that were less than 0.5. When we examined the LVCs with lower confidence scores, we saw that this was a mixed bag. For example, there were some LVCs like *bhojan kar* 'meal do; eat', which appeared to be non-LVCs. Others such as *photo le* 'photo take; take a photo' were perhaps cases of noun incorporation as suggested in Davison (2005). Still others were cases like *bojh daal* 'weight put; to be a burden (on someone)', which were more idiomatic in nature. This result shows that perhaps some of these cases are simply less frequent, but also that LVC annotation in the Hindi Treebank itself could be re-considered, or made more fine-grained based on the confidence scores of these models.

Our experiments show that LVCs in Hindi consist of diverse types that can be identified automatically using linguistic features. Unlike English, where the deverbal noun can be used as an important lexical indicator of 'lightness', in Hindi it becomes necessary to make use of other morpho-syntactic cues such as postpositions. However, it appears that the role of semantic features in general seems to be important for light verb identification in Hindi as well as English.

The models we have described in this paper show an improvement over previous work, but at the same time they can also be used to further refine the LVC annotation in the Hindi Treebank. This would give us more clarity with respect to the linguistic behaviour of these cases in Hindi and serve as a guideline

for LVC annotation in the future.

Abstract

Several recent studies have shown that eye movements during reading provide information about grammatical and syntactic processing, which can assist the induction of NLP models. All these studies have been limited to English, however. This study shows that gaze and part of speech (PoS) correlations largely transfer across English and French. This means that we can replicate previous studies on gaze-based PoS tagging for French, but also that we can use English gaze data to assist the induction of French NLP models.

1 Introduction

The eye movements during normal, skilled reading are known to reflect the processing load associated with reading. Recently, eye movement data has been integrated into natural language processing models for weakly supervised part-of-speech (PoS) induction (Barrett et al., 2016), sentence compression (Klerke et al., 2016), supervised PoS tagging (Barrett and Søgaard, 2015a), and supervised parsing (Barrett and Søgaard, 2015b).

Barrett et al. (2016) used eye movements from the English portion of a large eye tracking corpus, the Dundee corpus (Kennedy et al., 2003), for weakly supervised PoS induction for English, obtaining significant improvements over a baseline without gaze features. They used a second-order hidden Markov Model, which was type-constrained by Wiktionary dictionaries for their experiments. These results suggest an approach to weakly supervised PoS induction using only a dictionary and eye movement data. Such an approach would be applicable for low-resource languages, for which it is difficult to find professional annotators.

The present study further explores to which extent native readers' processing of PoS generalizes across related languages. We use a similar model as Barrett et al. (2016), but perform cross-lingual experiments with both the French and the English portion of the Dundee Corpus.

Contribution This is to the best of our knowledge the first study to explore how the eye movements of native readers that inform PoS models generalize from one language to another. We also introduce a new resource for studying the relation between grammatical class and eye movements in French: we provide PoS annotation for most of the French Dundee Corpus by aligning it with the morphosyntactic annotation of the French Treebank (Abeillé et al., 2003).

2 Data preparation

The data used for this experiment is the English and French portions of the Dundee Corpus (Kennedy et al., 2003). The Dundee Corpus is the largest available eye movement corpus by token count. For English and French, 10 native speakers of each language read 20 newspaper articles from either *The Independent* (English) or *Le Monde* (French). The corpus comprises around 50,000 tokens per language.

For both the English and the French part of the Dundee Corpus, the original tokenization follows the visual units of the text, and contractions and punctuation are attached to the word whose visual unit they belong to. For instance, *s'entendre* or *rappelle-t-il* are one token in the French Dundee Corpus but two and five, respectively, in the French Treebank. In the English Dundee Corpus, *don't!* is one token, but three in the Dundee Treebank. As a result, eye movement measures are only available for the entire visual unit. We address this issue by duplicating the eye movement measures for all treebank tokens that comprise a Dundee token (i.e., a visual unit). This is the same approach Barrett et al. (2016) used. As a result, the number of tokens increases in the PoS-tagged version of the Dundee Corpus; also, some tokens are associated with eye movement measures that reflect the processing of several tokens.

For English, the treebank tokenization leads to 13.8% increase of tokens to 58,599 tokens. For French, the treebank tokenization leads to an 17.7% increase on token count to 56,683 tokens. For the English training set, 76% of all Dundee Corpus tokens are mapped to one treebank token. The same goes for 62% of the Dundee Corpus tokens for French.

2.1 English

The Dundee Treebank (Barrett et al., 2015) is a recent manual, syntactic annotation layer for the English portion of the Dundee Corpus following the Universal Dependency formalism. For evaluation, we use the PoS labels from this resource. We mapped the Penn Treebank tagset used in the Dundee Treebank

automatically to the Universal PoS tag set (Petrov et al., 2011).

The split into training, development, and test set for the English Dundee corpus is identical to the splits used by Barrett et al. (2016), with 80% of the tokens for training and 10% of the tokens for development and testing, respectively, without splitting up sentences. This split results in 46,879 tokens in 1,896 sentences for training, 5,868 tokens in 230 sentences for development, and a test set of 5,832 tokens in 241 sentences.

2.2 French

The text for the French part of the Dundee Corpus is originally from the French Treebank version 1.4 (Abeillé et al., 2003) and we re-aligned the two corpora for this experiment. We first manually identified the relevant subset of the French Treebank (which is discontinuous). A small part (2,518 tokens equivalent of 5.31% of the French Dundee tokens) of the Dundee Corpus could not be found by manual search in the French Treebank and was therefore omitted from the experiment. Only entire sentences were removed. The morphosyntactic annotation of the French Treebank was semi-manually aligned with the Dundee Corpus by a set of heuristic rules and by manually fixing all exceptions. Due to tokenization inconsistencies in both the French Treebank and the Dundee Corpus, manual intervention was required.

For French there are some treebank tokens with no token string, only PoS, lemma etc. For example, *du* should be split into *de* and *le*, but in some instances the token string for *le* is missing. These missing tokens were omitted from this experiment.

The French Dundee Corpus does not come with a training-development-test split. We use a similar approach as for English, with the first 80% of the tokens for training, the next 10% of the tokens for development and the last 10% for testing. No sentences were split into separate sets. That results in 43,383 tokens in 1,585 sentences for training, 5,407 tokens in 240 sentences for development, and 5,444 tokens in 178 sentences for testing.

The tagset of the French Treebank was automatically mapped to the Universal PoS tag set (Petrov et al., 2011). We make the aligned, morphosyntactic annotation for the French Dundee Corpus available at `https://bitbucket.org/lowlands/release`.

2.3 Reading differences between English and French

This section discusses the results of existing studies comparing reading in French and English. The two main studies used the two Dundee corpora for their analysis.

Pynte and Kennedy (2006) compared the eye movements of the French and English Dundee corpus to explore local effects (e.g., word frequency, word length, local context) and global effects (e.g., predictability, reading strategy, inspection strategy) on five eye movement metrics.

They first of all noted that French was read slower than English with more and longer fixations. This effect is significant and is even more pronounced for long words and there are also significantly more re-fixations for French compared to English. Kennedy and Pynte (2005) argue that re-fixations reflect the most crucial difference between French and English. Besides being an obvious difference in the processing of the target word, more re-fixations also enhance preview of the next word. Pynte and Kennedy (2006) report that participants of the English and French experiments were matched (though not on which factors) and that the procedure, including calibration technique, equipment, control software, instructions, and data-reduction software, were identical across language, though the French data was collected in Aix-en-Provence, France and the English data in Dundee, UK. Therefore they ascribed this difference to the text itself. Even though they found that French words (5.2 characters) are on average longer than English ones (4.7 characters), there are more two-letter words in French (19.7%) than in English (17.2%). Therefore Kennedy and Pynte (2005) suggest that the reading difference is due the distribution of information across the letters of a given words, which is different across these two languages. For example, in French, terminal accents, case markers, and gender and tense marking convey crucial morphological information. This is in line with their finding that eye movements in the English part of the Dundee Corpus were more sensitive to the length of the next word, whereas French showed equivalent effects of the informativeness of the word-initial trigram.

Table 1: Accuracy on development and test set for type-and token-level experiments. Best condition per experimental set-up per language combination in bold. *) For test set results: $p < 0.001$ according to mid-p McNemar test when compared to baseline.

Overall, Pynte and Kennedy (2005; 2006) conclude that the English and French inspection strategies are remarkably similar, which is the same conclusion Sparrow et al. (2003) made when testing the English EZ reader model on another eye movement corpus of 134 words of French. Kennedy and Pynte (2005) provide an analysis of the statistical differences between English and French, but besides re-fixations being more frequent in French, they seem to conclude that the reading is in many respects similar, which is also supported by their choice of mainly analyzing French and English jointly.

The treebank annotation includes sentence boundaries, which makes it possible to compare the length and the complexity of the sentences for both languages. We find that the average sentence length of the English training set is 24.7 tokens (SD 13.1). For French it is 28.7 tokens (SD 17.8). Sentence length was not considered by Pynte and Kennedy (2005; 2006). A consequence of longer sentences is that reading difficulty increases. The Coleman-Liau index (Coleman and Liau, 1975) is 10.38 for the English training set and 12.98 for the French.[1] This could stem from different writing styles in *Le Monde* and *The Independent* or a biased sampling of articles.

The conclusion can go no further than to say that French and English readers *can* display a more or less similar inspection strategy when reading text under matched conditions. Some effects, e.g., the fact

that word-initial trigrams are more important for fixation durations in French than in English, could be due to cross-lingual differences in the spelling of the two languages, leading to re-fixations in order to increase preview. But slower reading could also be partly due to the presence of more difficult texts in the French corpus. See Section 7 for a further discussion on grammatical processing differences across languages.

2.3.1 Comparing reading of PoS for English and French

The statistics presented in the following section were computed on the French and English training sets and extends the comparison of Section 2.3 with respect to PoS. We show that the PoS classes are overall read similarly across the two languages with few exceptions due to systematic biases.

Figure 1 shows the distribution of PoS classes in the English and French data. The biggest differences are that there are no NUM tags in French. This is due to the annotation scheme and our automatic mapping, in which no tags map to NUM. There are also very few particles in the French data compared to English.

Figure 2 shows boxplots for two different reading metrics: number of fixations and first pass duration, across PoS class for English and French. The first pass duration is the sum of fixation durations for a token in the first pass through the text. This measure is said to encompass early syntactic and lexical processing. The number of fixations encompasses re-fixations and regressions to a token and reflects later syntactic and semantic processing.

Note that punctuation is almost always glued to a word and any eye movements on a punctuation will mainly—if not solely—reflect the processing of the other token. Therefore punctuation is excluded from Figure 2.

When comparing Figure 2d and 2b, we can confirm Pynte and Kennedy's (2006) finding that fixations

are generally longer in the French portion than in the English portion of Dundee. Average gaze duration in the training set is 236 ms for English and 303 ms for French.

It can be seen from Figure 2 that the measures differ across PoS for most classes in an intuitive way. For instance, PoS classes of short, frequent, closed-class words such as CONJ, ADP, PRON and DET get fewer and shorter fixations than, e.g., NOUN, VERB, ADJ, and ADV. This seems to be consistent across the two languages, and is in line with a similar analysis for English (Barrett and Søgaard, 2015a) for a smaller data set of naturally occurring text from five different domains.

The PRT category seems to be an exception. In French, PRT seems to require extensive early and late processing. Remember from Figure 1 that there are more PRTs for English (3.6%) and fewer for French (0.05%). The sets of PRT words for the two languages reveal a systematic bias in the annotation scheme or automatic mapping. For the French training set, the set of PRTs is {*vice-*, *pseudo-*, *post-*, *contre-*, *anti-*, *non-*, *quasi-*, *soviéto-*, *supra-*, *néo-*, *inter-*}. For English it is {*off*, *down*, *To*, *about*, *on*, *in*, *over*, *around*, *back*, *up*, *out*, *to*, *away*, *'*, *'s*}. French particles are therefore always at least two-token visual units that seem to be quite infrequent as well as long, whereas English particles are short and frequent.

3 Features

For our weakly supervised PoS tagging experiments, we use 22 gaze features that measure both early processing and late processing. They are equivalent to the 22 gaze features used by Barrett et al. (2016). Early processing measures are said to reflect different aspects of early syntactic and semantic processing and include first pass duration and first fixation duration. Late processing measures reflect, e.g., late syntactic and semantic integration (Rayner, 1998). Examples are number and duration of regressions going to a word, as well as the total reading time for a word.

Non-gaze features are usually included in eye movement models, because they explain a lot of the variance in fixation durations. Word frequency and word length together have been found to explain 69% of the variance in the mean gaze duration (Carpenter and Just, 1983). Like Barrett et al. (2016), we use word length, log word frequencies from a big corpus and log word frequencies from the Dundee training set for the target word, and the previous and next words. From the Dundee training set, we also extract the forward and backward transitional probability, i.e., the conditional probabilities for a word given the next or previous word. Our non-gaze features are almost equivalent to Barrett et al. (2016). The only difference is that they also used forward and backward transitional probabilities from a big corpus.

The big corpus log frequencies were obtained from the British National Corpus[2] for English, extracted with KenLM (Heafield, 2011) and Lexique[3] for French. The Dundee log frequencies were calculated on the respective training sets using CMU Language Modeling Toolkit[4] with Witten-Bell smooting.

In total we have 29 features. All features are first averaged over all 10 readers of the corpus, then scaled to a value between 0 and 1 by minmax scaling. The best model of the feature ablation study of Barrett et al. (2016) used all features, which suggests that grammatical processing of a broad set of PoS categories is reflected across many features and need non-gaze features as well.

4 Experiment

We replicate the experimental setup of Barrett et al. (2016), which used the best model from Li et al. (2012), a second-order hidden Markov model with maximum entropy emissions (SHMM-ME) constrained by Wiktionary tags such that emissions are confined to the allowed PoS tags of the Wiktionary given that the token exists in the Wiktionary. Li et al. (2012) report considerable improvements from the Wiktionary contraint when comparing to unsupervised methods.

The second-order model includes transition probabilities from the antecedent state like a first order model (Berg-Kirkpatrick et al., 2010) as well as from the second-order antecedent state.

We use the original implementation of Li et al. and we also include a subset of their word-level features, viz., four features detecting hyphens, numerals, punctuation and capitalization. We leave out the three

[2] http://www.natcorp.ox.ac.uk

[3] http://www.lexique.org

[4] http://www.speech.cs.cmu.edu/SLM/toolkit.html

suffix features from Li et al.'s basic feature model, as these features do not transfer across languages. These features were also included by Barrett et al. (2016).

We use the English Wiktionary dumps made available by Li et al.[5] The French Wiktionary dump is from Wisniewski et al. (2014) and does not include any punctuation. We therefore augment it with all punctuation entries from the English Wiktionary. Furthermore, tokens for the tag ADP are completely missing from the French Wiktionary, and the tokens for the class DET were sparse. We therefore add all examples of DET and ADP from the French training set to the French Wiktionary.

For the cross-lingual experiments, we use the union of the French and the English Wiktionary dictionaries.

Barrett et al. (2016) used Li et al.'s model for weakly supervising PoS induction with gaze features for English, and performed model tuning and feature ablation. We use their best hyper-parameter setting, i.e., five EM iterations, as well as the best feature combination: all features. Following Barrett et al. (2016), we try token-level and type-level features. For the token-level experiments, each token is represented by its feature vector. For the type-level experiments, each token is represented by an average of the feature vectors for all occurrences of the lower-cased word type of the training set.

5 Results

The tagging accuracy for all combinations of training and testing language on the development set and the test set can be seen in Table 1.

For all conditions, type-level features work better than token-level, though the type-level improvement over the baseline is not significant for FR-EN.

The English monolingual condition plus suffix is almost equivalent to the best model in Barrett et al. (2016). The only difference is the two missing non-gaze features described in Section 3. On the test set, they report a baseline accuracy of 79.77, a token-level accuracy of 81.00, and a type-level accuracy of 82.44, which is in line with our results. We observe that the suffix features seem to help in the monolingual conditions. For monolingual conditions, we confirm that type-level gaze-features and token-level ones outperform the baseline. These differences are significant, except for the EN-EN token-level plus suffix condition.

FR-FR PoS tagging seems to be a slightly an easier task than EN-EN PoS tagging, achieving overall higher accuracies.

The cross-lingual conditions generally achieve lower performance than the monolingual. When training on English and testing on French, both token-level and type-level conditions are significantly better than baseline.

Metric	Cosine sim

w-2 fixation duration	0.9992

Table 2: Cosine similarity between PoS averaged French and English train set gaze vectors across gaze features. Sorted by similarity.

6 Error Analysis

There are—as expected—more errors when using cross-lingual gaze data. This section will explore these errors by comparing the predictions of the cross-lingual experiments with the predictions of the mono-

[5] https://code.google.com/archive/p/wikily-supervised-pos-tagger/

lingual experiments. All analysis is on the development set output of the type-level models. We compare them to the output of the type-level monolingual models.

Figure 3 shows accuracy scores per PoS class comparing experiments with same test set. The accuracy of punctuations is due to the basic feature model and the Wiktionary constraints—not the eye movement measures. PRT and NUM are real challenges for FR-EN compared to EN-EN. This can be assumed to be due to the different use of the PRT tag and the missing NUM class in the French dataset described in Section 2.3.1. ADJ also seems like a cross-lingual challenge, though harder when trained on English and tested on French than the other way around.

Figure 4 shows the erroneous predictions per gold PoS tag, allowing us to compare error types across experiments. When comparing Figure 4a and Figure 4c, both evaluated on English, most classes seem to have almost the same set of misclassified labels though for some labels in different magnitude or ratio depending on whether they are trained on English or French. The main differences are: when trained on French, ADP and ADJ are generally more often misclassified, ADP is not mainly misclassified as CONJ, but more often as ADV, DET is also misclassified as VERB and ADV, PRT is misclassified as ADV and not mainly as ADP.

When comparing Figure 4b and Figure 4d, both evaluating on French, we also find that for many of the PoS classes, the misclassifications are of the same type, though different in magnitude or ratio. The main differences we observe when training on English are: ADJ is mainly misclassified as NOUN instead of ADP, ADV, DET, NOUN, and PRT; ADV is misclassified as VERB; DET is never misclassified as PRT, but more often as NOUN and ADJ; and NOUN is rarely misclassified as PRT. The last error probably has to do with the long gaze durations for PRT in the French data (resembling gaze durations of NOUNs) opposed to the short gaze durations of English PRT.

Table 2 shows the cosine similarity between the English and French PoS-averaged gaze vectors from the train set for all gaze features. This gives information about which gaze feature averages differ between French and English PoS. Pynte and Kennedy (2006) found that French had more re-fixations than English, which is reflected in the table. Measures correlating with re-fixations like re-read probability, number of fixtions, and total fixation duration are naturally also different across languages. First pass duration is not directly correlated with number of re-fixations, and must be considered an distinct pattern.

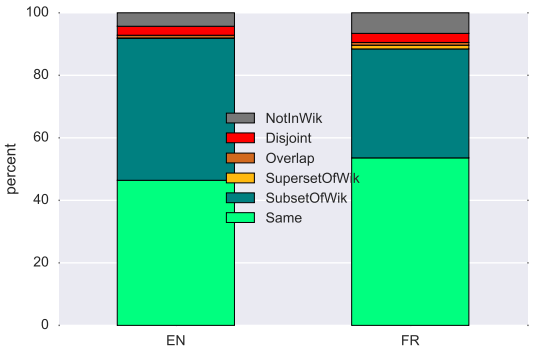

Figure 5: Development set word type lookup in Wiktionary for English and French: the percentage of word types assigned a set of tags that is either: identical to, a subset of, a superset of, overlapping with, disjoint with, or not in the Wiktionary.

6.1 Wiktionary agreement

Figure 5 shows the word types for the English and French development set according to their representation in the respective monolingual Wiktionary. This figure is inspired by Li et al. (2012). For English, more PoS types agree with the Wiktionary (Same or SubsetOfWik) than for French. We also computed token-level accuracies, where a tag licensed by Wiktionary counts as correct. For the French development set, this maximum dictionary accuracy is 0.95, whereas for English it is 0.92.

7 Discussion

We presented four experiments with PoS induction using gaze data in a monolingual and cross-lingual setup with a second-order hidden Markov model. Our experiments confirm the main conclusion from Barrett et al. (2016), viz., that type-level gaze vectors improve PoS induction. We replicated their result

for English and report the same finding for French as well as for French when trained on English gaze vectors.

It is difficult to determine how much the relatedness of the French and English languages is responsible for the ability of the model to generalize cross-lingually. The psycholinguistic literature does not reveal how different PoS categories are processed across languages; most experimental work in the literature studies single phenomena in one language. For instance, in reaction time studies of lexical decision tasks it has been found that the processing of English plural and singular nouns is influenced by surface frequency only[6] (Sereno and Jongman, 1997), whereas for Dutch (Baayen et al., 1997) and French (New et al., 2004), the lexical processing of singular and plural nouns is influenced by the base frequency[7]. The English data thus support a full-storage cognitive model, whereas the French and the Dutch data support the Parallel Dual-Route model where a word is processed as segments in parallel with whole word processing. These results suggest that nouns are processed differently in the brain for native speakers of different languages. This means that our results may not generalize to other combinations of languages and in the specific case of nouns it suggests that Dutch and French nouns are processed more similarly than French and English.

8 Conclusion

This is, to the best of our knowledge, the first study to explore whether gaze features generalize from one language to another for a broad set of syntactic categories. We used a type-constrained second-order HMM for monolingual and cross-lingual PoS induction on the English and French portions of the Dundee eye tracking corpus. We experimented with both token-level and type-level features and confirmed that type-level gaze features improve monolingual PoS induction for both English and French. We also showed that type-level gaze features significantly improve PoS induction for French, even when the model is trained on English gaze vectors.

Abstract

Most conventional sentence similarity methods only focus on similar parts of two input sentences, and simply ignore the dissimilar parts, which usually give us some clues and semantic meanings about the sentences. In this work, we propose a model to take into account both the similarities and dissimilarities by decomposing and composing lexical semantics over sentences. The model represents each word as a vector, and calculates a semantic matching vector for each word based on all words in the other sentence. Then, each word vector is decomposed into a similar component and a dissimilar component based on the semantic matching vector. After this, a two-channel CNN model is employed to capture features by composing the similar and dissimilar components. Finally, a similarity score is estimated over the composed feature vectors. Experimental results show that our model gets the state-of-the-art performance on the answer sentence selection task, and achieves a comparable result on the paraphrase identification task.

1 Introduction

Sentence similarity is a fundamental metric to measure the degree of likelihood between a pair of sentences. It plays an important role for a variety of tasks in both NLP and IR communities. For example, in paraphrase identification task, sentence similarity is used to determine whether two sentences are paraphrases or not (Yin and Schütze, 2015; He et al., 2015). For question answering and information retrieval tasks, sentence similarities between query-answer pairs are used for assessing the relevance and ranking all the candidate answers (Severyn and Moschitti, 2015; Wang and Ittycheriah, 2015).

However, sentence similarity learning has following challenges:

1. There is a lexical gap between semantically equivalent sentences. Take the E_1 and E_2 in Table 1 for example, they have the similar meaning but with different lexicons.

2. Semantic similarity should be measured at different levels of granularity (word-level, phrase-level and syntax-level). E.g., "not related" in E_2 is an indivisible phrase when matching with "irrelevant" in E_1 (shown in square brackets).

3. The dissimilarity (shown in angle brackets) between two sentences is also a significant clue (Qiu et al., 2006). For example, by judging the dissimilar parts, we can easily identify that E_3 and E_5 share the similar meaning "The study is about salmon", because "sockeye" belongs to the salmon family, and "flounder" does not. Whereas the meaning of E_4 is quite different from E_3, which emphasizes "The study is about red (a special kind of) salmon", because both "sockeye" and "coho" are in the salmon family. How we can extract and utilize those information becomes another challenge.

In order to handle the above challenges, researchers have been working on sentence similarity algorithms for a long time. To bridge the lexical gap (challenge 1), some word similarity metrics were proposed to match different but semantically related words. Examples include knowledge-based metrics (Resnik, 1995) and corpus-based metrics (Jiang and Conrath, 1997; Yin and Schütze, 2015; He et al., 2015). To measure sentence similarity from various granularities (challenge 2), researchers have explored features extracted from n-grams, continuous phrases, discontinuous phrases, and parse trees (Yin and Schütze, 2015; He et al., 2015; Heilman and Smith, 2010). The third challenge did not get much

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1340–1349, Osaka, Japan, December 11-17 2016.

E_1	The research is [irrelevant] to sockeye.
E_2	The study is [not related] to salmon.
E_3	The research is relevant to salmon.
E_4	The study is relevant to sockeye, ⟨instead of coho⟩.
E_5	The study is relevant to sockeye, ⟨rather than flounder⟩.

Table 1: Examples for sentence similarity learning, where sockeye means "red salmon", and coho means "silver salmon". "coho" and "sockeye" are in the salmon family, while "flounder" is not.

attention in the past, the only related work of Qiu et al. (2006) explored the dissimilarity between sentences in a pair for paraphrase identification task, but they require human annotations in order to train a classifier, and their performance is still below the state of the art.

In this paper, we propose a novel model to tackle all these challenges jointly by decomposing and composing lexical semantics over sentences. Given a sentence pair, the model represents each word as a low-dimensional vector (challenge 1), and calculates a semantic matching vector for each word based on all words in the other sentence (challenge 2). Then based on the semantic matching vector, each word vector is decomposed into two components: a similar component and a dissimilar component (challenge 3). We use similar components of all the words to represent the similar parts of the sentence pair, and dissimilar components of every word to model the dissimilar parts explicitly. After this, a two-channel CNN operation is performed to compose the similar and dissimilar components into a feature vector (challenge 2 and 3). Finally, the composed feature vector is utilized to predict the sentence similarity. Experimental results on two tasks show that our model gets the state-of-the-art performance on the answer sentence selection task, and achieves a comparable result on the paraphrase identification task.

In following parts, we start with a brief overview of our model (Section 2), followed by the details of our end-to-end implementation (Section 3). Then we evaluate our model on answer sentence selection and paraphrase identifications tasks (Section 4).

2 Model Overview

In this section, we propose a sentence similarity learning model to tackle all three challenges (mentioned in Section 1). To deal with the first challenge, we represent each word as a distributed vector, so that we can calculate similarities for formally different but semantically related words. To tackle the second challenge, we assume that each word can be semantically matched by several words in the other sentence, and we calculate a semantic matching vector for each word vector based on all the word vectors in the other side. To cope with the third challenge, we assume that each semantic unit (word) can be partially matched, and can be decomposed into a similar component and a dissimilar component based on its semantic matching vector.

Figure 1 shows an overview of our sentence similarity model. Given a pair of sentences S and T, our task is to calculate a similarity score $sim(S, T)$ in following steps:

Word Representation. Word embedding of Mikolov et al. (2013) is an effective way to handle the lexical gap challenge in the sentence similarity task, as it represents each word with a distributed vector, and words appearing in similar contexts tend to have similar meanings (Mikolov et al., 2013). With those pre-trained embeddings, we transform S and T into sentence matrixes $S = [s_1, ..., s_i, ..., s_m]$ and $T = [t_1, ..., t_j, ..., t_n]$, where s_i and t_j are d-dimension vectors of the corresponding words, and m and n are sentence length of S and T respectively.

Semantic Matching. In order to judge the similarity between two sentences, we need to check whether each semantic unit in one sentence is covered by the other sentence, or vice versa. For example, in Table 1, to check whether E_2 is a paraphrase of E_1, we need to know the single word "irrelevant" in E_1 is matched or covered by the phrase "not related" in E_2. In our model, we treat each word as a primitive semantic unit, and calculate a semantic matching vector $\hat{s}_i$ for each word s_i by composing part or full word vectors in the other sentence T. In this way, we can match a word s_i to a word or phrase in T.

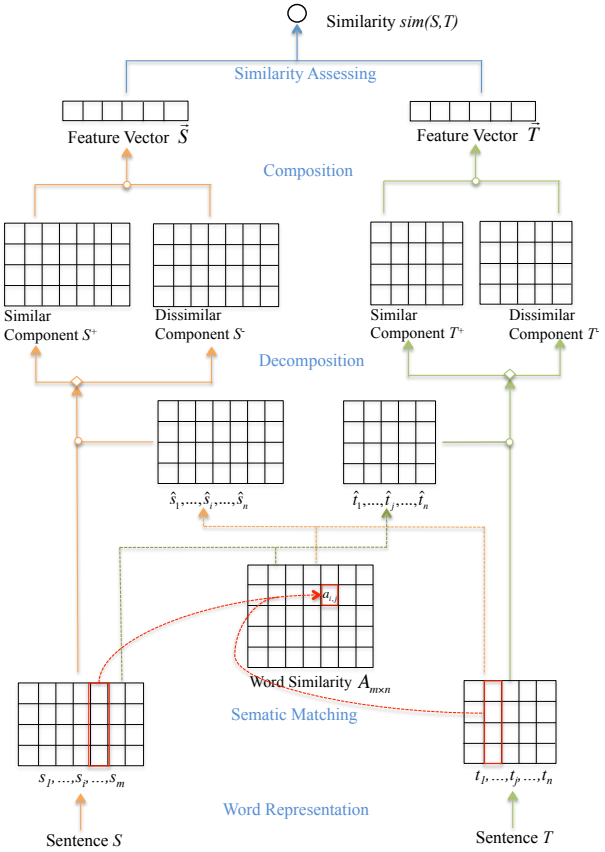

Figure 1: Model overview.

Similarly, for the reverse direction, we also calculate all semantic matching vectors $\hat{t_j}$ in T.

$$\begin{aligned} \hat{s_i} &= f_{match}(s_i, T) \qquad \forall s_i \in S \\ \hat{t_j} &= f_{match}(t_j, S) \qquad \forall t_j \in T \end{aligned} \tag{1}$$

We explore different f_{match} functions later in Section 3.

Decomposition. After the semantic matching phase, we have the semantic matching vectors of $\hat{s_i}$ and $\hat{t_j}$. We interpret $\hat{s_i}$ (or $\hat{t_j}$) as a semantic coverage of word s_i (or t_j) by the sentence T (or S). However, it is not necessary that all the semantics of s_i (or t_j) are fully covered by $\hat{s_i}$ (or $\hat{t_j}$). Take the E_1 and E_2 in Table 1 for example, the word "sockeye" in E_1 is only partially matched by the word "salmon" (the similar part) in E_2, as the full meaning of "sockeye" is "red salmon" (the semantic meaning of "red" is the dissimilar part). Motivated by this phenomenon, our model further decomposes word s_i (or t_j), based on its semantic matching vector $\hat{s_i}$ (or $\hat{t_j}$), into two components: similar component s_i^+ (or t_j^+) and dissimilar component s_i^- (or t_j^-). Formally, we define the decomposition function as:

$$\begin{aligned} [s_i^+; s_i^-] &= f_{decomp}(s_i, \hat{s_i}) \qquad \forall s_i \in S \\ [t_j^+; t_j^-] &= f_{decomp}(t_j, \hat{t_j}) \qquad \forall t_j \in T \end{aligned} \tag{2}$$

Composition. Given a similar component matrix $S^+ = [s_1^+, ..., s_m^+]$ (or $T^+ = [t_1^+, ..., t_n^+]$) and a dissimilar component matrix $S^- = [s_1^-, ..., s_m^-]$ (or $T^- = [t_1^-, ..., t_n^-]$), our goal in this step is how to utilize those information. Besides the suggestion from Qiu et al. (2006) that the significance of the dissimilar parts alone between two sentences has a great effect of their similarity, we also think that the dissimilar and similar components have strong connections. For example, in Table 1, if we only look at the dissimilar or similar part alone, it is hard to judge which one between E_4 and E_5 is more similar to E_3. We can easily identify that E_5 is more similar to E_3, when we consider both the similar and dissimilar

parts. Therefore, our model composes the similar component matrix and dissimilar component matrix into a feature vector $\vec{S}$ (or $\vec{T}$) with the composition function:

$$\begin{aligned} \vec{S} &= f_{comp}(S^+, S^-) \\ \vec{T} &= f_{comp}(T^+, T^-) \end{aligned} \tag{3}$$

Similarity assessing. In the final stage, we concatenate the two feature vectors ($\vec{S}$ and $\vec{T}$) and predict the final similarity score:

$$sim(S, T) = f_{sim}(\vec{S}, \vec{T}) \tag{4}$$

3 An End-to-End Implementation

Section 2 gives us a glance of our model. In this section, we describe details of each phase.

3.1 Semantic Matching Functions

This subsection describes our specifications for the semantic matching function f_{match} in Eq. (1). The goal of f_{match} is to generate a semantic matching vector $\hat{s}_i$ for s_i by composing the vectors from T.

For a sentence pair S and T, we first calculate a similarity matrix $A_{m\times n}$, where each element $a_{i,j} \in A_{m\times n}$ computes the cosine similarity between words s_i and t_j as

$$a_{i,j} = \frac{s_i^T t_j}{\|s_i\| \cdot \|t_j\|} \qquad \forall s_i \in S, \forall t_j \in T. \tag{5}$$

Then, we define three different semantic matching functions over $A_{m\times n}$:

$$f_{match}(s_i, T) = \begin{cases} \frac{\sum_{j=0}^{n} a_{i,j} t_j}{\sum_{j=0}^{n} a_{i,j}} & \textit{global} \\ \frac{\sum_{j=k-w}^{k+w} a_{i,j} t_j}{\sum_{j=k-w}^{k+w} a_{i,j}} & \textit{local-w} \\ t_k & \textit{max} \end{cases} \tag{6}$$

where $k = \text{argmax}_j\, a_{i,j}$. The idea of the *global* function is to consider all word vectors t_j in T. A semantic matching vector $\hat{s}_i$ is a weighted sum vector of all words t_j in T, where each weight is the normalized word similarity $a_{i,j}$. The *max* function moves to the other extreme. It generates the semantic matching vector by selecting the most similar word vector t_k from T. The *local-w* function takes a compromise between *global* and *max*, where w indicates the size of the window to consider centered at k (the most similar word position). So the semantic matching vector is a weighted average vector from t_{k-w} to t_{k+w}.

3.2 Decomposition Functions

This subsection describes the implementations for the decomposition function f_{decomp} in Eq. (2). The intention of f_{decomp} is to decompose a word vector s_j based on its semantic matching vector $\hat{s}_j$ into a similar component s_i^+ and a dissimilar component s_i^-, where s_i^+ indicates the semantics of s_i covered by $\hat{s}_i$ and s_i^- indicates the uncovered part. We implement three types of decomposition function: *rigid*, *linear* and *orthogonal*.

The *rigid* decomposition only adapts to the *max* version of f_{match}. First, it detects whether there is an exactly matched word in the other sentence, or s_i equal to $\hat{s}_i$. If yes, the vector s_i is dispatched to the similar component s_i^+, and the dissimilar component is assigned with a zero vector $\mathbf{0}$. Otherwise, the vector s_i is assigned to the dissimilar component s_i^-. Eq. (7) gives the formal definition:

$$\begin{aligned} &[s_i^+ = s_i;\ s_i^- = \mathbf{0}] \qquad if\ s_i = \hat{s}_i \\ &[s_i^+ = \mathbf{0};\ s_i^- = s_i] \qquad otherwise \end{aligned} \tag{7}$$

The motivation for the *linear* decomposition is that the more similar between s_i and $\hat{s}_i$, the higher proportion of s_i should be assigned to the similar component. First, we calculate the cosine similarity

α between s_i and $\hat{s}_i$. Then, we decompose s_i linearly based on α. Eq. (8) gives the corresponding definition:

$$\begin{aligned} \alpha &= \frac{s_i^T \hat{s}_i}{\|s_i\| \cdot \|\hat{s}_i\|} \\ s_i^+ &= \alpha s_i \\ s_i^- &= (1-\alpha) s_i \end{aligned} \tag{8}$$

The *orthogonal* decomposition is to decompose a vector in the geometric space. Based on the semantic matching vector $\hat{s}_i$, our model decomposes s_i into a parallel component and a perpendicular component. Then, the parallel component is viewed as the similar component s_i^+, and perpendicular component is taken as the dissimilar component s_i^-. Eq. (9) gives the concrete definitions.

$$\begin{aligned} s_i^+ &= \frac{s_i \cdot \hat{s}_i}{\hat{s}_i \cdot \hat{s}_i} \hat{s}_i \qquad parallel \\ s_i^- &= s_i - s_i^+ \qquad perpendicular \end{aligned} \tag{9}$$

3.3 Composition Functions

The aim of composition function f_{comp} in Eq. (3) is to extract features from both the similar component matrix and the dissimilar component matrix. We also want to acquire similarities and dissimilarities of various granularity during the composition phase. Inspired from Kim (2014), we utilize a two-channel convolutional neural networks (CNN) and design filters based on various order of n-grams, e.g., unigram, bigram and trigram.

The CNN model involves two sequential operations: *convolution* and *max-pooling*. For the *convolution* operation, we define a list of filters $\{w_o\}$. The shape of each filter is $d \times h$, where d is the dimension of word vectors and h is the window size. Each filter is applied to two patches (a window size h of vectors) from both similar and dissimilar channels, and generates a feature. Eq. (10) expresses this process.

$$c_{o,i} = f(w_o * S^+_{[i:i+h]} + w_o * S^-_{[i:i+h]} + b_o) \tag{10}$$

where the operation $A * B$ sums up all elements in B with the corresponding weights in A, $S^+_{[i:i+h]}$ and $S^-_{[i:i+h]}$ indicate the patches from S^+ and S^-, b_o is a bias term and f is a non-linear function (we use *tanh* in this work). We apply this filter to all possible patches, and produce a series of features $\vec{c_o} = [c_{o,1}, c_{o,2}, ..., c_{o,O}]$. The number of features in $\vec{c_o}$ depends on the shape of the filter w_o and the length of the input sentence. To deal with variable feature size, we perform a *max-pooling* operation over $\vec{c_o}$ by selecting the maximum value $c_o = max\ \vec{c_o}$. Therefore, after these two operations, each filter generates only one feature. We define several filters by varying the window size and the initial values. Eventually, a vector of features is captured by composing the two component matrixes, and the feature dimension is equal to the number of filters.

3.4 Similarity Assessment Function

The similarity assessment function f_{sim} in Eq. (4) predicts a similarity score by taking two feature vectors as input. We employ a linear function to sum up all the features and apply a *sigmoid* function to constrain the similarity within the range [0, 1].

3.5 Training

We train our sentence similariy model by maximizing the likelihood on a training set. Each training instance in the training set is represented as a triple (S_i, T_i, L_i), where S_i and T_i are a pair of sentences, and $L_i \in \{0, 1\}$ indicates the similarity between them. We assign $L_i = 1$ if T_i is a paraphrase of S_i for the paraphrase identification task, or T_i is a correct answer for S_i for the answer sentence selection task. Otherwise, we assign $L_i = 0$. We implement the mathematical expressions with Theano (Bastien et al., 2012) and use Adam (Kingma and Ba, 2014) for optimization.

4 Experiment

4.1 Experimental Setting

We evaluate our model on two tasks: answer sentence selection and paraphrase identification. The answer sentence selection task is to rank a list of candidate answers based on their similarities to a question sentence, and the performance is measured by mean average precision (MAP) and mean reciprocal rank (MRR). We experiment on two datasets: *QASent* and *WikiQA*. The statistics of the two datasets can be found in Yang et al. (2015), where *QASent* (Wang et al., 2007) was created from the TREC QA track, and *WikiQA* (Yang et al., 2015) is constructed from real queries of Bing and Wikipedia. The paraphrase identification task is to detect whether two sentences are paraphrases based on the similarity between them. The metrics include the accuracy and the positive class F_1 score. We experiment on the Microsoft Research Paraphrase corpus (MSRP) (Dolan et al., 2004), which includes 2753 true and 1323 false instances in the training set, and 1147 true and 578 false instances in the test set. We build a development set by randomly selecting 100 true and 100 false instances from the training set. In all experiments, we set the size of word vector dimension as d =300, and pre-train the vectors with the *word2vec* toolkit (Mikolov et al., 2013) on the English Gigaword (LDC2011T07).

4.2 Model Properties

There are several alternative options in our model, e.g., the semantic matching functions, the decomposition operations, and the filter types. The choice of these options may affect the final performance. In this subsection, we present some experiments to demonstrate the properties of our model, and find a good configuration that we use to evaluate our final model. All the experiments in this subsection were performed on the *QASent* dataset and evaluated on the development set.

First, we evaluated the effectiveness of various semantic matching functions. We switched the semantic matching functions among {*max*, *global*, *local-l*}, where $l \in \{1, 2, 3, 4\}$, and fixed the other options as: the *linear* decomposition, the filter types including {unigram, bigram, trigram}, and 500 filters for each type. Figure 2 (a) presents the results. We found that the *max* function worked better than the *global* function on both MAP and MRR. By increasing the window size, the *local-l* function acquired progressive improvements when the window size is smaller than 4. But after we enlarged the window size to 4, the performance dropped. The *local-3* function worked better than the *max* function in term of the MAP, and also got a comparable MRR. Therefore, we use the *local-3* function in the following experiments.

Second, we studied the effect of various decomposition operations. We varied the decomposition operation among {*rigid*, *linear*, *orthogonal*}, and kept the other options unchanged. Figure 2 (b) shows the performance. We found that the *rigid* operation got the worst result. This is reasonable, because the *rigid* operation decomposes word vectors by exactly matching words. The *orthogonal* operation got a similar MAP as the *linear* operation, and it worked better in term of MRR. Therefore, we choose the *orthogonal* operation in the following experiments.

Third, we tested the influence of various filter types. We constructed 5 groups of filters: *win-1* contains only the unigram filters, *win-2* contains both unigram and bigram filters, *win-3* contains all the filters in *win-2* plus trigram filters, *win-4* extends filters in *win-3* with 4-gram filters, and *win-5* adds 5-gram filters into *win-4*. We generate 500 filters for each filter type (with different initial values). Experimental results are shown in Figure 2 (c). At the beginning, adding higher-order ngram filters was helpful for the performance. The performance reached to the peak, when we used the *win-3* filters. After that, adding more complex filters decreased the performance. Therefore, the trigram is the best granularity for our model. In the following experiments, we utilize filter types in *win-3*.

4.3 Comparing with State-of-the-art Models

In this subsection, we evaluated our model on the test sets of *QASent*, *WikiQA* and *MSRP*.

***QASent* dataset.** Table 2 presents the performances of the state-of-the-art systems and our model, where the performances were evaluated with the standard trec_eval-8.1 script [1]. Given a pair of sentences,

This work	**0.7058**	**0.7226**

Table 3: Results on the WikiQA dataset.

Severyn and Moschitti (2015) employed a CNN model to compose each sentence into a vector separately, and joined the two sentence vectors to compute the sentence similarity. Because only the sentence-level granularity was used, the performance is much lower (the second row of Table 2). After adding some word overlap features between the two sentences, the performance was improved significantly (the third row of Table 2). Therefore, the lower-level granularity is an indispensable factor for a good performance. Wang and Ittycheriah (2015) conducted word alignment for a sentence pair based on word vectors, and measured the sentence similarity based on a couple of word alignment features. They got a slightly better performance (the fourth row of Table 2), which indicates that the vector representation for words is helpful to bridging the lexical gap problem. dos Santos et al. (2016) introduced the attention mechanism into the CNN model, and learnt sentence representation by considering the influence of the other sentence. They got better performance than all the other previous work. Our model makes use of all these useful factors and also considers the dissimilarities of a sentence pair. We can see that our model (the last row of Table 2) got the best MAP among all previous work, and a comparable MRR than dos Santos et al. (2016).

***WikiQA* dataset.** Table 3 presents the results of our model and several state-of-the-art models. Yang et al. (2015) constructed the dataset and reimplemented several baseline models. The best performance (shown at the second row of Table 3) was acquired by a bigram CNN model combining with the word overlap features. Miao et al. (2015) models the sentence similarity by enriching LSTMs with a latent stochastic attention mechanism. The corresponding performance is given at the fourth row of Table 3. Yin et al. (2015) introduced the attention mechanism into the CNN model, and captured the best performance (the fifth row of Table 3). The semantic matching phase in our model is similar to the attention mechanism. But different from the previous models, our model utilizes both the similarity and dissimilarity simultaneously. The last row of Table 3 shows that our model is more effective than the other models.

***MSRP* dataset.** Table 4 summarized the results from our model and several state-of-the-art models. Yin and Schütze (2015) employed a CNN model to learn sentence representations on multiple level of

Models	Acc	F1

granularity and modeled interaction features at each level for a pair of sentences. They obtained their best performance by pretraining the model on a language modeling task (the 3rd row of Table 4). However, their model heavily depends on the pretraining strategy. Without pretraining, they got a much worse performance (the second row of Table 4). He et al. (2015) proposed a similar model to Yin and Schütze (2015). Similarly, they also used a CNN model to extract features at multiple levels of granularity. Differently, they utilized some extra annotated resources, e.g., embeddings from part-of-speech (POS) tags and PARAGRAM vectors trained from the Paraphrase Database (Ganitkevitch et al., 2013). Their model outperformed Yin and Schütze (2015) without the need of pretraining (the sixth row of Table 4). However, the performance was reduced after removing the extra resources (the fourth and fifth rows of Table 4). Yin et al. (2015) applied their attention-based CNN model on this dataset. By adding a couple of sparse features and using a layerwise training strategy, they got a pretty good performance. Comparing to these neural network based models, our model obtained a comparable performance (the last row of Table 4) without using any sparse features, extra annotated resources and specific training strategies. However, the best performance so far on this dataset is obtained by Ji and Eisenstein (2013). In their model, they just utilized several hand-crafted features in a Support Vector Machine (SVM) model. Therefore, the deep learning methods still have a long way to go for this task.

5 Related Work

The semantic matching functions in subsection 3.1 are inspired from the attention-based neural machine translation (Bahdanau et al., 2014; Luong et al., 2015). However, most of the previous work using the attention mechanism in only LSTM models. Whereas our model introduces the attention mechanism into the CNN model. A similar work is the attention-based CNN model proposed by Yin et al. (2015). They first build an attention matrix for a sentence pair, and then directly take the attention matrix as a new channel of the CNN model. Differently, our model uses the attention matrix (or similarity matrix) to decompose the original sentence matrix into a similar component matrix and a dissimilar component matrix, and then feeds these two matrixes into a two-channel CNN model. The model can then focus much on the interactions between similar and dissimilar parts of a sentence pair.

6 Conclusion

In this work, we proposed a model to assess sentence similarity by decomposing and composing lexical semantics. To bridge the lexical gap problem, our model represents each word with its context vector. To extract features from both the similarity and dissimilarity of a sentence pair, we designed several methods to decompose the word vector into a similar component and a dissimilar component. To extract features at multiple levels of granularity, we employed a two-channel CNN model and equipped it with multiple types of ngram filters. Experimental results show that our model is quite effective on both the

answer sentence selection task and the paraphrase identification task .

Chinese Hypernym-Hyponym Extraction from User Generated Categories

Chengyu Wang, Xiaofeng He*
School of Computer Science and Software Engineering
East China Normal University, Shanghai, China
chywang2013@gmail.com, xfhe@sei.ecnu.edu.cn

Abstract

Hypernym-hyponym ("*is-a*") relations are key components in taxonomies, object hierarchies and knowledge graphs. While there is abundant research on *is-a* relation extraction in English, it still remains a challenge to identify such relations from Chinese knowledge sources accurately due to the flexibility of language expression. In this paper, we introduce a weakly supervised framework to extract Chinese *is-a* relations from user generated categories. It employs piecewise linear projection models trained on a Chinese taxonomy and an iterative learning algorithm to update models incrementally. A pattern-based relation selection method is proposed to prevent "semantic drift" in the learning process using bi-criteria optimization. Experimental results illustrate that the proposed approach outperforms state-of-the-art methods.

1 Introduction

A hypernym-hyponym ("*is-a*") relation is a word/phrase pair (x, y) such that x is a hyponym of y. These relations are extensively employed in machine reading (Etzioni et al., 2011), query understanding (Hua et al., 2015) and other NLP tasks. The extraction of *is-a* relations is necessary to construct taxonomies for Web-scale knowledge graphs (Suchanek et al., 2007; Wu et al., 2012; Wang et al., 2015).

In previous work, *is-a* relations were obtained by either using expert-compiled thesauri such as WordNet (Miller, 1995), or harvested automatically from the Web. Since knowledge in thesauri is usually limited in quantity and variety, it is more prevalent to harvest *is-a* relations from online encyclopedias (Ponzetto and Strube, 2007), Web corpora (Wu et al., 2012), etc. Currently, a majority of existing methods focus on syntactic, lexical and/or semantic analysis on English corpora, but most of these approaches are language dependent. It is not easy to apply methods for one language to knowledge sources in another language directly. For example, in Chinese, the word formation, grammar, semantics and tenses are flexible and more irregular. Thus patttern-based methods can only cover few linguistic circumstances. As pointed out by Li et al. (2013), the performance of syntactic analysis and named entity recognition on Chinese corpora still needs to be improved to support robust relation extraction. Furthermore, it is still difficult to use machine translation-based methods to extract such relations because there are great differences in word orders between English and Chinese (Cai et al., 2014).

More recently, word embedding (or distributed word representation) has been empirically proved effective in modeling some of the semantic relations between words by offsets of word vectors (Mikolov et al., 2013a; Mikolov et al., 2013b). The learning of word embeddings only requires shallow processing of a large text corpus. As Fu et al. (2014) suggest, the representation of *is-a* relations is more complicated than vector offsets. By studying the relations of word embeddings between hyponyms and their respective hypernyms, *is-a* relations can be identified by learning semantic prediction models.

In this paper, we consider the problem of harvesting Chinese *is-a* relations from user generated categories, which frequently appear in online encyclopedias and vertical websites. These category names

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1350–1361, Osaka, Japan, December 11-17 2016.

are classes, concepts or topics manually added by human contributors. For instance, in *Baidu Baike*[1], the page "奥巴马(Barack Obama)" has the following categories: "政治人物(Political Figure)", "外国(Foreign Country)", "元首(Leader)" and "人物(Person)". Given an entity and its category set, we aim to predict whether each category name is the hypernym of the entity. We observe that vector offsets of *is-a* relations are quite different in varied data sources and domains (discussed in Section 3). This implies that using a single model is difficult to preserve all the linguistic regularities of *is-a* relations. Furthermore, models learned from one knowledge source are not necessarily effective to extract *is-a* relations from another source, while it is a common practice to construct large-scale taxonomies from multiple Web sources (Fu et al., 2013; Dong et al., 2014; Wang et al., 2014).

To address this problem, we propose a weakly supervised framework to extract *is-a* relations automatically. In the initial stage, we build piecewise linear projection models trained on samples from an existing Chinese taxonomy (Li et al., 2015). In this stage, a K-means based incremental clustering technique is employed to group *is-a* relations with similar semantics together. In each cluster, a separate model maps entities to their respective hypernyms in the embedding space. After that, clustering results are updated incrementally with projection models retrained in an iterative manner. In each iteration, we extract previously unseen *is-a* relations from a collection of unlabeled <entity, category> pairs. To avoid "semantic drift" (Carlson et al., 2010b), a bi-criteria optimization method is proposed such that only those extracted *is-a* relations that are validated by three types of Chinese patterns in a corpus can be labeled as "positive" and added to the training set. In this way, projection models for the target knowledge source are trained without any labeling efforts.

The rest of this paper is organized as follows. Section 2 summarizes the related work. Details of our approach for addressing the *is-a* relation extraction problem are described in Section 3. Experimental results are presented in Section 4. We conclude our paper and discuss the future work in Section 5.

2 Related Work

The *is-a* relation extraction problem has been addressed by identifying hyponyms and their hypernyms from various data sources. Here, we present a summarization on methods on *is-a* relation extraction.

Pattern matching based methods employ syntactic/lexical patterns to extract *is-a* relations. The early work introduced by Hearst (1992) utilizes manually designed patterns to obtain *is-a* relations from text corpora. For instance, based on "NP_1 such as NP_2", it can be inferred that NP_2 is the hypernym of NP_1, where NP_1 and NP_2 are noun phases. These patterns are effective for English and are used to build the largest taxonomy Probase (Wu et al., 2012). However, it is hard to handcraft all valid *is-a* patterns. Ortega-Mendoza et al. (2007) use "seed instances" (i.e., *is-a* word pairs) to discover lexical patterns from the Web using search engines and harvest new instances automatically. Snow et al. (2004) detect syntactic *is-a* patterns by analyzing the parse trees and train a hypernym classifier based on syntactic features. Similar approaches have been adopted in a variety of research (Caraballo, 1999; Etzioni et al., 2004; Sang, 2007; Ritter et al., 2009; Pantel and Pennacchiotti, 2006; Kozareva and Hovy, 2010). As Fu et al. (2014) suggest, many *is-a* relations are expressed in highly flexible manners in Chinese and these approaches have limited extraction accuracy.

Thesauri and encyclopedias can serve as knowledge sources to construct object hierarchies. Suchanek et al. (2007) link concepts in Wikipedia to WordNet synsets (Miller, 1995) by considering the textual patterns of Wikipedia categories. Ponzetto and Strube (2007) design lexical, syntactic and connectivity features to predict whether there is an *is-a* relation between a Wikipedia entity and its category. For Chinese language, Li et al. (2015) introduce a set of language-specific features to predict *is-a* relations using a SVM classifier and construct a large-scale Chinese taxonomy from Wikipedia. Fu et al. (2013) utilize multiple data sources such as encyclopedias and search engine results to design a ranking function in order to extract the most possible hypernym given an entity. Cross-lingual links in Wikipedia are leveraged in (Wang et al., 2014) to derive a bilingual taxonomy by a dynamic boosting model. These methods are more precise than free text extraction but have limited scope constrained by sources.

[1]Baidu Baike (http://baike.baidu.com/) is one of the largest encyclopedias in China, with over 13M entries up till July, 2016.

Text inference approaches make use of distributional similarity measures, which go beyond pattern matching and instead compare the contexts of word pairs in a corpus to infer their relations indirectly. Kotlerman et al. (2010) consider the asymmetric property of *is-a* relations and design directional similarity measures to make lexical inference. Other directional measures are proposed in (Bhagat et al., 2007; Szpektor et al., 2007; Clarke, 2012; Lenci and Benotto, 2012). These methods assume that a hyponym can only appear in some of the contexts of its hypernym and a hypernym can appear in all contexts of its hyponyms. One potential limitation is that the contexts in Chinese are usually flexible and sparse.

To tackle the data sparsity problem, word embedding based approaches have been proposed to solve a series of NLP tasks, such as sentiment classification (Zhou et al., 2015), machine translation (Zhang et al., 2014) and question answering (Yang et al., 2014). In these approaches, words are mapped to a low dimensional space by training neural network based language models, such as *CBOW* and *Skip-gram* models (Mikolov et al., 2013a). The dense word representations are more likely to deal with the context sparsity issue in Chinese stemmed from the flexible expressions. The state-of-the-art method in (Fu et al., 2014) is most related to ours, which takes a Chinese thesaurus as a-priori knowledge and train piecewise linear projection models based on word embeddings. In this paper, we further improve the performance of the word embedding based method by iterative learning of projection models and *is-a* relation selection based on Chinese textual patterns.

3 Weakly Supervised Is-a Relation Extraction

In this section, we describe the formal definition of our problem. The motivation of our method is discussed and the detailed steps introduced, namely, initial model training and iterative learning process.

3.1 Problem Statement

A taxonomy is a *direct acyclic graph* $G = (E, R)$ where nodes E represent entities/classes and edges R denote *is-a* relations. Following the work in Fu et al. (2014), *is-a* relations are regarded as *asymmetric* and *transitive* relations. Therefore, all correct *is-a* relations derived from G are in the transitive closure of R, denoted as R^* where $R^* = \bigcup_{i=0}^{\infty} R^{(i)}$ and $R^{(i+1)} = R \circ R^{(i)}$ with initial condition $R^{(0)} = R$ and $\circ$ being the composition operator of relations.

To extract *is-a* relations from user generated categories, we obtain the collection of entities E^* from the knowledge source (such as *Baidu Baike*). The set of user generated categories for each $e \in E^*$ is denoted as $Cat(e)$. Thus we need to design a learning algorithm F based on R^* to predict whether there is an *is-a* relation between e and c where $e \in E^*$ and $c \in Cat(e)$. In this way, we can utilize an existing taxonomy to harvest new *is-a* knowledge automatically.

3.2 Motivation of Our Method

The state-of-the-art method for Chinese *is-a* relation extraction is the word embedding based approach in (Fu et al., 2014). In their work, the projection parameters of a piecewise linear projection model learned from a Chinese thesaurus are used to identify *is-a* relations in encyclopedias. In this paper, we take a deeper look at the word vectors of hyponyms and hypernyms. As a preliminary experiment, we randomly sample *is-a* relations from a Wikipedia-based Chinese taxonomy (Li et al., 2015) and a Chinese thesaurus *CilinE*[2]. We compute the offsets of embedding vectors (i.e., $\vec{v}(x) - \vec{v}(y)$) where x is the hyponym of y. We have three observations, with examples shown in Table 1[3].

- **Observation 1.** For a fixed x, if y_1 and y_2 are hypernyms of different levels, it is likely that $\vec{v}(x) - \vec{v}(y_1) \not\approx \vec{v}(x) - \vec{v}(y_2)$. For example, "Country" is a high-level hypernym of "Japan" while "Asian Country" covers a narrow spectrum of entities.

- **Observation 2.** If $(x_1, instanceOf, y_1)$ and $(x_2, subClassOf, y_2)$ hold, it is likely that $\vec{v}(x_1) - \vec{v}(y_1) \not\approx \vec{v}(x_2) - \vec{v}(y_2)$. Although both *instanceOf* and *subClassOf* are *is-a* relations in a broad

[2]http://www.ltp-cloud.com/download/

[3]We use the l_2 norm of vector offsets to quantify the difference.

	Example with English Translation	Vector Offsets
True Positive	$\vec{v}$(日本) − $\vec{v}$(国家) ≈ $\vec{v}$(澳大利亚) − $\vec{v}$(国家) $\vec{v}$(Japan) − $\vec{v}$(Country) ≈ $\vec{v}$(Australia) − $\vec{v}$(Country)	$1.03 \approx 0.99$
Observation 1	$\vec{v}$(日本) − $\vec{v}$(国家) $\not\approx$ $\vec{v}$(日本) − $\vec{v}$(亚洲国家) $\vec{v}$(Japan) − $\vec{v}$(Country) $\not\approx$ $\vec{v}$(Japan) − $\vec{v}$(Asian Country)	$1.03 \not\approx 0.71$
Observation 2	$\vec{v}$(日本) − $\vec{v}$(国家) $\not\approx$ $\vec{v}$(主权国) − $\vec{v}$(国家) $\vec{v}$(Japan) − $\vec{v}$(Country) $\not\approx$ $\vec{v}$(Sovereign State) − $\vec{v}$(Country)	$1.03 \not\approx 1.32$
Observation 3	$\vec{v}$(日本) − $\vec{v}$(国家) $\not\approx$ $\vec{v}$(西瓜) − $\vec{v}$(水果) $\vec{v}$(Japan) − $\vec{v}$(Country) $\not\approx$ $\vec{v}$(Watermelon) − $\vec{v}$(Fruit)	$1.03 \not\approx 0.39$

Table 1: Examples of three observations.

sense, the *is-a* relations between (i) entities and classes, and (ii) classes and classes are different in semantics.

- **Observation 3.** For *is-a* pairs in two different domains (x_1, y_1) and (x_2, y_2), it is likely that $\vec{v}(x_1) - \vec{v}(y_1) \not\approx \vec{v}(x_2) - \vec{v}(y_2)$. This implies that *is-a* relations can be divided into more fine-grained relations based on their topics, such as politics, grocery, etc. A similar finding is also presented in (Fu et al., 2014).

These situations bring the challenges in modeling *is-a* relations correctly. Furthermore, *is-a* relations across different knowledge sources vary in characteristics. For example, *is-a* relations in a taxonomy are mostly *subClassOf* relations between concepts, while a large number of *is-a* relations derived from online encyclopedias are *instanceOf* relations, especially in the emerging domains, such as the Internet, new technologies, etc. The differences of *is-a* representations between knowledge sources suggest that a simple model trained on the taxonomy is not effective for *is-a* extraction from encyclopedias. The observations prompt us to take a two-stage process to deal with this problem. In the initial stage, we train piecewise linear projection models based on the taxonomy, aiming to learn prior representations of *is-a* relations in the embedding space. Next, we iteratively extract new *is-a* relations from user generated categories using models in the previous round and adjust our models accordingly. The characteristics of *is-a* relations of the target source are learned in a step-by-step manner.

3.3 Initial Model Training

We first train a *Skip-gram* model over a Chinese text corpus with over 1 billion words to obtain word embeddings. We randomly sample *is-a* relations from R^* as training data, denoted as $R^{'} \subset R^*$. In previous work, Mikolov et al. (2013b) and Fu et al. (2014) employ vector offsets and projection matrices to map words to their hypernyms, respectively. In this paper, we further combine the two relation representations together in the embedding space. For a pair (x_i, y_i), we assume a projection matrix $\mathbf{M}$ and an offset vector $\vec{b}$ map x_i to y_i in the form: $\mathbf{M} \cdot \vec{v}(x_i) + \vec{b} = \vec{v}(y_i)$.

To capture the multiple implicit language regularities in the training data, we follow the piecewise model training technique in (Fu et al., 2014). We first partition $R^{'}$ into K groups by K-means, denoted as $R^{'} = \bigcup_{k=1}^{K} C_k$ where C_k is the collection of *is-a* pairs in the kth cluster. Each pair $(x_i, y_i) \in R^{'}$ is represented as the vector offset $\vec{v}(x_i) - \vec{v}(y_i)$ for clustering. In each cluster, we assume *is-a* relations share the same projection matrix and vector offset. Therefore, we aim to learn K projection matrices and offset vectors as representations of *is-a* relations. For each cluster C_k $(k = 1, 2, \cdots, K)$, we aim to minimize the following objective function:

$$J(\mathbf{M}_k, \vec{b}_k; C_k) = \frac{1}{|C_k|} \sum_{(x_i, y_i) \in C_k} \|\mathbf{M}_k \cdot \vec{v}(x_i) + \vec{b}_k - \vec{v}(y_i)\|^2$$

where $\mathbf{M}_k$ and $\vec{b}_k$ are the projection matrix and the offset vector for C_k, learned via Stochastic Gradient Descent.

3.4 Iterative Learning Process

In the iterative learning process, we train *is-a* relation projection models on a series of dynamically enlarged training set $R^{(t)}$ ($t = 1, 2, \cdots, T$). The main idea is to update clustering results and prediction models iteratively in order to achieve a better generalization ability on the target knowledge source.

Initialization. We have two datasets: (i) the positive dataset $R^{(1)} = R^{'}$ and (ii) the unlabeled dataset $U = \{(x_i, y_i)\}$, which is created from user generated categories. Usually, we have $|U| \gg |R^{(1)}|$. Denote $C_k^{(t)}$ as the collection of *is-a* pairs, $\vec{c}_k^{(t)}$ as the cluster centroid, and $\mathbf{M}_k^{(t)}$ and $\vec{b}_k^{(t)}$ as model parameters in the kth cluster of the tth iteration. We set $C_k^{(1)} = C_k$, $\vec{c}_k^{(1)} = \frac{1}{|C_k|} \sum_{(x_i,y_i) \in C_k} \vec{v}(x_i) - \vec{v}(y_i)$, $\mathbf{M}_k^{(1)} = \mathbf{M}_k$ and $\vec{b}_k^{(1)} = \vec{b}_k$ as the initial values.

Iterative Process. For each iteration $t = 1, \cdots, T$, the models are updated as follows:

- **Step 1.** Randomly sample $\delta \cdot |U|$ instances from U and denote it as $U^{(t)}$ where δ is a sampling factor. For each $(x_i, y_i) \in U^{(t)}$, compute the cluster ID as $p_i = \arg\min_{k=1,\cdots,K} \|\vec{v}(x_i) - \vec{v}(y_i) - \vec{c}_k^{(t)}\|$. We first compute the difference $d^{(t)}(x_i, y_i)$ as $d^{(t)}(x_i, y_i) = \|\mathbf{M}_{p_i} \cdot \vec{v}(x_i) + \vec{b}_{p_i} - \vec{v}(y_i)\|$. The prediction result is $f_M^{(t)}(x_i, y_i) = I(d^{(t)}(x_i, y_i) < \epsilon)$ where $I(\cdot)$ is an indicator function and ϵ is a pre-defined threshold. We use $U_-^{(t)}$ to represent word pairs in $U^{(t)}$ predicted as "positive" in this step.

- **Step 2.** For each $(x_i, y_i) \in U_-^{(t)}$, predict the label (*is-a* or *not-is-a*) by pattern-based relation selection method (introduced in Section 3.5), denoted as $f_P^{(t)}(x_i, y_i)$. Define $U_+^{(t)} = \{(x_i, y_i) \in U_-^{(t)} | f_P^{(t)}(x_i, y_i) = 1\}$. Update the two datasets as follows: (i) $U = U \setminus U_+^{(t)}$ and (ii) $R^{(t+1)} = R^{(t)} \cup U_+^{(t)}$.

- **Step 3.** Denote the collection of *is-a* pairs in $U_+^{(t)}$ that belongs to the kth cluster as $U_k^{(t)}$. Update the cluster centroid $\vec{c}_k^{(t)}$ as follows:

$$\vec{c}_k^{(t+1)} = \vec{c}_k^{(t)} + \lambda \cdot \frac{1}{|U_k^{(t)}|} \sum_{(x_i,y_i) \in U_k^{(t)}} (\vec{v}(x_i) - \vec{v}(y_i) - \vec{c}_k^{(t)})$$

  where λ is a learning rate in $(0, 1)$ that controls the speed of cluster centroid "drift" over time. Re-assign the membership of clusters $C_k^{(t+1)}$ for each $(x_i, y_i) \in R^{(t+1)}$ based on new centroids.

- **Step 4.** For each cluster $C_k^{(t+1)}$, update model parameters by minimizing the objective function:

$$J(\mathbf{M}_k^{(t+1)}, \vec{b}_k^{(t+1)}; C_k^{(t+1)}) = \frac{1}{|C_k^{(t+1)}|} \sum_{(x_i,y_i) \in C_k^{(t+1)}} \|\mathbf{M}_k^{(t+1)} \cdot \vec{v}(x_i) + \vec{b}_k^{(t+1)} - \vec{v}(y_i)\|^2$$

  with the initial parameter values $\mathbf{M}_k^{(t+1)} = \mathbf{M}_k^{(t)}$ and $\vec{b}_k^{(t+1)} = \vec{b}_k^{(t)}$.

Model Prediction. After the training phase, given a pair (x_i, y_i) in the test set, our method predicts that x_i is the hyponym of y_i if at least one of the following conditions holds:

1. (x_i, y_i) is in the transitive closure of $R^{(T+1)}$ (based on *transitivity* property of *is-a* relations).

2. $f_M^{(T+1)}(x_i, y_i) = 1$ (based on final model prediction).

Discussion. The key techniques of the algorithm lie in two aspects: (i) combination of *semantic* and *syntactic-lexico is-a* extraction and (ii) incremental learning. The positive relation selection method in Step 2 can also be regarded as a variant of coupled learning (Carlson et al., 2010a). We ensure only when the results of semantic projection and pattern-based approach are consistent, these relations are added to our training set. Also, at each iteration, the model parameters are updated incrementally. By solving the recurrent formula, the update rule of centroids in Step 3 is equivalent to:

$$\vec{c}_k^{(T+1)} = (1-\lambda)^T \cdot \vec{c}_k^{(1)} + \lambda \cdot \sum_{t=1}^{T} \left(\frac{(1-\lambda)^{T-t}}{|U_k^{(t)}|} \cdot \sum_{(x_i,y_i) \in U_k^{(t)}} (\vec{v}(x_i) - \vec{v}(y_i) - \vec{c}_k^{(t)}) \right)$$

We can see that $\vec{c}_k^{(T+1)}$ is a weighted average of vector offsets of *is-a* relations added into the cluster, where the weight increases exponentially over time. With cluster assignments and prediction models updated, our models gradually fit the semantics of new *is-a* relations extracted from the unlabeled dataset.

3.5 Pattern-Based Relation Selection

We now introduce the pattern-based approach used in Step 2 of the iterative learning process. Although Chinese patterns for relation extraction can not guarantee high precision and coverage, we employ them as a "validation" source for model-based extraction results. The goal of this method is to select only a small portion of relations as $U_+^{(t)}$ from $U_-^{(t)}$ with high confidence to add to the training set $R^{(t)}$.

Previously, Fu et al. (2013) design several Chinese Hearst-style patterns manually for *is-a* extraction. In this paper, we collect a broader spectrum of patterns related to *is-a* relations, and categorize them into three types: "Is-A", "Such-As" and "Co-Hyponym". The examples are shown in Table 2[4]. We have the following two observations:

- **Observation 4.** If x_i and y match an "Is-A" or "Such-As" pattern, there is a large probability that x_i is the hyponym of y. Let $n_1(x_i, y)$ be the number of matches for x_i and y in a text corpus.
- **Observation 5.** If x_i and x_j match a "Such-As" or "Co-Hyponym" pattern, there is a large probability that no *is-a* relation exists between x_i and x_j. Let $n_2(x_i, x_j)$ be the number of matches for x_i and x_j, and $n_2(x_i)$ be the number of matches for x_i and x^* where x^* is an arbitrary hyponym other than x_i.

Category	Examples	Corresponding English Translation
Is-A	x_i是一个y	x_i is a kind of y
	x_i是y之一	x_i is one of y
Such-As	y，例如x_i、x_j	y, such as x_i and x_j
	y，包括x_i、x_j	y, including x_i and x_j
Co-Hyponym	x_i、x_j等	x_i, x_j and others
	x_i和x_j	x_i and x_j

Table 2: Examples of Chinese hypernym/hyponym patterns.

In this algorithm, we utilize the prediction of projection models and Chinese hypernym/hyponym patterns jointly to decide which relations in $U_-^{(t)}$ should be added into $U_+^{(t)}$. For each $(x_i, y_i) \in U_-^{(t)}$, denote $PS^{(t)}(x_i, y_i)$ and $NS^{(t)}(x_i, y_i)$ as the positive and negative scores that indicate the level of confidence. We define the positive score based on model prediction and Observation 4:

$$PS^{(t)}(x_i, y_i) = \alpha \cdot \left(1 - \frac{d^{(t)}(x_i, y_i)}{\max_{(x,y) \in U_-^{(t)}} d^{(t)}(x, y)}\right) + (1-\alpha) \cdot \frac{n_1(x_i, y_i) + \gamma}{\max_{(x,y) \in U_-^{(t)}} n_1(x, y) + \gamma}$$

[4]In practice, there can be over two candidate hyponyms in "Such-As" and "Co-Hyponym" patterns. For simplicity, we only list two here, denoted as x_i and x_j.

where $\alpha \in (0,1)$ is a tuning weight to balance the two factors and γ is a smoothing parameter. For simplicity, we empirically set $\alpha = 0.5$ and $\gamma = 1$ in this paper. We define the negative score based on Observation 5 as follows:

$$NS^{(t)}(x_i, y_i) = \log \frac{n_2(x_i, y_i) + \gamma}{(n_2(x_i) + \gamma) \cdot (n_2(y_i) + \gamma)}$$

A high negative score between x_i and y_i means the strong evidence of the frequent co-occurrence of x_i and y_i in "Such-As" or "Co-Hyponym" patterns, where x_i and y_i are likely to be co-hyponyms. This indicates that there is a low probability of the existence of an *is-a* relation between them.

A bi-criteria optimization problem can be formed where positive and negative scores should be maximized and minimized simultaneously, which is hard to optimize. We further covert it into a positive score maximization problem with negative score constraints:

$$\begin{aligned} \max \quad & \sum_{(x_i,y_i)\in U_+^{(t)}} PS^{(t)}(x_i, y_i) \\ \text{s. t.} \quad & \sum_{(x_i,y_i)\in U_+^{(t)}} NS^{(t)}(x_i, y_i) < \theta, U_+^{(t)} \subset U_-^{(t)}, |U_+^{(t)}| = m \end{aligned}$$

where m is the size of $U_+^{(t)}$ and θ is used to constrain negative score limits. This problem is a special case of the *budgeted maximum coverage problem* (Khuller et al., 1999), which is NP-hard. Based on the proof in (Khuller et al., 1999), the objective function is *monotone* and *submodular*. Therefore, we design a greedy relation selection algorithm to solve this problem with the accuracy of $1 - \frac{1}{e}$, shown in Algorithm 1. Finally, for each $(x_i, y_i) \in U_+^{(t)}$, we make the prediction as: $f_P^{(t)}(x_i, y_i) = I((x_i, y_i) \in U_+^{(t)})$.

Algorithm 1 Greedy Relation Selection Algorithm

```
Initialize U_+^(t) = ∅;
while |U_+^(t)| < m do
    Select candidate is-a pair with largest PS: (x_i, y_i) = arg max_{(x_i,y_i)∈U_+^(t)} PS^(t)(x_i, y_i);
    Remove the pair from U_-^(t): U_-^(t) = U_-^(t) \ {(x_i, y_i)};
    if NS^(t)(x_i, y_i) + Σ_{(x,y)∈U_+^(t)} NS^(t)(x, y) < θ then
        Add the pair to U_+^(t): U_+^(t) = U_+^(t) ∪ {(x_i, y_i)};
    end if
end while
return Collection of is-a relations U_+^(t);
```

4 Experiments

In this section, we conduct comprehensive experiments to evaluate our method on publicly available datasets. We also compare it with state-of-the-art approaches to make the convincing conclusion.

4.1 Experimental Data

In the experiments, we use four datasets consisting of word pairs, and a large Chinese text corpus. The statistics of our datasets are summarized in Table 3.

Dataset	Positive	Negative	Unknown
Wiki Taxonomy	7,312	-	-
Unlabeled Set	-	-	78,080
Validation Set	349	1,071	-
Test Set	1,042	3,223	-

Table 3: Datasets summarization.

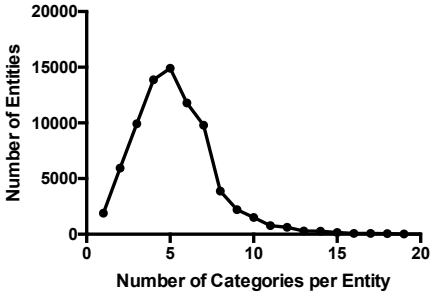

Figure 1: Unlabeled data statistics.

To learn word embeddings, we crawl Web pages from *Baidu Baike* and extract the contents to form a Chinese text corpus, consisting of 1.088B words. We use the open source toolkit *Ansj*[5] for word segmentation. Finally, we train a *Skip-gram* model to obtain 100-dimensional embedding vectors of 5.8M words. We calculate statistics for the pattern-based method in Section 3.5 using the same corpus.

The taxonomy data is obtained from the authors (Li et al., 2015), which consists of 1.3M *is-a* relations derived from Chinese Wikipedia. We use 7,312 *is-a* relations sampled from the taxonomy to train the initial projection models. To construct the unlabeled set, we randomly sample 0.1M entities from our *Baidu Baike* data, filter out entities without user generated categories and extract 78K <entity, category> pairs. The distribution of the number of categories per entity is illustrated in Figure 1.

To our knowledge, the only publicly available dataset for evaluating Chinese *is-a* relation extraction is published in (Fu et al., 2014), containing 1,391 *is-a* relations and 4,294 unrelated entity pairs. We use it to evaluate our method by splitting the dataset into 1/4 for validation and 3/4 for testing randomly.

4.2 Evaluation of Our Method

To tune the parameters of our method, we first run the K-means algorithm several times and train projection models. When we set the cluster number $K = 10$, our initial model achieves the best performance with a 73.9% F-measure. We also vary the value of parameter ϵ from 0.5 to 2 and find that the highest F-measure is achieved when $\epsilon = 1.05$.

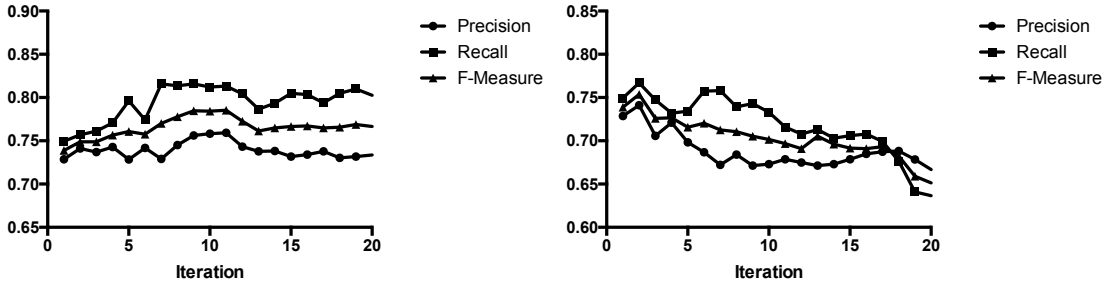
We report the performance of our method in 20 iterations to illustrate the effectiveness of the iterative process. We tune the parameters on the validation set and finally set $\delta = 0.2$, $\lambda = 0.5$ and add 500 new *is-a* relations into the training set in each iteration. In Figure 2(a), these new *is-a* relations are selected based on Algorithm 1. The F-measure increases from 74.9% to 78.5% in the first 10 iterations, which shows that newly extracted *is-a* relations can be of help to boost the performance of our models. The F-measure slightly drops and finally keeps stable after 15 iterations with F-measure around 76.7%. The possible cause of the drop is that a few false positive pairs are still inevitably selected by Algorithm 1 and added to the training set. After manual checking of these pairs, the average accuracy is 98.8%. Some of the erroneous cases include <脂肪(Fat), 健康(Health)>, <萧亚轩(Elva Hsiao), 时尚(Fashion)>, <信息(Information), 科学(Science)>, etc. They express *topic-of* relations rather than is-a relations. The performance becomes stable because the newly selected *is-a* relations tend to be similar to ones already in the training set after a sufficient number of iterations. In Figure 2(b), we directly sample 500 word pairs that are predicted as "positive" into our training set. Despite the slight improvement in the first iteration, the performance drops significantly because a large number of false positive instances are added to the training set for projection learning.

4.3 Comparison with Previous Methods

We evaluate our method and previous methods on the test set. The results are shown in Table 4.

We first re-implement three corpus-based *is-a* relation extraction methods on the *Baidu Baike* corpus. The pattern matching method for English *is-a* relations is originally proposed in (Hearst, 1992). For a Chinese corpus, we implement this method by employing Chinese Hearst-style patterns translated by Fu et al. (2013). The result shows that hand-craft patterns have low coverage for Chinese relation extraction

[5]http://nlpchina.github.io/ansj_seg/



(a) With the pattern-based relation selection method

(b) With no relation selection method

Figure 2: Performance of our method in each iteration.

because the language expressions are flexible. The automatic pattern detection approach in (Snow et al., 2004) improves the recall from 19.8% to 28.1%. However, the precision drops 28.9% because the syntactic parser for Chinese is still not sufficiently accurate, causing errors in feature extraction. The distributional similarity measure introduced in (Lenci and Benotto, 2012) has a 58.1% F-measure and is not effective for our task because the contexts of entities appeared in the free text are noisy. We also directly take the Chinese Wikipedia-based taxonomy (Li et al., 2015) to match *is-a* relations in the testing set. The result has a 98.5% precision but low recall due to the limited coverage of *is-a* relations in Chinese Wikipedia. The word embedding based approach in (Fu et al., 2014) achieves the highest F-measure 73.3% compared to all the previous methods. It shows the projection of word embeddings can model the semantics of Chinese *is-a* relations.

We now discuss our weakly supervised relation extraction method (WSRE) and its variants. In Table 4, *WSRE (Initial)* refers to the *is-a* extraction models trained in the initial stage. Although it is similar to (Fu et al., 2014), F-measure is improved by 2% because we consider both vector offsets and matrix projection in *is-a* representation learning, which is more precise. *WSRE (Random)*, *WSRE (Positive)* and *WSRE* employ the iterative learning process for *is-a* extraction. In *WSRE (Random)*, new *is-a* relations added to the training set are selected randomly from word pairs predicted as "positive" by our model. *WSRE (Positive)* considers only maximizing positive scores in relation selection, ignoring the effects of negative scores. *WSRE* is the full implementation of our method. Based on the results, the performance of *WSRE (Random)* decreases because of false positives in the training set. The F-measure of the latter two methods is increased by 2.3% and 3.3%, respectively, compared to *WSRE (Initial)*, which indicates that the proposed approach can improve prediction performance and generalization ability. *WSRE* outperforms *WSRE (Positive)* by 1% in F-measure, which shows the negative score constraint reduces the error rate in the relation selection process. Overall, our approach outperforms the state-of-the-art method (Fu et al., 2014) by 5.3% in F-measure. We further combine our method with the taxonomy (*WSRE+Taxonomy*) and achieve an 81.6% F-measure, which also has a better performance than Fu's method combined with the extension of a manually-built hierarchy, as shown in (Fu et al., 2014).

4.4 Error Analysis

We analyze errors occurred in our algorithm. The majority of the errors (approximately 72%) stems from the difficulty in distinguishing *related-to* and is-a relations. Some word pairs in the test set have very close semantic relations but are not strictly *is-a* relations. Such cases include <中药(Traditional Chinese medicine), 药草(Herb)>, <元帅(Marshal), 军事家(Strategist)>, etc. For example, most major components in traditional Chinese medicine are herbs, however, "药草(Herb)" is not a hypernym of "中药(Traditional Chinese medicine)" from a medical point of view. These cases are difficult to handle without additional knowledge. The errors in the iterative learning process (discussed in Section 4.2) also contribute to inaccurate prediction of this type.

The rest of the errors are caused by the inaccurate representation learning for fine-grained hypernyms. Take an example of the hyponym "兰科(Orchids)" in the test set, our algorithm recognizes that "植物(Plant)" is a correct hypernym, but it fails for "单子叶植物纲(Monocotyledon)". The possible causes

Method	Precision (%)	Recall (%)	F-Measure (%)
Previous Methods			
Hearst (Hearst, 1992)	96.2	19.8	32.8
Snow (Snow et al., 2004)	67.3	28.1	39.6
Taxonomy (Li et al., 2015)	**98.5**	25.4	40.4
DSM (Lenci and Benotto, 2012)	48.5	58.1	52.9
Embedding (Fu et al., 2014)	71.7	74.9	73.3
Our Method and Its Variants			
WSRE (Initial)	74.1	76.7	75.3
WSRE (Random)	69.0	75.7	72.2
WSRE (Positive)	75.4	80.1	77.6
WSRE	75.8	81.4	78.6
WSRE+Taxonomy	78.8	**84.7**	**81.6**

Table 4: Performance comparison between different methods.

is that "单子叶植物纲(Monocotyledon)" rarely appears in the corpus and is not well represented in the embedding space. We will improve learning of word and relation embeddings in the future.

5 Conclusion and Future Work

In this paper, we propose to extract Chinese *is-a* relations from user generated categories. Specifically, the task can be divided into two steps: initial model training and iterative learning. In the initial stage, word embedding based piecewise linear projection models are trained on a Chinese taxonomy to map entities to hypernyms. Next, an iterative learning process combined with a pattern-based relation selection algorithm is introduced to update models without human supervision. Experimental results show that this approach outperforms state-of-the-art methods. However, our experiments illustrate that free-text Chinese relation extraction still suffers from low coverage. We aim to address this issue by learning generalized pattern representations under the guidance of existing relations in the future.

Abstract

As time passes words can acquire meanings they did not previously have, such as the 'twitter post' usage of 'tweet'. We address how this can be detected from time-stamped raw text. We propose a generative model with senses dependent on times and context words dependent on senses but otherwise eternal, and a Gibbs sampler for estimation. We obtain promising parameter estimates for positive (resp. negative) cases of known sense emergence (resp non-emergence) and adapt the 'pseudo-word' technique (Schütze, 1998) to give a novel further evaluation via 'pseudo-neologisms'. The question of ground-truth is also addressed and a technique proposed to locate an emergence date for evaluation purposes.

1 Introduction

It is widely noted that a single word can have several senses. The diachronic aspect of this is that the set of senses possessed by a word changes over time. (1a) and (1b) below illustrate this:

(1) (a) *she was a* **gay** *little soul, enjoying everything and always trilling with laughter* (1905)
(b) *applying heightened scrutiny to discrimination against* **gay** *men and lesbians* (1990)
(a′) *sie war ein* **Homosexuell** *kleine Seele, alles zu genießen und immer rollen vor Lachen*

(1a), from 1905, illustrates a 'being happy' sense of *gay*, while (1b), dating from 1990, illustrates a 'homosexual' sense, a sense which the word did not possess in 1905, and came to possess at some time since. The advent of a new sense for an existing form is sometimes called a *semantic* neologism (Tournier, 1985), in contrast to the simpler *formal* neologism, where simply a new form arrives (eg. *selfie*). The concern of this paper is to propose an unsupervised algorithm for detecting semantic neologisms, an algorithm which can be given time-stamped but plain-text examples of a particular word and detect whether (and when) the word gained a sense.

Information about such lexical change could be useful to NLP tasks. For example, if a SMT system is trained on data from particular times and is to be applied to texts from different times, either later or earlier, advance warning of sense changes could be of use. To illustrate, (1a′) gives the English→German translation via Google translate[1] of (1a), mistranslating the 1905 usage of *gay* as *Homosexuell*, probably due to the newer sense predominating in training data.

We will propose a diachronic sense model where a target's sense is conditioned on time and the context words are conditioned just on the target's sense, and not the time. We use the Google n-gram data set (Michel et al., 2011) which provides time-stamped data but *no* sense information and develop a Gibbs sampling algorithm (Gelfand and Smith, 1990) to estimate the parameters in an unsupervised fashion. We will show that the algorithm is able to provide an accurate date of sense emergence (true positives), and also to detect the absence of sense emergence when appropriate (true negatives). We adapt also the 'pseudo-word' technique first proposed by Schütze (1998) to give a further means of algorithm assessment. We also make a number of points concerning difficulties and possibilities evaluating such a sense-emergence system.

2 A Diachronic Sense Model

Assume we have a corpus of D *time-stamped* occurrences of some particular target expression σ, with each time-stamp shared by many items. Let $\boldsymbol{w}$ be the sequence of words in a window around σ, and Y be its time-stamp, ranging from 1 to N. Assume σ exhibits K different senses and let S be the sense of a particular item. S will be treated as a hidden variable: the actual data provides values just for Y and $\boldsymbol{w}$. We will now propose a particular model of the joint probability $p(Y, S, \boldsymbol{w})$.

It may be factorised as $P(Y) \times P(S|Y) \times p(\boldsymbol{w}|S, Y)$ without loss of generality. We now make two independence assumptions: (a) that conditioned on S the words $\boldsymbol{w}$ are independent of Y, so $p(\boldsymbol{w}|S, Y) = P(\boldsymbol{w}|S)$ and (b) that conditioned on S the words are independent of each other, so $P(\boldsymbol{w}|S) = \prod_i p(w_i|S)$. With these assumptions the equation for a single data item is

$$P(Y, S, \boldsymbol{w}; \boldsymbol{\pi}_{1:N}, \boldsymbol{\theta}_{1:K}, \boldsymbol{\tau}_{1:N}) = P(Y; \boldsymbol{\tau}_{1:N}) \times P(S|Y; \boldsymbol{\pi}_{1:N}) \times \prod_i p(w_i|S; \boldsymbol{\theta}_{1:K}) \quad (2)$$

where we have also introduced explicit notations for model parameters: (i) for every time t, $\boldsymbol{\pi}_t$ is a length K vector of sense probabilities (ii) for every sense k, $\boldsymbol{\theta}_k$ is a length V vector of context word probabilities for target sense k — V is the size of the vocabulary encountered in all the data and (iii) for every t, τ_t is a 'time' probability reflecting simply the abundance of target σ at t.

The fact that for every time t there is a parameter $\boldsymbol{\pi}_t$ directly models that a sense's likelihood varies temporally; for an *established* sense this variation might be due to changes in the world and in people's concerns, but for an *emergent* sense, part of the variation represents genuine *language* change and for some k, for some early range of times, $\pi_t[k]$ should ideally be *zero*. Assumption (a) reflects an expectation that the vocabulary co-occuring with a particular *sense* is comparatively time independent. This particular time-independence is perhaps plausible but certainly is not absolute and its viability as an assumption can only be confirmed or disconfirmed by our later experiments.

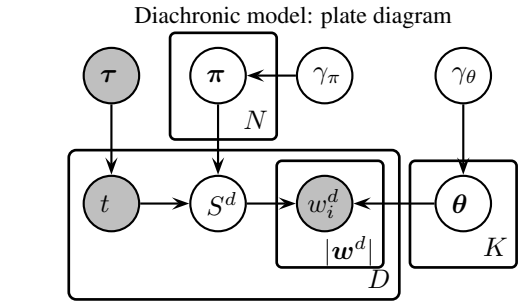
To develop the model further to the level of a corpus and incorporate parameter priors, let $\boldsymbol{t}^{1:D}, \boldsymbol{s}^{1:D}, \boldsymbol{w}^{1:D}$ be the values of Y, S and $\boldsymbol{W}$ on D items, and let the $\boldsymbol{\pi}_t$ sense probability vectors have a K-dimensional Dirichlet prior with parameter γ_π and the $\boldsymbol{\theta}_k$ word probability vectors have a V-dimensional Dirichlet prior with parameter γ_θ. We consider the joint probability $P(\boldsymbol{t}^{1:D}, \boldsymbol{s}^{1:D}, \boldsymbol{w}^{1:D}, \boldsymbol{\pi}_{1:N}, \boldsymbol{\theta}_{1:K}; \boldsymbol{\gamma}_\pi, \boldsymbol{\gamma}_\theta, \boldsymbol{\tau}_{1:N})$ and its formula under our assumptions is equation (3) in Figure 1, above which the model is depicted as a plate diagram.

From a generative perspective, the $\boldsymbol{\pi}_{1:N}$ and $\boldsymbol{\theta}_{1:K}$ are generated from N and K samplings and then used for *all* D data items. In actual data, the time-stamps and words are known, so for any fixed setting of $\boldsymbol{\gamma}_\pi, \boldsymbol{\gamma}_\theta$ there is a defined *posterior* distribution on $\boldsymbol{s}^{1:D}, \boldsymbol{\pi}_{1:N}, \boldsymbol{\theta}_{1:K}$. A Gibbs sampling algorithm (Gelfand and Smith, 1990) can be derived, generating a large set of samples of this $(D + N + K)$-tuple, representative of this posterior, from which *mean* values of the model parameters $\boldsymbol{\pi}_{1:N}$ and $\boldsymbol{\theta}_{1:K}$ can be derived. To arrive at the Gibbs sampler, sampling distributions for s^d, $\boldsymbol{\pi}_t$ and $\boldsymbol{\theta}_k$ are needed, in each case conditioned on all *other* parts of the sample tuple. The formulae for these sampling distributions are shown as (4 – 6) in Figure 1 : in these formulae $\mathbb{S}_t[k]$ is the number of data items with time-stamp t and sampled sense k and $\mathbb{V}_k[v]$ is the number of times word v occurs in data items with sampled sense k. The derivation of these formulae is relatively straightforward given well-known conjugacy properties of Dirichlet priors – Appendix A gives an outline derivation for $\boldsymbol{\pi}_t$. The sampling algorithm is given in pseudo-code in Figure 1.

2.1 Ground truth for semantic neologisms?

Given a large-scale, time-stamped and *sense*-labeled corpus for a target expression σ, it would be easy to determine a true emergence date — call it C_0 — at which a new sense for σ first departed from zero frequency (and continued to climb from zero). It has been noted (Lau et al., 2012; Cook et al., 2013) that such reference corpora do not exist, thus posing the question of what can serve as ground truth instead.

One option, sometimes adopted though far from ideal, is simple speaker intuition, which is subjective, of low temporal resolution and at best applicable to recent innovations. It is natural to consider dictionaries for something better. Form/meaning pairings are added to dictionaries at some particular time, so inspecting a series of dictionary editions, though labour intensive, can give a *first inclusion* date – call



$$P(\boldsymbol{t}^{1:D}, \boldsymbol{s}^{1:D}, \boldsymbol{w}^{1:D}, \boldsymbol{\pi}_{1:N}, \boldsymbol{\theta}_{1:K}; \boldsymbol{\gamma}_\pi, \boldsymbol{\gamma}_\theta, \boldsymbol{\tau}_{1:N}) = \prod_t \text{Dir}(\boldsymbol{\pi}_t; \boldsymbol{\gamma}_\pi) \times \prod_k \text{Dir}(\boldsymbol{\theta}_k; \boldsymbol{\gamma}_\theta) \times \prod_d [\, P(t^d; \boldsymbol{\tau}_{1:N}) \times P(s^d | t^d; \boldsymbol{\pi}_{1:N}) \times \prod_i P(w_i^d | s^d; \boldsymbol{\theta}_{1:K}) \,] \quad (3)$$

$$P(s^d) = \frac{\pi_{t,k} \prod_{i=1}^{|\boldsymbol{w}^d|} \theta_{k,w_i^d}}{\sum_{k'} \pi_{t,k'} \prod_{i=1}^{|\boldsymbol{w}^d|} \theta_{k',w_i^d}} \quad (4)$$

$$P(\boldsymbol{\pi}_t) = \text{Dir}(\boldsymbol{\pi}_t; \boldsymbol{\gamma}_\pi + \mathbb{S}_t) \quad (5)$$

$$P(\boldsymbol{\theta}_k) = \text{Dir}(\boldsymbol{\theta}_k; \boldsymbol{\gamma}_\theta + \mathbb{V}_k) \quad (6)$$

as in text, assume data as
context words $\boldsymbol{w}^{1:D}$, time-stamps $\boldsymbol{t}^{1:D}$
assume K is a supplied no of senses
create $S[D]$; `// data sense labels`
create $\mathbb{S}[T][K]$; `// see text`
create $\mathbb{V}[K][V]$; `// see text`
for *itr:=1 to no-iterations* **do**
  set $\mathbb{S}[t][k] = \mathbb{V}[k][v] = 0$ for all t,k,v
  for *d:=1 to D* **do**
    $k \sim P(s^d)$ see (4);
    $S[d] = k$;

Algorithm 1: Gibbs sampling estimation

Figure 1: From top left in anti-clockwise shows: plate digram for diachronic model, Gibbs sampler updates, and pseudo-code for Gibbs sampler

this D_0^i. The time resolution of this is low and the subtle criteria involved in inclusion decisions make it a non-ideal approximation of C_0 (Sheidlower, 1995; Simpson, 2000; Barnhart, 2007). Some researchers (Lau et al., 2012) use this, though we will not. More accessibly, an historically oriented dictionary (eg. the Oxford English Dictionary (OED)) strives to include the earliest known use of a word in a particular sense — the so-called *earliest citation*. If we call this D_0^c, it seems to makes sense to use D_0^c as a *lower* bound on C_0, and we will do this. D_0^c represents a first use, which might be followed by a long interlude before the usage is really taken up: the experiments in Section 3.2 will highlight examples of this.

We propose to use a different technique to establish C_0 more precisely. If there are words which it is intuitive to expect in the vicinity of a target word σ in the novel sense, and not in other senses, then by consulting a time-stamped corpus one should see the probability of finding these words in σ's context start to climb at a particular time. For example, *mouse* has come to have a 'computer pointing device' sense, and in this usage it is intuitive to expect words like *click*, *button*, *pointer* and *drag* in it's context. For any word w and target σ let $P_t(w|\sigma)$ be w's probability of occurring in σ's context in data from time t, and let $track_\sigma(w)$ to be the sequence these values. If when $track_{mouse}(w)$ is plotted for the above words, they all show a sharp increase at the *same* time point, this is good evidence that this is C_0 – the right-hand plot in Figure 3(a) is an example of this. This combines co-occurrence intuitions with corpus data, and does *not* rely on somewhat unreliable speaker intuitions of recency. To forestall any possible confusion, this procedure of inspecting the probabilities of words thought especially associated with a particular sense is *not* being advanced as a proposed unsupervised algorithm to locate sense emergences. It is advanced as a way to establish a ground-truth concerning emergence by which to evaluate our proposed unsupervised algorithm.

3 Data and Experiments

In the experiments reported below we use the Google N-gram dataset (Michel et al., 2011). This is a data-set based on Google's digitized publication holdings and it provides per-year counts of n-grams, for

Target	Years	Lines	New sense	OED	Tracks	GS-Date	$< 10\%$
mouse	1950-2008	910k	computer pointing device	1965	1983	1982	yes
gay	1900-2008	1253k	homosexual person	1922	1966	1969	yes
strike	1800-2008	5052k	industrial action	1810	1880	1866	yes
bit	1920-2008	7393k	basic unit of information	1948	1965	1954	no
paste	1950-2008	318k	duplicate text in computer edit	1975	1982	1981	yes
compile	1950-2008	689k	transform to machine code	1952	1966	1971	yes
surf	1950-2008	182k	exploring internet	1992	1994	1993	yes
boot	1920-2008	1285k	computer start up	1980	1980	1984	yes
rock	1920-2008	4136k	genre of music	1956	1965	1965	yes
stoned	1930-2008	79k	under drug influence	1952	1970	1979	no

Target	Years	Lines
ostensible	1800-2008	130k
present	1850-2008	56333k
cinema	1950-2008	305k
promotion	1930-2008	1681k
theatre	1950-2008	1125k
play	1950-2008	13726k
plant	1900-2008	8175k
spirit	1930-2008	11573k

Table 1: Google 5 gram dataset - the left table provides the information for targets that are neologisms while the right one has the targets for non-neologisms – see text for explanation of columns

$1 \leq n \leq 5$: so for any given n-gram, $\boldsymbol{x}$, and any year, t, it gives the total frequency[2] of occurrences of $\boldsymbol{x}$ across all books dated to year t. For a given target word σ we use the subset of all the data consisting of the *5*-grams that contain σ; we use the 5-grams as they provide most context around the target σ. For the target *mouse* the following is an example of a line of data from the corpus

```
Enter or click the mouse 1990 9 7
```

The first of the final three numbers is a year. The penultimate number is the number of occurrences of the 5-gram in all publications from that year – this is the significant count data for the algorithm. The final number is the number of publications from the year that contain the 5-gram, which is not significant for the algorithm.

For the experiments reported in Section 3.2 two sets of targets were chosen. The first set {*mouse, gay, strike, bit, paste, compile, surf, boot, rock, stoned*} are words which, relative to particular time periods, are known to exhibit sense emergence. The second set {*ostensible, present, cinema, promotion, theatre, play, plant, spirit*} are words which, relative to particular time periods, are thought *not* to exhibit sense emergence. Following Lau et al. (2012) the idea is that these should provide both positive and negative tests for the algorithm. Table 1 lists the targets. For each target, the 'Years' and 'Lines' columns give the range of years used and the total number of 5-gram lines of data for that year-range. For the positive targets the 'New sense' column gives an indication of the emergent sense and the next two columns give two kinds of reference dating information – see Section 2.1 – the OED first citation date and the 'tracks'-based date that is apparent from 'tracks' plots for words that are intuitively associated with the emergent sense (the right-hand plot in Figure 3(a) is an example). The 'GS date' column gives the emergence date inferred when the inference algorithm was run and will be discussed further in Section 3.2.

Before describing the experiments it is necessary to emphasize the Google n-gram data-set is best thought of as a frequency table giving per-year counts associated with 5-gram *types*. It is not really a corpus of text tokens. For brevity Algorithm 1 was formulated assuming that each data item represented a single target *token*. Any original publication token of a target σ could have contributed to several different 5-gram *type* counts (up to 5) but the data-set makes it impossible to know to what extent this is so. We therefore effectively treat each 5-gram data entry d listed with frequency of n_d as if it derives from n_d tokens of σ which contributed to no other 5-gram counts. This leads to changing the count increment operations in Algorithm 1 to add n_d rather than 1, that is, $\mathbb{S}[t][k]{+}{=}n_d$ and $\mathbb{V}[k][w]{+}{=}n_d$.

For all of the experiments sampling is done according to Algorithm 1, for 10000 iterations, with the first 1000 discarded as 'burn-in' samples and then means are determined for the model parameters $\boldsymbol{\pi}_{1:N}$ (sense-given-year) and $\boldsymbol{\theta}_{1:K}$ (word-given-sense) from the sampled values. The parameters $\boldsymbol{\gamma}_\pi$ and $\boldsymbol{\gamma}_\theta$ of the Dirichlet priors are set to have 1 in all positions to make them non-informative priors so uniform over all possible $\boldsymbol{\pi}_t$ and $\boldsymbol{\theta}_k$. The sampler is initialised with values $\boldsymbol{\pi}_{1:N}$ and $\boldsymbol{\theta}_{1:K}$ in the following way. Let P_{corp} be the observable corpus word probabilities in $\boldsymbol{w}^{1:D}$. Each $\boldsymbol{\theta}_k$ is set to $(1-\alpha)P_{corp} + \alpha P_{ran}$, where P_{ran} is a random word distribution and α is a mixing proportion, here set to 10^{-1}. The π_t are set to some shared set of sense probabilities. Thus initially the word distributions for each sense k are almost identical, and the sense distributions are the same at all times, so far from the neologism situation.

[2]They exclude 5-grams with total count < 40.

The procedure was implemented in C++. To obtain the code or data see `www.scss.tcd.ie/Martin.Emms/SenseDynamics`.

3.1 Experiments with 'pseudo'-neologisms

The '*pseudo-word*' technique was introduced in Schütze (1998) as a possible means to test unsupervised word-sense discrimination. It can be given a diachronic twist to furnish what might be called '*pseudo-neologisms*' in the following way. Relative to some period of time select two words, σ_1 and σ_2, both unambiguous, with σ_1 in use throughout the time period, but with σ_2 first emerging at some point, t_e, in the period. If the 5-grams for σ_1 and σ_2 are then all treated as examples of the fake word 'σ_1-σ_2' this functions as an artifical *semantic* neologism, manifesting σ_2's sense only from t_e onwards. Furthermore, if we say $f_t(\sigma_i)$ gives the true empirical probability of target σ_i in pooled σ_1,σ_2 data for time t, then ideally the outcome of inference when run for $K = 2$ should be that for each k, the trajectory of the $\pi_t[k]$ values is very similar to that for one of the $f_t(\sigma_i)$. We tested this, for the time-period 1850–2008, with 'ostensible' for σ_1 (present throughout), and 'supermarket', 'genocide' and 'byte' as possibilities for σ_2 (which emerged as new words over this time frame) and indeed obtained the desired correspondence between inferred $\pi_t[k]$ and empirical $f_t(\sigma_i)$ trajectories – Figure 2 shows the outcomes for the first two. For the first case the succession of $\pi_t[1]$ values matches closely the succession of f_t('supermarket') values, and in the second case the $\pi_t[0]$ values match the f_t('genocide') values. To get an insight into the inferred $\boldsymbol{\theta}_k$ values, we defined $gist(S)$ to be the top 20 words when ranked according to the ratio of $P(w|S)$ to $P_{corp}(w)$. For the apparently neologistic sense S, Figure 2 also shows $gist(S)$ and it can be seen that these sets of words seem very consistent with relevant parts of the pseudo-neologisms.

Thus on these pseudo-neologisms, the proposed model and algorithm has been successful, identifying an emerging 'sense' in an unsupervised fashion. Moving on from this first test of the algorithm, the next section considers outcomes on authentic words.

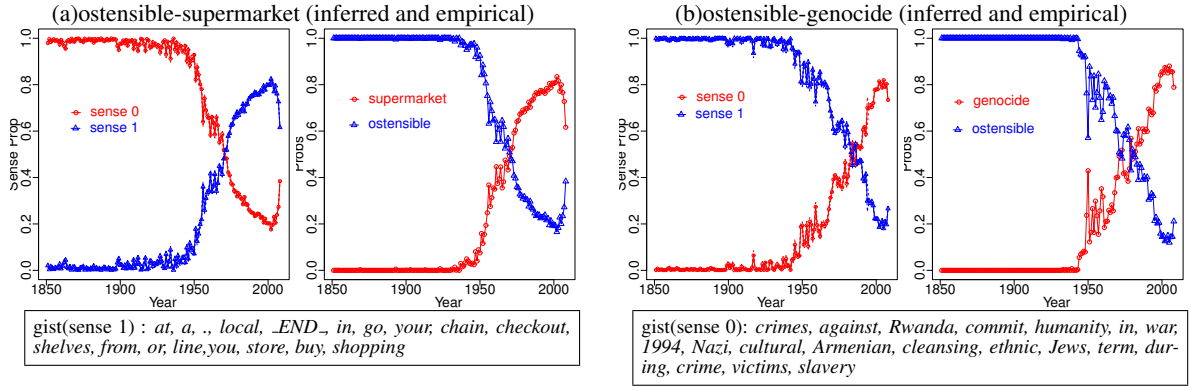

Figure 2: For (a-b), the left-hand plots show the inferred $\pi_t[k]$ sense parameters for a pseudo-neologism σ_1-σ_2, and right-hand plot shows the known σ_1 and σ_2 proportions. Below the plots are 'gist(S)' words associated to the apparent neologism sense – see text.

3.2 Experiments with genuine neologisms

Table 1 listed both targets expected to show sense emergence and targets expected to not show sense emergence. For several of the sense emergence targets, Figure 3(a-d) depicts various aspects of the outcomes. In each case the leftmost plot for a target σ shows for each k the succession of inferred $\pi_t[k]$ values – the sense-given-year values – plotted as a solid line[3]; the rightmost plot in each case is a 'tracks' plot (see Section 2.1), showing for some collection of words considered to be associated with the novel sense the succession of their probabilities of occuring in n-grams for the target σ, $P_t(w|\sigma)$. These are the basis for the 'tracks' column in Table 1.

mouse Figure 3(a): The algorithm was run looking for 3 sense variants on data between 1950 and 2008. The blue line for the $\pi_t[1]$ sequence in the left-hand plot shows a neologistic pattern, starting near 0 and

[3]also shown is the HPD interval around the mean as dotted lines

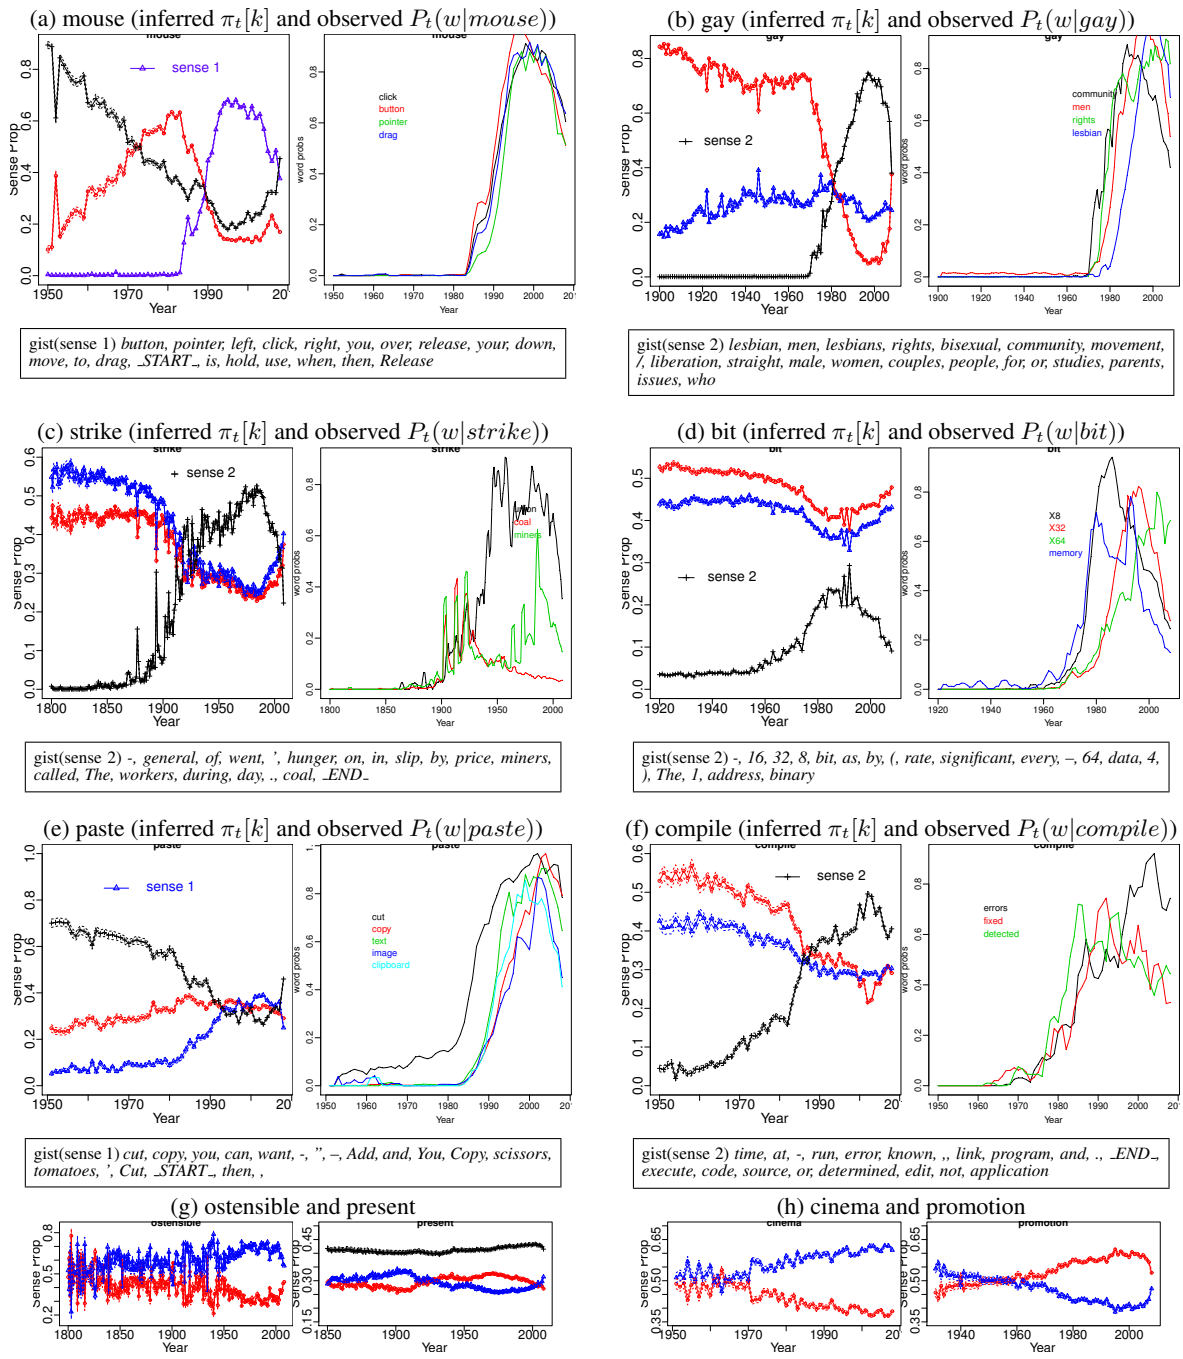

Figure 3: For (a-f), the left-hand plot shows the inferred $\pi_t[k]$ sense parameters, with the sense number S of the potential neologism labeled; the right-hand plot show probability 'tracks' for some words intuitively associated with the neologism (see text for further details). The box below the plots has top 20 $gist(S)$ words for the neologism sense S. (g-h) show the inferred $\pi_t[k]$ sense parameters for negative targets

departing from 0 around 1983. The 'tracks' plot also shows that several words intuitively associated with the neologistic sense, also drastically increase their probability conditioned on *mouse* around the same time. The 'GS-date' column of Table 1 gives the time t, if any, in a $\pi_t[k]$ sequence where it appears to depart from, and continues to climb from, zero. The '$< 10\%$' column records whether this agrees with the tracks-based date to within 10% of the time-span considered – which it does in this case. Notably in this case, the GS-based emergence date, though close to the tracks-based date, is more than 20 years *later* than the OED first citation date. The OED first citation comes from a research paper in 1965, but the mouse computer peripheral only became popular considerably later and it is not unexpected that the

date at which this use of the term *mouse* departed and continued to climb from zero in the n-grams books based data is substantially later. We take this to illustrate why simply taking the OED first citation date, D_0^c, as a gold standard for the true corpus emergence date, C_0, would be a mistake[4]. The box below the plots in Figure 3(a) tries to give some insight into the estimated $\boldsymbol{\theta}_1$ parameter concerning word-given-sense probabilities by showing the words belonging to $gist(1)$ (see definition in section 3.1). They seem mostly consistent with the 'pointing device' sense.

gay Figure 3(b): In this case the procedure was run on data from 1900 to 2008, for 3 senses. In the left-hand plot the black line, for the $\pi_t[2]$ sequence, shows sense emergence, appearing to depart from near zero first around 1969. The 'tracks' plots to the right seem to increase around around 1966. The OED first citation date of 1922 predates both considerably. The 'gist' words for $S = 2$ also seem mostly consistent the 'homosexual' sense.

Similar to *mouse* and *gay*, the detailed outcomes for *strike, bit, paste, compile* are shown in figures (c - f) with the procedures run on data for 3 senses. For space reasons, these details are not shown for *boot, surf, strike, rock* and *stoned* but Table 1 summarizes all outcomes: in each case the inferred date was later than the OED first citation date, and in all cases close to the tracks-based date, just missing the 10% margin in two cases.

Turning to the words which were *not* expected to exhibit an emergent sense, Figure 3(g-h) shows the plots of the inferred $\pi_t[k]$ sequences for the targets *ostensible, present, cinema* and *promotion*. None show a clear neologistic pattern, in line with expectations. Though the details are not shown in Figure 3 the same kind of outcome was found for the other negative targets listed in Table 1.

The value of K varied somewhat between the experiments. That the number of senses possessed by the different targets varies is somewhat to be expected and in some cases where a neologistic trend was less clear with n senses, it became clearer with $n + 1$. The automatic setting of this parameter remains an area for future work.

4 Comparisons to related work and conclusions

We have looked at the detection that a word has acquired the possibility to express a meaning which it could not hitherto (eg. *mouse* as pointing device). One can also look at senses themselves as changing over time, perhaps widening or narrowing, and there has been prior work addressing this issue (Sagi et al., 2009). We would like to treat this as a separate issue, though drawing a conclusive line between the two is tricky.

Concerning sense emergence specifically, it has to be stressed there is no strict quantitative state-of-the-art, because it is not the case that prior works share the same targets, use the same data, or address in the same way the tricky ground-truth issue (see Section 2.1). Bearing this in mind we have tried to organise the discussion below around major design options and papers that exemplify these.

There have been some proposals concerning sense emergence detection *without* modelling senses at all (Cook and Hirst, 2011; Kim et al., 2014). Though able to detect a difference between corpora from different eras, these systems tend to lack a capacity to pick out instances exemplifying a putative novel sense, which is arguably a desirable feature.

Moving on to systems which do involve some kind of modelling of senses, a noteworthy characteristic of many is that they often apply a WSI algorithm which is time-*unaware*. One design option is to *pool* all training data for the WSI phase, then assign likeliest senses to examples, and then to finally check for a correlation with time, such as a sense only being assigned after a particular time. Another design option is to *separate* the data into eras, perform independent WSI on each subset and then seek to consider how the sense representations from each era may (or may not) be *linked* to each other.

The *pooling* design option is exemplified in (Lau et al., 2012; Cook et al., 2013; Cook et al., 2014). Their time-unaware WSI system is based on LDA (Blei et al., 2003), and treats the I words of a context as generated from I topics, and then identifies a target's *sense* with the most frequent amongst the I topics of the context words. It is furthermore an HDP variant of LDA (Teh et al., 2004) in which the

[4] other than as a lower bound

number of topics is self-determined by the training process. The equating of senses with topics could be questioned (Wang et al., 2015) and also the self-determined sense number in their illustrative examples seems strikingly high (10), with many unintuitive components included. Rather than a year-by-year time-line, their data is time-stamped to just two time *eras*, $\mathcal{E}_1$ and $\mathcal{E}_2$ (eg. in one of their papers $\mathcal{E}_1$ is the late 20^{th} century (BNC) and $\mathcal{E}_2$ is 2007 (UkWaC)), and so they attempt a much lower resolution of emergence dating than we do. Their approach to ground-truth on sense emergence was different also, being that using D_0^i (dictionary *inclusion date*, mentioned in section 2.1), and so has some of the drawbacks that were noted there. As we did, they had both positive and negative targets. Without a time-line their evaluation cannot be a comparison of true and inferred emergence date and instead they count success as a tendency to place positives above negatives when ranked by a 'novelty' score: the max over k of the ratio of $\mathcal{E}_2$ to $\mathcal{E}_1$ frequency of assigned sense k. They obtain thus a ranking on their targets: { **domain**(116.2), **worm**(68.4), **mirror**(38.4), *guess*(16.5), **export**(13.8), *founder*(11.0), *cinema*(9.7), **poster**(7.9), *racism*(2.4), *symptom*(2.1) } (with positive targets in bold and negative in italics). As a possible generalisation of this score to a time-line, consider a 'novelty' score computed in the following way: from the sequence of $\pi_t[k]$ values, find 'min' and 'max' values and divide the temporally later value by the temporally earlier one, letting the novelty score be the max over k of this ratio. On our targets this gives a ranking: { **stoned**(10^5), **strike**(5442.7), **gay**(2791.1), **mouse**(1485.9), **surf**(156.7), **compile**(26.6), **bit**(10), **rock**(7.4), **boot**(7), *ostensible*(3.5), *plant*(1.89), *play*(1.8), *promotion*(1.4), *cinema*(1.3), *theatre*(1.1), *spirit*(1) }, separating the positive from the negative targets. Due to the data and target differences it would not make sense to compare these rankings. Earlier work by Rohrdantz et al. (2011) also instantiates the *pooling* option to exploit a time-unaware system. Their system was again LDA-based, their ground-truth approach was also D_0^i-based and their data was news articles between 1987 and 2007.

The *separate-then-link* strategy for deploying time-unaware WSI to nonetheless attempt to detect sense dynamics is exemplified in (Mitra et al., 2014; Mitra et al., 2015). The time-unaware WSI system in this case is a so-called 'Distributional Thesaurus' clustering approach (Rychlý and Kilgarriff, 2007; Biemann and Riedl, 2013), which starting from a word(type) co-occurrence graph where edges reflect co-occurrence, induces sets of words to represent a sense. Their data set consists of 'syntactic dependency n-grams' as produced by Goldberg and Orwant (2013) from the same digitised books as those from which the Google n-gram data is derived. They divide the entire time-line into eras $\mathcal{E}_1 \ldots \mathcal{E}_8$ of ever shortening duration but containing equal amounts of data (eg. $\mathcal{E}_2$ = 1909–53, $\mathcal{E}_7$ = 2002-05). For a given target, for each era they run their clustering to induce sense-representing word sets, and then they propose ways to link the clusters for $\mathcal{E}_i$, $\{s_1^i, \ldots s_m^i\}$ to the clusters of later era $\mathcal{E}_j$, $\{s_1^j, \ldots s_n^j\}$. Roughly speaking a cluster in $\mathcal{E}_j$ is judged a 'birth' (ie. sense emergence) if sufficiently few of its member words belong to the any of the clusters for the earlier era $\mathcal{E}_i$. In the paper they discuss outcomes concerning apparent 'births' when comparing the 1909-1953 and 2002-2005 eras. They do not test with respect to known positive and negative examples. Instead they apply the procedure to *all* words, obtain a very large set of candidate 'births', apply a relatively complex multi-stage filtering process to this and then on a randomly selected 48 cases from the filtered 'births' they find 60% are correct. Their approach to ground-truth concerning sense emergence (cf. Section 2.1) is somewhat varied but essentially was author intuition in (Mitra et al., 2014) and dictionary first citation D_0^c in (Mitra et al., 2015), though as we have noted this should only serve as lower bound[5].

Unlike these proposals, the experiments in this paper concern a model which is *not* time-unaware: the model has variables and parameters referring to time. Earlier versions of this idea were discussed in (Emms, 2013; Emms and Jayapal, 2014; Emms and Jayapal, 2015) though differing from the work presented here in number of respects (such as the estimation approach (EM), data used (text snippets via Google custom date search) and the targets considered (multiword expressions)). This aspect of including time explicitly in a probabilistic model seems to have been considered much less often than the above-mentioned essentially time-unaware approaches. The work of Wijaya and Yeniterzi (2011) is one example. They do not propose a sense-emergence detection algorithm per-se but do make some

[5]Without getting too lost in case-by-case details, it is worth noting that some seem incorrectly judged true 'births' relative to the eras considered, such as an assailant sense of *thug*, a calculus sense of *derivative*

analyses on the Google n-gram data to seek indicators of sense change. They sought to apply the *Topics Over Time* variant of *LDA* (Wang and McCallum, 2006), to do which they somewhat curiously collapse a year's worth of n-grams for a target into a *single* 'document' for that year. They found for example that for *gay*, training for 2 topics, there is a switch from a strong preference for one topic to preference for the other around 1970.

The recent work of Frermann and Lapata (2016) is a further example of a time-aware probabilistic model, in fact one having much in common with the model we have been discussing. They, as we have done, consider a generative model in which for a given time t a sense k is chosen, according to some discrete distribution[6] $\boldsymbol{\pi}_t$, and then, again as we have assumed, the context words in $\boldsymbol{w}$ are generated independently of each other. Whereas we have assumed that word choices are conditionally independent of the time t given the sense k, and so have for each sense k a parameter $\boldsymbol{\theta}_k$ of word probabilities, they do *not* assume this independence, and so for each *time* t and sense k have a parameter $\boldsymbol{\theta}_{tk}$ of word probabilities. The key further feature of their model is their use of *intrinsic Gaussian Markov Random Fields* (iGRMFs) to have priors which control how the distributions $\boldsymbol{\pi}_t$ and $\boldsymbol{\theta}_{tk}$ change over time: basically there is a precision hyper-parameter κ such that a *high* κ favours *small* changes in successive values. For the succession of $\boldsymbol{\theta}_{tk}$ values, they set κ to a high value, so that although $\boldsymbol{\theta}_{tk}$ does not have to be constant over time, only small variation is anticipated by the prior. The succession of π_t values is allowed greater variation. This use of iGMRF-based priors requires in its turn a more sophisticated Gibbs sampling approach to parameter estimation than that which we have used – which they achieve following ideas of Mimno et al. (2008). From the perspective of their model, our model is more or less what would be arrived at by (i) letting κ for $\boldsymbol{\theta}_{tk}$ tend to ∞, preventing any change of word-given-sense probabilites in successive times and (ii) letting κ for $\boldsymbol{\pi}_t$ tend to 0, allowing arbitrary change of sense-given-time probabilities. They evaluated their model in a variety of ways, the most comparable of which was to consider particular target words in the *Corpus of Historical American English* (Davies, 2010) with number of senses set to 10 and a time-resolution of 10-year time spans. As with the other papers already discussed, their use of different targets and a different data-set means again there is not the possibility at the moment of a quantitative comparison. In our work whilst we do not have a prior to encourage smooth change of the $\boldsymbol{\pi}_t$ values, nonetheless relatively smooth change *is* obtained, and sense emergence was successively detected in a number of cases, suggesting that for the n-gram data at least, the more complex system of Frermann and Lapata (2016) is not required. It may be of interest in future work to investigate to what extent this is dependent on the data-set used: the data-set they used contains ~100 times fewer occurrences for a given target per time-period compared to the n-gram data-set we have used and it could be that with less data the priors they propose become more necessary.

In conclusion we have proposed a simple generative model, with a $P(S|Y)$ term for time-dependent sense likelihood, and a $p(\boldsymbol{W}|S)$ term expressing that the context words are independent of time given the target's sense. The fact that intuitive outcomes were obtained on our pseudo-neologisms, and on some authentic cases of sense emergence and non-emergence is indicative at least that the model's assumptions are tolerable. It remains for future work involving further targets to test the limits of these assumptions. Amongst several possibiities for further investigation it would be of interest to reformulate the model to refer not just to plain words but rather to syntactic annotations, as well as to consider data sources representing other and more recent text types, such as social media posts.

Appendix A. Derivation of sampling formula for $\boldsymbol{\pi}_t$

For the sampling formula for $\boldsymbol{\pi}_t$ we need the conditional probability $P(\boldsymbol{\pi}_t|\boldsymbol{\pi}_{-(t)}, \boldsymbol{s}^{1:D}, \boldsymbol{w}^{1:D}, \boldsymbol{t}^{1:D}, \boldsymbol{\tau}_{1:N}, \boldsymbol{\theta}_{1:K}; \boldsymbol{\gamma}_\pi, \boldsymbol{\gamma}_\theta)$, where indexing by $-(t)$ is meant to indicate consideration of all indices *except* t. This conditional probability is given by

$$\frac{P(\boldsymbol{\pi}_t, \boldsymbol{\pi}_{-(t)}, \boldsymbol{s}^{1:D}, \boldsymbol{w}^{1:D}, \boldsymbol{t}^{1:D}, \boldsymbol{\tau}_{1:N}, \boldsymbol{\theta}_{1:K}; \boldsymbol{\gamma}_\pi, \boldsymbol{\gamma}_\theta)}{\int_{\boldsymbol{\pi}_t} P(\boldsymbol{\pi}_t, \boldsymbol{\pi}_{-(t)}, \boldsymbol{s}^{1:D}, \boldsymbol{w}^{1:D}, \boldsymbol{t}^{1:D}, \boldsymbol{\tau}_{1:N}, \boldsymbol{\theta}_{1:K}; \boldsymbol{\gamma}_\pi, \boldsymbol{\gamma}_\theta)}$$

Recalling the model formula (3) given in Figure 1 the numerator in this fraction is

[6] Adapting their notation to make things as comparable as possible: they have Φ^t rather than $\boldsymbol{\pi}_t$ and $\Psi^{t,k}$ rather than $\boldsymbol{\theta}_{tk}$.

$$\prod_d \left[\tau_{t^d} \times \pi_{t^d,s^d} \times \prod_{i=1}^{|\boldsymbol{w}^d|} \theta_{s^d,w_i^d} \right] \times \text{Dir}(\boldsymbol{\pi}_t;\boldsymbol{\gamma}_\pi) \times \prod_{-(t)} \text{Dir}(\boldsymbol{\pi}_{-(t)};\boldsymbol{\gamma}_\pi) \times \prod_{1:K} \text{Dir}(\boldsymbol{\theta}_k;\boldsymbol{\gamma}_\theta)$$

and the denominator differs only by the the integral over $\boldsymbol{\pi}_t$. $\boldsymbol{\pi}_t$ is involved in the $\text{Dir}(\boldsymbol{\pi}_t;\boldsymbol{\gamma}_\pi)$ term and in those parts of the product for d where you have $t_d = t$. Because of this most terms in the denominator can be taken outside the scope of the integral and then cancel with corresponding terms in the numerator. Because of this, the fraction can be written

$$\frac{\prod_{d:t_d=t} [\boldsymbol{\pi}_{t,s_d}] \times \text{Dir}(\boldsymbol{\pi}_t;\boldsymbol{\gamma}_\pi)}{\int_{\boldsymbol{\pi}_t} \left[\prod_{d:t_d=t} [\boldsymbol{\pi}_{t,s_d}] \times \text{Dir}(\boldsymbol{\pi}_t;\boldsymbol{\gamma}_\pi) \right]}$$

In the data items $\{d : t_d = t\}$ a variety of sense values have been sampled and the numerator can instead be expressed using $\mathbb{S}_{t,k}$, which counts the sampled sense values (see Section 2). Re-expressing the numerator in this way and using the definition of the Dirichlet (Heinrich, 2005), we get

$$\prod_k \boldsymbol{\pi}_{t,k}^{\mathbb{S}_{t,k}} \times \frac{1}{\beta(\boldsymbol{\gamma}_\pi)} \prod_k \boldsymbol{\pi}_{t,k}^{\boldsymbol{\gamma}_\pi[k]-1} = \frac{1}{\beta(\boldsymbol{\gamma}_\pi)} \prod_k \boldsymbol{\pi}_{t,k}^{\mathbb{S}_{t,k}+\boldsymbol{\gamma}_\pi[k]-1}$$

Hence the fraction can be written

$$\frac{\prod_k \boldsymbol{\pi}_{t,k}^{\mathbb{S}_{t,k}+\boldsymbol{\gamma}_\pi[k]-1}}{\int_{\boldsymbol{\pi}_t} [\prod_k \boldsymbol{\pi}_{t,k}^{\mathbb{S}_{t,k}+\boldsymbol{\gamma}_\pi[k]-1}]} = \frac{1}{\beta(\mathbb{S}_t + \boldsymbol{\gamma}_\pi)} \prod_k \boldsymbol{\pi}_{t,k}^{\mathbb{S}_{t,k}+\boldsymbol{\gamma}_\pi[k]-1}$$

where the last step uses the fact that in any Dirichlet $\text{Dir}(\boldsymbol{x}_{1:K};\boldsymbol{\alpha}_{1:K}) = \frac{1}{\beta(\boldsymbol{\alpha}_{1:K})} \prod_{k=1}^K x_k^{\alpha_k-1}$, the 'normalizing' constant $\beta(\boldsymbol{\alpha}_{1:K})$ is the integral of the main product term. Hence we finally obtain

$$P(\boldsymbol{\pi}_t|\boldsymbol{\pi}_{-(t)}, \boldsymbol{s}^{1:D}, \boldsymbol{w}^{1:D}, \boldsymbol{t}^{1:D}, \boldsymbol{\theta}_{1:K}; \boldsymbol{\gamma}_\pi, \boldsymbol{\gamma}_\theta) = \text{Dir}(\boldsymbol{\pi}_t; \boldsymbol{\gamma}_\pi + \mathbb{S}_t)$$

which is the sampling formula given earlier as (6). The derivation of the sampling formula for $\boldsymbol{\theta}_k$ is similar, and that for the discrete s^d is straightforward.

Semi-supervised Word Sense Disambiguation with Neural Models

Abstract

Determining the intended sense of words in text – word sense disambiguation (WSD) – is a long-standing problem in natural language processing. Recently, researchers have shown promising results using word vectors extracted from a neural network language model as features in WSD algorithms. However, a simple average or concatenation of word vectors for each word in a text loses the sequential and syntactic information of the text. In this paper, we study WSD with a sequence learning neural net, LSTM, to better capture the sequential and syntactic patterns of the text. To alleviate the lack of training data in all-words WSD, we employ the same LSTM in a semi-supervised label propagation classifier. We demonstrate state-of-the-art results, especially on verbs.

1 Introduction

Word sense disambiguation (WSD) is a long-standing problem in natural language processing (NLP) with broad applications. Supervised, unsupervised, and knowledge-based approaches have been studied for WSD (Navigli, 2009). However, for *all-words* WSD, where all words in a corpus need to be annotated with word senses, it has proven extremely challenging to beat the strong baseline, which always assigns the most frequent sense of a word without considering the context (Pradhan et al., 2007a; Navigli, 2009; Navigli et al., 2013; Moro and Navigli, 2015). Given the good performance of published supervised WSD systems when provided with significant training data on specific words (Zhong and Ng, 2010), it appears lack of sufficient labeled training data for large vocabularies is the central problem.

One way to leverage unlabeled data is to train a neural network language model (NNLM) on the data. Word embeddings extracted from such a NNLM (often Word2Vec (Mikolov et al., 2013)) can be incorporated as features into a WSD algorithm. Iacobacci et al. (2016) show that this can substantially improve WSD performance and indeed that competitive performance can be attained using word embeddings alone.

In this paper, we describe two novel WSD algorithms. The first is based on a Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997). Since this model is able to take into account word order when classifying, it performs significantly better than an algorithm based on a continuous bag of words model (Word2vec) (Mikolov et al., 2013; Iacobacci et al., 2016), especially on verbs.

We then present a semi-supervised algorithm which uses label propagation (Talukdar and Crammer, 2009; Ravi and Diao, 2016) to label unlabeled sentences based on their similarity to labeled ones. This allows us to better estimate the distribution of word senses, obtaining more accurate decision boundaries and higher classification accuracy.

The best performance was achieved by using an LSTM language model with label propagation. Our algorithm achieves state-of-art performance on many SemEval all-words tasks. It also outperforms the most-frequent-sense and Word2Vec baselines by 10% (see Section 5.2 for details).

Organization: We review related work in Section 2. We introduce our supervised WSD algorithm in Section 3, and the semi-supervised WSD algorithm in Section 4. Experimental results are discussed in Section 5. We provide further discussion and future work in Section 6.

2 Related Work

The development of large lexical resources, such as WordNet (Fellbaum, 1998) and BabelNet (Navigli and Ponzetto, 2012), has enabled knowledge-based algorithms which show promising results on all-words prediction tasks (Ponzetto and Navigli, 2010; Navigli et al., 2013; Moro and Navigli, 2015). WSD algorithms based on supervised learning are generally believed to perform better than knowledge-based WSD algorithms, but they need large training sets to perform well (Pradhan et al., 2007a; Navigli et al., 2007; Navigli, 2009; Zhong and Ng, 2010). Acquiring large training sets is costly. In this paper, we show that a supervised WSD algorithm can perform well with ~ 20 training examples per sense.

In the past few years, much progress has been made on using neural networks to learn word embeddings (Mikolov et al., 2013; Levy and Goldberg, 2014), to construct language models (Mikolov et al., 2011), perform sentiment analysis (Socher et al., 2013), machine translation (Sutskever et al., 2014) and many other NLP applications.

A number of different ways have been studied for using word embeddings in WSD. There are some common elements:

- Context embeddings. Given a window of text $w_{n-k}, ..., w_n, ..., w_{n+k}$ surrounding a focus word w_n (whose label is either known in the case of example sentences or to be determined in the case of classification), an embedding for the context is computed as a concatenation or weighted sum of the embeddings of the words $w_i, i \neq n$. Context embeddings of various kinds are used in both (Chen et al., 2014) and (Iacobacci et al., 2016).
- Sense embeddings. Embeddings are computed for each word sense in the word sense inventory (e.g. WordNet). In (Rothe and Schütze, 2015), equations are derived relating embeddings for word senses with embeddings for undisambiguated words. The equations are solved to compute the sense embeddings. In (Chen et al., 2014), sense embeddings are computed first as weighted sums of the embeddings of words in the WordNet gloss for each sense. These are used in an initial bootstrapping WSD phase, and then refined by a neural network which is trained on this bootstrap data.
- Embeddings as SVM features. Context embeddings (Iacobacci et al., 2016; Taghipour and Ng, 2015b), or features computed by combining context embeddings with sense embeddings (Rothe and Schütze, 2015), can be used as additional features in a supervised WSD system e.g. the SVM-based *IMS* (Zhong and Ng, 2010). Indeed Iacobacci et al. (2016) found that using embeddings as the only features in *IMS* gave competitive WSD performance.
- Nearest neighbor classifier. Another way to perform classification is to find the word sense whose sense embedding is closest, as measured by cosine similarity, to the embedding of the classification context. This is used, for example, in the bootstrapping phase of (Chen et al., 2014).
- Retraining embeddings. A feedforward neural network can be used to jointly perform WSD and adjust embeddings (Chen et al., 2014; Taghipour and Ng, 2015b).

In our work, we start with a baseline classifier which uses 1000-dimensional embeddings trained on a 100 billion word news corpus using Word2Vec (Mikolov et al., 2013). The vocabulary consists of the most frequent $1,000,000$ words, without lemmatization or case normalization. Sense embeddings are computed by averaging the context embeddings of sentences which have been labeled with that sense. To classify a word in a context, we assign the word sense whose embedding has maximal cosine similarity with the embedding of the context. This classifier has similar performance to the best classifier in (Iacobacci et al., 2016) when SemCor is used as a source of labeled sentences. The Word2Vec embeddings are trained using a bag of words model, i.e. without considering word order in the training context, and word order is also not considered in the classification context. In Section 3 we show that using a more expressive language model which takes account of word order yields significant improvements.

Semi-supervised learning has previously been applied successfully to word sense disambiguation. In (Yarowsky, 1995) bootstrapping was used to learn a high precision WSD classifier. A low recall classifier was learned from a small set of labeled examples, and the labeled set then extended with those sentences from an unlabeled corpus which the classifier could label with high confidence. The classifier was then retrained, and this iterative training process continued to convergence. Additional heuristics helped to maintain the stability of the bootstrapping process. The method was evaluated on a small data set.

In (Niu et al., 2005), a label propagation algorithm was proposed for word sense disambiguation and compared to bootstrapping and a SVM supervised classifier. Label propagation can achieve better performance because it assigns labels to optimize a *global* objective, whereas bootstrapping propagates labels based on *local* similarity of examples.

In Section 4 we describe our use of label propagation to improve on nearest neighbor for classification.

3 Supervised WSD with LSTM

Neural networks with long short-term memory (LSTM) units (Hochreiter and Schmidhuber, 1997) make good language models which take into account word order (Sundermeyer et al., 2012). We train a LSTM language model to predict the held-out word in a sentence. As shown in Figure 1, we first replace the held-out word with a special symbol \$, and then, after consuming the remaining words in the sentence, project the h dimensional hidden layer to a p dimensional context layer, and finally predict the held out word with softmax. By default, the LSTM model has 2048 hidden units, 512 dimensional context layer and 512 dimensional word embeddings. We also studied other settings, see Section 5.2.2 for details. We train the LSTM on a news corpus of about 100 billion tokens, with a vocabulary of $1,000,000$ words. Words in the vocabulary are neither lemmatized nor case normalized.

Our LSTM model is different from that of Kgebck and Salomonsson (Kågebäck and Salomonsson, 2016). We train a LSTM language model, which predicts a held-out word given the surrounding context, with a large amount of unlabeled text as training data. The huge training dataset allows us to train a high-capacity model (2048 hidden units, 512 dimensional embeddings), which achieves high precision without overfitting. In our experiments, this directional LSTM model was faster and easier to train than a bidirectional LSTM, especially given our huge training dataset. Kgebck and Salomonsson's LSTM directly predicts the word senses and it is trained with a limited number of word sense-labeled examples. Although regularization and dropout are used to avoid overfitting the training data, the bidirectional LSTM is small with only $74 + 74$ neurons and 100 dimensional word embeddings (Kågebäck and Salomonsson, 2016). Because our LSTM is generally applicable to any word, it achieves high performance on *all-words WSD* tasks (see Section 5 for details), which is the focus of this paper. Kgebck and Salomonsson's LSTM is only evaluated on *lexical sample WSD* tasks of SemEval 2 and 3 (Kågebäck and Salomonsson, 2016).

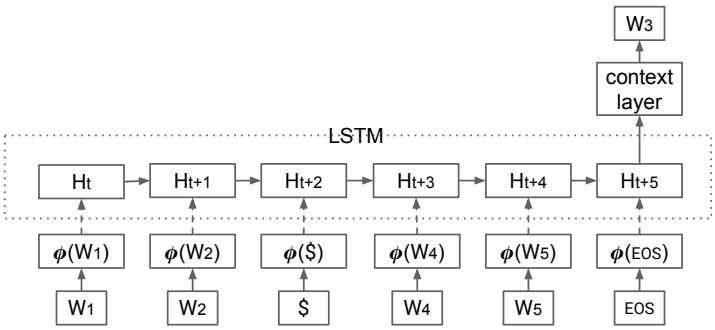

Figure 1: LSTM: Replace the focus word w_3 with a special symbol \$ and predict w_3 at the end of the sentence.

The behavior of the LSTM can be intuited by its predictions. Table 1 shows the top 10 words predicted by an LSTM language model for the word 'stock' in sentences containing various senses of 'stock'.

In our initial experiments, we computed similarity between two contexts by the overlap between their bags of predicted words. For example (Table 1) the top predictions for the query overlap most with the LSTM predictions for 'sense#1' —we predict that 'sense#1' is the correct sense. This bag of predictions, while easily interpretable, is just a discrete approximation to the internal state of the LSTM when predicting the held out word. We therefore directly use the LSTM's context layer from which the bag of predictions was computed as a representation of the context (see Figure 1). Given context vectors extracted from the LSTM, our supervised WSD algorithms classify a word in a context by finding the sense vector which has maximum cosine similarity to the context vector (Figure 2a). We find the sense vectors

id	sentence	top 10 predictions from LSTM	sense
1	Employee compensation is offered in the form of cash and/or *stock*.	cash, stock, equity, shares, loans, bonus, benefits, awards, equivalents, deposits	sense#1
2	The *stock* would be redeemed in five years, subject to terms of the company's debt.	bonds, debt, notes, shares, stock, balance, securities, rest, Notes, debentures	
3	These stores sell excess *stock* or factory overruns .	inventory, goods, parts, sales, inventories, capacity, products, oil, items, fuel	sense#2
4	Our soups are cooked with vegan *stock* and seasonal vegetables.	foods, food, vegetables, meats, recipes, cheese, meat, chicken, pasta, milk	sense#3
query	In addition, they will receive *stock* in the reorganized company, which will be named Ranger Industries Inc.	shares, positions, equity, jobs, awards, representation, stock, investments, roles, funds	?

Table 1: Top predictions of 'stock' in 5 sentences of different word senses

by averaging context vectors of all training sentences of the same sense. We observed in a few cases that the context vector is far from the held-out word's embedding, especially when the input sentence is not informative. For example, the LSTM language model will predict "night" for the input sentence "I fell asleep at [work]." when we hold out "work". Currently, we treat the above cases as outliers. We would like explore alternative solutions, e.g., forcing the model to predict words that are close to one sense vector of the held-out word, in further work. As can be seen in SemEval all-words tasks and Tables 6, this LSTM model has significantly better performance than the Word2Vec models.

4 Semi-supervised WSD

(a) nearest neighbor (b) semi-supervised WSD with label propagation

Figure 2: WSD classifiers. Filled nodes represent labeled sentences. Unfilled nodes represent unlabeled sentences.

The non-parametric nearest neighbor algorithm described in Section 3 has the following drawbacks:

- It assumes a spherical shape for each sense cluster, being unable to accurately model the decision boundaries given the limited number of examples.
- It has no training data for, and does not model, the sense prior, omitting an extremely powerful potential signal.

To overcome these drawbacks we present a semi-supervised method which augments the labeled example sentences with a large number of unlabeled sentences from the web. Sense labels are then propagated from the labeled to the unlabeled sentences. Adding a large number of unlabeled sentences allows the decision boundary between different senses to be better approximated.

A *label-propagation graph* consists of (a) vertices with a number of labeled seed nodes and (b) undirected weighted edges. Label propagation (LP) (Talukdar and Crammer, 2009) iteratively computes a distribution of labels on the graph's vertices to minimize a weighted combination of:

- The discrepancy between seed labels and their computed labels distributions.
- The disagreement between the label distributions of connected vertices.
- A regularization term which penalizes distributions which differ from the prior (by default, a uniform distribution).

We construct a graph for each lemma with labeled vertices for the labeled example sentences, and unlabeled vertices for sentences containing the lemma, drawn from some additional corpus. Vertices for sufficiently similar sentences (based on criteria discussed below) are connected by an edge whose weight is the cosine similarity between the respective context vectors, using the LSTM language model. To

classify an occurrence of the lemma, we create an additional vertex for the new sentence and run LP to propagate the sense labels from the seed vertices to the unlabeled vertices.

Figure 2 (b) illustrates the graph configuration. Spatial proximity represents similarity of the sentences attached to each vertex and the shape of each node represents the word sense. Filled nodes represent seed nodes with known word senses. Unfilled nodes represent sentences with no word sense label, and the ? represents the word we want to classify.

With too many edges, sense labels propagate too far, giving low precision. With too few, sense labels do not propagate sufficiently, giving low recall. We found that the graph has about the right density for common senses when we ranked vertex pairs by similarity and connected the pairs above the 95 percentile. This may still leave rare senses sparsely connected, so we additionally added edges to ensure that every vertex is connected to at least 10 other vertices. Our experiments (Table 9) show that this setting achieves good performance on WSD, and the performance is stable when the percentile ranges between 85 to 98. Since it requires running LP for every classification, the algorithm is slow compared to the nearest neighbor algorithm.

5 Experiments

We evaluated the LSTM algorithm with and without label propagation on standard SemEval all-words tasks using WordNet as the inventory. Our proposed algorithms achieve state-of-art performance on many SemEval all-words WSD tasks. In order to assess the effects of training corpus size and language model capacity we also evaluate our algorithms using the New Oxford American Dictionary (NOAD) inventory with SemCor (Miller et al., 1993) or MASC [1].

5.1 SemEval Tasks

In this section, we study the performance of our classifiers on Senseval2 (Edmonds and Cotton, 2001), Senseval3 (Snyder and Palmer, 2004), SemEval-2007 (Pradhan et al., 2007b), SemEval-2013 Task 12 (Navigli et al., 2013) and SemEval-2015 task 13 (Moro and Navigli, 2015) [2]. We focus the study on all-words WSD tasks. For a fair comparison with related works, the classifiers are evaluated on all words (both polysemous and monosemous).

Following related works, we use SemCor or OMSTI (Taghipour and Ng, 2015a) for training. In our LP classifiers, unlabeled data for each lemma consists either of 1000 sentences which contain the lemma, randomly sampled from the web, or all OMSTI sentences (without labels) which contain the lemma.

	Senseval2		Senseval3		SemEval7		SemEval7-Coarse		SemEval13
model	**all**	**n.**	**all**	**n.**	**all**	**n.**	**all**	**n.**	**n.**
IMS + Word2Vec (T:SemCor)	0.634	0.742	0.653	0.701	0.578	0.686			
IMS + Word2Vec (T:OMSTI)	0.683	0.777	0.682	0.741	0.591	0.715			
Taghipour and Ng (2015b)			0.682						
Chen et al. (2014)							0.826	**0.853**	
Weissenborn et al. (2015)				0.688		0.660		**0.855**	**0.728**
Word2Vec (T:SemCor)	0.678	0.737	0.621	0.714	0.585	0.673	0.795	0.814	0.661
LSTM (T:SemCor)	0.736	0.786	0.692	0.723	0.642	**0.723**	0.828	0.834	0.670
LSTM (T:OMSTI)	0.724	0.777	0.643	0.680	0.607	0.673	0.811	0.820	0.673
LSTMLP (T:SemCor, U:OMSTI)	0.739	0.797	0.711	0.748	**0.637**	0.704	**0.843**	0.834	0.679
LSTMLP (T:SemCor, U:1K)	0.738	0.796	**0.718**	**0.763**	0.635	0.717	0.836	0.831	0.695
LSTMLP (T:OMSTI, U:1K)	**0.744**	**0.799**	0.710	0.753	0.633	0.717	0.833	0.825	0.681

Table 2: F1 scores on SemEval all-words tasks. T:SemCor stands for models trained with SemCor. U:OMSTI stands for using OMSTI as unlabeled sentences in semi-supervised WSD. IMS + Word2Vec scores are from (Iacobacci et al., 2016)

Table 2 shows the Sem-Eval results. Our proposed algorithms achieve the highest all-words F1 scores except for Sem-Eval 2013. Weissenborn et al.(2015) only disambiguates nouns, and it outperforms our algorithms on Sem-Eval 2013 by 4%, but is ranked behind our algorithms on Senseval-3 and SemEval-7

[1] http://www.anc.org/MASC/About.html/

[2] We mapped all senses to WordNet3.0 by using maps in https://wordnet.princeton.edu/wordnet/download/current-version/ and http://web.eecs.umich.edu/ mihalcea/downloads.html

tasks with an F1 score more than 6% lower than our algorithms. Unified WSD (Chen et al., 2014) has the highest F1 score on Nouns (Sem-Eval-7 Coarse), but our algorithms outperform Unified WSD on other part-of-speech tags.

Settings For a fair comparison of Word2Vec and LSTM, we do not use pre-trained word-embeddings as in (Iacobacci et al., 2016), but instead train the Word2Vec and LSTM models on a 100 billion word news corpus [3] with a vocabulary of the most frequent 1,000,000 words. Our self-trained word embeddings have similar performance to the pre-trained embeddings, as shown in Table 2. The Word2Vec word vectors are of dimension 1024. The LSTM model has 2048 hidden units, and inputs are 512-dimensional word vectors. We train the LSTM model by minimizing sampled softmax loss (Jean et al., 2014) with Adagrad (Duchi et al., 2011). The learning rate is 0.1. We experimented with other learning rates, and observed no significant performance difference after the training converges. We also downsample frequent terms in the same way as (Mikolov et al., 2013).

Word2Vec vectors Vs. LSTM To better compare LSTM with word vectors we also build a nearest neighbor classifier using Word2Vec word embeddings and SemCor example sentences, Word2Vec (T:SemCor). It performs similar to IMS + Word2Vec (T:SemCor), a SVM-based classifier studied in (Iacobacci et al., 2016). Table 2 shows that the LSTM classifier outperforms the Word2Vec classifier across the board.

SemCor Vs. OMSTI Contrary to the results observed in (Iacobacci et al., 2016), the LSTM classifier trained with OMSTI performs worse than that trained with SemCor. It seems that the larger size of the OMSTI training data set is more than offset by noise present in its automatically generated labels. While the SVM classifier studied in (Iacobacci et al., 2016) may be able to learn a model which copes with this noise, our naive nearest neighbor classifiers do not have a learned model and deal less well with noisy labels.

Label propagation We use the implementation of DIST_EXPANDER (Ravi and Diao, 2016). We test the label propagation algorithm with SemCor or OMSTI as labeled data sets and OMSTI or 1000 random sentences from the web per lemma as unlabeled data. The algorithm performs similarly on the different data sets.

Table 3 shows the results of Sem-Eval 2015. The LSTM LP classifier with an LSTM language model achieves the highest scores on nouns and adverbs as well as overall F1. The LSTM classifier has the highest F1 on verbs.

algorithm	**all**	**n.**	**v.**	**adj.**	**adv.**
LIMSI	0.647				0.795
DFKI		0.703	0.577		
UNIBA				0.790	
BFS Baseline	0.663	0.667	0.551	**0.821**	0.825
Word2Vec (T:SemCor)	0.667	0.661	0.555	0.789	0.810
LSTM (T:SemCor)	0.721	0.713	**0.642**	0.813	0.845
LSTMLP (T:SemCor, U:1K)	**0.726**	**0.728**	0.622	0.813	**0.857**

Table 3: F1 Scores of SemEval-2015 English Dataset. The BFS baseline uses BabelNet first sense.

5.2 NOAD Eval

Many dictionary lemmas and senses have no examples in SemCor or OSTMI, giving rise to losses in all-words WSD when these corpora are used as training data. The above SemEval scores do not distinguish errors caused by missing training data for certain labels or inaccurate classifier. To better study the proposed algorithms, we train the classifiers with the New Oxford American Dictionary (NOAD) (Stevenson and Lindberg, 2010), in which there are example sentences for each word sense.

[3] The training corpus could not be released, but we have plans to open source the well-trained models

5.2.1 Word Sense Inventory

The NOAD focuses on American English and is based on the Oxford Dictionary of English (ODE) (Stevenson, 2010). It distinguishes between coarse (*core*) and fine-grained (*sub*) word senses in the same manner as ODE. Previous investigations (Navigli, 2006; Navigli et al., 2007) using the ODE have shown that coarse-grained word senses induced by the ODE inventory address problems with WordNet's fine-grained inventory, and that the inventory is useful for word sense disambiguation.

For our experiments, we use NOAD's core senses, and we also use lexicographer-curated example sentences from the Semantic English Language Database (SELD)[4], provided by Oxford University Press. We manually annotated all words of the English language SemCor corpus and MASC corpora with NOAD word senses in order to evaluate performance [5]. Table 4 shows the total number of polysemes (more than one core sense) and average number of senses per polyseme in NOAD/SELD (hereafter, NOAD), SemCor and MASC. Both SemCor and MASC individually cover around 45% of NOAD polysemes and 62% of senses of those polysemes.

		noun	verb	adj.	adv.
Number of polysemous lemmas in dictionary / corpus	NOAD	8097	2124	2126	266
	SemCor	2833	1362	911	193
	MASC	2738	1250	829	181
Sense count per polyseme	NOAD	2.46	2.58	2.30	2.47
	SemCor	1.44	1.69	1.49	1.84
	MASC	1.48	1.66	1.48	2.01

Table 4: NOAD polysemous lemma in NOAD, SemCor and MASC

Table 5 gives the number of labeled sentences of these datasets. Note that although NOAD has more labeled sentences than SemCor or MASC, the average numbers of sentences per sense of these datasets are similar. This is because NOAD has labeled sentences for each word sense, whereas SemCor (MASC) only covers a subset of lemmas and senses (Table 4). The last column of Table 5 shows that each annotated word in SemCor and MASC has an average of more than 4 NOAD corse senses. Hence, a random guess will have a precision around $1/4$.

	example count (in 1000's)					example count	number of candidate
dataset	all	n.	v.	adj.	adv	per sense	senses per example
NOAD	580	312	150	95	13	18.43	3.1
SemCor	115	38	57	11.6	8.6	14.27	4.1
MASC	133	50	57	12.7	13.6	17.38	4.2

Table 5: Number of examples in each dataset and the average sense count per example.

In the default setting, we use NOAD example sentences as labeled training data and evaluate on SemCor and MASC. We evaluate all polysemous words in the evaluation corpus.

5.2.2 LSTM classifier

We compare our algorithms with two baseline algorithms:

- Most frequent sense: Compute the sense frequency (from a labeled corpus) and label word w with w's most frequent sense.
- Word2Vec: a nearest-neighbor classifier with Word2Vec word embedding, which has similar performance to cutting-edge algorithms studied in (Iacobacci et al., 2016) on SemEval tasks.

Table 6 compares the F1 scores of the LSTM and baseline algorithms. LSTM outperforms Word2Vec by more than 10% over all words, where most of the gains are from verbs and adverbs. The results suggest that syntactic information, which is well modeled by LSTM but ignored by Word2Vec, is important to distinguishing word senses of verbs and adverbs.

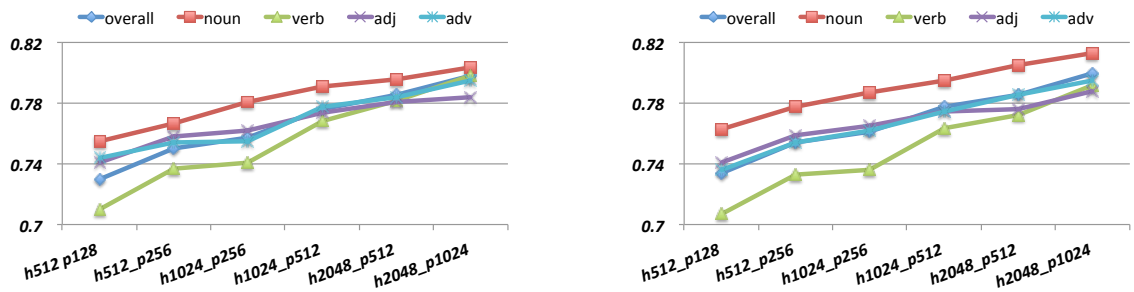
Table 7: Macro F1 scores of LSTM classifier

Change of training data By default, the WSD classifier uses the NOAD example sentences as training data. We build a larger training dataset by adding labeled sentences from SemCor and MASC, and study the change of F1 scores in Table 6. Across all part of speech tags and datasets, F1 scores increase after adding more training data. We further test our algorithm by using SemCor (or MASC) as training data (without NOAD examples). The SemCor (or MASC) trained classifier is on a par with the NOAD trained classifier on F1 score. However, the macro F1 score of the former is much lower than the latter, as shown in Table 7, because of the limited coverage of rare senses and words in SemCor and MASC.

Change of language model capacity In this experiment, we change the LSTM model capacity by varying the number of hidden units h and the dimensions of the input embeddings p and measuring F1. Figure 3 shows strong positive correlation between F1 and the capacity of the language model. However, larger models are slower to train and use more memory. To balance the accuracy and resource usage, we use the second best LSTM model ($h = 2048$ and $p = 512$) by default.



(a) eval on SemCor

(b) eval on MASC

Figure 3: F1 scores of LSTM models with different capacity: h is the number of hidden units; p is the embedding dimension.

5.2.3 Semi-supervised WSD

We evaluate our semi-supervised WSD classifier in this subsection. We construct the graph as described in Section 4 and run LP to propagate sense labels from the seed vertices to the unlabeled vertices. We evaluate the performance of the algorithm by comparing the predicted labels and the gold labels on eval nodes. As can be observed from Table 8, LP did not yield clear benefits when using the Word2Vec language model. We did see significant improvements, 6.3% increase on SemCor and 7.3% increase on MASC, using LP with the LSTM language model. We hypothesize that this is because LP is sensitive to the quality of the graph distance metric.

eval data		SemCor					MASC				
model	**train data**	**all**	**n.**	**v.**	**adj.**	**adv.**	**all**	**n.**	**v.**	**adj.**	**adv.**
Word2Vec LP	NOAD	0.642	0.733	0.554	0.705	0.725	0.643	0.752	0.524	0.726	0.664
LSTM LP	NOAD	0.822	0.859	0.800	0.817	0.816	0.831	0.865	0.806	0.825	0.821
LSTM LP	NOAD,SemCor						**0.872**	**0.897**	**0.852**	**0.865**	**0.868**
LSTM LP	NOAD,MASC	**0.873**	**0.883**	**0.870**	**0.858**	**0.874**					

Table 8: F1 scores of label propagation

Change of seed data: As can be seen in Table 8, LP substantially improves classifier F1 when the training datasets are SemCor+NOAD or MASC+NOAD. As discussed in Section 4, the improvement may come from explicitly modeling the sense prior. We did not see much performance lift by increasing the number of unlabeled sentences per lemma.

Change of graph density: By default, we construct the LP graph by connecting two nodes if their affinity is above 95% percentile. We also force each node to connect to at least 10 neighbors to prevent isolated nodes. Table 9 shows the performance of the LP algorithm by changing the percentile threshold. The F1 scores are relatively stable when the percentile ranges between 85 to 98, but decrease when the percentile drops to 80. Also, it takes longer to run the LP algorithm on a denser graph. We pick the 95 percentile in our default setting to achieve both high F1 scores and short running time.

	SemCor						MASC					
pos-tag	**98**	**95**	**90**	**85**	**80**	**70**	**98**	**95**	**90**	**85**	**80**	**70**

n.	0.848	**0.859**	0.852	0.846	0.840	0.828	0.863	0.865	**0.868**	0.865	0.861	0.847
v.	**0.810**	0.800	0.803	0.797	0.792	0.778	0.800	**0.806**	**0.806**	0.799	0.794	0.769

Table 9: F1 scores of the LSTM LP trained on NOAD with varying graph density.

6 Conclusions and Future Work

In this paper, we have presented two WSD algorithms which combine (1) LSTM neural network language models trained on a large unlabeled text corpus, with (2) labeled data in the form of example sentences, and, optionally, (3) unlabeled data in the form of additional sentences. Using an LSTM language model gave better performance than one based on Word2Vec embeddings. The best performance was achieved by our semi-supervised WSD algorithm which builds a graph containing labeled example sentences augmented with a large number of unlabeled sentences from the web, and classifies by propagating sense labels through this graph.

Several unanswered questions suggest lines of future work. Since our general approach is amenable to incorporating any language model, further developments in NNLMs may permit increased performance. We would also like to better understand the *limitations* of language modeling for this task: we expect there are situations – e.g., in idiomatic phrases – where per-word predictions carry little information.

We believe our model should generalize to languages other than English, but have not yet explored this. Character-level LSTMs (Kim et al., 2015) may provide robustness to morphology and diacritics and may prove useful even in English for spelling errors and out of vocabulary words.

We would like to see whether our results can be improved by incorporating global (document) context and multiple embeddings for polysemous words (Huang et al., 2012).

Finally, many applications of WSD systems for nominal resolution require integration with resolution systems for named entities, since surface forms often overlap (Moro et al., 2014; Navigli and Ponzetto, 2012). This will require inventory alignment work and model reformulation, since we currently use no document-level, topical, or knowledge-base coherence features.

We thank our colleagues and the anonymous reviewers for their insightful comments on this paper.

Abstract

Neural network training has been shown to be advantageous in many natural language processing applications, such as language modelling or machine translation. In this paper, we describe in detail a novel domain adaptation mechanism in neural network training. Instead of learning and adapting the neural network on millions of training sentences – which can be very time-consuming or even infeasible in some cases – we design a domain adaptation gating mechanism which can be used in recurrent neural networks and quickly learn the out-of-domain knowledge directly from the word vector representations with little speed overhead. In our experiments, we use the recurrent neural network language model (LM) as a case study. We show that the neural LM perplexity can be reduced by 7.395 and 12.011 using the proposed domain adaptation mechanism on the Penn Treebank and News data, respectively. Furthermore, we show that using the domain-adapted neural LM to re-rank the statistical machine translation *n*-best list on the French-to-English language pair can significantly improve translation quality.

1 Introduction

One challenge which rises above others in natural language processing (NLP) is where application performance decreases when there are *dissimilarities* between the training and the testing environments. In research on domain adaptation, training data with the same style and topic (van der Wees et al., 2015) as the test data is often defined as in-domain (ID) data, with everything else called general-domain (GD) data. The ID data is often scarce and expensive to obtain, whereas the GD is plentiful and easy to access.

One approach to address the situation of scarce ID training data is through data selection. For example, using the perplexity difference between ID and GD can select data that is close to ID and away from GD (Moore and Lewis, 2010). The selected data can then be concatenated with ID data for training. However, the drawback of using data selection is a threshold needs to be set, which often requires many models to be trained and evaluated. The situation will worsen if neural networks are used since the computational cost is immense in neural network training, where models often require days to converge even with the help of GPU-accelerated computing. Thus, simply adapting previous domain adaptation techniques into the neural network framework may not be efficient or effective. Ideally, we want to have an adaptation approach which has the ability to learn knowledge from huge corpora at speed. The question that arises here is how to make use of large amounts of GD data but avoiding long training times.

In neural network training, words are represented as distributed representations, so-called "word vectors", which can be pre-trained or trained with a specific task in mind. Although a pre-trained word vector model is also learned with a neural network, the training can be very fast. Recent optimized work shows learning word vectors can process more than 100 billion tokens in one day on a single machine (Mikolov et al., 2013c). Another advantage of a pre-trained word vector model is its flexibility, as it can be used later for different task-specific models. Furthermore, the pre-trained and the task-specific word vector models have no functional difference. Accordingly, we think it is very natural to use them

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1386–1397, Osaka, Japan, December 11-17 2016.

together. In this paper, we propose to perform domain adaptation from the large pre-trained word vector models instead of the raw text, i.e. adapting from large pre-trained word vector into the task-specific one. In this approach, we can make use of huge GD corpora with little speed overhead. We can also adapt the richer GD word representations into ID training.

2 Background

2.1 Word Vectors

Word vectors are important building blocks in neural networks. While much work has been proposed (Hinton et al., 1986; Mikolov et al., 2013b), we focus on the most popular approach of Mikolov et al. (2013b), which uses a neural network to produce distributed word representations. Unlike other training algorithms, labeled data is not required. It uses context words as features to make predictions. Word vectors can capture linguistic regularities and similarities (Mikolov et al., 2013d) in the training corpus. For example, using vector operations "king" - "man" + "woman" can result in a vector which is close to the word "queen".[1]

2.2 Neural Language Model

In a nutshell, the Recurrent Neural Network (RNN) language model (LM) uses the previous words to estimate the probability of the next word. The simplest RNN LM consists of a look-up layer, a hidden layer with recurrent connections and an output layer. The input words are firstly taken by the look-up layer and converted into word vector representations. Then, the hidden layers project the word vectors into a context vector with the states of input histories maintained. The output layer is a *Softmax* function. It decodes the context vector and distributes probabilities over all words in the vocabulary. The word with the highest probability is then chosen as the predicted output.

For notational convenience, the look-up layer, the hidden layer and the output layer of RNN LM can be represented as in Equations (1), (2) and (3), respectively:

$$x_t = \textit{look-up}(s) \tag{1}$$

$$h_t = \textit{RNN}(x_t, h_{t-1}) \tag{2}$$

$$y(t) = Softmax(f(h_t)) \tag{3}$$

where x_t is the word vector representation of s, s is the input at time t, and *look-up* is the look-up layer. The hidden layer *RNN* is then applied on x_t and the previous hidden state h_{t-1} to obtain the current hidden state h_t. f is a function that can map the hidden state into a vocabulary size vector. $y(t)$ is the prediction, which is the distribution over all words in the vocabulary.

Early work on neural LMs used simpler networks, such as the feed-forward neural network (Bengio et al., 2003). Later work (Mikolov et al., 2010) used simple RNNs for the input sentences, which showed large improvements over neural LMs. However, the simple RNN suffers from the vanishing gradient problem (Bengio et al., 1994). The Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) or the more recently introduced gated recurrent unit (GRU) (Chung et al., 2014) use gates to control the information flow from previous words. Thus, LSTM and GRU are better at capturing long-term dependencies than simple RNNs, and are often chosen in practice.

2.3 Gated Recurrent Unit

We use the GRU as a case study in this paper. The GRU consists of an update gate and a reset gate, as in Equation (4):

$$\begin{aligned} u_t &= \sigma(W_u x_t + U_u h_{t-1} + b_u) \\ r_t &= \sigma(W_r x_t + U_r h_{t-1} + b_r) \\ \tilde{h}_t &= tanh(W x_t + U(r_t \odot h_{t-1}) + b) \\ h_t &= (1 - u_t) \odot h_{t-1} + u_t \odot \tilde{h}_t \end{aligned} \tag{4}$$

[1]The example is taken from Mikolov et al. (2013d)

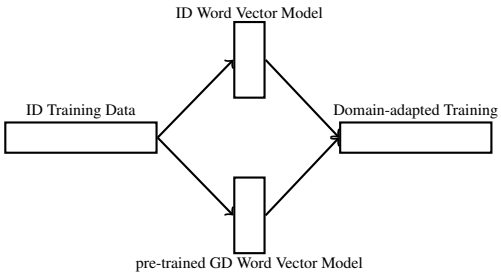

Figure 1: Adaptation Flow

where u_t is the update gate; r_t is the reset gate; $\tilde{h}_t$ is the candidate activation; $\odot$ is the element-wise multiplication operation, and h_t is the linear interpolated output between the previous hidden state h_{t-1} and the candidate activation. Intuitively, the update gate determines the interpolation weights between the previous hidden state h_{t-1} and the candidate activation, and the reset gate determines the information flow from previous hidden states. If the reset gate is set to be 1 and the update gate is set to be 0, the GRU is equivalent to the simple RNN. W_u, U_u, W_r, U_r, W and U are the weight parameters, and b_u, b_r and b are the bias values of the corresponding gates. σ is the sigmoid function and $tanh$ is the hyperbolic tangent function.

3 Adaptation Mechanisms

In this section, we describe several adaptation mechanisms proposed in this paper. In order to distinguish the input layers or hidden layers used in the network, we use Equations (1) and (2) to represent the ID training path. We use Equations (5) and (6) to notate the training path of GD:

$$x_t^* = \textit{look-up}^*_{pre-trained}(s) \tag{5}$$

$$h_t^* = \textit{RNN}^*(x_t^*, h_{t-1}^*) \tag{6}$$

where $\textit{look-up}^*_{pre-trained}$ is a pre-trained word vector model and static.[2] x_t^* is the word vector representation of input s, h_t^* is the hidden state and h_{t-1}^* is the previous hidden state of word s. For example, given input s from the ID training data, we can obtain two word vector representations (x_t and x_t^*). In addition, the two representations can then be fed into the corresponding hidden layer (*RNN* and *RNN**[3]). It is also worth mentioning that the proposed LMs are trained from scratch on ID training data, but adapting knowledge from the GD word vector model. Thus, the hidden state in Equation (6) is not strictly the "GD hidden state"; it uses the word embeddings from the GD pre-trained word vector model, but the inputs are still ID data.[4] Figure 1 shows the adaptation flow proposed in this paper, where the domain-adapted training is presented in Section 3.1, 3.2 and 3.3.

3.1 Adaptation on Word Vectors

The look-up table in the neural network contains word vector representations for all words in the vocabulary. We first propose to integrate the word vectors of ID and GD. The word vector from the ID look-up table contains the input word meanings with adaptation, whereas the GD look-up table contains richer word representations trained on a very large data set. We propose the following two approaches to adapt from the GD look-up table:

1. Word Vector Concatenation (WVC): we concatenate the word vectors obtained from ID and GD lookup-tables, as in Equation (7):

$$x_t^{WVC} = [x_t^*, x_t] \tag{7}$$

[2]By static, we mean the pre-trained word vector model is not updated during training.

[3]Depending on the adaptation methods that we will describe in this section, *RNN** is not always used. For example, when the adaptation is performed on word vectors (Section 3.1), *RNN** is not used.

[4]Note that Equation (1) and Equation (5) have the same input s.

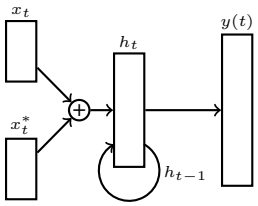

Figure 2: RNN LM with adaptation on word vectors, where $\oplus$ indicates the adaptation mechanisms described in Section 3.1.

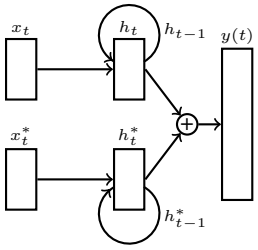

Figure 3: RNN LM with adaptation on context representations, where $\oplus$ indicates the adaptation mechanisms described in Section 3.2.

2. Word Vector Sum (WVS): we sum the two word vectors from ID and GD lookup-tables. In this approach, the two word vectors need to always have the same dimensionality, as in Equation (8):

$$x_t^{WVS} = x_t^* + x_t \tag{8}$$

When adapting, we replace the x_t in Equation (2) with x_t^{WVC} or x_t^{WVS}. Figure 2 is a graphical illustration of adaptation on word vectors.

3.2 Adaptation on Context Representations

Another approach is to delay the domain adaptation step until the context information is available. The RNN encapsulates the word vectors of the current words and previous context, and then produces a representation of the current context. Intuitively, if we maintain separate RNNs, where one uses the ID word representation and another one uses the GD word representation, there will be two pieces of context information available to us, namely contexts with the meaning of ID and GD. In this case, the following domain adaptation approaches can be taken:

1. Context Vector Concatenation (CVC): we can concatenate the two context vectors, as in Equation (9):

$$h_t^{CVC} = [h_t^*, h_t] \tag{9}$$

2. Weighted Context Vector Concatenation (WCVC): we can extend the CVC approach by applying a concatenation weight on h_t^* in Equation (6). Thus, the network can have simple control over the amount of the information flowing from GD, as in Equation (10):

$$h_t^{WCVC} = [Wh_t^*, h_t] \tag{10}$$

3. Context Vector Sum (CVS): we can also add the ID context vector and the GD context vector. We then have the compacted information from two domains to represent the context, as in Equation (11):

$$h_t^{CVS} = h_t^* + h_t \tag{11}$$

4. Weighted Context Vector Sum (WCVS): another approach is to apply a weight vector on the GD context vector. Thus the information from GD can be controlled before compacting, as in Equation (12):

$$h_t^{WCVS} = Wh_t^* + h_t \tag{12}$$

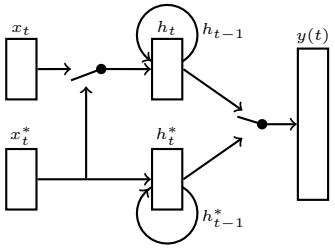

Figure 4: RNN LM with gated adaptation, where ● indicates the gates mechanisms described in Section 3.3.

Therefore, we replace the h_t in Equation (3) with h_t^{CVC}, h_t^{WCVC}, h_t^{CVS} or h_t^{WCVS} when adapting. Figure 3 is a graphical illustration of adaptation on context representations.

3.3 Gated Adaptation

However, directly applying adaptation on the context may not be efficient. The information adapted from GD is forced to be used by ID, i.e. the concatenation or sum operations. Furthermore, the adaptation operations are segmented. Ideally, we want to have an adaptation mechanism that can sequentially adapt the information from GD for the sequence inputs. Thus, we propose various gated domain adaptation mechanisms.

1. Word Vector Gating (WVG): in the WVG approach, we first design a gate to control the information flow from GD word vectors, as in Equation (13):

$$u_t^{WVG} = \sigma(W_u x_t + U_u h_{t-1} + W_u^* x_t^* + U_u^* h_{t-1}^* + b_u) \tag{13}$$

   where u_t^{WVG} is the adapted update gate on word vectors. It is computed using the known knowledge, i.e. x_t and x_t^* are the word vectors of the current word from ID and GD, respectively, and h_{t-1} and h_{t-1}^* are the previous context vectors of ID and GD, respectively. We then use a linear sum to combine the word vector representations (ID and GD), as in Equation (14):

$$x_t^{WVG} = u_t^{WVG} \odot x_t + (1 - u_t^{WVG}) \odot x_t^* \tag{14}$$

   where x_t^{WVG} is the domain-adapted word vector. Such an adaptation approach ensures that when the gate u_t^{WVG} tends to 1, we only use the ID word vector x_t, and when u_t^{WVG} tends to 0, the information from GD is fully cascaded to the current word vector.

   To use the domain-adapted word vector, we can simply replace the original x_t in Equation (2) with x_t^{WVG}.

2. Context Vector Gating (CVG): a similar gating mechanism can also be applied to the context vector, as in Equation (15):

$$r_t^{CVG} = \sigma(W_r x_t + U_r h_{t-1} + W_r^* x_t^* + U_r^* h_{t-1}^* + b_r) \tag{15}$$

   where r_t^{CVG} is the adapted update gate on the context vectors. We can also use the linear sum operation to combine the context vectors of ID and GD, as in Equation (16):

$$h_{t-1}^{CVG} = r_t^{CVG} \odot h_{t-1} + (1 - r_t^{CVG}) \odot h_{t-1}^* \tag{16}$$

   We then use the domain-adapted context vector h_{t-1}^{CVG} to replace the original context vector h_{t-1} in Equation (2).

3. Domain-Adapted GRU (DAGRU): the WVG and CVG mechanisms can also be used together. In this way, we can adapt both the word and context information of GD to the ID word and context vectors.

Figure 4 illustrates the gated adaptation mechanisms.

3.4 Properties

It is also worth mentioning the following properties in our proposed adaptation mechanisms:

Property 1: One of the main differences between our proposed adaptation mechanisms and previous adaptation mechanisms is that we adapt word vector representations from a pre-trained word vector model trained using a large GD data set. However, previous work focused on adapting raw word(s) from GD, i.e. the data selection approach or the model combination approach. Our adaptation method is a more natural fit for neural network training. Furthermore, we think there is no contradiction between our approach and the previous data selection approach (Moore and Lewis, 2010), as data selection can always be performed before LM training. Note that our approach performs domain adaptation during LM training.

Property 2: Our approach also differs in the notation of GD data. Previous work defines a large corpus as the GD data, whereas our GD data here is the pre-trained GD word vector model. Thus, our adapted RNN LM model is still (only) trained using ID sentences. In practice, this is an efficient adaptation mechanism since there will be no extra training time brought by the additional training corpus.

Property 3: The pre-trained GD word vector model is static, which means it is not updated during training. This is because the pre-trained word vector model is obtained from a very large GD data set. The word vectors in such a model are not domain-specific. By keeping it static, we interpret it as a "knowledge database", and the knowledge should be consistent. Another practical reason for not updating the pre-trained GD word vector model is that fewer parameters need to be optimized in the network.

4 Experiments

4.1 Adaptation on Penn Treebank and News Corpus

The typical setting of domain adaptation is small amount of ID training data and large amount of DG training data. Accordingly, we choose to use the availability of widely known Penn Treebank (Marcus et al., 1993) portion of the Wall Street Journal corpus in our LM adaptation experiment.[5] The words outside the 10K vocabulary frequency list are mapped to the special *unk* token; sections 0-20 are used for training, and sections 21-22 are used for validation. We report the perplexity on data from sections 23-24. More detailed data statistics are summarized in Table 1. We use the pre-trained word vector Google *word2vec*[6] (Mikolov et al., 2013a) as the GD "look-up table". It is trained on about 100 billion words, and consists of 3 million words and phrases. The word vectors are 300-dimensional in the *word2vec* model.

In the experiments, our LM is trained with a single GRU hidden layer containing 600 hidden units. We uniformly initialize the weight parameters between [-0.1,0.1]. We set the maximum training iterations to 25. We set the initial learning rate to be 1, and then apply the learning rate with a decay factor of 0.5 after 13 iterations. The model is optimized using stochastic gradient descent with batch size of 20. We set the back-propagation through time to 40 time steps. The word embedding size in the loop-up layer is set to 600 for the baseline models. For a fair comparison, we use word embedding size 300 in the gated adaptation experiments since we are also using the pre-trained word vectors of 300.

Table 2 lists the perplexity results for the LM experiments. The baseline (KN5) model is a 5-gram LM trained using modified Kneser-Ney smoothing. It results in 148.007 and 141.186 perplexities on the validation and test data set, respectively. The baseline (*word2vec*) model is a neural LM, which uses the

Table 3: Statistics of the News corpus.

pre-trained *word2vec* model as the embedding layer. It can achieve 121.871 and 117.730 perplexities on the validation and test data set, respectively. The baseline (Standard) model is a neural LM, which is trained only on the ID data, it can achieve 92.983 and 89.295 perplexities on the validation and test data set, respectively. For the baseline (*word2vec*) model, we observe a sudden explosion in the evaluation perplexity. We experimentally set the learning rate with a decay factor of 0.5 after 4 iterations.

In the adaptation on word representations experiments, we found that summing up the word vectors in WVS can outperform the concatenation approach of WVC. Adding up the context representations in CVS is also more useful than concatenating the context representations in CVC. Thus, we can draw the conclusion that information from GD should be compressed (summed) into ID rather than using scattered (concatenated) representations. However, weighted vectors can be harmful to the sum approaches in WCVS. We think this is because the adapted representation is a newly computed vector after the sum operation, where the weight vectors are hidden behind the sum operation. Thus the model can be hard to optimize. In contrast, when applying weight vectors in the concatenation cases in WCVC, the adapted representation is still separable into domains. Thus the weights in the adapted model are easy to optimize. However, observing the experimental results, only a small positive impact can be observed when applying weighted vectors to the concatenation approaches. For example, approximately 1 perplexity point difference can be found between CVC and WCVC models. This indicates that the approach of using weight vectors for domain adaptation in neural network training is too simple.

We now move our focus to the News corpus. We test the DAGRU adaptation approach on the target side of the French-to-English News Commentary v10 corpus from the WMT2015 translation task. We use corpus newstest 2013 for evaluation and newstest 2014 for testing the trained LMs. More detailed data statistics are summarized in Table 3. Table 4 presents the LM perplexity differences between the baseline LM and the adapted LM. On the News training corpus, the adapted LM can also produce a better result than the baseline LM with a perplexity reduction of 12.

4.2 Statistical Machine Translation Re-ranking

In this experiment, we apply the DAGRU-adapted LMs trained in Table 4 on the statistical machine translation (SMT) *n*-best re-ranking task. We use the French-to-English News Commentary v10 and Europarl v7 corpus from the WMT2015 translation task to train our baseline SMT system. The newstest 2013 and 2014 data sets are used for tuning and testing for the SMT, respectively. The SMT baseline

is trained using Moses (Koehn et al., 2007), with a lexicalized reordering model (Galley and Manning, 2008) and a 5-gram KenLM (Heafield, 2011) LM trained on the target side of the SMT training data.

The re-ranked SMT systems can both increase the baseline BLEU score significantly as seen in Table 5. Using the baseline LM for re-ranking, we can observe a 0.51 absolute improvement (1.8% relative). Using the DAGRU LM for re-ranking, we an obtain a 0.82 absolute (3% relative) improvement. Comparing the two re-ranked systems, we observe that using DAGRU LM for re-ranking can provide an additional increase of 0.31 (1.1% relatively) in BLEU score. The improvement is statistically significant (Koehn, 2004). The significance testing uses bootstrapping method at the level p = 0.05 level with 1,000 iterations.

Table 6: The DAGRU adaptation on different word vector models

4.3 Observations

There are many reasons to explain the efficiency of the DAGRU approach. First, from the perspective of adapted information, our method is not only adapting knowledge from GD, but also with very little speed overhead in the neural network training framework. It makes use of the internal data representation in neural network training. We adapt GD information directly from distributed word representations, which is a more natural way of learning in the neural network.

A further possible explanation is that the DAGRU approach is a better fit to the sequence learning tasks. We proposed several adaptation methods in Section 3, where adapting word vector representations ignores the previously adapted histories. Words are adapted individually from GD at each step. The approach of adapting context vector representations has the same issue. Although the adapted information is the context vectors which are generated by previous histories, the adaptation is still segmented. Taking the CVC approach as an example, the adapted context vector h_t^{CVC} is only used for predicting outputs in the output layer at step t, but not in the adaptation operation at step $t+1$. In contrast, the DAGRU approach can achieve sequential adaptation. The gates (u_t^{WVG} and r_t^{CVG}) are computed by the previous adapted context vector h_{t-1} and the previous GD context vector $h_{t_1}^*$. Furthermore, the computation of the current adapted representation also involves h_{t-1} and $h_{t_1}^*$. Thus, the adaptation histories are managed by the model and sequentially traverse along the input string.

Furthermore, we also compare the learning curves between the baseline LM and the DAGRU LM on validation and test data of the Penn Treebank. As Figure 5 shows, the predictions become more certain and accurate after iterations for training both LMs. Already after training iteration 2, the DAGRU LM starts to outperform the baseline LM in terms of perplexity at every iteration. The plots flatten after 18 iterations, and the learning begins to converge for both the baseline LM and DAGRU LM.

To demonstrate the scalability of the DAGRU adaptation approach, we also train LMs adapting from other freely available word vector models. SENNA (Semantic/syntactic Extraction using a Neural Network Architecture) is the word vector model received after a LM training (Collobert et al., 2011). The training data is obtained from Wikipedia. GloVe (Pennington et al., 2014) – Global Vectors for Word Representation – provides several versions of word vector models. The glove_6b model is trained on Wikipedia data and the English Gigaword Fifth Edition corpus;[7] the glove_42b model is trained on the Common Crawl data; and the glove_840b model is trained on the the Common Crawl and additional web data.

Table 6 presents the experimental results of DAGRU adaptation using different word vector models as GD data. The baseline models are trained on the Penn Treebank only. The word embedding numbers in Table 6 indicate the word vector size of the adapting word vector model, e.g. the SENNA model has a word vector size of 50 under Word Embedding = 50 setting. For the baseline systems with embedding

size 50 and 100, we observe a sudden explosion in the evaluation perplexities with the decay factor setting described in Section 4.1. We experimentally set the learning rate to a decay factor of 0.5 after 8 iterations. In Table 6, the DAGRU approach can produce better perplexity results in all settings.

5 Related Work

Domain adaptation for *n*-gram LMs is a well-studied research field. In general, there are approaches to select data which are similar to ID from GD (Moore and Lewis, 2010; Axelrod et al., 2011; Duh et al., 2013; Toral, 2013). There are also model mixture approaches (Bellegarda, 2004; Hsu and Glass, 2006; Allauzen and Riley, 2011), which try to find a weight to combine the ID LM and GD LM.

In neural LM work, one approach to perform domain adaptation is to use an additional adaptation layer to combine the GD neural LM into the ID neural LM (Park et al., 2010; Ter-Sarkisov et al., 2014). However, an LM trained on all GD data is required. Curriculum learning (Bengio et al., 2009), which rearranges the training data in a particular order to improve generalization, is also applied on domain adaptation on a neural LM (Shi et al., 2013). In the work of Mikolov and Zweig (2012), word predictions are conditioned on the word topic representations. Thus, building multiple topic-specific language models is avoided.

6 Conclusions and Future Work

In this paper, we present and compare several domain adaptation approaches using neural LM training. Compared to previous domain adaptation methods, we propose the idea of learning GD knowledge directly from GD word vectors instead of from raw sentences. Using the proposed domain adaptation gating mechanism, we demonstrate LM perplexity improvements on the Penn Treebank and News domain data sets. We compare the adaptation performance on several publicly available word vector models. We also apply the adapted LM in the SMT re-ranking task. The experimental results suggest that the proposed domain adaptation gating approach can efficiently produce a better LM and significantly improve SMT translation performance.

Our domain adaptation gating mechanism is not only limited to LM training. We are interested in further exploring its performance on other NLP tasks, e.g. neural machine translation. In future work, we are also interested to find out the efficiency of applying it to other gated RNNs, such as LSTM.

Abstract

Evaluation of machine translation (MT) into morphologically rich languages (MRL) has not been well studied despite posing many challenges. In this paper, we explore the use of embeddings obtained from different levels of lexical and morpho-syntactic linguistic analysis and show that they improve MT evaluation into an MRL. Specifically we report on Arabic, a language with complex and rich morphology. Our results show that using a neural-network model with different input representations produces results that clearly outperform the state-of-the-art for MT evaluation into Arabic, by almost over 75% increase in correlation with human judgments on pairwise MT evaluation quality task. More importantly, we demonstrate the usefulness of morpho-syntactic representations to model sentence similarity for MT evaluation and address complex linguistic phenomena of Arabic.

1 Introduction

Statistical machine translation (SMT) into morphologically rich languages (MRL) faces many challenges: from handling a complex and rich vocabulary, to designing adequate MT metrics that take morphology into account. While the first problem has widely explored (e.g. by using morphological analysis tools to reduce sparsity), the evaluation part has only been partly addressed. This is problematic since traditional MT metrics struggle to distinguish between (*i*) incorrect lexical choices; (*ii*) valid alternative lexical or syntactic variations; and (*iii*) differences in morphological inflection that are the result of incorrect case assignment or morphological agreement. While metrics like METEOR (Denkowski and Lavie, 2011) have made it possible to distinguish between (*i*) and (*ii*) by using paraphrases, (*iii*) is still an open problem. As a result, progress in SMT for MRL is hindered by the lack of adequate evaluation metrics. Since SMT metrics are used not only for evaluation but also for tuning system parameters, it is crucial that the MT metrics correctly handle morphology.

Most recently, deep learning models have been used more heavily in different parts of the natural language processing (NLP) community, including MT and MT evaluation. One of the main advantages of such models is the use of distributed word representations (embeddings). It has been shown that word embeddings are able to capture to certain semantic and syntactic aspects of words (Mikolov et al., 2013). Further refinements allow the inclusion of morphological information into distributed representations (Cotterell and Schütze, 2015). Word embeddings have been shown to help with modeling textual similarity well in the context of MT evaluation for MT into English (Guzmán et al., 2015), and community Question Answering (Guzmán et al., 2016). Nonetheless little exploration has been done on the use of embeddings for MT into MRL.

In this paper, we investigate how embeddings obtained from different levels of lexical and morpho-syntactic linguistic analysis can improve MT evaluation into a MRL. Specifically we report on Arabic, a language with complex and rich morphology paired with a high degree of ambiguity (Habash, 2010). Our results show that using a pairwise neural-network over different representations produces results

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1398–1408, Osaka, Japan, December 11-17 2016.

that clearly outperform the state-of-the-art for MT evaluation into Arabic, by almost over 75% increase in correlation with human judgments on pairwise MT evaluation quality task. More importantly, we demonstrate that the use of embeddings based on morpho-syntactic representations in conjunction with the non-linear modeling capabilities of a neural-network help to capture the preferences of human judges.

Next, we present related work in Section 2. We describe our approach in detail in Section 3; and we evaluate in Section 4. We present a discussion of our findings in Section 5.

2 Related Work

Despite its well-known shortcomings (Callison-Burch et al., 2006), BLEU continues to be the de-facto MT evaluation metric. Several studies have attempted to improve upon it by taking into account different aspects of linguistic structures including: (*i*) synonym dictionaries or paraphrase tables (Denkowski and Lavie, 2011; Snover et al., 2010); (*ii*) syntactic information (Liu and Gildea, 2005; Giménez and Màrquez, 2007; Liu et al., 2010; Chen and Kuhn, 2011); (*iii*) morphology (Tantug et al., 2008); (*iv*) semantics (Dahlmeier et al., 2011; Lo et al., 2012) and (*v*) discourse (Guzmán et al., 2014b; Joty et al., 2014). Generally, these metrics have been focused on translation into English. However, there has been little attention into their direct applicability to languages with rich morphology.

Our work focuses on automatic evaluation of translation into morphologically rich languages, Arabic more specifically. In that sense, our work is related to AL-BLEU (Bouamor et al., 2014) which is an adaptation of BLEU that gives partial credits for stem and morphological matchings of hypothesis and reference words. Here, in addition to using lexical information captured by n-gram metrics, we show that using morpho-syntactic representations can significantly improve the correlation with human judgments. Furthermore, we use a neural-network, which uses non-linearities to improve modeling.

Over the past few years, neural network models have dramatically improved the state-of-the-art of different NLP applications (Goldberg, 2015). For instance, in SMT we have observed an increased use of neural nets for language modeling (Bengio et al., 2003; Mikolov et al., 2010), for improving answer ranking in community Question Answering (Guzmán et al., 2016), for improving the translation modeling (Devlin et al., 2014; Bahdanau et al., 2014; Cho et al., 2014) and for machine translation evaluation (Guzmán et al., 2015; Gupta et al., 2015). Our work is related to Guzmán et al. (2015), in several levels of lexical, syntactic and semantic are combined in a compact fashion using a pairwise neural framework. There are several differences between that work and ours: (*i*) we do not use syntactic embedding representations, (*ii*) we include additional pairwise features, namely the pairwise cosine similarity between embeddings; and (*ii*) we focus on an MRL language. While use of syntactic representations has proven a useful component to evaluate English, it relies heavily on an syntactic neural parser (Socher et al., 2013), which increases the complexity of the evaluation setup, and is not readily available for every language. Here, we instead use morpho-syntactic representations which capture both syntactic and morphological aspects of language. In our experiments, these simple representations are powerful enough to provide state-of-the-art performance.

In this work, we use neural network models to improve MT evaluation into Arabic using representations that capture morphology. Morphological structure has been shown to improve the quality of word clusters (Clark, 2003), word vector representations (Cotterell and Schütze, 2015) and neural language models (Botha and Blunsom, 2014). The novelty of our work resides in the way we integrate lexical and morpho-syntactic distributed representations into a neural-network. We demonstrate that combining several sources of complementary information is useful to capture sentence similarity in a translation evaluation scenario. And arguably, capture complex phenomena like morphological agreement.

3 Approach

We use a pairwise approach to translation evaluation (Guzmán et al., 2014a) using neural networks. We use neural networks for two reasons. First, to take advantage of their ability to model complex non-linear relationships efficiently. Second, to have a framework that allows for easy incorporation of distributed representations captured by lexical and morpho-syntactic embeddings. In this section, we describe the neural-network model and the distributed representations we use as features in this work.

3.1 Learning framework

Neural Network Model Our full neural network model for pairwise evaluation is depicted in Figure 1. It is a direct adaptation of the feed-forward NN proposed for English MTE (Guzmán et al., 2015). Technically, we have a binary classification task with input $x = (r, t_1, t_2)$, which outputs 1 if t_1 is a *better* translation than t_2 in the context of the reference r, or 0 otherwise. The network computes a sigmoid function $f(r, t_1, t_2) = \text{sig}(\mathbf{w_v^T}\phi(r, t_1, t_2) + b_v)$, where $\phi(x)$ transforms the input x through the hidden layer, $\mathbf{w_v}$ are the weights from the hidden layer to the output layer, and b_v is a bias term.

To decide which hypothesis is *better* given the tuple (r, t_1, t_2) as input, we map the hypotheses and the reference to a fixed-length vector $[\mathbf{x}_r, \mathbf{x}_{t_1}, \mathbf{x}_{t_2}]$, using embeddings based on different lexical and morpho-syntactic representations.

We model three types of interactions (between t_1, t_2 and r) using different groups of nodes in the hidden layer h_{12}, h_{1r}, h_{2r}. The input to each of these groups is the concatenation of the vector representations of the two interacting components i.e., $\mathbf{x_{1r}} = [\mathbf{x}_{t_1}, \mathbf{x}_r]$, $\mathbf{x_{2r}} = [\mathbf{x}_{t_2}, \mathbf{x}_r]$, $\mathbf{x_{12}} = [\mathbf{x}_{t_1}, \mathbf{x}_{t_2}]$.

In summary, the transformation $\phi(t_1, t_2, r) = [\mathbf{h_{12}}, \mathbf{h_{1r}}, \mathbf{h_{2r}}]$ can be written as :

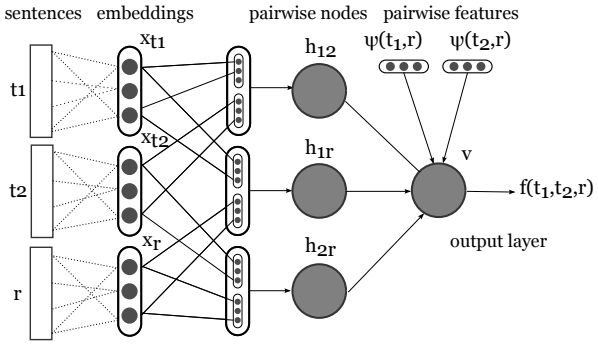

Figure 1: Overall architecture of the neural network.

$$\mathbf{h_{ij}} = \tanh(\mathbf{W_{ij}}\mathbf{x_{ij}} + \mathbf{b_{ij}})$$

where $ij \in \{12, 1r, 2r\}$, $\tanh(.)$ is a non-linear component-wise activation function, $\mathbf{W} \in \mathbb{R}^{H \times N}$ are the associated weights between the input layer and the hidden layer, and $\mathbf{b}$ are the bias terms.

The model further allows to incorporate external sources of information in the form of *skip arcs* ψ that go directly from the input to the output layer. These arcs represent pairwise *similarity* between each translation and the reference (we denote them as $\psi_{1r} = \psi(t_1, r)$ and $\psi_{2r} = \psi(t_2, r)$). We use these feature vectors to encode two basic elements: (*i*) the pairwise cosine similarity between the embeddings from each translation and the reference; and (*ii*) N-gram based MT evaluation measures (e.g., AL-BLEU, METEOR, and NIST). We provide more detail about pairwise features in the next section.

Pairwise Network Training The negative log-likelihood of the training data for the model parameters $\theta = (\mathbf{W_{12}}, \mathbf{W_{1r}}, \mathbf{W_{2r}}, \mathbf{w_v}, \mathbf{b_{12}}, \mathbf{b_{1r}}, \mathbf{b_{2r}}, b_v)$ can be written as follows:

$$J_\theta = -\sum_n y_n \log \hat{y}_{n\theta} + (1 - y_n) \log (1 - \hat{y}_{n\theta}) + \lambda \sum \theta^2 \quad (1)$$

where $\hat{y}_{n\theta} = f_n(t_1, t_2, r)$ is the activation at the output layer for the n-th data instance, and λ is the L_2 regularization penalty. The network is trained with stochastic gradient descent (SGD), mini-batches and adagrad updates (Duchi et al., 2011), using Theano (Bergstra et al., 2010).

Evaluating a single translation Most of the MT evaluation metrics are not designed to do pairwise, but absolute evaluation. In other words, we are interested in generating a score for a single translation t_1 given a reference r. To achieve this with our pairwise network, we compute the *goodness* margin, which tells us how good translation t_1 is better than any other translation $t_\varnothing$ given the reference r. In this case, $t_\varnothing$ is the average representation for all translations observed during training.

To compute the margin, we subtract the scores for the direct and reverse network predictions, and generate the final score for the sentence: $score(t, r) = 1 + (f(r, t, t_\varnothing) - f(r, t_\varnothing, t))/2$.

Note that we use both direct and reverse predictions as our network is not exactly symmetric. We also shift the score to range between $[0, 1]$.

3.2 Features

In this work, we compare different sets of features representing different levels lexical and morpho-syntactic information. As a baseline, we also used several MT metrics that are based on n-gram matches.

Lexical units A distinguishing characteristic of Arabic morphology is the presence of concatenative morphemes, where words are formed via concatenations of stems, affixes and clitics. To allow our system to model how morphemes interact at a finer level, we split the morphemes. We used MADAMIRA (Pasha et al., 2014), the state-of-the-art morphological analyzer and disambiguator, to perform morphological tokenization following ATB scheme (Habash and Sadat, 2006). We extracted two forms of lexical features: NORM and TOKEN, which are tokens with and without Alef/Yaa normalization, respectively. We also extract the LEMMA feature; a morphological abstraction that represents words related by inflectional morphology.

Morpho-Syntactic units We extracted part-of-speech (POS) tags according to different POS tagsets including: (*i*) CATIBPOS(Habash et al., 2009), (*ii*) KULICKPOS[1] (Kulick et al., 2006), (*iii*) BUCKWALTERPOS (Buckwalter, 2004) and (*iv*) STANFORDPOS tagsets. These tagsets differ in their richness and complexity they capture. CATIBPOS is the simplest with only 6 base tags[2], BUCKWALTERPOS is the richest with 485 base tags, and KULICKPOS and STANFORDPOS come in-between with 43 and 32 base tags, respectively. These tags were extracted using MADAMIRA, except for the Stanford tags, for which we used Stanford CoreNLP (Manning et al., 2014). Table 1 illustrates an example sentence with its lexical and morpho-syntactic features.[3]

Sentence:	عاد المصريون الذين اختطفوا إلى بلدهم – *ςAd AlmSrywn Alðyn AxtTfwA Ălý bldhm*						
TOKEN	+هم *+hm*	بلد *bld*	إلى *Ălý*	اختطفوا *AxtTfwA*	الذين *Alðyn*	المصريون *AlmSrywn*	عاد *ςAd*
NORM	+هم *+hm*	بلد *bld*	الي *Ăly*	اختطفوا *AxtTfwA*	الذين *Alðyn*	المصريون *AlmSrywn*	عاد *ςAd*
LEMMA	+هُم *+hum*	بَلَد *balad*	إِلَى *Ăilaý*	اِخْتَطَف *Aix.taTaf*	الَّذِي *Al~aðiy*	مِصرِيّ *miS.riy~*	عَاد *ςaAd*
CATIBPOS	+NOM	NOM	PRT	VBD-PASS	NOM	NOM	VRB
KULICKPOS	+PRP$	NN	IN	VBN	WP	DT+NNS	VBD
STANFORDPOS	PRP$	NN	IN	VBN	WP	DTNNS	VBD
BUCKWALTERPOS	+POSS _PRON _3MP	NOUN +CASE _DEF_GEN	PREP	PV_PASS +PVSUFF _SUBJ:3MP	REL_PRON	DET+NOUN +NSUFF _MASC_PL_NOM	PV+ PVSUFF _SUBJ:3MS
GLOSS	their	country	to	were abducted	which	the Egyptians	returned
English	The Egyptians who were abducted returned to their country.						

Table 1: Illustration of the lexical and morpho-syntactic feature representations extracted for an example sentence. The sentence is presented from right to left following the directionality of writing Arabic.

Distributed representations To obtain embeddings based on the lexical and morpho-syntactic units described above, we annotated the fifth edition of the Gigaword corpus (LDC2011T11) with each of the representations. Then, we trained word embeddings using word2vec (Mikolov et al., 2013). To

[1](Pasha et al., 2014) refers to Kulick tagset as the Penn ATB tagset, while it is Buckwalter tagset that is used in Penn ATB.

[2]The size of each tagset is expected to increase since Arabic morphemes can function as clitics, and their corresponding POS tags are then assigned a clitic marker (+). The final sizes of the extracted POS tags are shown in Table 4.

[3]Arabic transliteration is presented in the Habash-Soudi-Buckwalter scheme (Habash et al., 2007) (in alphabetical order): أ ب ت ث ج ح خ د ذ ر ز س ش ص ض ط ظ ع غ ف ق ك ل م ن ه و ي *Â b t θ j H x d ð r z s š S D T Ď ς γ f q k l m n h w y*, and the additional symbols: ء ’, أ Â, إ Ă, آ Ā, ؤ ŵ, ئ ŷ, ة ħ, ى ý. Diacritics are represented as: ـَ a, ـُ u, ـِ i, ـْ ., ـً ã, ـٌ ũ, ـٍ ĩ, and ـّ ~.

obtain sentence-level representations for each of the translations and the references, we used additive composition (Mitchell and Lapata, 2010) with dropping unknown words.

N-gram MT metrics We used the different n-gram based metrics to serve as a benchmark, and as additional features that capture lexical similarity. We used: BLEU+1 (Nakov et al., 2012),NIST (Doddington, 2002); METEOR (Denkowski and Lavie, 2011), 1-TER (Snover et al., 2006), and AL-BLEU (Bouamor et al., 2014), to compute scores at the sentence-level. For consistency with previous work, we report scores over words, and not over morphemes.

4 Experimental Setup

In this section, we describe the experimental settings we used through our study. First, we introduce our evaluation criteria, then we elaborate on the dataset and various settings we used for our experiments.

4.1 Performance evaluation

Automatic evaluation metrics are evaluated based on their correlation with human-performed evaluations (Soricut and Brill, 2004). In this work, we use Kendall's τ, a coefficient that measures the agreement between rankings produced by human judgments and rankings produced by an automatic metric, at the sentence-level. We use the WMT'12 (workshop of machine translation) definition of Kendall's τ that ignores ties, and is calculated as follows: $[\tau = (\#\text{ concordant pairs} - \#\text{ discordant pairs})\,/\text{total pairs}]$, where the *# concordant pairs* is the number of times the human judgment and the automatic metric agree in the ranking of any two translations that belong to the same source sentence. The *# discordant pairs* is the opposite. The value of τ ranges from -1 (all pairs are discordant) to $+1$ (all pairs are concordant).

4.2 Data

To evaluate the performance of the neural-network, we evaluated its Kendall's τ given different input representations. We used a medium-scale corpus of human judgments for Arabic MT outputs covering different topics in the news domain (Bouamor et al., 2014). The corpus is composed of 1,383 sentences selected from two datasets: (*i*) the standard English-Arabic NIST 2005 corpus, commonly used for MT evaluations and composed of political news stories; and (*ii*) a small dataset of translated Wikipedia articles. This corpus contains the source and target text along with the automatic translations produced by five English-to-Arabic MT systems: three research-oriented phrase-based systems with various morphological and syntactic features and two commercial, off-the-shelf systems. The corpus contains annotations that assess the quality of the five systems, by ranking their translation candidates from best to worst for each source sentence in the corpus. The annotation was conducted by mirroring the WMT evaluation campaigns (Callison-Burch et al., 2011), but with few key differences: (*i*) the full corpus was annotated with no random sampling, and (*ii*) the task was performed by two independent native speakers of Arabic. The total number of annotated pairs in this corpus is 33,192 (each sentence has two annotations, each yielding 12 rankings). The agreement between the annotators in terms of Kendall's τ is 49.20 (which roughly translates to agreement in 75% of all rankings). We used random partitions of 783 sentences for training (TRAIN), 300 sentences for tuning (DEV) and 300 sentences for testing (TEST).

4.3 Network Settings

We train our model on TRAIN with hidden layers of size 10 for 30 epochs with mini batches of size 30, L_2 regularization of 0.0001, and a learning rate of 0.01. We normalize the input feature values to the $[-1; 1]$ interval using minmax, and we initialize the network weights by sampling from a uniform distribution as in (Bengio and Glorot, 2010).

We evaluate the model on DEV after each epoch, and keep the one that achieves the highest accuracy. We selected the above parameter values on the DEV dataset using the full model, and we use them for all experiments described in Section 5, where we evaluate on the official TEST dataset.

Note that, we train the pairwise neural-network using all pairwise rankings in the TRAIN set. At test time, we compute the scores of the translations in TEST using the absolute scoring previously described.

5 Results

In this section we present the main results from our experiments. Since the dataset is new, we first present the Kendall's τ scores obtained from five n-gram based metrics that are popular in the community. Then, we present the results of using embeddings obtained from different representations as input to train the neural-network. Finally, we present combination of representations, that shed light on the capabilities of the neural-network to learn how to exploit different levels of lexical and morpho-syntactic information.

A. MT Metrics		**Kendall's τ**	**B. Embeddings**		**Kendall's τ**
			Lexical		
1	NIST	17.94	7	TOKEN	**24.35**
2	METEOR	17.90	8	NORM	23.22
3	AL-BLEU	17.02	9	LEMMA	21.17
4	BLEU	16.11	*Morpho-syntactic*		
5	1-TER	4.97	10	BUCKWALTERPOS	**25.49**
			11	KULICKPOS	16.25
6	5METRICS	**18.12**	12	STANFORDPOS	10.90
			13	CATIBPOS	5.41

Table 2: Kendall's τ on the TEST set for traditional n-gram based metrics as well as metrics built using different lexical and morpho-syntactic embeddings as input to the neural-network.

5.1 MT Metrics

In Table 2.A, we present four of the most popular MT metrics: BLEU, NIST, METEOR and 1-TER, along with AL-BLEU; a precision-based metric that is designed to handle Arabic morphology. These metrics were calculated over tokenized text. From the results, we observe that NIST and METEOR obtain very similar performances for this task, with 17.94 and 17.90, respectively.[4] This suggests that both the paraphrasing that METEOR uses, and the precision weighting by n-gram *importance* that NIST does, yield results that are more in line with human judgments than other metrics. Additionally, the role of morphology is important, as AL-BLEU presents an improvement over BLEU (17.02 vs 16.11).

Next, we combine the five metrics in a logistic regression model. We observe that the 5METRICS combination yields only minor improvements over the best single metrics, suggesting limited complementarity. We use this 5METRICS combination as a baseline to compare to next experiments.

5.2 Embeddings

In Table 2.B, we present the results of using the neural-network with embeddings for different representations. Using the embeddings for any lexical representations (TOKEN, NORM, LEMMA) produces significant improvements (+3%) over any of the MT metrics and their combination, yielding state-of-the-art results. The relative increase over 5METRICS ranges from 17% (+3.05% absolute with LEMMA) to 34% (+6.23% absolute with TOKEN).

Using the embeddings obtained for morpho-syntactic representations results in a wide-range of results. Surprisingly, the BUCKWALTERPOS representation obtains very competitive scores, even surpassing the lexical representations and yielding the highest score yet with a 41% relative increase over 5METRICS (+7.37% absolute). However, none of the other morpho-syntactic representations improve on 5METRICS. There is a clear correlation between the size of the POS tag-set and the performance of the metric. We explore this relationship more in depth in Section. 5.4.

5.3 Combination of Representations

Given the complimentary information embedded in the different representations, it is natural to combine them to obtain a stronger metric. To combine different embedding representations, we simply concatenate the different embedding representations before feeding them to the network. Below, we present

[4]Note that the Kendall's τ results for METEOR are in the range of the results for translation from English into other two morphologically rich languages (German: 18.0 and Czech 16.0) reported in WMT 2012 (Callison-Burch et al., 2012)

	Combinations	Kendall's τ result	prev. best	delta
C. Embeddings and N-gram based metrics				
Lexical				
14	5METRICS+TOKEN	23.62	24.35	(-0.73)
15	5METRICS+NORM	**24.17**	23.22	(+0.95)
16	5METRICS+LEMMA	23.51	21.17	(+2.34)
Morpho-syntactic				
17	5METRICS+BUCKWALTERPOS	**29.81**	25.49	(+4.32)
18	5METRICS+KULICKPOS	23.58	18.12	(+5.46)
19	5METRICS+STANFORDPOS	21.79	18.12	(+3.67)
20	5METRICS+CATIBPOS	18.93	18.12	(+0.81)
D. Embedding mixtures				
Lexical + Lexical				
21	TOKEN +NORM	25.12	24.35	(+0.77)
22	NORM + LEMMA	**25.42**	23.22	(+2.20)
23	TOKEN+LEMMA	24.90	24.35	(+0.55)
24	TOKEN+NORM+LEMMA	25.34	25.42	(-0.08)
Lexical + Morpho-syntactic				
25	BUCKWALTERPOS+TOKEN	* **31.87**	25.49	(+6.38)
26	BUCKWALTERPOS+NORM	30.69	25.49	(+5.19)
27	BUCKWALTERPOS+LEMMA	30.69	25.49	(+5.19)
E. Embedding mixtures + Ngram-based metrics				
Lexical + Lexical				
28	5METRICS+TOKEN+NORM	25.56	25.12	(+0.44)
29	5METRICS+NORM+LEMMA	25.42	25.42	(+0.00)
30	5METRICS+TOKEN+LEMMA	25.45	24.90	(+0.55)
31	5METRICS+TOKEN+NORM+LEMMA	**28.35**	25.42	(+2.93)
Lexical + Morpho-syntactic				
32	5METRICS+BUCKWALTERPOS+TOKEN	29.78	31.87	(-2.09)
33	5METRICS+BUCKWALTERPOS+NORM	**30.73**	30.69	(+0.04)
34	5METRICS+BUCKWALTERPOS+TOKEN+LEMMA+NORM	30.44	31.87	(-1.43)

Table 3: Kendall's τ on the TEST set for metrics built using combination of lexical and morpho-syntactic embeddings in addition to the 5METRICS. For comparison, we compare the result of the combination to the best result of any of the components in the combination. The best result overall is marked with *.

three sets of results involving different types of combinations in Table 3. In addition to the Kendall's τ of a particular combination x, we indicate the best previous result (i.e., result of a sub-combination that was presented already, *underlined*), and its delta from combination x.

Embeddings and MT Metrics In Table 3.C, we present the results of adding the 5METRICS to the different embeddings in Table 2.B as *skip-arc* features. For lexical embeddings, we observe slight improvements, except for the TOKEN representation, which has a small decrease. The combination of each of the morpho-syntactic embeddings with 5METRICS improves over 5METRICS. For the best performer so far, BUCKWALTERPOS, we get even more improvements, reaching an 11.69 absolute increase over 5METRICS (65% relative). This showcases that the neural-network is able to successfully make use of the complementarity between n-gram-based MT metrics and other sources of morpho-syntactic information.

Embedding Mixtures Table 3.D presents the results of combining lexical and morpho-syntactic embeddings. Every pairwise combination of lexical embeddings improves over either embedding combined. However, putting all lexical embeddings together is not as good as NORM+LEMMA. Combining the best morpho-syntactic performer (BUCKWALTERPOS) with each lexical embedding produces large improvements. This highlights the ability of the neural-network to exploit the interactions between different representations to provide a more robust metric. With BUCKWALTERPOS+TOKEN, we reach our best results, improving over the 5METRICS baseline by 13.75% (or 75.9% relative improvement).

Embedding Mixtures and MT Metrics Finally, we present in Table 3.E the results of combining 5METRICS with different combinations of embeddings. The addition of 5METRICS to pairs of lexical embeddings does not hurt and only slightly improves the scores. However, putting all of the lexical embeddings together with 5METRICS makes a nice increase, although still not competitive with our best result so far. Finally, combining 5METRICS+BUCKWALTERPOS with different lexical embeddings seems to make little improvement if any.

5.4 Discussion

One of the interesting results from Table 2.B is the wide range of scores for the different embeddings. Surprisingly, the BUCKWALTERPOS representation does remarkably well. Here we investigate some possibilities for this behavior.

Feature expressiveness In Table 4, we consider different aspects of the different embeddings: their vocabulary size, their token out-of-vocabulary rate, the standard deviation of the cosine similarity scores they assign to each sentence in TEST, as well as their respective Kendall's τ scores. The larger the variance, the more expressive and informative the representation is, as it gives more diverse values for cosine similarity between translation and references.

	Vocab Size	Token OOV Rate (%)	StDev Cos Sim	Kendall's τ
TOKEN	98,923	1.32	$9.57{\cdot}10^{-2}$	24.35
NORM	97,870	1.29	$9.51{\cdot}10^{-2}$	23.22
LEMMA	51,493	1.25	$9.12{\cdot}10^{-2}$	21.17
BUCKWALTERPOS	714	0.00	$9.87{\cdot}10^{-2}$	25.49
KULICKPOS	53	0.00	$4.97{\cdot}10^{-2}$	16.25
STANFORDPOS	32	0.00	$4.16{\cdot}10^{-2}$	10.90
CATIBPOS	11	0.00	$3.84{\cdot}10^{-2}$	5.41

Table 4: Statistics for the different embedding representations and their impact on TEST: vocabulary size of the embedding representations, token OOV rate of the embedding vocabulary on the TEST set, the standard deviation (StDev) of cosine similarity values for all translation–reference pairs in the TEST set and the Kendall's τon the TEST.

Overall, we observe that the variance (or the standard deviation) of the values in the cosine similarity and the Kendall's τ scores correlate very well at $\rho = 0.94$. One way to interpret this is that the more expressive the representation is, the better it performs at MT evaluation. The size of the vocabulary generally adds expressiveness to a feature, and correlates within the lexical subset and the morpho-syntactic subset of the representations (but not across or overall). However, lexical representations lose expressiveness because OOVs.

Agreement The BUCKWALTERPOS representation is particularly rich and captures the morphological complexity of Arabic. Thus, it can be used to represent patterns of grammatical agreement across words, e.g., verb-subject and noun-adjective. While the lexical embedding may capture that the two verbs يكتب *yktb* 'he writes' and تكتب *tktb* 'she writes' may occur in similar contexts, the BUCKWALTERPOS representation models for agreement with the context they appear in. Since Arabic uses agreement heavily across verbs and noun phrases, we expect that the simple additive combination used with word embeddings is able to capture impressions of gender or number, just enough to allow the model to distinguish between sequences that are closer to the reference from those that are not. For example, the sentence يريد الطفل الصغير أن يكتب *yryd AlTfl AlSγyr Ân yktb* 'the little boy wants to write' encodes the masculine singular gender in four of its words. Simpler POS tags do not mark this information and thus are unable to distinguish between sentences that use the correct and incorrect gender information. In our experience, human judges pay careful attention to agreement errors as they reduce the fluency of the text even as the basic "accuracy" of it is kept.

Morpho-semantics The BUCKWALTERPOS representation contains some semantic features related to specific POS tags. To give a concrete example, in our data set, a future verb was translated correctly

using the particle سوف *swf* 'will' (BUCKWALTERPOS: FUT_PART) by system A, and incorrectly as the particle لن *ln* 'will not' (BUCKWALTERPOS: NEG_PART) by system B. However, the reference had no future particle. While both translations were penalized equally (in terms of cosine similarity) in the TOKEN representation, the sentence with the negation POS NEG_PART was penalized more in the BUCKWALTERPOS representation. There are a number of negative particles in Arabic and all get the same BUCKWALTERPOS tag. This, we believe allows the neural-network to abstract and model them correctly.

Task specific Another reason that using morpho-syntactic helps MT evaluation even in isolation is that by definition, the setup of the MT evaluation forces translation and references to be somewhat close. Here, capturing agreement and POS semantics seem to correlate well with human judgments. We don't expect that using the morpho-syntactic to capture other type of sentence similarity (e.g mining sentence pairs in comparable corpora) will work as well.

6 Conclusions and Future Work

In this paper, we explored the use of different lexical and morpho-syntactic representations to model similarity in the context of MT evaluation for a morphologically rich language such as Arabic. Our results show that using the neural-network with the input embeddings obtained from different representations makes impressive gains individually and, especially, in combination. This confirms the neural-network ability to model complex interactions between the feature sets. The fact that the best performers in each of these subsets when combined (BUCKWALTERPOS+TOKEN) show very high gains; suggests that they are modeling very different aspects of the text. The lexical embeddings we posit model semantic similarity between test and reference; while the morpho-syntactic embeddings model syntactic similarity, and complex phenomena like morphological agreement.

Furthermore, when paired to morpho-syntactic representations, the distributed lexical information seems to be a good alternative to n-gram metrics to obtain state-of-the-art results. In the future, we would like to use rich morpho-syntactic representations for evaluation into other MRL languages to validate our observations for Arabic. For instance, this framework can be easily ported to European languages, such as German, Russian or Czech, where: (*i*) there the existence of morphological analyzers makes it feasible to develop morpho-syntactic embeddings, and (*ii*) there are datasets available (from WMT Evaluation Campaigns) to develop and evaluate such metrics. Finally, we want to test the use of morpho-syntactic representation in other tasks such as source language modeling for Neural Machine Translation.

Acknowledgment

We would like to thank the annotators, Fatma Tlili and Aisha Mohamed, for providing the machine translation quality human judgments.

Abstract

In this paper we describe and evaluate methods to perform ensemble prediction in neural machine translation (NMT). We compare two methods of ensemble set induction: sampling parameter initializations for an NMT system, which is a relatively established method in NMT (Sutskever et al., 2014), and NMT systems translating from different source languages into the same target language, i.e., multi-source ensembles, a method recently introduced by Firat et al. (2016). We are motivated by the observation that for different language pairs systems make different types of mistakes. We propose several methods with different degrees of parameterization to combine individual predictions of NMT systems so that they mutually compensate for each other's mistakes and improve overall performance. We find that the biggest improvements can be obtained from a context-dependent weighting scheme for multi-source ensembles. This result offers stronger support for the linguistic motivation of using multi-source ensembles than previous approaches. Evaluation is carried out for German and French into English translation. The best multi-source ensemble method achieves an improvement of up to 2.2 BLEU points over the strongest single-source ensemble baseline, and a 2 BLEU improvement over a multi-source ensemble baseline.

1 Introduction

It has been shown for various machine learning applications that combining multiple systems can substantially improve performance (Rokach, 2010). System combination has also been successfully applied to statistical machine translation system (SMT) (Och and Ney, 2001; Matusov et al., 2006; Schwartz, 2008; Schroeder et al., 2009). However, system combination methods in the phrase-based (PBSMT) (Koehn et al., 2003) and hierarchical (HSMT) frameworks (Chiang, 2007) tend to be rather complex, requiring potentially non-trivial mappings between the partial hypotheses across the search spaces of the individual systems. For this reason SMT system combination is often limited to combining hypotheses from the n-best list. Alternatively, SMT systems can also be combined by processing different inputs as is the case for multilingual system combination. Unfortunately, input sentences in different languages may have very different structure, requiring elaborate methods to align sentences, which means that multilingual system combination is in practice restricted to languages with similar structures.

On the other hand, the recently emerged neural machine translation (NMT) framework offers a straightforward way to combine multiple systems. Most of the current NMT architectures (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015) formalize the target sentence generation as a word sequence prediction task. At each step during sequence prediction, a translation system outputs a *full* probability distribution over the target vocabulary. Therefore, the task of NMT system combination can be cast as an ensemble prediction task and a variety of existing general prediction combination methods can be applied. While this paper focuses on word-based models, the ensemble methods discussed in this paper can be applied to character-based sequential NMT models (Ling et al., 2015) in a very similar fashion.

Ensemble prediction is frequently used in NMT. A commonly reported method is uniform weighting of the output layers, i.e., distributions over the target vocabulary, produced by different trained instances of the same NMT architecture for the same language pair (Bojar et al., 2014). We use this method as

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1409–1418, Osaka, Japan, December 11-17 2016.

a baseline where the variations of the same system are produced by different parameter initializations. Alternatively, it is also possible to take parameter snapshots from different training epochs (Sennrich and Haddow, 2016). Recently, a new type of ensemble has been introduced in NMT: a *multi-source ensemble* (Firat et al., 2016), which is a set of NMT systems that translate from different source languages into the same target language. The general idea behind ensembles is that different predictors are likely to produce slightly different errors for different input instances, and if their predictions are combined, the overall error is reduced. Therefore, it is essential to introduce a minimum of diversity into an ensemble. Different random initializations force the same training algorithm to converge to different local optima. Different source sentences may differ quite significantly in their structure and thus present a different training task to an NMT learning algorithm. Multi-source ensembles offer a *linguistic* source of variation for translation systems, which may range from the way particular words are translated to the way the whole sentence is structured. This is in line with the common observation that translation systems trained on language pairs with different source languages differ in their performance (Bojar et al., 2014).

Besides the linguistic interest, multi-source translation can be applied in practical real-life scenarios. Examples include multi-lingual websites, where some content has already been made available in a couple of languages (by human translators) but needs to be further translated into other languages. Another example are parliamentary proceedings, typically available in many languages. Furthermore, Firat et al. (2016) study neural multi-source translation in the context of zero-resource translation, and experimentally show that multi-source pivot-based translation improves translation quality compared to simple pivot-based translation.

In this paper, we compare ensemble combination methods and evaluate how much performance gain they provide in the multi-source translation setting. All previous approaches employing NMT ensembles do so by applying a simple linear, uniform weighting of the output probability distributions. However, it seems intuitive to assign different weights to different systems, especially for the case of multi-source translation. Firat et al. (2016) evaluate multi-source ensemble method on French-Spanish into English. All three languages, and especially French and Spanish are very similar, so for this scenario their contribution may be close to equal. In order to explore the diversity offered by linguistic variation, we chose to evaluate on English, German, and French. German is structurally substantially different from both English and French, while English and French are quite similar and are typically easily mutually translatable (Bojar et al., 2014). Here, we translate from French into English and from German into English and we expect the former translation direction to perform substantially better than the latter. As we mentioned above, the performance of translation systems can vary with respect to different aspects of translation quality, such as correct reordering or lexical translation choice. In order to combine the strengths of individual systems, we train different combination functions on a held-out data set. We consider two types of combination: global (fixed weight for every prediction instance) and context-dependent, where weights are estimated for every prediction step. The latter is more fine-grained and is in principle able to capture more linguistic nuance, but may be difficult to train due to data sparsity.

This paper proceeds as follows: In Section 2 we describe the NMT architecture and optimization parameters that we use to train our translation systems. We further describe the training data and report individual translation performances of the trained systems. In Section 3 we discuss in detail the ensemble methods that we wish to employ. We present a grid search experiment to explore the performance potential of the two types of ensemble sets (single-source with different random initializations and multi-source). The experiment confirms our intuition that linguistic diversity can be beneficial for building NMT ensembles. In Section 4 we describe two models to train an ensemble combination function: a global weighting function and a context-dependent gating network. Section 5 contains results of translation experiments with different types of ensembles and their discussion. Section 6 provides some conclusions and outlook on future work.

2 Attention-based sequence-to-sequence NMT

We use an encoder-decoder neural translation model as described in Luong et al. (2015) to train individual predictors in an ensemble. The source encoder is a four-layer unidirectional LSTM. The final hidden

Table 1: Data statistics for (a) NMT training, (b) ensemble combination function training, and (c) testing.

states of the encoder are used to initialize the decoder, which is also a four-layer unidirectional LSTM. On top of that, at each time step i the target hidden state from the top layer h_i^t and the set of all source hidden states $\{h_1^s, ..., h_n^s\}$ are used to compute a context vector c_i, where n is the length of the source sentence. We use the global attention mechanism with the *dot score* function from Luong et al. (2015):

$$c_i = \sum_{j=1}^{n} \text{softmax}(\textit{score}(h_i^t, h_j^s))h_j^s \tag{1}$$

$$\textit{score}(h^t, h^s) = (h^t)^\top h^s \tag{2}$$

Finally, the last (non-recurrent) hidden state $\widetilde{h_i}$ is computed to produce the output layer y_i, which in turn is used to compute a probability distribution over the target vocabulary by applying the softmax function:

$$\widetilde{h_i} = \tanh(W_c[c_i; h_i^t]) \tag{3}$$

$$y_i = \text{softmax}(W_y\widetilde{h_i}) \tag{4}$$

In the following two subsections we describe how we train the translation systems, which are later used as part of an ensemble during beam decoding, and how they perform individually.

2.1 Training details

2.1.1 Data

We consider a multi-source scenario based on French, German, and English. We chose these languages to introduce diversity into ensembles: German is structurally substantially different from both English and French, while English and French are structurally similar and are typically easily mutually translatable (Bojar et al., 2014). We expect a French-English system to perform better than German-English. But also, given the linguistic intuition about the structural differences between these translation pairs, we hope that the two systems compensate for each other's weaknesses when used in an ensemble.

To ensure that the only distinguishing factor between different language pairs is the source language, we chose training data which is to a large extent parallel across all three languages, i.e., it is a trilingual parallel text with small bilingual parts. To this end, we train all of our systems on the TED talks data set (Cettolo et al., 2012). All available data is split into a training and a validation set to train individual NMT systems, a training and a validation set to train a combination function for ensembles, and a test set for the final evaluation. The training data for learning the ensemble combination function and the test set should necessarily be fully parallel (tri-parallel). Therefore, we extracted our test set from the available trilingual data and did not use the test sets provided by (Cettolo et al., 2012) since they are not parallel across all three languages. Of course, the test set does not overlap with the training data. Table 1 provides some statistics of the training data.

2.1.2 Network and optimization details

We set the size of all embeddings and hidden layers to $1,000$. We use LSTM units for the recurrent hidden states and apply dropout with a probability of 0.2 (Luong et al., 2015). We make sure that the output (target vocabulary) layer is exactly the same for all NMT systems in an ensemble. To this end we precomputed the intersection of the target vocabularies for the respective language pairs in an ensemble.

system	BLEU	MET EOR
de→ en best	20.58	49.16
de→ en mean	20.31 ± 0.34	48.88 ± 0.33
fr→ en best	27.80	56.91
fr→ en mean	27.03 ± 0.87	56.05 ± 0.82

Table 2: Translation results for individual NMT systems. Decoding beam size is equal to 20. For each language pair we trained four NMT systems with different weight parameter initializations. For each pair we provide the best score and the mean score with standard deviation.

We rank the words in the intersection by their summed frequencies in order to select the top n words for the output later and map the remaining words to $\langle unk \rangle$. For the source sides, we applied the same procedure except for computing the intersection. For French and German we set the vocabulary size to $35,000$ and for English to $24,000$.

For network training we use a Neural MT system Tardis implemented in Torch.[1] All parameters are uniformly initialized, except for the embeddings which were initialized by sampling from a Gaussian with unit variance. Each translation system is trained for 20 epochs. We use SGD with mini-batches of size 20 with a learning rate of 1 and a decay rate of 0.8 after the fifth epoch. During training we limit the lengths of predicted sequences to 50 tokens.

2.2 Translation experiments with individual systems

For each language pair we train four systems by sampling different initial parameter values. Table 2 summarizes the performances of the individual systems. In all of the translation experiments the beam decoding size was set to 20. We evaluate performance with BLEU (Papineni et al., 2002) and METEOR (Lavie and Denkowski, 2009). The first thing to notice is that distributions for both metrics are consistent.

Since we focus on ensemble translation, we are interested in how diverse the translation systems are in their performance. First, we can see that the two language pairs have different degrees of internal variation. The performance variance of German-English is smaller than that of French-English. Second, we see differences between the two source languages when translating into the same target language. These differences are much higher than those within one language pair. This raises the question how helpful a source language with a significantly lower performance will be in a multi-source ensemble.

3 Ensemble prediction in NMT

Generally speaking, in order to specify an ensemble method, one needs to specify how a set of predictors is induced and how they are subsequently combined to make joint predictions (Rokach, 2010). For the construction of the set of predictors, it is essential that they make diverse predictions, to decrease the prediction error. Our goal in this paper is two-fold: First, understand how different ensemble induction methods influence the quality of translation. Second, find the optimal way to combine individual predictors into an ensemble. In Section 2.2 we discussed diversity across different NMT systems. In the remainder of this section we describe the induction and combination methods we evaluate in this paper. We also present experimental analysis of achievable translation improvements.

In this paper we consider two ways to induce an ensemble of translators:

1) different random initializations of NMT parameter values;

2) using semantically equivalent source sentences in different languages to translate into the same target language (translation systems with different source languages but the same target language).

The second method can be seen as different hidden state initializations of a (trained) NMT decoder. Different languages encode the same information in structurally different ways, which may influence the way the decoder is able to infer the translation from that.

Table 3: Summary of the grid search of the scalar combination weights

In NMT the decision of which word to predict is based on the output layer and therefore we have to combine the output layers (Equation 4) of individual translators to obtain an ensemble prediction (Equation 5). The word thus predicted by an ensemble is then fed as input at the next prediction step in a sequence-to-sequence model.

$$y^{\mathcal{E}} = comb(y^1, ..., y^m) \tag{5}$$

We would like the method to be applicable to a situation where a trilingual parallel corpus, i.e., the corpus needed to train a multi-source combination function, is a scarce resource, which is a realistic assumption. Therefore we are interested in combination functions with a small number of trainable parameters. In our approach, we concentrate on *scalar* prediction combination: $comb(y^1, ...; , y^m) = w_1 y^1 + ... + w_m y^m$, where $\sum_i w_i = 1$ are scalar weights. In addition to the methods described in this paper we also investigated geometric mean combination ($\sqrt[m]{w_1 y^1 \cdot ... \cdot w_m y^m}$), but the resulting ensemble system under-performed the stronger individual system of the ensemble, therefore in the rest of the experiments we proceeded with the arithmetic mean function only.

Both single-source ensembles with different initializations (Sutskever et al., 2014) and multi-source ensembles have been used before (Firat et al., 2016). However all of the previous approaches use simple, uniform weighting. We refer to this method as *uniform combination*, as it does not assume anything about the contributions of the individual predictors. We perform grid search over the global combination weights[2] $\langle w_1, w_2 \rangle$ for a two-element ensemble (for both ensemble induction methods) over our test set with a step size of 0.1; see Section 2.1.1 for data and system setup.

The results of the grid search experiments are presented in Figure 1 and summarized in Table 3. We observe an increase in performance for both metrics for all ensembles. Moreover, we see that the metric scores are higher in the region of 0.5, which justifies uniform ensemble combination. At the same time, none of the graphs are completely symmetric: the highest scores are achieved with a weight value of 0.6 or 0.7 assigned to the stronger system in an ensemble. This result is intuitive, and it suggests

[2]I.e., a weight value is fixed for every instance in the test set.

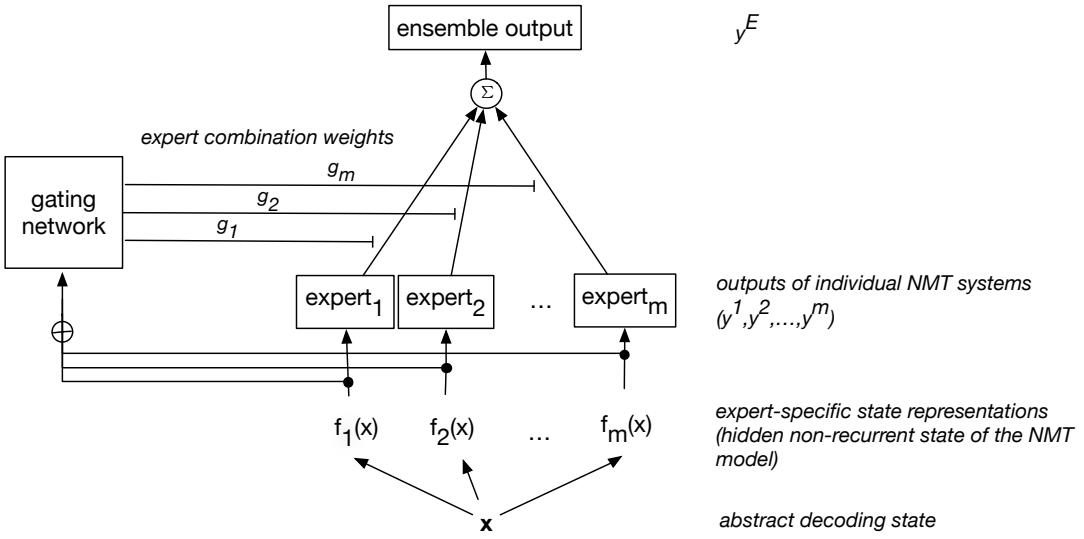

Figure 2: Mixture of NMT experts used to make context dependent translation prediction.

to investigate a combination method that could distinguish between the relative contributions of the individual members of an ensemble. We will distinguish between two kinds of combination functions: global and context-dependent. The former combines NMT predictions in the same way for every input at every decoding time step. The latter can combine predictions differently depending on the current context during decoding. We describe the corresponding learning methods in Section 4.

The second major finding of our parameter sweep is that the multi-source ensemble gives a higher upper bound performance than single-source ensembles, even though one of the ensemble members is substantially weaker in its individual performance. This finding reinforces the original linguistic motivation for multi-source ensembles with which we can obtain improvements of up to 0.87 BLEU and 0.77 METEOR over the highest single-source ensemble result.

In the following sections we describe how we make use of the uncovered potential of the two types of ensembles. We are especially interested in making full use of the complementary strengths of systems with different source languages.

4 Combination function learning

Having established that contributions of individual systems towards a correct prediction in single-source and multi-source ensembles are not equal, we develop an approach that is capable of training a function that can combine them optimally. For the case of multi-source ensembles the combination training set is a trilingual set consisting of $19,000$ lines (see Section 2.1.1 for details). We deliberately chose a small data set to establish how applicable the method is in a low-resource scenario. We use the same training set to train single-source ensembles. In this section we present two kinds of combination models, as well as their training details.

First, when a scalar combination vector is fixed for every prediction step, we refer to it as *global combination*. The optimized function is a vector $\langle w_1, ..., w_m \rangle$, where m is the size of the ensemble set. We train it with AdaGrad (Duchi et al., 2011) for 10 epochs with a learning rate of 0.001.

Second, we explore a more fine-grained combination method, where the contributions of individual predictors are assessed based on the decoding state. We adapt a mixture of experts model (Jacobs et al., 1991) to learn the *context-dependent combination*. The original mixture of experts model works as follows: We have a set of experts (predictors) and an input x, which is fed to each of the predictors. x is also fed to a gating network which outputs weights for each of the experts. The resulting prediction is a weighted sum of experts: $\mu = \sum_i g_i \mu_i$, where μ_i is the output of the i-th expert and g_i is its gating weight. Here, we realize context dependence by making use of a parameterized gating network.

Adapting the mixture of experts model (Jacobs et al., 1991) to the NMT scenario presents itself with a few challenges. NMT models are sequential and therefore the output at time step i depends on the current input word and the previous hidden state, which encodes the translation history for a *given* expert. This leads to two problems: the input representation is specific to an expert and it is also quite complex as it is a combination of hidden state and previously predicted word. We address the first problem by simply concatenating vectors which are inputs to each of the translators at time step i. There are a number of ways to address the second problem. But essentially, we would like to think of input x as some abstract decoding state corresponding to the context of the ensemble translation process at time step i.

In the first set of experiments, we opt for using the already available representations for the decoding state x, rather than formulating an explicitly, linguistically-motivated definition. Given the complex modular structure of an NMT model, there are a number of hidden states, such as the hidden recurrent states, the context vector, or the non-recurrent hidden state $\widetilde{h}$, which can be chosen to represent the decoder state which is the input to the gating network. In our approach, we use the last hidden state $\widetilde{h}$. We choose $\widetilde{h}$ because it already captures a large amount of information such as the previously predicted word, previous hidden state, and attention distribution over the source words.[3] In addition, the output layer is more directly connected to $\widetilde{h}$ than any of the states from lower layers. This is an important consideration given that the amount of training data is severely limited.

The architecture of our context-dependent combination function is presented graphically in Figure 2. The ensemble output $y^{\mathcal{E}}$ is computed as in Equation 6, where g_j is the gating weight, x represents the abstract decoding state at step i and $f^j(x)$ is its expert-specific representation (for expert j), namely $\widetilde{h}^j$:

$$y^{\mathcal{E}}(x) = \sum_j g_j \mu_j(x) \tag{6}$$

$$\mu_j(x) = \text{softmax}(W_y f^j(x)) \tag{7}$$
$$= \text{softmax}(W_y \widetilde{h}^j) \tag{8}$$
$$= y^j \tag{9}$$

g_j is the j-th output unit of the gating network computed as in Equation 10. The gating network is a feed-forward neural network with one hidden layer of size 250 and tanh non-linear activation function. The output layer is of size m, where m is the number of experts. Values of the output layer are normalized by applying softmax. The mixture model allows to back propagate errors both to the gating network and the experts themselves. However, considering the small size of the training data and the complexity of the experts, in terms of number of parameters, full back propagation is likely to result in over-fitting. Therefore, we only update the weights of the gating network, where the weights of the NMT predictors have been pre-trained separately. We train our mixture model for 10 epochs with AdaGrad with a learning rate of 0.001.

$$g = \mathit{softmax}(W_{\mathit{gate}} \mathit{tanh}(W_{\mathit{hid}}[f^1(x); ...; f^m(x)] + b_{\mathit{hid}}) + b_{\mathit{gate}}) \tag{10}$$

5 Translation experiments with trained ensembles

In the previous sections we have shown that NMT ensembles, and in particular multi-source ensembles, can improve translation quality. We proposed two methods to learn an ensemble combination function from data, which is more capable of exploiting the potential of ensembles than simple uniform weighting. In this section we test these methods in translation experiments. We compare the two ensemble induction methods (same-source systems with different parameter initializations and multi-source set) and apply all combination methods. All results are presented in Table 4.

[3] In our preliminary experiments, we also experimented with using other layers of the NMT model as the decoding state x: the top-most recurrent layer of decoder, the context vector, and the embedding of the previously predicted target word as the decoding state. However, using the non-recurrent hidden state $\widetilde{h}$ achieved the best results overall.

Table 4: Translation experiments for the French, German into English scenario. *Ensemble set* designates ensemble induction method. *Combination type* refers to the method used to combine predictions during decoding. We use curly brackets to denote hierarchical ensemble combination.

For each ensemble set type, we evaluate ensembles of size 2 and 4. The notation below should be understood as follows: $de_k^{k+l} \rightarrow$ en stands for a single-source ensemble of l German-English systems. Analogously for French-English. de,fr $\rightarrow$ en is a multi-source ensemble of size 2, and we use subscript indices if there are more than 2 systems in an ensemble covering the same source language. We only apply context-dependent combination for ensembles of size 2 to avoid overfitting for bigger ensembles. Note that this does not prevent the application of our context-dependent combination method to bigger ensembles, as we can combine systems hierarchically. In a hierarchical ensemble the set of predictors is divided into disjoint subsets and each of the subsets is combined separately. The resulting combination systems can then be treated as predictors in a new ensemble, and thus can be further combined for a joint prediction. In our case the maximal number of predictors is 4, therefore our hierarchical ensembles have 2 levels. Hierarchical ensembles allow one to make prediction combinations multiple times which can further boost the potential of an ensemble. Since in this paper we only consider a low-resourced scenario with a small amount of training trilingual data, we do not train a hierarchical combination function. Instead, we do global or context dependent combination for ensemble sets at the bottom level (level of individual NMT systems) and then weight their outputs uniformly (level of combined systems). We use curly brackets denote hierarchical combination.

We see in Table 4 that multi-source ensembles generally perform better that single-source ensembles. The largest improvements for multi-source ensembles are due to our context-dependent combination method. This suggests that the trained gating network is able to capture linguistic context. We note that a multi-source ensemble with contextual combination outperforms the empirical upper bound estimated in Section 3, although it should be noted that this is an upper bound for a global combination method. On the other hand, for single-source ensembles, context-dependent combination (by itself) does not provide additional improvements as compared to global weighting. This suggests that the variation found in single-source ensembles is not as systematic as in multi-source ensembles. As part of future work, we are planning to perform a more linguistically oriented analysis to identify contexts triggering a high degree variation in ensembles. The results of such analysis will also provide the basis for a more linguistically oriented definition of the decoding state x as defined in Section 4.

We also note that simply increasing the size of an ensemble does not necessarily improve translation performance. Previous approaches using NMT ensembles often report performance increases for ensembles consisting of a larger number of systems, typically 8 or 12. One could therefore speculate that ensembles of 4 systems are not enough to significantly increase diversity as compared to an ensemble of size 2. Of course, our result are also influenced by several other factors such as the choice of languages, training data, etc. However, we should point out that hierarchically combining a set of 4 systems does improve translation quality. At this point, hierarchical combination still requires further investigation,

but for the time being, it can be seen as a simple 'recipe' to boost translation quality further.

6 Conclusions

In this paper we compared existing ensemble set induction methods for NMT and proposed a number of system combination methods: global (across instances) weighting of predictors' outputs and context-dependent weighting. Our main goal was to validate the linguistic hypothesis that translation systems from different source language into the same target language have complementary strengths and weaknesses in terms of translation performance and introduce an approach that can exploit the respective strenghts and weaknesses to achieve better translation quality. In our experiments with German-English and French-English we found that multi-source ensembles yield the best performance, compared to the individual translation systems, as well as compared to single-source ensembles of NMTs produced by different random initializations. This is an interesting finding because individually the two systems differ substantially in their translation quality. We also found that ensemble combination based on a gating network that decides how to combine systems at every prediction step achieves better performance as compared to a global (constant) combination function or uniform weighting in the majority of cases.

Overall this is a compelling result and it leaves us with a number of questions for future work. First, can we characterize linguistically what types of contexts are mores suited to be translated by a German-English system, and which are more suited to be translated by a French-English system? Gaining insights in that direction can help us answer another question: is there a better way to represent the current context which is the input to the gating network? In this paper we used a concatenation of each system's last hidden state $\widetilde{h}$, but a potentially more effective and linguistically more intuitive representation may be found. Finally, it would be interesting to see to what extent our approach can benefit from three or more mutually different source languages.

Abstract

In this paper, we propose a new decoding method for phrase-based statistical machine translation which directly uses multiple preordering candidates as a graph structure. Compared with previous phrase-based decoding methods, our method is based on a simple left-to-right dynamic programming in which no decoding-time reordering is performed. As a result, its runtime is very fast and implementing the algorithm becomes easy. Our system does not depend on specific preordering methods as long as they output multiple preordering candidates, and it is trivial to employ existing preordering methods into our system. In our experiments for translating diverse 11 languages into English, the proposed method outperforms conventional phrase-based decoder in terms of translation qualities under comparable or faster decoding time.

1 Introduction

One of the main problem of phrase-based statistical machine translation (PBMT) (Koehn et al., 2003; Och and Ney, 2004) is handling the difference of word orders between source and target languages. Decoding-time reordering models (Koehn et al., 2005; Zens and Ney, 2006; Galley and Manning, 2008) measure positional relationship between each phrase at the decoding time. However, reordering models have a common problem in that it is difficult to take global information in the source sentence into account, and as a result the decoder may generate grammatically incorrect word orders. In addition, using reordering models demands a complicated decoding algorithm, in which the decoder has to consider concatenations of source phrases with arbitrary orders.

On the other hand, preordering methods (Xia and McCord, 2004; Isozaki et al., 2010; Neubig et al., 2012; Nakagawa, 2015) change word orders of source sentence to be close to the target sentence before starting the decoding process. These methods can use global information in the source sentence and may generate grammatically correct reordering results. However, previous PBMT methods with preordering usually take only one-best preordered sentence and it is difficult to avoid the noise of the input caused by the errors from preordering methods.

One of the trivial way to avoid preordering errors is to obtain N-best preordering candidates, translate each candidate one-by-one and select the most probable result (Li et al., 2007; Zhu, 2014). This method has an obvious problem on computation time because the decoding process is executed N times. Another way to resolve preordering errors is combining a preordering method and decoding-time reordering models. However, it is not trivial to integrating these methods in a single system while comprehending their interactions.

In this study, we propose a new phrase-based decoding method which employs multiple preordering candidates for a source sentence. Our method first encodes multiple preordering candidates as a compact graph structure (we call it *preordering lattice*), and generates translations by a single-pass traversal on the preordering lattice which can take into account all preordering candidates.

Several previous work proposed decoding methods using graph structures with respect to preordering (Niehues and Kolss, 2009; Herrmann et al., 2013a; Herrmann et al., 2013b); however, these methods are tightly integrated with a specific graph structure defined on top of the methods themselves. Another previous work focused on multi-source translation based on a confusion network of multiple source

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1419–1428, Osaka, Japan, December 11-17 2016.

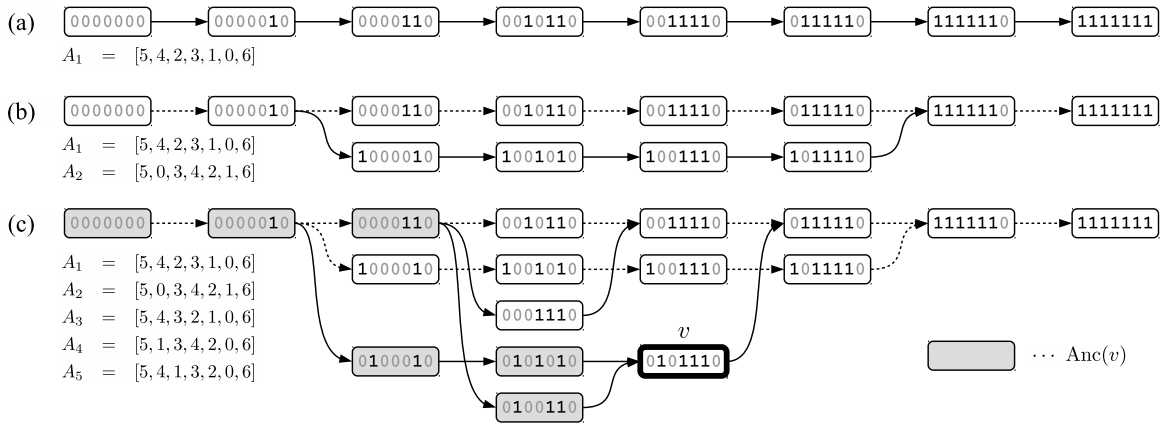

Figure 1: Generating preordering lattice from multiple preordering candidates.

sentences (Schroeder et al., 2009; Jiang et al., 2011); however, the derived confusion network is too constrained to represent variation of preordering, and it cannot take the advantage of alternative reordering in the multiple source sentences.

Compared with above previous works, our method is more generic in that the preordering lattice is constructed based only on the word permutations of the source sentence which are generated from arbitrary and independent preordering methods, and the preordering lattice guarantees that all preordering candidates are compactly encoded in the graph structure. In addition, we show that our preordering lattice approach ourperforms conventional decoding-time reordering methods even with a simple left-to-right dynamic programming algorithm. Our experiments show that the proposed method can achieve comparable or higher translation qualities against a conventional phrase-based method under diverse 11 language pairs: Ar/Zh/Fr/De/It/Ja/Ko/Pt/Ru/Es/Tr into English.

2 Graph Representation of Multiple Preordering Candidates

We denote the source sentence S as an array of words $S = [s_1, s_2, \cdots, s_I]$, and assume that a preordering method takes the source sentence S as an input and returns multiple preordering candidates $\mathcal{A} = \{A_1, A_2, \cdots, A_N\}$, $A_n = [a_1^n, a_2^n, \cdots, a_I^n]$ together with their confidence scores $\mathcal{C} = \{C_1, C_2, \cdots, C_N\} \in \mathbb{R}^N$, where I is the number of words in the source sentence, and N is the number of preordering candidates, and each confidence scores satisfies that $C_j > C_k$ if $j < k$. Each $a_i^n \in \{0, 1, \cdots, I-1\}$ denotes an original position of the source word in S. For example, if we take a Japanese sentence $S =$ [“今日 (today)”, “は”, “いい (good)”, “天気 (weather)”, “です (be)”, “ね”, “。”] (“It is nice weather today.”) and a preordering candidate $A = [5, 4, 2, 3, 1, 0, 6]$, then we obtain a preordered sentence $S' =$ [“ね”, “です”, “いい”, “天気”, “は”, “今日”, “。”].

We introduce an alternative view of the preordering candidate A_n which is represented as a chain graph structure illustrated in Figure 1(a), and we call this graph *preordering lattice*. Each node in the preordering lattice has a *coverage* generated by the preordering candidate, and each edge represents the one-word transition between two coverages. Each coverage represents a set of *processed* words at each timing of decoding, and we encoded each coverage as a bit vector representation in the same way as those used in a conventional phrase-based decoding algorithm. For example, a coverage vector $[0000110]$ indicated that 7 source words should be translated while decoding, and 5th and 6th words are already translated before reaching this coverage. Preordering lattice can be uniquely obtained from a preordering candidate by starting from an empty coverage ($[000\cdots]$) and adding 1 into a_n-th element one-by-one. The process can be regarded as a left-to-right decoding process with single word phrase pairs in a phrase-based decoding.

When multiple preordering candidates are available, we merge them into a single graph structure. Specifically, we integrate nodes in two preordering lattices if their nodes have same coverage vectors each other as shown in Figure 1(b), in which another preordering candidate $[5, 0, 3, 4, 2, 1, 6]$ is merged

Algorithm 1 Integrating preordering lattices

1: $\mathcal{A} \leftarrow$ Array of preordering candidates
2: $G \leftarrow$ Empty lattice
3: **for** $A \in \mathcal{A}$ **do**
4: $\quad G' \leftarrow \mathrm{Lattice}(A)$
5: $\quad$ **for** $v' \in V(G')$ **do**
6: $\quad\quad$ **if** $\neg(\exists v, v \in V(G) \wedge L(v) = L(v'))$ **then**
7: $\quad\quad\quad V(G) \leftarrow V(G) \cup \{v'\}$
8: $\quad\quad$ **end if**
9: $\quad$ **end for**
10: $\quad$ **for** $(v'_1, v'_2) \in E(G')$ **do**
11: $\quad\quad$ **if** $\neg(\exists v_1, v_2, (v_1, v_2) \in E(G) \wedge L(v_1) = L(v'_1) \wedge L(v_2) = L(v'_2))$ **then**
12: $\quad\quad\quad v''_1 \leftarrow v$ s.t. $v \in V(G) \wedge L(v) = L(v'_1)$
13: $\quad\quad\quad v''_2 \leftarrow v$ s.t. $v \in V(G) \wedge L(v) = L(v'_2)$
14: $\quad\quad\quad E(G) \leftarrow E(G) \cup \{(v''_1, v''_2)\}$
15: $\quad\quad$ **end if**
16: $\quad$ **end for**
17: **end for**

together. In this case, there are 4 nodes with same coverage vectors [0000000], [0000010], [1111110], [1111111] in two preordering lattices, which are integrated as shared nodes. Figure 1(c) shows an example of merging 5 preordering candidates in $\mathcal{A}$ as a single preordering lattice. It is guaranteed that this preordering lattice is uniquely determined given a set of preordering candidates $\mathcal{A}$, and the final graph structure does not depend on the integrating order. Thus, we can merge new lattice paths by enumerating preordering candidates one-by-one. Algorithm 1 shows the method to generate integrated preordering lattice G from $\mathcal{A}$, where $V(G), E(G), E_i(v), E_o(v), L(v)$ represent the sets of nodes/edges in G, input/output edges of given node v, head (exit side) and tail (entrance side) nodes of the edge e, and the label (= coverage vector) of given node v, respectively. $\mathrm{Lattice}(A)$ represents a unique chain graph determined by a preordering candidate A as described above.

Preordeing lattices generated by Algorithm 1 guarantee that all integrated preordering candidates are represented as a path over the lattice, and also guarantee that all words in the source sentence appear only once in any paths over the lattice. In addition, the preordering lattice often includes extra paths which represents other preordering candidates not in the original candidate set $\mathcal{A}$. Thus, the decoding algorithm described in the next section actually explores more preordering candidates when compared with a decoding algorithm which relies only on $\mathcal{A}$.

The preordering lattice is similar to the word lattice structure (Dyer et al., 2008), but all edges in the preordering lattice represent specific words in one source sentence. Daiber et al. (2016) also described a similar structure to our lattice using finite-state transducer (FST), and applied determinization and minimization to compress the lattice. On the other hand, we introduced more simple algorithm described in Algorithm 1 to achieve similar compression.

3 Decoding Algorithm over the Preordering Lattice

We also intoduce a simple decoding algorithm to generate translations directly using the preordering lattice. Our algorithm runs by traversing the lattice in a left-to-right manner. Algorithm 2 presents our decoding algorithm over the preordering lattice without score calculation, where $\mathrm{Begin}(G)$ and $\mathrm{End}(G)$ represents leftmost and rightmost nodes in a given preordering lattice. The decoder determines partial translations at each node in the preordering lattice according to a topological order ($\mathrm{TopologicalSort}(\cdots)$ in line 4), and finally returns the one-best hypothesis at $\mathrm{End}(G)$ ($\mathrm{BestResult}(\cdots)$ in line 15).

Now we focus on the partial translation hypotheses generated at the node v in Figure 1(c). When

Algorithm 2 Decoding over the Preordering Lattice

```
1: G ← Preordering lattice
2: v_L ← Begin(G)
3: H[v_L] ← {""}
4: for v ← TopologicalSort(V(G)\{v_L}) do
5:     H'[v] ← { }
6:     for ∀v'. v' ∈ Anc(v) ∧ IsCandidatePath(v', v) do
7:         for h' ← H[v'] do
8:             for φ ← PhrasePairs(v', v) do
9:                 H'[v] ← H'[v] ∪ {Join(h', φ)}
10:            end for
11:        end for
12:    end for
13:    H[v] ← Prune(H'[v]; K)
14: end for
15: return BestResult(H[End(G)])
```

computing a partial translation hypothesis at v, the decoder first computes ancestor nodes $\mathrm{Anc}(v)$, i.e., a set of nodes from which v is reachable, as shown in the gray nodes in Figure 1(c). Partial hypotheses $H[v'], v' \in \mathrm{Anc}(v)$ is already determined, and the decoder then enumerates new hypotheses $H'[v]$ by concatenating one hypothesis ($\mathrm{Join}(\cdots)$ in line 9) in $H[v']$ and a phrase pair ($\mathrm{PhrasePairs}(\cdots)$ in line 8) connecting v' and v. Note that $H[\cdot]$ and $H'[\cdot]$ may encode additional state information for features requiring non-local contexts, e.g., history of an n-gram language model. Finally, only K top scored hypotheses are preserved in $H[v]$ by applying a beam search strategy ($\mathrm{Prune}(\cdots)$ in line 13).

$\mathrm{IsCandidatePath}(v', v)$ checks whether at least one path exists between v and v' in the original preordering candidates in order to avoid enumerating spurious many phrase pairs.

Each hypothesis $h \in H[v]$ has a score calculated from its feature functions, which are used by $\mathrm{Prune}(\cdots)$ and $\mathrm{BestResult}(\cdots)$ to choose better hypothesis. We used the weighted linear combination for the scoring policy:

$$\mathrm{Score}(h) := \boldsymbol{w}^\top \boldsymbol{f}(h), \tag{1}$$

where $\boldsymbol{w}$ is a weight vector and $\boldsymbol{f}(h)$ is a set of feature functions for each hypothesis h, e.g., features associated with phrase pairs or extra features, such as n-gram language models.

We add scores for each existing path between v' and v in the preordering lattice according to the confidence of preordering candidates, which are used as an additional feature during decoding. After numbers of preliminary experiments, we adopted the product of maximum preordering confidence score and the ratio of phrase length based on our preliminary studies:

$$f(p) := \frac{|p|}{I} \cdot \max_n \gamma(n, p), \tag{2}$$

$$\gamma(n, p) := \begin{cases} C_n, & \text{if } p \subset \mathrm{Lattice}(A_n) \\ -\infty, & \text{otherwise,} \end{cases} \tag{3}$$

where p represents an arbitrary path over the preordering lattice. $-\infty$ means the decoder never choose the path p, and this formulation corresponds to $\mathrm{IsCandidatePath}$ condition in Algorithm 2.

Compared with the conventional decoding method (Zens and Ney, 2008), the proposed method can eliminate some complex score calculations, e.g., rest cost estimation and decoding-time reorderings, because each path in the reordering lattice holds complete information of the word order. As a result, the proposed method makes the decoding algorithm simpler than the conventional method.

4 Experiments

4.1 Experimental settings

We evaluated our proposed method under the settings of translating into English. We chose 11 language pairs consisting of 6 European languages (Fr/De/It/Pt/Ru/Es) and 5 Asian languages (Ar/Zh/Ja/Ko/Tr), which have different linguistic characteristics when compared with English.

For the training data, we used a parallel corpus by mining from the Web using an in-house crawler. The corpus contains 9.5M sentences and 160M words on average, at least 8.0M sentences and 140M words for each language pair. For the development/test data, we separately sampled and manually translated 3,000/5,000 sentences from other data sources on the Web for each language pair. All hyperparameters for each method are optimized using the development data and final evaluation is performed using the test data. During word alignment, IBM Model 1 (Brown et al., 1993) and HMM alignment (Vogel et al., 1996) were performed using one-best preordered source sentences and corresponding target sentences. The phrase table was built according to the alignment results, and shared with all decoding methods. For the English language model, a 4-gram model with stupid backoff smoothing (Brants et al., 2007) was built and commonly used for all settings. Each configuration of the word alignment and the language model was decided according to the preliminary experiments on the baseline system.

For the baseline system, we employed a standard PBMT system, similar to that of (Och and Ney, 2004) with a lexical reordering model (Zens and Ney, 2006) enhanced by a state-of-the-art preordering method based on bracketing transduction grammar (Nakagawa, 2015). We used similar decoding strategy and other basic feature functions to Moses (Koehn et al., 2007) except some neural lexical features such as NNJM (Devlin et al., 2014). Only one-best preordering candidate is used for the baseline system. We chose the best distortion limit of the baseline system for each language pair by the BLEU (Papineni et al., 2002) score on the development data.

We also compared the reranking method (Li et al., 2007), which translates all preordering candidates using conventional PBMT (our baseline system) and chose one with the best score. To do that, we used simple linear interpolation between decoder's score D and preordering confidence C with a hyperparameter λ as follows:

$$\mathrm{Score}(C, D) := \lambda \cdot C + (1 - \lambda) \cdot D. \tag{4}$$

We varied the number of preordering candidates (1, 2, 4, 8, 16, 32, 64-bests) for the proposed method and the reranking method, and chose the one with the best BLEU on the development data. For the reranking method, we trained two variants by differentiating distortion limits, a system sharing the same limit with the PBMT baseline and those with 0, in order to examine the effects of preordering and decoding-time reordering.

For all methods, we used lattice-based Minimum Error-rate Training (MERT) (Macherey et al., 2008) to optimize weights of features.

Evaluation is carried out by BLEU using all test data, and subjective evaluation with 7-grade (0 to 6) Likert scale about translation acceptance using 400 randomly selected samples from the test data in each language pair.

4.2 Results and Discussion

Figure 2 shows the number of nodes in actual preordering lattices generated from each source sentence in Japanese-English test data under 64-best preordering candidates. Upper group in this graph shows the number of unmerged nodes in which nodes are not shared when combining multiple preordering candidates in Algorithm 1, and lower group shows the number of merged nodes. The numbers directly reflect actual computation for decoding. There are averagely 10 times fewer nodes in merged preordering lattices, so our lattice construction of Algorithm 1 efficiently suppress the complexity of decoding when compared with directly using each preordering candidate independently.

Table 1 shows BLEU scores of the PBMT baseline, proposed method, and reranking method, respectively. The table also shows distortion limits (DL) for the PBMT baseline, and numbers of preordering candidates (N) for the proposed method and the reranking method. First, there are roughly the same

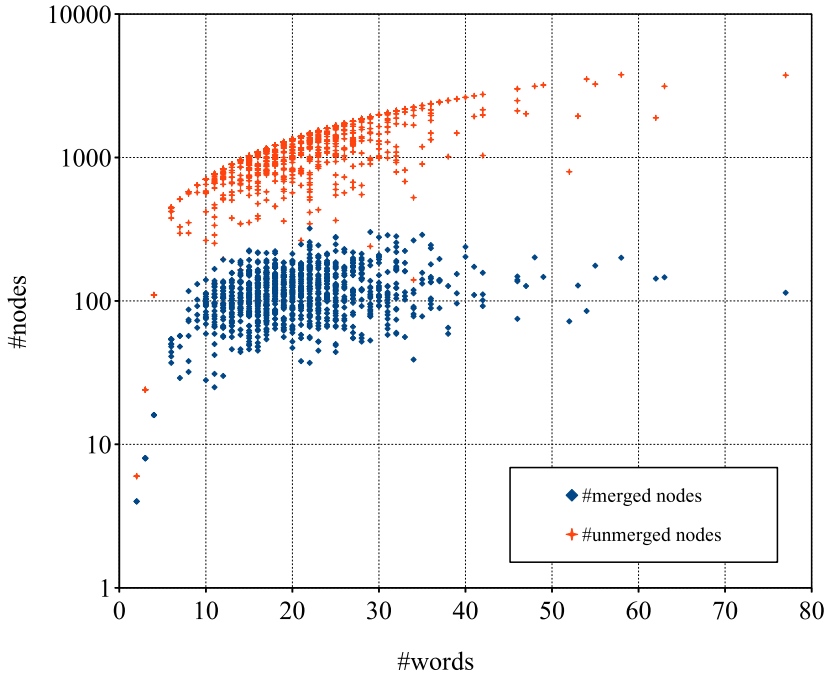

Figure 2: Number of nodes in preordering lattices in Japanese-English translation.

tendencies between the proposed method and the reranking method with similar BLEU improvement, and their systems averagely improves BLEU scores against the PBMT baseline in most language pairs. These results clearly indicate that multiple preordering candidates can largely improve the translation accuracy. In addition, we also see that there are high variance of N mainly in the reranking method. This tendency might come from the accuracy of the preordering method, i.e., if the preordering could perform well, then we require only few preordering candidates to generate accurate translations, and large N introduces less information. Actually, we observed that there is BLEU satulation in some language pairs when using large N, which means low-rank preordering candidates are rarely used to the final translation, according to the language pair.

In comparison between the proposed method and two reranking systems (DL>0 or $=0$), the proposed method without distortion (DL$=0$) often achieves higher BLEU score than DL>0. We conjecture that the tendencies may come from the use of better preordering among multiple candidates instead of a distortion-wise decoding-time reordering. These results clearly show that the decoding-time reordering is not necessary if better reordering is encoded in a preordering lattice.

We also see that there are comparatively higher BLEU improvements when translating from Ja/Ko/Tr than other languages. We speculate that these tendencies come from the grammatical characteristics of source languages. For example, Japanese is one of languages with high flexibility of word order, and the ambiguity may make it difficult to estimate correct preordering. In this case, the use of multiple preordering candidates is a straight-forward way to avoid this problem.

Table 2 shows the results of subjective evaluation for the proposed method against the PBMT baseline. We evaluated statistical significance of each system via t-test of difference between two averages, and this table shows their two-tailed p-values. Note that $\emptyset$ represents some small values ($p < 0.001$). We also included the change rate of these systems, which represents the amount of different translations by both PBMT baseline and the proposed method.

In this table, the proposed method achieves better translations with statistical significance ($p < 0.05$). We can also see that, in 5 Asian to English settings, the proposed method also achieved high translation accuracies under the subjective evaluation, although the proposed method generates divergent translations compared with the PBMT baseline. These languages have more large divergences from English,

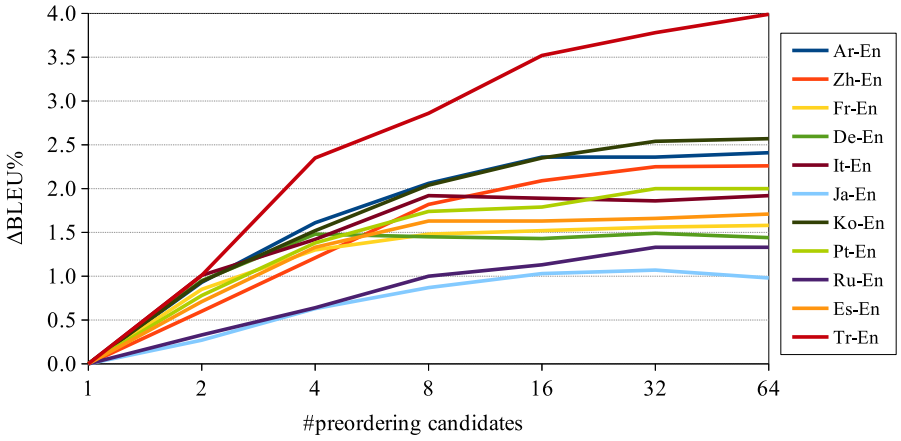
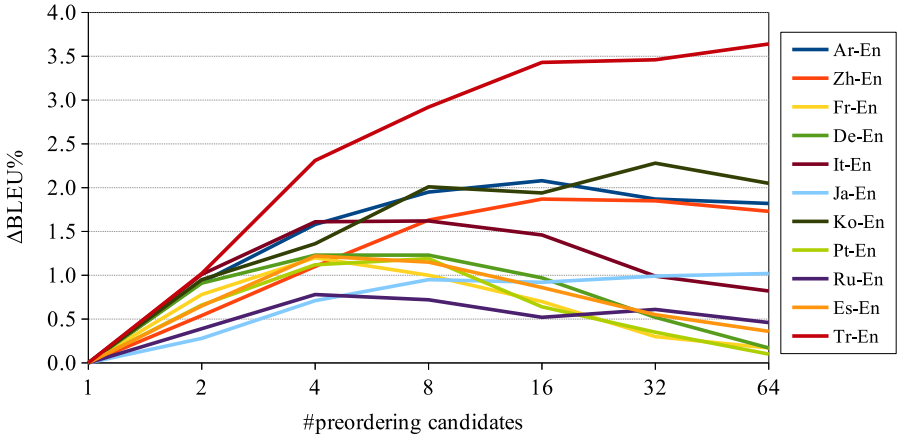
and estimating correct preorderings is more difficult than European languages. By these results, we can also say that the proposed method performs more effectively than PBMT baseline under BLEU and subjective evaluation.

Figure 3 shows BLEU changes of the proposed method by increasing the number of preordering candidates N. The baselines of these graphs are the BLEU score using only one-best preordering candidate, and these scores are roughly similar to a conventional PBMT system with DL$=0$. Figure 3(a) shows cases that use preordering confidence scores described in Section 2 as an additional feature, and Figure 3(b) shows cases of ignoring those scores. In Figure 3(a), the proposed method improves translation accuracy by increasing the number of preordering candidates in nearly all language pairs. Figure 3(a) also shows the BLEU satulation when using large N described in the previous paragraph. And in Figure 3(b), there are non-negligible BLEU reduction by using many preordering candidates. This tendency is expected, because ignoring confidence scores of preordering candidates implies treating all preordering candidates with the same importance, and the decoder have finally chosen the hypothesis with accidentally high scores by other features. Thus, introducing preordering confidence into decoding features is effective to prevent these kind of errors and guarantee translation accuracies.

Figure 4 shows mean decoding times of the PBMT baseline and the proposed method in Japanese-English setting with various decoding parameters. In the PBMT baseline, we changed both distortion limit (0 to 6) and beam width for each coverage of source sentence (1, 2, 4, 8,16 ,32 ,64 ,128). In the proposed method, we varied the number of preordering candidates (1, 2, 4, 8, 16, 32, 64) and beam width as same as PBMT baseline. Basically, increasing distortion limit or the number of preordering candi-



(a) With path score



(b) Without path score

Figure 3: BLEU changes according to the number of applied preordering candidates.

dates require much computation amount. In this figure, the proposed method using many preordering candidates can achieve high translation accuracy, as well as the proposed method runs as same range of computation time as PBMT.

Table 3 shows some examples in Japanese-English setting. In the first and second examples, the proposed method achieves better translation by exploiting multiple candidates. However, the last example demonstrates a weakness in our method mainly caused by the low confidence in preordering decision, e.g., parallel phrases. In this case, the language model of "image information" is stronger than that of "information and images" and this difference of scores exceeds the preordering confidence. As a result, the decoder fails to choose correct preordering. Avoiding these kinds of problems should be one of our future work.

5 Conclusion

In this paper, we proposed a new phrase-based decoding method using multiple preordering candidates. Our method outperforms previous PBMT systems without using any decoding-time reordering.

In this study, we used only one preordering method. Our method can be easily extended to any preordering methods along as they can emit N-best preordering candidates with optional confidence scores. In addition, the proposed method further may be able to combine multiple preordering candidates from different preordering methods by introducing multiple path scores for each preordering methods. In future work, we will plan to evaluate the effect of using or combining other preordering methods for the proposed method.

Abstract

Community Question Answering (cQA) forums have become a popular medium for soliciting answers to specific user questions from experts and experienced users in a given topic. However, for a given question, users sometimes have to sift through a large number of low-quality or irrelevant answers to find out the answer which satisfies their information need. To alleviate this, the problem of Answer Quality Prediction (AQP) aims to predict the quality of an answer posted in response to a forum question. Current AQP systems either learn models using - a) various hand-crafted features (HCF) or b) Deep Learning (DL) techniques which automatically learn the feature representations.

In this paper, we propose a novel approach for AQP known as - *"Deep Feature Fusion Network (DFFN)"* which combines the advantages of both hand-crafted features and deep learning based systems. Given a question-answer pair along with its metadata, a DFFN architecture independently - a) learns features using the Deep Neural Network (DNN) and b) computes hand-crafted features leveraging various external resources and then *combines them* using a fully connected neural network trained to predict the quality of the given answer. DFFN is an end-end differentiable model and trained as a single system. We propose two different DFFN architectures which vary mainly in the way they model the input question/answer pair - a) DFFN-CNN which uses a Convolutional Neural Network (CNN) and b) DFFN-BLNA which uses a Bi-directional LSTM with Neural Attention (BLNA). Both these proposed variants of DFFN (DFFN-CNN and DFFN-BLNA) achieve *state-of-the-art performance* on the standard SemEval-2015 and SemEval-2016 benchmark datasets and outperforms baseline approaches which individually employ either HCF or DL based techniques alone.

1 Introduction

Community Question Answering (cQA) forums (such as *Yahoo! Answers*, *Stack Overflow*, *etc.*) have become a popular medium for many internet users to get precise answers or opinions to their questions from experts or other experienced users in the topic. Such forums are usually open, allowing any user to respond to a given question. As a result, for a question posed by the user, the quality of response often varies a lot - ranging from highly precise and detailed answers given by authentic users to highly imprecise or non-comprehensible one-word or single line answers posted by spammy and other non-serious users. This severely hampers the effectiveness of cQA forums since users will have to sift through a large number of irrelevant posts to find the answer which satisfies their information need. To alleviate this problem, cQA forums often include feedback mechanisms such as votes, ratings *etc.* for evaluating the quality of answers and users. Such user feedback could also be used as signals for ranking multiple answers for given a question. However, popularity based signals (votes, ratings) are often prone to spam

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1429–1440, Osaka, Japan, December 11-17 2016.

due to users who may artificially inflate their ratings, votes with the help of other users whom they know. To overcome the above problems, recent approaches (Tran et al., 2015; Hou et al., 2015; Nicosia et al., 2015; Yi et al., 2015; Wang et al., 2009; Zhou et al., 2015; Severyn and Moschitti, 2015; Yu et al., 2014; Filice et al., 2016; Barrón-Cedeño et al., 2016) have focused on automatically ranking answers for a given question based on their quality.

The problem of answer quality prediction is defined as follows: Given a question Q and its set of community answers $C = \{A_1, A_2, \ldots, A_n\}$, rate the answers corresponding to their quality. The cQA tasks of SemEval-2015 (Task A) (Nakov et al., 2015) and SemEval-2016 (Task A) (Nakov et al., 2016) provide a universal benchmark dataset for evaluating research on this problem. In SemEval-2015, the answers are to be rated as {*good,potentially useful or bad*} and in SemEval-2016, the answers are to be rated as either {*good or bad*}.

Recent approaches for answer quality prediction can be categorized into - a) Hand-crafted Feature (HCF) based approaches (Tran et al., 2015; Hou et al., 2015; Nicosia et al., 2015; Yi et al., 2015; Wang et al., 2009; Filice et al., 2016; Barrón-Cedeño et al., 2016) or b) Deep Learning (DL) based approaches (Zhou et al., 2015; Severyn and Moschitti, 2015; Tymoshenko et al., 2016; Yu et al., 2014). HCF based approaches mainly rely on capturing various semantic and syntactic similarities between the question and answer and behavior of users using manual feature engineering. For computing these similarities, recent approaches have also leveraged external knowledge resources such as WordNet and other text corpora. DL based approaches, on the other hand, automatically learn the feature representations while learning the target quality scoring function. As a result, they are language-agnostic and don't require feature engineering or any external resources except for a large training corpus.

In this paper, we propose "Deep Feature Fusion Network (DFFN)" - a novel approach which combines HCF and DL based approaches. The DFFN architecture is designed as a Deep Neural Network (DNN) which takes the question, answer and their metadata as inputs and predicts the quality of answer as output. In the above architecture, HCF is also introduced separately as inputs into the overall DNN. We propose two different architectures of DFFN which mainly differ in the way they model the input question, answer pair - a) Convolutional Neural Network Model (DFFN-CNN) which employs a Convolutional Neural Network (CNN) to model the input question/answer pair and b) Bi-directional Long Short-Term Memory (LSTM) Network Model with Neural Attention (DFFN-BLNA) which uses a Bi-Directional LSTM Model with Neural Attention (BLNA) to model the question/answer pair. DFFN effectively leverages the advantage of both HCF and DL based approaches *i.e.* ability to - a) encode similarities between question-answer pair using external knowledge resources such as Wikipedia, Anchor Text information from Google Cross-Lingual Dictionary (GCD) and Clickthrough data and b) automatically learning features relevant to the target function. During training phase, given a question, answer pair along with its metadata and HCF, DFFN automatically learns deep features which are relevant for the target task using CNN or BLNA. Later, DFFN combines these deep features with HCF, which are computed using various external resources, for predicting the quality rating of the answer. The two proposed architectures of DFFN achieve *state-of-the-art performance* on the standard SemEval-2015 and SemEval-2016 benchmark datasets and also perform better than baseline approaches which individually employ either HCF or DL based techniques. In this context, the following are our main contributions:

- We propose a novel approach to combine resource-based hand-crafted and automatically learnt DL features for the answer quality prediction task.
- We also propose two different architectures of combining HCF and DL based features using CNNs and BLNA.
- Using the above novel architectures, we achieve state-of-the-art performance on SemEval 2015 and SemEval 2016 cQA answer quality prediction tasks.

The rest of the paper is organized as follows: Section 2 discusses the related work in this area. Section 3 presents our contribution DFFN in detail. Section 4 discusses our experimental set-up. Section 5 presents our results and finally Section 6 concludes the paper.

2 Related Work

AQP in cQA forums has been researched a lot in the IR community. (Jeon et al., 2006) employ non-textual features such as clicks, print counts, copy counts *etc.* to predict the quality of an answer in a cQA forum. (Liu et al., 2008) investigate a slightly related problem i.e. predicting whether an asker would be satisfied with the answers provided so far to the given question. (Burel et al., 2012) have used a combination of content, user and thread related features for predicting answer quality. (Dalip et al., 2013) propose a learning to rank approach for AQP using eight different groups of features. (Yao et al., 2013; Wang and Manning, 2010) used CRF models with extracted features for AQP. (Li et al., 2015) studied the various factors such as shorter length, authors reputation which lead to a high answer quality rating as rated by peers.

More recently, (Tran et al., 2015) made use of topic models, word vectors and other hand crafted rules to train a SVM classifier for AQP. (Hou et al., 2015) made use of statistics like avg. word length of a sentence (question or answer), sentence length with other hand-crafted features to train an ensemble of classifiers for AQP. (Wang et al., 2009) use Bayesian logistic regression and link prediction models for AQP. (Filice et al., 2016) used kernel based features for AQP.

(Wang and Nyberg, 2015) apply a combination of stacked Bi-Directional LSTMs and keyword matching. (Nicosia et al., 2015) have used lexical similarity between word n-grams, tree kernels, word-embeddings and other hand crafted features for AQP. (Severyn and Moschitti, 2015) used a CNN to automatically learn features for matching short text pairs. (Zhou et al., 2015) used a 2-dimensional CNN to represent a question-answer pair and ranked the representations using a RNN.

Our current work resembles the work of (Wu et al., 2016), in the computer vision community, who employ the idea of combining hand-crafted features and deep features for person re-identification task. However, in our case, the idea of using hand-crafted features is motivated by the availability of large similarity resources such as Wikipedia text, Anchor text of Google Cross-Lingual Dictionary and Click-through data which could be leveraged to infer richer syntactic and semantic similarities between textual elements.

3 Deep Feature Fusion Network (DFFN)

The central idea in a DFFN is to design a Deep Neural Network (DNN) which takes the question (Q), answer (A) and its metadata (MD) as inputs and predicts the quality of an answer as output. DFFN also computes various HCF between Q, A and MD using external resources such as Wikipedia text and Anchor text of Google Cross-Lingual Dictionary (GCD) and Click-through data. These HCFs are also included into the overall DNN as inputs. We propose two different architectures of DFFN depending on the way in which the Q, A pairs are modeled in a NN - a) DFFN-CNN which employs a Convolutional Neural Network (CNN) to model the input question-answer pair and b) DFFN-BLNA which uses a Bi-Directional LSTM Model with Neural Attention (BLNA) to model the question-answer pair. Figures 1,2

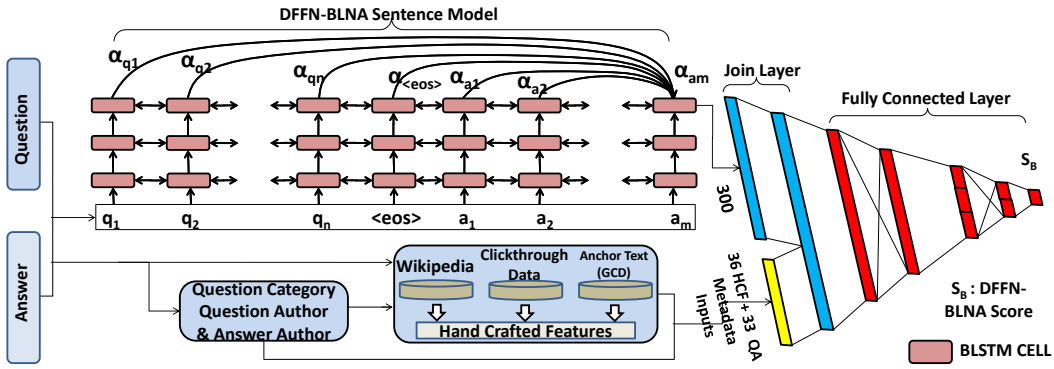

Figure 2: System Architecture of Deep Feature Fusion Network - Bi-directional Long-Short Term Memory Network with Neural Attention (DFFN-BLNA)

depict the architectures of the two proposed variants. Both these variants are end-end differentiable and hence the training is performed end-end.

DFFN-CNN comprises of two parallel CNN based sentence models for the question and answer while DFFN-BLNA has a sequential Bi-directional Long Short-Term Memory Network model with Neural Attention for the question and answer together. Let CNN-FR and BLNA-FR be the deep feature representations generated by using CNN and BLNA respectively. CNN-FR and BLNA-FR are individually joined with HC-FR and metadata and are given as input to a Fully Connected Neural Network (FCNN) which predicts the score representing answer quality. We will now discuss DFFN in detail.

3.1 Sentence Model

DFFN has a sentence model which projects a sentence (question/answer) into the semantic space and learns a good intermediate representation of the given question/answer. The different architectures DFFN-CNN and DFFN-BLNA vary in the way they perform sentence modeling. Here is a brief description of their sentence models:

3.1.1 DFFN - Convolutional Neural Network (DFFN-CNN)

In this architecture, the sentence model is a deep Convolutional Neural Network (CNN). CNN extract features independent of the position in the sentence to create (sub-)sentence representations. CNN consists of sentence matrix and multiple convolutional, pooling and non-linearity layers as in Figure 1 .

Sentence Matrix: The input to the sentence matrix is a vector of words from the sentence (question/answer) $s = [w_1, w_2, ...w_{|s|}]$. We build the sentence matrix by mapping each word w_i in the sentence to its corresponding word embedding in d dimensions. Word embeddings represent similar words by similar vectors and, thus, identify synonyms and other important context words.

We use GLoVE (Pennington et al., 2014) based embeddings of 300 dimensions to map the words in the question and answer. We limit the size of the sentence upto certain threshold. We ignore the words in the sentence after a certain threshold if the length of the sentence is greater than the threshold and pad zeros upto the threshold if the length of the sentence is less than the threshold. The sentence matrix is given as input to the convolutional layer.

Convolution: Convolution is an operation where the feature map (input sentence matrix) and the convolution filter mix together to form a transformed feature map. The convolutional layer extracts patterns i.e, discriminative word sequences that are common in the input train sentences. The convolutional layer is applied on the sentence matrix by convolving a filter with weights $F \in R^{h \times w}$ where h is the filter height and w is the filter width. A filter consisting of a layer of weights is applied to a small patch of sentence matrix to get a single unit as output. The filter is slided across the sentence matrix and the outputs of each patch are combined to get the resultant transformed feature map as the output.

Max Pooling: Max pooling extracts globally most relevant features through local convolution. Max pooling performs a type of non-linear down-sampling. It combines the information and reduce the size

of feature map. It partitions the output of the convolutional layer into small non-overlapping slices and independently operates on every slice by taking the maximum value in each slice as the value in the output of reduced size. We apply max pooling layer on the top of output given by the convolutional layer to extract crucial local features and form a reduced size feature map representation.

Non-Linearity: We use Randomized Leaky Rectified Linear unit (RReLU) (Xu et al., 2015) to learn non-linear decision boundaries. It is a randomized version of leaky ReLU (Xu et al., 2015). RReLU is applied to every element of the output of the max pool layer, thus the resultant feature map will be of the same dimension as the input feature map.The sentence matrix is convolved through multiple convolution, pooling and non-linearity layers to get the feature representations of the question/answer. Using this variation of sentence model, we get the individual feature representations (270 dimensions) of the question and answer. These are concatenated to produce a combined feature representation (540 dimensions).

3.1.2 DFFN - Bi-directional LSTMs with Neural Attention (DFFN-BLNA)

Although, CNN extracts similar patterns on all the patches of the sentence matrix but they do not capture sequential relationships that exists between question-answer pair. LSTMs are memory models which overcome this limitation by feeding the hidden layers from the previous step as an additional input into the next step. In DFFN-BLNA architecture as shown in Figure 2, in stead of a CNN, we use a Bi-directional Long-Short Term Memory (BLSTM) Network with Neural Attention (Bahdanau et al., 2014), for modeling the sentences of question and answer. A question-answer sequence is given as input to BLNA where the sequence is passed through a Bi-directional LSTM Network and the outputs at each step are attended with Neural Attention mechanism. Here, we describe the architecture in more detail.

Long-Short Term Memory (LSTMs) (Hochreiter and Schmidhuber, 1997) are variants of Recurrent Neural Network (RNN) (Werbos, 1990; Rumelhart et al., 1988) architectures which - a) overcome the vanishing and exploding gradients problem of conventional RNNs and b) have the ability to capture long-term dependencies between symbols of a sequence using their gating mechanism which controls information flow. LSTMs only utilize previous context without making use of future context. To overcome this issue, Bidirectional LSTMs (BLSTMs) learn the sequential patterns from both forward and backward directions and then combine information from both directions. The drawback of LSTMs or BLSTMs is that we represent a very long sentence as a single vector which is the output of the last time step. However, using BLSTM with Neural Attention (NA) mechanism, we represent the sequence of vectors as a combined weighted representation vector by selectively attending to the past outputs.

We map the words of the question and answer to their corresponding vector representations using GLoVE embeddings. <eos> is a special symbol used to separate question and answer. A question-answer sequence is generated by concatenating question sentence, <eos> and answer sentence. A BLSTM has two LSTMs that read the QA sequence in both forward and backward directions. At each time step, the output vector is generated by combining the output vectors of two LSTMs, thereby allowing it to consider the contextual information across the entire question-answer sequence i.e. both the question and answer sentence. The neural attention mechanism represents sequence of vectors as a combined weighted representation vector by selectively attending to the past outputs. Thus at each time step, DFFN-BLNA considers the whole context of question and answer and adaptively attends to the subset of past outputs of the BLSTM Network which contributes in better modeling the similarity between question and answer.

Let $Q = [q_1, q_2, ..., q_n]$ be a question of length n and $A = [a_1, a_2, ..., a_m]$ be an answer of length m, then total number of steps in BLSTM will be n+m+1 (additional step is for <eos> after the question). Let $Y = [y_1, y_2, ...y_n, y_{<eos>}, y_{n+2}, y_{n+3}.....y_{n+m+1}]$ be output of BLSTM Network without attention. The combined weighted vector representation c generated using attention mechanism is computed as

$$c = \sum_{i=1}^{n} \alpha_i y_i + (\alpha_{n+1} y_{n+1}) + \sum_{i=n+2}^{m} \alpha_i y_i \tag{1}$$

and $a(y_i, y_k)$ is a latent alignment model which outputs higher score if y_i is useful in capturing the

similarity between question answer pair. where

$$\alpha_i = \frac{\exp(a(y_i, y_{n+m+1}))}{\sum_{j=1}^{n+m+1} \exp(a(y_j, y_{n+m+1}))} \tag{2}$$

Using this variation of sentence model, we generate a combined feature representation of question and answer (300 dimensions). In each of the above architectures, the feature representation derived from the sentence model is combined with the hand crafted features and metadata and is given as input to the Fully Connected Neural Network. We describe these in detail in the following subsections.

3.2 Hand Crafted Features (HCF)

The question and answer text usually consists of several Named Entities (NEs) and concepts along with their various variants. For example, the cricketer *Sachin Tendulkar* could be referred to as *Sachin*, *Tendulkar*, *The Little Master etc.* Such variants are hard to capture using CNN or BLNA based features alone. Hence, we make use of resources such as Wikipedia text, Anchor text of Google Cross-Lingual Dictionary (GCD), Named Entity Recognizers (NER) and Clickthrough data to come up with hand-crafted features which can capture such rich similarities. We also observe that user behavior and specific patterns on metadata and question-answer text are useful. We use these features to compute individual similarity scores between question and answer and combine these scores as Hand Crafted Features to give them as input to the Fully Connected Neural Network. We describe the details of the features below:

3.2.1 Wikipedia Based Features

In this section, we describe the similarity features which are computed by using Wikipedia as a resource.

TagMe Similarity: We extract TagMe concepts from the question and answer by mapping the question and answer to their corresponding Wikipedia page titles using TagMe (Ferragina and Scaiella, 2010). TagMe identifies meaningful substrings in an unstructured text and links them to their relevant wikipedia pages. We compute the similarity between two TagMe concepts using WikiMiner (Milne and Witten, 2013). WikiMiner computes similarity between two wikipedia pages based on the number of common inlinks and outlinks between them. Similarity between question and answer, represented by TagMe concepts, using WikiMiner is computed as the mean average of the similarity between pairs of TagMe concepts (one each from the question and the answer) as in Equation 3

$$qa_{sim} = \frac{\sum_{i=1}^{n} \sum_{j=1}^{m} sim(c_i, c_j)}{nm} \tag{3}$$

where qa_{sim} is the similarity between question and answer based on TagMe Similarity n, m are the number of TagMe concepts in the question and answer respectively, c_i, c_j are the i^{th} and j^{th} TagMe concepts in the question and answer respectively, $sim(c_i, c_j)$ is the similarity between c_i and c_j calculated using WikiMiner.

Named Entities Similarity: We extract Named Entities from the question and answer, using Stanford CoreNLP NER Tagger (Toutanova et al., 2003) and compute the similarity between two Named Entities using a Google Cross-Lingual Dictionary(GCD) based similarity feature. The GCD based similarity between two Named Entities is computed as the ratio of number of wikipedia documents in which these two named entities co-occur in the top k retrieved documents when queried on GCD. Similarity between question and answer represented by Named Entities is calculated as in Equation 3 where we use Named Entities instead of TagMe concepts and GCD based similarity feature instead of WikiMiner to calculate the similarity between two Named Entities.

3.2.2 AnchorText based Features:

Google Cross-Lingual Dictionary (GCD) (Spitkovsky and Chang, 2012) is a string to concept mapping on the vast link structure of the web, created using anchor text from various pages across the web. A concept is an individual Wikipedia document. The text strings are the anchor texts that refer to these concepts. Thus, each anchor text string represents a concept.

We extract common and proper nouns from the question and answer using Stanford CoreNLP POS Tagger (Toutanova et al., 2003) and query them individually on GCD anchor texts to get top ten unique concepts related to question and answer. We calculate the similarity between two GCD concepts using WikiMiner. The similarity between question and answer represented by GCD concepts is calculated as in Equation 3 where we use GCD concepts instead of TagMe concepts.

3.2.3 Clickthrough Features

Sent2Vec Similarity: Sent2Vec maps a pair of short texts to a pair of feature vectors in a continuous, low-dimensional space. Sent2Vec performs the mapping using the Deep Structured Semantic Model (DSSM) built using Clickthrough data (Huang et al., 2013), or the DSSM with convolutional-pooling structure (CDSSM) (Gao et al., 2014; Shen et al., 2014).

We map the question and answer to vectors using both DSSM and CDSSM. We compute the Sent2Vec DSSM similarity between the question and answer as the cosine similarity between the vectors of question and answer obtained by using Sent2Vec performing the mapping of vectors using DSSM. Similarly by using CDSSM instead of DSSM we also compute the Sent2Vec CDSSM similarity between the question and answer.

Paragraph2vec Similarity: Paragraph2Vec(Le and Mikolov, 2014) allows to model vectors for text of any arbitrary length. It learns continuous distributed vector representations for pieces of texts. We train the para2vec model on the training data of the particular tasks only (SemEval'15 and SemEval'16) by treating each question-answer pair as a single document. We train only on the good question-answer pairs from the training data. A good question-answer pair is a pair in which answer is rated as a "good" answer for that question. We map the question and answer to vectors using para2vec and compute the similarity between the question and answer as the cosine similarity between their para2vec vectors.

3.2.4 Metadata Based Features

Author Reputation Score: We observed that the reputation of an answer author, within a forum plays a key role in determining the quality of answer. We capture this through a author reputation feature. We have two reputation features namely Good Reputation and Bad Reputation. Good reputation of an author is computed as the ratio of the number of good answers given by that author to the maximum number of good answers given by any individual author in the entire forum. Similarly, by using the number of bad answers instead of good answers, we compute a score for the bad reputation of an author. In addition, we also compute Good and Bad reputation scores of an author across each question category.

Is Answer Seeker?: We have a boolean feature to represent whether the answer (comment) is written by the person who has asked the question.

Authors' Response Pattern: We compute features based on whether the question author has commented before or after the present answer and if that comment by the question author is a question. Usually, the question author posts comments/questions below an answer if one is not satisfied with the current answer. Similarly we compute features based on whether the answer author has commented before or after the present answer and if that comment by the answer author is a question. Usually, the answer author posts further questions or comments below ones answer to seek additional information regarding the question or explain his answer more briefly. These features capture the behavior.

Miscellaneous: Besides, we extract and add features related to - a) statistics of each question category (number of good, potential and bad answers in that category) b) position of the answer. c) presence of URL, e-mail in the answer d) presence of question marks, exclamation marks in the answer e) boolean features for the presence of various emoticons such as happy (eg: ":)", ":D"), sad (eg: ":(" , ":'(") in the answer. We obtain the similarity scores and together call them as Hand-crafted features (36 dimensions). We join them as a vector and give them as input to Fully Connected Neural Network along with Metadata as described below.

3.3 Metadata Information

We observe that category of the question plays an important role in answer quality prediction as it may be easy to write good answers for some categories and difficult for some. We encode question category,

SemEval 2015			SemEval 2016

question author and answer author using a logarithmic function and give them as input to the Fully Connected Neural Network.

3.4 Fully Connected Neural Network (FCNN)

The vector representations from the sentence model (540 dimensions from DFFN-CNN or 300 dimensions from DFFN-BLNA), the feature representations from HCF (36 dimensions) and direct inputs from Metadata (33 dimensions) are combined to get a single feature vector of 609 dimensions (DFFN-CNN) or 369 dimensions (DFFN-BLNA). This vector is given as input to FCNN consisting of fully connected layers. These layers model various interactions between the features present in the vector and finally output a score predicting the answer quality.

3.5 Training

The parameters of the network are learnt with an objective to maximize the accuracy of prediction given the target categories. For example, in SemEval-2015, the target categories were $\{good, potentially\ useful, bad\}$ and $\{good, bad\}$ in SemEval-2016 . For training, we used the training data provided in the SemEval 2015 (Nakov et al., 2015) and 2016 (Nakov et al., 2016) tasks which consists of question, answer, metadata along with their ideal quality rating. We tuned the DFFN parameters on the corresponding development sets of SemEval 2015 and 2016. We used adagrad (Duchi et al., 2011) and stochastic gradient descent (SGD) for optimization in DFFN-CNN and DFFN-BLNA respectively.

Given an input (p, t) where p is the predicted answer quality score by DFFN-CNN and t is the true label depicting answer quality, we used SmoothL1 loss criterions which is computed as:

$$loss_{smoothl1}(p,t) = \frac{1}{n} \times \begin{cases} 0.5 \times (p-t)^2, & \text{if } |p-t| < 1 \\ |p-t| - 0.5, & \text{if } |p-t| \geq 1 \end{cases}$$

t is 1 for good question-answer pair (answer labeled as *good* for that question) and -1 for bad question answer pair. (answer labeled as *bad* for that question). The model is trained by minimizing the loss function in a batch of size n. For DFFN-BLNA we used Mean Squared Error (MSE) as loss criterion.

4 Experimental Setup

We use the SemEval 2016 (Nakov et al., 2016) and SemEval 2015 (Nakov et al., 2015) datasets for our experiments as they exactly match our problem description. We use standard evaluation metrics - Mean Average Precision (MAP), F1 score and Accuracy. We compare our approach with the top two best performing systems from SemEval 2015 - JAIST (Tran et al., 2015) and HITSZ-ICRC (Hou et al., 2015) both of which use HCF based models. We also compare with ICRC-HIT (Zhou et al., 2015) as it uses a purely DL based model. Similarly, for SemEval 2016, we compare with their corresponding top two

Q: Hi friends, I have State Bank of India Debit card. I try to with draw the money to the atm. It's not accepted. Anybody know which bank atm will accept SBI debit card for withdraw the money ? **A:** dear all banks here accept all international (visa/master/diner club/american express) ATM's cards unless you activate international withdrawal from your mother bank in your mother country.	G	G	B	G	B	***TagMe*** links *visa, master, diner club, american express* to their wiki pages and finds out that they all belong to debit/atm/credit card class.
Q: Can anyone plz help me this problem? I need to send a mobile phone to (Jaipur) India. I contacted DHL but they are charging very high. Is there any other company like DHL? Plz specify... **A:** You can send by post office for cheap price (compare to Courier service)	G	G	B	P	P	***GCD*** similarity feature captures that *post office, DHL, courier* are linked to similar pages when they occur as anchor texts.
Q: What softwares are you using for downloading movies? I'm using limewire and utorrent. How about you? **A:** im using azureus client..limewire sucks (lol)	G	G	B	G	B	***TagMe*** links *azureus, limewire, utorrent* to their wiki pages and finds out that they all belong to movie torrent software class.
Q: I saw a little girl running by the streets , and she had a cat attached to her .....is that normal in this country? **A:** I saw a little girl running by the streets , and she had a parent attached to her .....is that normal in this country?	B	P	P	B	B	***Author Reputation*** gives neutral sim. score; author had written very few answers and had almost equal number of Good and Bad answers. ***Question-Authors' Response Pattern*** gives neutral;author has commented before and after this answer. ***Wiki based*** features gave high scores as question and answer are exactly same except for one word.

Table 2: Qualitative Analysis of DFFN-CNN Results with respect to other baseline approaches. **Note: G: Good, B: Bad, P: Potential; DC: DFFN-CNN, JA: JAIST, HI:HITSZ-ICRC IH:ICRC-HIT**

best performing systems - Kelp (Filice et al., 2016) and ConvKN (Barrón-Cedeño et al., 2016) both of which use kernel-based features.

5 Results and Discussion

Table 1 shows the overall results of DFFN-CNN and DFFN-BLNA on SemEval 2015 and SemEval 2016 datasets. Both the architectures perform better than the top systems across all the metrics. The improvement is higher in SemEval 2015 although the task is harder due to lesser training data and more granularity in target labels. We also observe that DFFN-CNN and DFFN-BLNA perform better than CNN (without HCF) or BLNA (without HCF). Also, the model outperforms hand-crafted feature based model (DFFN with HCF but without CNN or BLNA). Overall, the best performing model was found to be DFFN-BLNA as it more closely models and encodes the semantic dependencies in the QA pair. In Table 2, we present the qualitative analysis of DFFN-CNN architecture results with the best performing baselines on SemEval 2015 dataset. In Table 3, we present the qualitative analysis of DFFN-BLNA architecture results with the best performing baselines on SemEval 2016 dataset. Finally, in Table 4, we compare the performance of DFFN-CNN and DFFN-BLNA using some results from the above datasets.

6 Conclusion

We present a novel approach *"Deep Feature Fusion Networks (DFFN)"*, an end-to-end differentiable approach which combines HCF features into CNN and BLNA models for improving answer quality prediction. DFFN enriches the feature representations learnt through CNN and BLNA by introducing more similarity features computed using external resources such as Wikipedia text, Anchor text of Google Cross-Lingual Dictionary (GCD) and Clickthrough Data. As a result, we show that DFFN achieves *state-of-the-art performance* on the standard SemEval-2015 and SemEval-2016 benchmark datasets and shows better performance than baseline approaches which individually employ either HCF or DL based techniques.

Question and Answer	TL	DB	KE	CK	Comment
Q: I am very interested to know if there are any expatriate tennis clubs in Doha that anyone can join? I am at a decent standard and would like to play once / twice per week so joining a club would be ideal. If anyone would like a game then please drop me an e-mail and we can arrange something. **A:** We normally play tennis at Khalifa Tennis at least twice a week (Tuesday and Friday); but I would prefer to play for at least 3 times a week or even more. So; if you are interested; I could introduce you to some players so that we could play together.	G	G	B	B	DFFN-BLNA matches with keywords *"tennis","interested,"*. Also due to right intent/response matching.
Q: Has anyone in QL bought any laptop from Jarir bookstore on loan through Qatar Finance company? One more thing;what do you guys think about HP laptops? As i've never bought anything on loan through a bank or a finance company in Qatar **A:** Jarir has an arrangements with QFC that let the customers to purchase laptops and pay back in installments. but their formalities r a bit complex; a lot of documentations required; etc..	G	G	B	G	DFFN-BLNA identifies *Finance Company, Loan* are related to *installments, formalities* . NE *Jarir* matched in both Q&A
Q: My visa is issued and the agency told me it will be going to authenticate it in the embassy here in the philippines how long is the process??? after my visa is stamp what will be the next process?? **A:** If you are going through an agency in the Philippines like what happened to me; it will take at least 1 month of waiting. But in Doha; based on the processing of our PRO in the office; it only takes a week or less. Even for visa renewal; in one week i can have the original I.D.	G	G	G	B	*visa, agency, month, week* co-occur in wiki pages and anchor text of web pages. GCD identified them as similar.
Q: Qtel's settings for mobile internet? I cant seem to access the internet through my Iphone. I've called 111 and they gave me the settings which would be: General - Networks - Cellular Data Network - APN: gprs.qtel Still no signs of getting the internet going. Anyone else have this problem with Iphone? I'm on Shary value pack btw if that info helps. **A:** QTEL is difficult but Vodafone has it's settings on their website. It helped me on my iPhone w/ Vodafone sim.	B	G	B	G	DFFN-BLNA predicts incorrectly due to multiple NE *(Qtel, Iphone)* perfect matches.

Table 3: Qualitative Analysis of DFFN-BLNA Results with respect to other baseline approaches. **Note: G: Good, B: Bad; DB: DFFN-BLNA, KE: Kelp, CK: ConvKN**

Question and Answer	TL	DB	DC	Comment
Q: Hi; my wife was on a visit visa; today; her residency visa was issued; so i went to immigration and paid 500 so there is no need to leave the country and enter again on the residency visa. she has done her medical before for the visit visa extension; do we need to do the medical again for the residency visa? thanks **A:** Hi can u pls. help me ? I just want to know what is the requirements for the family visit visa here in Qatar i want to apply family visit visa for my wife and to my daughter. and also is it true that i can extend the visa up to 6 months? Is there any salary bracket requirements for this visa? I hope u can help me thanks	B	B	G	DFFN-CNN merely compares extent of similarity since keywords like *visa* match while DFFN-BLNA identifies question intent expressed in the sentence.
Q: What is best mall in Doha to buy good furniture? Where are best furniture stores and showrooms. **A:** There are several; my Favorite is Pan Emirates @ Salwa Road.	G	G	B	DFFN-BLNA identified intent of phrase *"There are several"* while DFFN-CNN does not find more explicit matches.
Q: I would like to get some opinion about online job recruitment sites like bayt; gulftalent etc.. Do they really consider the CV's send ? Has anybody got jobs via these online sites ? **A:** They look for key words to match against a given criteria. They have no means of assessing an individual or his/her real skills.	G	B	G	DFFN-CNN finds related keywords in the context such as *"job", "skills", "assessing", "criteria"*.

Table 4: Qualitative Comparison of DFFN-CNN and DFFN-BLNA Results. **Note: G: Good, B: Bad; DB: DFFN-BLNA, DC: DFFN-CNN**

Abstract

Identifying events of a specific type is a challenging task as events in texts are described in numerous and diverse ways. Aiming to resolve high complexities of event descriptions, previous work (Huang and Riloff, 2013) proposes multi-faceted event recognition and a bootstrapping method to automatically acquire both event facet phrases and event expressions from unannotated texts. However, to ensure high quality of learned phrases, this method is constrained to only learn phrases that match certain syntactic structures. In this paper, we propose a bilingual structure projection algorithm that explores linguistic divergences between two languages (Chinese and English) and mines new phrases with new syntactic structures, which have been ignored in the previous work. Experiments show that our approach can successfully find novel event phrases and structures, e.g., phrases headed by nouns. Furthermore, the newly mined phrases are capable of recognizing additional event descriptions and increasing the recall of event recognition.

1 Introduction

Event recognition aims to identify documents that describe a specific type of event. Accurate event recognition is challenging due to ambiguities of event keywords. In the previous work, Huang and Riloff (2013) (hereafter H&R) proposed multi-faceted event recognition method that uses event expressions as well as event defining characteristics (aka "event facets", such as "agents" and "purpose") to achieve high accuracy in identifying civil unrest events. They also presented a bootstrapping solution that can learn event expressions and event facet phrases from unannotated texts. However, to achieve high quality phrases, strict syntactic constraints have been enforced and their bootstrapping algorithm can only learn two particular types of V-O (Verb-Object) Structure for both event expressions and facet phrases. Obviously, diverse forms of other verb phrases and non-verb phrases exist to describe events and are ignored by the proposed algorithm. For instance, a verb phrase where two verbs are connected with a particular dependency relation "xcomp"[1], (e.g., "came out to demonstrate") is one of these structures. Civil unrest events can also be invoked by some noun structure phrases, such as just a noun word phrase (e.g., "sit-ins") or phrases starting with a noun (e.g., "disobedience of order"), even a passive form phrase structure like "rallies held (in)".

In order to address this issue, we propose a simple yet effective bilingual structure projection method that explores syntactic divergences (Georgi et al., 2012) between two languages and mines new syntactic structures for event expressions and event facet phrases effectively using parallel corpora. This is inspired by many recent cross-lingual research that utilize the second language to provide a different view (Balcan and Blum, 2005; Burkett et al., 2010; Ganchev et al., 2012) and complementary cues (Che et al., 2013; Wang et al., 2013) in improving Natural language Processing (NLP) tasks for the target language, analogous to co-training (Chen and Ji, 2009; Wan, 2009; Hajmohammadi et al., 2015) but between two different languages. In order to learn new event phrases and their syntactic structures, we map phrases[2] back and

*Corresponding author

[1]"xcomp" is a dependency relation between a verb or an adjective and its open clausal complement in a dependency tree. In sentence "Workers came out to demonstrate", the relation between verb "came" and verb "demonstrate" is "xcomp".

[2]We start with initial phrases learned by H&R, thanks to the authors for sharing the learned phrases and evaluation data.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1441–1450, Osaka, Japan, December 11-17 2016.

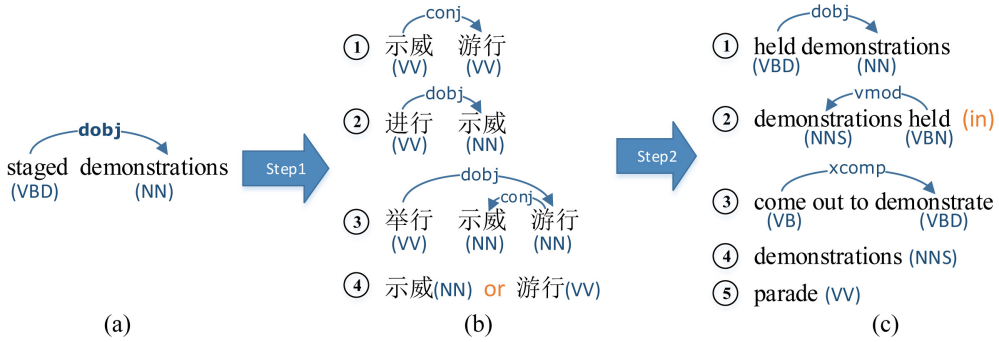

Figure 1: The bilingual structure mapping procedure

forth multiple times between two languages using parallel corpora to make full use of these divergence information. We choose Chinese as the pivot language to learn English event phrases and event facet phrases. On the one hand, both Chinese and English share a common sentence structure SVO (Subject-Verb-Object) and other similar sentence composition. On the other hand, these two languages have many significant differences, e.g., an uninflected language (Chinese) vs. an inflected language (English). The commonalities enable bilingual projection while the language divergences stimulate occurrences of new phrases and new phrase structures. The input to our bilingual structure projection system are two English verb phrase lists, event phrases and purpose facet phrases which are learned by H&R's multi-faceted event recognition method. After each mapping step, new syntactic structures and new phrases are learned.

Figure 1 illustrates one iteration of bilingual structure mapping with examples. Given the English phrase "staged demonstrations" with the structure of "VBD<dobj>NN", English sentences containing this phrase in the parallel corpora are identified. Then various Chinese phrases (Figure 1(b)) are generated when mapping the English phrase to its Chinese correspondence based on word alignments of the parallel sentences. Interestingly, a multi-word verb phrase in English can be expressed with only one noun (e.g., "示威"/demonstration) or a verb (e.g., "游行"/parade) in Chinese. Furthermore, we have observed that Chinese tends to use a conjunction of two verbs that have roughly the same meaning when referring to one single event, e.g., "示威 游行" in Figure 1(b). More examples are given in Figure 1. When we map these already diversified Chinese phrases back to English, new phrases with richer syntactic structures (Figure 1(c)) are generated, including some interesting noun structure phrases and one single-word phrase. To fully exploit language divergences, the bilingual structure projection run back and forth between the two languages and continues for several iterations.

Experiment results show that our approach can successfully find hundreds of new English phrasal structures, e.g., structures headed by nouns, and learn thousands of new event expression and event facet phrases. Furthermore, using the same evaluation data and evaluation method as in H&R, the newly mined phrases are capable of recognizing additional event descriptions, and significantly increasing the recall of event recognition by 8.2 points and the overall F_1-score by 3.5 points.

This paper is structured as follows: Section 2 describes the H&R's multi-faceted event recognition approach. Section 3 details our bilingual structure projection method and some heuristic rules used in our method. Section 4 describes our experimental design and evaluation results. Then section 5 discusses a variety of new phrases and structures generated by our approach. Section 6 introduces the related work of bilingual methods for various NLP tasks. Last, section 7 summarizes the bilingual structure method and expounds our future work.

2 Background

Accurately identifying documents that describe a specific type of event is a challenging task because events can be mentioned in various complex contexts. Using event keywords alone are barely reliable. For example, while the words "strike", "rally" and "riot" are commonly used to describe civil unrest events, they frequently refer to other events that are dramatically different from civil unrest events including "bowling strike", "rally car" and "imagination riot". In the previous work, Huang and Riloff

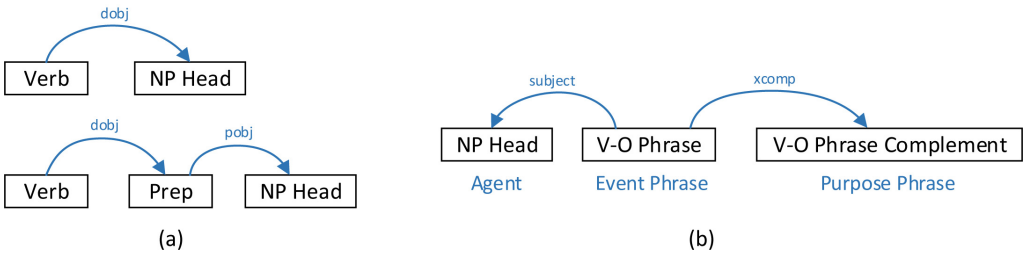

Figure 2: Syntactic constraints in H&R's method. (a) shows two pre-defined phrase structures, (b) is the sentence pattern in H&R's bootstrapping system

(2013) proposed the multi-faceted event recognition approach that uses both event expressions and event defining characteristics (called event facets) to accurately identify event occurrences. As described in the paper, agents and purpose are two types of event facets that are essential to distinguish many types of events. For instance, both natural disasters and military incidents can mention injuries and deaths as consequences, however, their agents are distinct. The agents of natural disasters have to be natural force while the agents of military incidents have to include military personnel. Similarly, purposes describe motivations of events and are extremely helpful to distinguish various types of events.

H&R also proposed a bootstrapping framework to learn event expressions and event facet dictionaries from the unannotated texts automatically requiring only minimal supervision with a few event keywords and a few seed phrases for each event facet. They observed that event facet phrases and event expressions tend to co-occur in event introductory sentences. Therefore, the bootstrapping system first learns event expressions from the sentences that contain both types of event facets and then learns more event facet phrases from the sentences that contain an event expression and a different type of event facet, in an iterative manner. Their multi-faceted event recognition with bootstrapped event dictionaries achieved high precision (88%) with a reasonable recall (71%) on identifying civil unrest events. However, to ensure high quality of learned phrases, strict syntactic constraints were enforced at both the phrasal and sentential level. Specifically, they only considered event expressions and purpose phrases as verb phrases in two types (Figure 2(a)), the first phrasal type is a verb followed by the head noun of its direct object and the second phrasal type is a verb with an attached prepositional phrase, while reasonably both event expressions and purpose phrases can exist in many other syntactic structures. Furthermore, within a sentence, specific dependency relations are required between both facet phrases and the main event expression (Figure 2(b)), the agent term has to be the syntactic subject of the event expression and the purpose phrase has to be a clausal complement of the event expression. Obviously, these harsh syntactic constraints pose limitations to the types of event phrases and event facet phrases that can be learned using this framework. Our research is committed to mine new phrases and phrase structures that go beyond these constraints leveraging divergences across two languages.

3 Learning Event Expressions via Bilingual Structure Projection

Our algorithm can iterate multiple times to learn new phrases in new syntactic structures automatically. In our experiments, we expand two types of phrases: event phrases (EP) and purpose phrases (PP) learned by H&R's method.

3.1 One Iteration of Bilingual Structure Projection

In our bilingual projection, we use structured phrases for mapping. Structured phrases[3] comprise both lexical and structural information. One iteration of the projection consists of two stages: mapping English event phrases to Chinese and projecting Chinese equivalents back to English. Next, we use an example as shown in Figure 2 to illustrate the projection process from English to Chinese.

[3]A structured phrase is defined as "start_node <relation1> in_node1 <relation2> in_node2 <realation3> ... <realtionN> end_node", where each node is a word, and the relation between two nodes is their dependency relation. Structured phrases capture both lexical and structural information for event expressions. Each structured phrase is essentially a path between two nodes in a dependency parse tree.

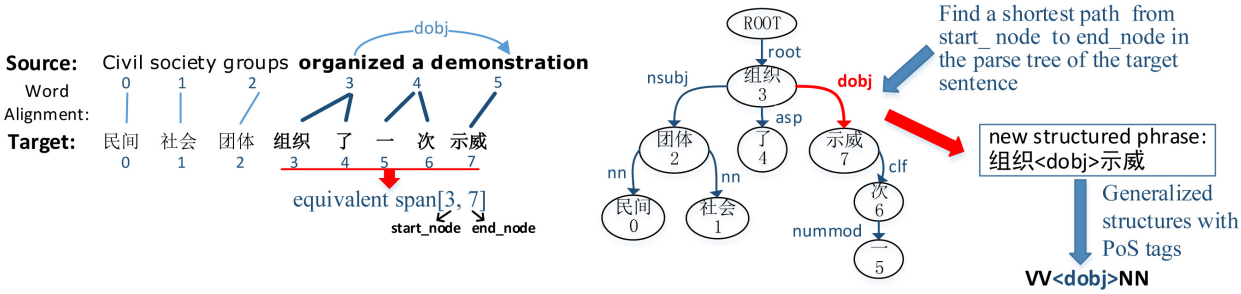

Figure 3: The illustration of projection from English to Chinese

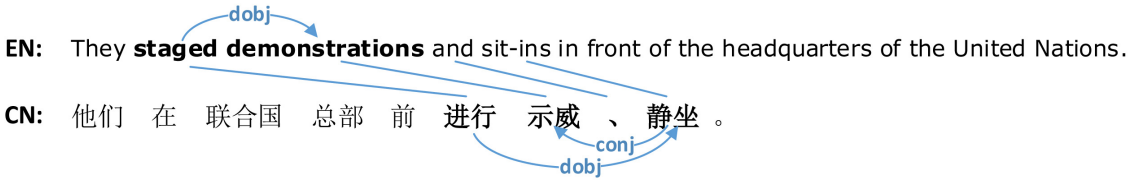

Figure 4: One verb with two coordinate objects

First, we identify an English event phrase on the source side of our parallel corpora, e.g., "organized a demonstration" in Figure 3, and extract the corresponding structured phrase "organized <dobj> demonstration" according to the dependency tree. Second, we detect phrase span of the translation equivalent for the extracted structured phrase by computing the aligned span on the target side via word alignments. In Figure 3, the equivalent span on the Chinese side is [3, 7]. In the third step, we take the leftmost and rightmost word of the translation equivalent span as the start_node and end_node. Then we further generate the structured phrase on the target side by finding the shortest path from the start_node to the end_node in the dependency tree, e.g., "组织 <dobj> 示威". For the in-depth analysis in Section 5, we use part-of-speech (PoS) tags to replace words in the found structured phrase to obtain a generalized structure, e.g., VV<dobj>NN in Figure 3. Then, mapping the new generated Chinese structured phrases ("组织 <dobj> 示威" in Figure 3 for example) back to English in the second stage of the bilingual projection following the similar procedure as described above. After the two-stages mapping, we obtain diversified English event phrases.

3.2 Phrase Decomposition

From our training data, we have learned many phrases with a conjunction. We find that most of them follow two structure patterns. The first is that one verb has two coordinate objects that express two related events. For example, the Chinese equivalent of English phrase "staged demonstrations" in Figure 4 is "进行 示威". However, there is not a direct dependency relation between "进行" and "示威" in the dependency tree. Instead, they are connected by a word "静坐" (sit-ins). Apparently, " staged demonstrations" (进行 示威) and "staged sit-ins" (进行 静坐) are two related events. The other pattern is an interesting phenomenon we have observed in our structure projection experiments. Chinese language tends to use a conjunction of two words that have roughly the same meaning when referring to an event while in English only one of the two coordinates is used to refer to the same event. For example, "捍卫 <dobj> 人权 <conj> 民主" (defend human rights and democracy) is a common expression in Chinese. However, in English, "defend human rights" is used to express the same meaning. To exploit this conjunction structure and linguistic divergence, we split such phrases into two separate phrases and keep both original phrases and decomposed phrases in the bilingual projection. For example, "进行 示威、静坐" is separated into two phrases "进行 示威" and "进行 静坐".

3.3 Phrase Filtering

In order to alleviate error propagation from word alignments and dependency trees, we apply phrase filtering. Particularly, we adopt three strategies to filter out inappropriate phrases.

Filtering by phrase frequencies: We keep phrases that occur at least t times and discard phrases occurring less than t times to minimize the impact of word alignment and dependency parse errors. Parameter t is tuned on the development set as we harvest new phrases.

Structural filtering: We use syntactic structure information to rule out incomplete phrases. For instance, Chinese phrase "进行 了" (carry on sth.) with a phrase structure "VV<asp>AS" is not a complete phrase since it does not have an object. Similarly, we filter out phrases ending with "AS", "P", "DEC", "LC", "PU", "CD", "MSP" [4].

Filtering by phrase specificity: We keep phrases that are closely related to our topic. Some phrases occur many times during the learning procedure for two reasons. The first reason is that they are closely related to our topic. The second is because they are high-frequency phrases in our corpora. We have observed that some highly frequent and general phrases in our corpora often occur in the learning process, mainly due to word alignment errors or dependency parsing errors. Aiming to learn phrases that are specific event expressions, we define a metric called phrase specificity to avoid bringing in corpora-wide frequent phrases. The metric for phrase *p* is defined as follows:

$$phrase\_specificity(p) = \frac{N_l}{N_c} * 100 \quad (1)$$

where N_l denotes the number of occurrences of phrase *p* in our projection procedure, N_c denotes the number of occurrences in our entire corpora. This metric measures how close a new phrase is related to the topic of events that we want to detect. If N_ls of two phrases are close to each other, but N_c of one phrase is bigger than that of the other, we deem the phrase with bigger N_c more likely to be a high-frequency phrase. In our experiments, we only consider phrases that have this metric over a certain threshold. We use a development set (section 4.1) to determine the threshold.

3.4 Iterative Projection

We further extend the projection process described in Section 3.1 with phrase decomposition (Section 3.2) and phrase filtering (Section 3.3) to an automatic iterative system. This allows us to use newly learned phrases to learn more new phrases. The most straightforward idea is executing the projection procedure in Section 3.1 many times. However in practice, the growth rate of the number of newly learned phrases is far beyond our imagination. During the iterative projection between the two languages, thousands of incomplete or incorrect phrases are generated. In order to control the growth rate of new phrases and to avoid generating bad phrases, we only keep new phrases that are found at least twice by the iterative system. We deem phrases learned repeatedly more reliable than those occasionally learned. For example, we can learn five different phrases: "举行 <dobj> 示威"(4)、"示威"(2)、"举行 <dobj> 游行"(2)、"举行 <dobj> 活动"(1)、"示威者"(1) when phrase "held<dobj>demonstrations" is mapped to Chinese. The numbers in brackets show the times of phrase learned. According to the strategy, the last two phrases are removed. This is different from filtering by phrase frequencies strategy in Section 3.3. The phrase frequency in section 3.3 means the total times of a new phrase learned by all original phrases. But in the iterative projection, we talk about the frequency of different new phrases learned by one particular original phrase.

4 Experiments

After each structure projection iteration, we appended the newly learned phrases to their corresponding phrase list (EP or PP) and ran the same event recognition evaluation procedure as in H&R's but with the appended longer phrase lists.

4.1 Data

Our experiment bilingual data consists of 3.57M bilingual sentences from LDC corpora LDC2004E12, LDC2004T08, LDC2005T10, LDC2003E14, LDC2002E18, LDC2005T06, LDC2003E07,

[4] AS: aspect markers, P: prepositions, DEC: Chinese "的" for relative clauses, LC: localizers, PU: punctuations, CD: cardinal numbers, MSP: some particles.

Method	Phrases	Recall	Precision	F_1
H&R's Iter #4	EP:623 PP:569	71	88	79
Iteration 1	EP:1096 PP:2219	76.2	86.5	81.1
Iteration 2	EP:4273 PP:4597	79.2	86.0	82.5
Iteration 3	EP:8041 PP:9169	79.2	86.0	82.5
Iteration 4	EP:9868 PP:11705	79.2	86.0	82.5

Table 1: Results of the projection method using H&R's phrase lists as seed phrases for expansion and projection

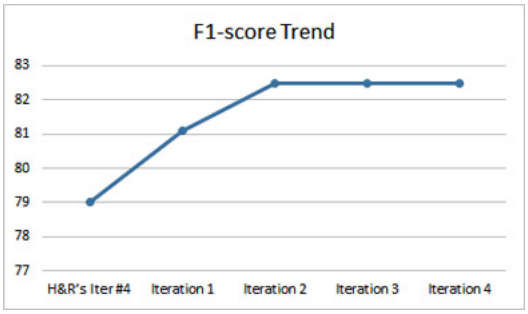

Figure 5: F1-score curve against the number of iterations

LDC2004T07. We ran Giza++ (Och, 2003) and Stanford dependency parser (De Marneffe et al., 2006; Chang et al., 2009) on the parallel sentence pairs to obtain word alignments and dependency trees. In addition, we used the same evaluation method and data as H&R's. The evaluation data contains 400 news articles that were randomly sampled from the English Gigaword Fifth Edition corpora (Parker et al., 2011). Each article contains one of six commonly used civil unrest keywords or their morphological variations. The development set contains 100 documents and the rest 300 documents are used as the test set.

4.2 Event Recognition with Expanded Phrases

We examine the effectiveness of our bilingual structure projection algorithm on the task of event recognition. We choose H&R's best result as our baseline. H&R's multi-faceted event recognition approach achieves the best result after four iterations of bootstrapping.

Our first experiment was designed to expand the EP and PP lists learned by H&R's method at the 4th iteration with our bilingual structure projection system. Our system ran for multiple iterations. According to the development data, the best F_1-score was achieved after the first two iterations. Table 1 shows the event recognition performance of our bilingual structure projection method. The original multi-faceted event recognition approach at the 4th iteration has achieved a high accuracy (88%) with a relatively low recall (71%). After the first iteration of projection, we obtained an improvement of 5.2 points on recall and 2.1 points on F_1-score over the baseline. With the newly learned phrases in the first iteration projection, the event recognition recall can be further improved by another 3 points after the second iteration. Overall, with a little loss in precision, the recall has increased by 8.2 points and the F_1-score 3.5 points. We further observed that results cannot be elevated further after the 2nd iteration even with more phrases, as shown in Figure 5. We conjecture that the reasons are twofold. First, the limited original phrases may not supply more useful phrases after two iterations, which results in a saturated useful phrase list. Second, we do get more useful phrases. However the test data is not large enough so that all newly learned phrases can be found in the test data. Therefore, we cannot see further changes in performance. From the results, we can see the bilingual structure projection algorithm can mine thousands of new phrases. With the newly learned phrases, we can successfully identify additional civil unrest events in the test data.

Due to the noise in H&R's phrase lists (the precision is 88%, indicating 12% noisy phrases) and the features of bootstrap system, phrases learned in previous iterations often have a high precision, but the quality of phrases normally decrease in the succeeding iterations. We further conducted experiments with the phrase lists (EP and PP) learned from the first to the third iteration by H&R's method, which have a high quality. The results are shown in Table 2. In these three iterations, our bilingual structure projection algorithm can improve the recall with almost no loss in precision. This illustrates that our method can recall more phrases and patterns still with a high precision. Note that our method has already outperformed H&R's best result at the third iteration (73.3% in recall and 79.6% in F1-score) while H&R's method achieved this performance after the 4th iteration. Therefore, with bilingual structure projection, the number of iterations of the original bootstrapping learning process can be decreased.

phrase iteration	Method	EP numbers	PP numbers	Recall	Precision	F_1
Iter #1	H&R's Method	145	124	50	88	63
	Bilingual Projection	279	888	53.5	90.0	67.1(+4.1)
Iter #2	H&R's Method	410	356	63	89	74
	Bilingual Projection	790	1387	68.3	88.5	77.1(+3.1)
Iter #3	H&R's Method	504	402	68	88	77
	Bilingual Projection	968	1501	73.3	87.1	79.6(+2.6)

Table 2: Results at the first three iterations

phrase iteration	Method	Recall	Precision	F_1
TermLex	H&R's Method	66	85	74
	Bilingual Projection	61	81	70
PairLex	H&R's Method	10	91	18
	Bilingual Projection	12	100	21
TermSets	H&R's Method	59	83	69
	Bilingual Projection	57	73	64
PairSets	H&R's Method	68	84	75
	Bilingual Projection	79	78	79
ALLSets	H&R's Method	70	84	76
	Bilingual Projection	78	78	78
Average of Five	H&R's Method	54.6	85.4	62.4
	Bilingual Projection	57.4	82.0	62.4

Table 3: Results of SVM with the bilingual projection method

4.3 SVM Classifiers with Bilingual Structure Projection

H&R also experimented with a suite of supervised classifiers by engineering features based on their learned event dictionaries. In their presented results, supervised classifiers yielded worse event recognition performance than the multi-faceted approach that simply relies on exact match with learned event dictionaries. One guess for this inferior comparison is that their learned phrases are still not diverse and rich enough and their induced feature vectors are too sparse. We have learned many more phrase for both event expressions and the purpose facet through our bilingual structure projection method. We rebuilt the same set of supervised classifiers with the same features. But the features are induced based on the augmented EP lists and PP lists using our bilingual structure projection algorithm. Agent phrase lists (AP) keep the same as H&R's. We ran experiments on five SVM classifiers as shown in Table 3 and performed ten-fold cross validation on the test set, the same as H&R's. All features are binary. We use a vector of 0 and 1 to represent a document. TermLex encodes a binary feature for every phrase in all three phrase lists. PairLex encodes a binary feature for each pair combination from two different lists and requires them to occur in one same sentence. TermSets encodes three binary features for each list, a feature gets 1 when at least one phrase occurs in the document from the corresponding list. PairSets encodes three binary features and each feature represents a combination of two different lists (EP+PP, PP+AG, EP+AG). If any pair occurs in the same sentence, the value gets 1 otherwise 0. Last, the ALLSets encodes 7 binary features, the previous six features plus another binary feature of a sentence containing at least an entry combination from all three lists. Table 3 shows the comparison of our projection method and H&R's method. Although our expanded phrases do not work well on TermLex and TermSets, they still can improve other three classifiers in different degrees. The last row in Table 3 shows the average performance of two methods. Generally, compared to multi-faceted based phrases, our expanded phrases increase the recall, but lower the precision, overall F is the same. Our experiments reconfirm that multi-faceted event dictionary match based event recognition approach, while simple, is more effective than trained supervised classifiers that use dictionary matches as features.

5 Analysis: New Phrases and Structures

We further analyze syntactic structures of the newly learned phrases by bilingual structure projection. Due to linguistic divergences between English and Chinese, various novel new structures are observed in learned Chinese phrases and English phrases.

New Chinese Structures and Examples
NN: 静坐 (stage sit-ins), 怠工 (stop work), 罢工 (went on strike)
VV: 纵火 (set fire), 泄愤 (vent their anger)
VV<rcomp>VV: 纵火 焚烧 (set fire), 进行 绝食 (go on hunger strike)
VV<dobj>NN<conj>NN: 举行 游行 示威 (stage demonstrations), 加入 抗议 罢工 (join the strike and protest)
VV<dobj>NN<relcl>VV: 放火 焚烧 车辆 (set fire to vehicles), 表达 反对 呼声 (express opposition)

Table 4: Examples of new Chinese structures learned

New English Structures and Examples
NN: self-immolation, demonstrations, sit-ins
NN<prep>NN: overuse of force, boycott of elections, disobedience of order
NN<vmod>VBN: rallies held (in), objections expressed (by), rocks thrown (at), disturbances caused (by)
VV: demonstrated, parade
VB<xcomp>VB: cease (to) function, came (out to) demonstrate, pledged (to) support, urge (them to) resign
VB<dobj>NN<conj>NN: held rallies and demonstrations, staged sit-ins and hunger strikes
VB<dobj>NN<prep_of>NN: prevent acts of discrimination, condemned acts of terrorism

Table 5: Examples of new English structures learned

Table 4 shows examples of several new Chinese phrase structures. Interestingly, a multi-word verb phrase in English can be expressed with only one noun or verb word in Chinese, e.g., "went on strike" vs. "罢工" (a noun in Chinese), "vent their anger" vs. "泄愤" (a verb in Chinese). Even more interestingly, we have observed that Chinese tends to put together two coordinate words with roughly the same meaning when referring to one single event, e.g., "staged demonstrations" aligned to "举行 游行 示威" ("游行" and "示威" both mean demonstrations). The reason for putting two words with similar meanings together is to emphasize on the occurrence of the event. More examples are given in Table 4.

Table 5 shows a few examples of new English phrase structures. Dramatically different from the two pre-defined types of verb phrases as specified in H&R's research, many new phrases are headed by nouns, including individual nouns "sit-ins", nouns with a prepositional attachment "boycott of elections" and nouns modified by a passive voiced verb phrase "rallies held in". In addition, we have seen some new verb structures in English phrases that consist of a single verb or a verb with complex objects as shown in Table 5.

6 Related Work

Recent years have witnessed increasing interests in leveraging bilingual corpora or resources to improve performance of monolingual NLP tasks. Generally, The introduction of bilingual corpora or resources serves two purposes. The first purpose is to alleviate the problem that we have few labeled instances in some resource-impoverished languages by a resource-rich language (Hwa et al., 2005; Ganchev et al., 2009; Das and Petrov, 2011; He et al., 2015). The second purpose is to leverage divergences found in different languages to obtain complementary cues (Li et al., 2012; Wang et al., 2013; Che et al., 2013) or extra information (Snyder et al., 2009; Burkett et al., 2010) from another language. Our projection method follows the latter.

In the first purpose, Das and Petrov (2011) explored existing abundant English labeled resources as features to assist building tools for eight European languages. Different to projecting labels as feature, Wang and Manning (2014) proposed a method that projected model expectations as feature for training. He et al. (2015) transferred the sentiment information of a resource-rich language to replenish the lost information of the target language.

In the second purpose, Chen and Ji (2009) proposed a bootstrap framework of co-training among two languages, which uses Chinese event extraction as a case study and bilingual texts as a new source of information. Burkett et al. (2010) attached a bilingual model as a second view (Balcan and Blum, 2005; Ganchev et al., 2012) onto original monolingual models, and used rich features from unannotated bitext to train parameters in bilingual models, which can help to reproduce training data of monolingual model. Che et al. (2013) exploited the complementary cues between two languages as bilingual constraints to help detect errors in a mono-lingual tagger task, which can improve the annotation quality of named entities. Zhu et al. (2013) translated English sentences into Chinese sentences (with the same topic) in ACE 2005 evaluation data with google machine translation system as a second text representation feature

so as to alleviate the data sparseness problem effectively.

Our method is also related to paraphrase learning (Bannard and Callison-Burch, 2005; Callison-Burch, 2008; Zhao et al., 2008; Snover et al., 2009; Ganitkevitch et al., 2013). However, there are two significant differences. First, paraphrase learning translates phrases strictly via word alignments while we use word alignments to find phrase spans on the target language. Second, our purpose is to obtain structured phrases (with syntactic constraints) rather than plain phrases as structured phrases can help us find new phrase structures as shown in Section 3.

7 Conclusion and Future Work

We have presented a bilingual structure projection algorithm that explores structural divergences between languages and can effectively dig up new phrase with various new structures by mapping phrases back and forth across two languages. We combine syntactic information with machine translation technology, not only can reduce the effect of word alignment errors, but also diversify the original two pre-defined event phrase structures. Our experiments show that the newly learned event phrases are capable of recognizing additional event descriptions and considerably increasing the recall of event recognition with minimal loss on precision. Bilingual structural divergences between human languages are common, the proposed bilingual structure projection algorithm is general and can be applied to any pair of languages, and easily extended to the scenario with multiple languages. In addition to event recognition, the proposed structure projection algorithm across languages is potentially useful to many other NLP tasks that utilize extraction patterns by automatically generating novel and diverse phrasal patterns. In our future work, we will attempt to explore the possibility and effect of expanding phrases among other language pairs and other NLP tasks using our bilingual structure projection method.

Abstract

Previous studies on temporal relation extraction focus on mining sentence-level information or enforcing coherence on different temporal relation types among various event mentions in the same sentence or neighboring sentences, largely ignoring those discourse-level temporal relations in nonadjacent sentences. In this paper, we propose a discourse-level global inference model to mine those temporal relations between event mentions in document-level, especially in nonadjacent sentences. Moreover, we provide various kinds of discourse-level constraints, which derived from event semantics, to further improve our global inference model. Evaluation on a Chinese corpus justifies the effectiveness of our discourse-level global inference model over two strong baselines.

1 Introduction

Temporal relation extraction is to determine the temporal relationship (e.g., *Before* and *After*) holding among events. It has been drawing more and more attention due to the crucial importance of temporal information to various natural language processing (NLP) applications, such as language generation, information extraction, summarization, and question answering. The difficulty with this task is that temporal information about event mentions is sometimes not stated explicitly and one can only infer from their context. Currently, temporal relation extraction still remains a challenge in corpus construction and inference mechanism.

On one hand, although the TimeBank corpus (Pustejovsky et al., 2003), the commonly used corpus in previous studies, has largely promoted the development of temporal relation extraction, it only annotates a small subset of easily-identified event mention pairs. Moreover, it largely ignores almost all temporal relations between event mentions in nonadjacent sentences. These lead to fragmented relations and limit its applications to other NLP tasks, such as information extraction, and summarization. Finally, while constructing a fully-annotated corpus is expensive and time-consuming, many NLP tasks are normally interested in specific types of events. For example, a summarization or information extraction system on terrorism attacks may only concern with a few event types (e.g., *Attack*, *Die*, and *Injure*). Therefore, annotating an event-driven fully-annotated temporal relation corpus becomes a crucial issue to the success of real-life applications.

On the other hand, previous studies on temporal relation extraction focus on mining sentence-level information or enforcing coherence on different temporal relation types among various mentions in the same sentence or neighboring sentences, largely ignoring those discourse-level temporal relations in nonadjacent sentences. Specifically, only a few studies apply global inference models to exploit temporal relations in discourse level. Therefore, how to acquire discourse-level temporal information from those long-distance event mention pairs in nonadjacent sentences becomes another crucial issue to temporal relation extraction, especially for Chinese, as a discourse-driven language with a broad range of ellipsis and flexible sentence structures.

In this paper, we first annotate an event-driven fully-annotated Chinese temporal relation corpus, on the top of the ACE (Automatic Content Extraction) 2005 Chinese corpus. Then, we propose a discourse-

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1451–1460, Osaka, Japan, December 11-17 2016.

level global inference model to mine those temporal relations between event mentions in document-level (especially in nonadjacent sentences) with various kinds of discourse-level constraints, which derived from event semantics, to further improve the global inference model. Evaluation indicates the appropriateness of our event-driven fully-annotated Chinese corpus and justifies the effectiveness of our discourse-level global inference model over two strong baselines.

2 Related Work

In this section, we give a brief overview of temporal relation extraction from two aspects: corpus construction and inference mechanism.

2.1 Corpus Construction

Most of existing corpora for temporal relation extraction focus on English. As the commonly used corpus in temporal relation extraction, the TimeBank corpus (Pustejovsky et al., 2003) has been adopted in a series of TempEval competitions (Verhagen et al., 2007; Verhagen et al., 2010; Uz-Zaman et al., 2013), facilitating the development and evaluation of temporal relation extraction systems. The problems with the TimeBank corpus are that it only annotates a small subset of easily-identified event mention pairs and that it largely ignores those temporal relations between event mentions in nonadjacent sentences. These lead to fragmented relations and much limit its applications.

To overcome above problems, Do et al. (2012) produced an event-driven corpus on the ACE 2005 English corpus. However, "the annotator was not required to annotate all pairs of event mentions, but as many as possible", as stated in their paper. This makes the annotation inconsistent and difficult to follow. Recently, Cassidy et al. (2014) enriched the TimeBank-Dense corpus, on the top of TimeBank. Specifically, they approximated the completeness by labeling locally complete graphs over neighboring sentences.

In comparison, there are few corpora for Chinese temporal relation extraction. Li et al. (2004) annotated a Chinese corpus including 700 sentences. The TempEval-2 competition (Verhagen et al., 2010) provided 780 instances of Chinese temporal event relations. Obviously, both corpora are rather small and largely impede the research in Chinese temporal relation extraction. For example, no team participated in the TempEval-2 competition on Chinese temporal relation extraction.

2.2 Inference Mechanism

Due to the corpus limitation, previous studies on temporal relation extraction focus on inferring temporal relations between event mentions in the same sentence or neighboring sentences from English text, dominated by feature-based approaches. Mani et al. (2006) applied the temporal transitivity rule to greatly expand the corpus. Lapata and Lascarides (2006) introduced various kinds of syntactic and clause-ordering features to classify the temporal relationship. Chambers et al. (2007) used previously learned event attributes to classify the temporal relationship. Laokulrat et al. (2013), the best performing one in the TempEval-3 competition, applied various predicate-argument structure features from a deep syntactic parser to enhance their classifier. Mirza and Tonelli (2014) illustrated that simple features resulted in a better performance than sophisticated features. Chambers et al. (2014) proposed a sieve-based architecture to joint those different tasks of temporal relation extraction.

In comparison, few studies concern temporal relation extraction from Chinese text. Chen et al. (2008) used verbal attributes to identify temporal relations of verbs. Li et al. (2004) presented a classifier-based collaborative bootstrapping approach to analyze temporal relations in a small Chinese corpus.

While above studies focus on local information, a few studies sort to global inference, with focus on exploiting global information via various kinds of temporal logic reflexivity and transitivity constraints, using frameworks like Integer Linear Programming and Markov Logic Networks (Bramsen et al., 2006; Chambers and Jurafsky, 2008; Yoshikawa et al., 2009). However, their gains are rather small, largely due to the common disconnectedness in the sparsely annotated corpora (Chambers et al., 2014). To overcome this problem, Denis and Muller (2011) decomposed temporal entities into sub-graphs and enforced the coherence only within these substructures, while Do et al. (2012) proposed a joint event-event and event-time classification model to enforce various coreference constraints.

Different from previous studies, we build an event-driven fully-annotated Chinese corpus and propose

a discourse-level global inference model to extract temporal relations between event mentions in document level, especially in nonadjacent sentences. To our knowledge, this is the first attempt in discourse-level global inference for temporal relation extraction from an event-driven fully-annotated corpus.

3 Data Construction and Baseline

In this section, we present the construction of our Chinese temporal relation corpus and the learning-based baseline.

3.1 Data Construction

To address various problems in existing corpora, as described above, we build an event-driven fully-annotated Chinese temporal relation corpus, on the top of the ACE 2005 Chinese corpus with 8 predefined event types and 33 predefined event subtypes (e.g., *Die*, *Attack*, and *Transport*). That is, all other event mentions of non-predefined event types are ignored in our corpus.

Different from previous corpora, each document in our corpus is annotated with the temporal relations between the mentions of all the events relevant to concerned events in the document, with the constraint of event-relevant completeness. Besides, we focus on four temporal relations, i.e. *Before*, *After*, *Overlap* and *Unknown* (without relationship or with vague relationship). This is a simplification of the TimeBank corpus, which defines 14 temporal relations. Since differentiating 14 temporal relation types is too hard, even for a well-educated person, much work has been done to simplify the temporal relation types, e.g. 6 types (Mani et al., 2006; Chambers et al., 2007; Cassidy et al., 2014) and 4 types (Do et al., 2012; UzZaman et al., 2013 (Chinese subtask)). Our work is a typical practice of such tendency.

Specifically, 163 documents from the ACE 2005 Chinese corpus are selected as our experimental data, which contains 1166 event mentions. These documents are from three different data sources (i.e., Broadcast News, Newswire and WebLog), very different in various aspects, such as quality, length and style. Two postgraduates in computer science are involved in corpus annotation and the Kappa value between the two annotators is 0.70, similar to TimeBank's 0.71.

Table 1 shows 4 temporal relations and their occurrence frequencies in our event-driven fully-annotated corpus. The total number of event pairs in our corpus is three times larger than that of TimeBank. Since the ACE 2005 corpus is licensed, we cannot upload our annotated data. If anyone obtain the license of the ACE 2005 corpus, our corpus is free available for research purpose on request.

Type	Before	After	Overlap	Unknown	Total
#Number	7402	7402	4834	1494	21132

Table 1. The 4 temporal relations and their occurrence frequencies

We have implemented a tool to help the annotators to tag event relations easily and enforce the coherence in document level. Due to the reflexive property of event-event relationship, the annotators only need annotate half of the relations shown in Table 1. Besides, 7.1% of annotated event relations are *Unknown*, and this figure is much lower than that in TimeBank. The reason is that the relations between two ACE events of the predefined event types are relatively easy to be identified and this also verifies the relatively high Kappa value between the two annotators. In our corpus, the maximal size of the relations in a document is 625 (25 event mentions), while the minimal size is 2 (only 2 event mentions). If we ignore those *Unknown* relations, 32% of documents are not graph, but forest.

3.2 Baseline

Similar to the state-of-the-art system in temporal relation extraction, we employ a learning-based system as one of our baselines. As an event-event (E-E) classifier, this baseline predicts one of the four temporal relations, i.e. *Before(B)*, *After(A)*, *Overlap(O)*, and *Unknown(U)*, between two event mentions e_i and e_j as follows:

$$C_{E-E}(e_i, e_j) \rightarrow \{\underline{B}, \underline{A}, \underline{O}, \underline{U}\} \quad (1)$$

Besides those features adopted in English temporal relation extraction (e.g., D'Souza and Ng, 2014; Mirza and Tonelli, 2014), we also apply various kinds of Chinese-specific features to further boost the

performance of this baseline. Specifically, for each event mention pair <e_1, e_2> in a document, with trigger mentions t_1 and t_2 respectively, its feature set can be divided into 5 categories:

1) **Lexical features (14)**: the tokens of t_1 and t_2 (2); their POS tags (2); their preceding and succeeding words (4); the POS tags of their preceding and succeeding words (4); the hedge or negative word before t_1 or t_2 (2);
2) **Syntactic features (4)**: the dependency path between t_1 and t_2 (1); the governors of t_1 and t_2 (2); the constituent path between t_1 and t_2 (1);
3) **Event features (18)**: the tense, polarity, genericity, modality and event type of e_1 and e_2 (10); the agents (2), the patients (2), the times (2), and the places of e_1 and e_2 (2);
4) **Pairwise features (9)**: the conjunction between e_1 and e_2 (1); whether e_1 and e_2 are in the same sentence (1); whether e_1 and e_2 have the same tense (1), the same polarity (1), the same genericity (1), the same modality (1), the same event type (1), and the same *Time* argument (1); whether e_1 is before e_2 in the document (1);
5) **Semantic features (7)**: whether t_1 and t_2 are synonym (1); whether the agent of e_1 is the patient of e_2 (1); whether the agent of e_2 is the patient of e_1 (1); whether e_1 and e_2 have the same time (1), place (1), agent (1) or patient (1).

All the sentences in the corpus are divided into words using the word segmentation tool ICTCLAS. Besides, we use *Berkley Parser* and *Stanford Parser* to create the constituent and dependency parse trees respectively. The event features (e.g., trigger, event tense, event type, event arguments) are derived from the annotated data in the ACE 2005 Chinese corpus. After creating the training instances, we train four *one-vs-rest* classifiers using the Maximum Entropy tool *MaxEnt*.

4 Global Inference on Event Semantics

While existing approaches, as the baseline described above, focus on limited event mention pairs in the same sentence or neighboring sentences, our global inference model attempts to address those in non-adjacent sentences. In this section, we first present the discourse-level global inference model to temporal relation extraction and then introduce various kinds of discourse-level constraints to achieve global optimization on the temporal relations of event mention pairs in both nonadjacent and adjacent sentences.

4.1 Global Inference Model

To mine the interaction among events in a document, we optimize the predicted temporal graph, formed by prediction from $C_{E\text{-}E}$, with various kinds of discourse-level constraints derived from event semantics.

Let $E=\{e_1,e_2,\ldots,e_n\}$ denote the set of event mentions in a document, $\varepsilon=\{(e_i,e_j)\in E\times E|e_i,e_j\in E, i\neq j\}$ the set of event mention pairs, and $R=\{\underline{B},\underline{A},\underline{O},\underline{U}\}$ the set of temporal relations. Besides, let $P_{<i,j,r>}$ denote the prediction probability of (e_i,e_j) with relation r ($r\in R$), given by the event-event classifier $C_{E\text{-}E}$, and $x_{<i,j,r>}$ the binary indicator on the existence of relation r for (e_i,e_j). Following Roth and Yih (2004) and Li et al. (2013) in information extraction, we define the following log costs:

$$c_{<i,j,r>} = -\log(P_{<i,j,r>}) \tag{2}$$

$$\bar{c}_{<i,j,r>} = -\log(1-P_{<i,j,r>}) \tag{3}$$

Specifically, ILP (Integer Logical Programming), a global inference is employed to achieve global optimization with the following objective function to maximize over a document as follows:

$$\arg\min_{x} \sum_{(e_i,e_j)\in\varepsilon} \sum_{r\in R} (c_{<i,j,r>} \times x_{<i,j,r>} + (1-x_{<i,j,r>}) \times \bar{c}_{<i,j,r>}) \tag{4}$$

s.t.

$$x_{<i,j,r>} \in \{0,1\} \tag{5}$$

$$\sum_{r\in R} x_{<i,j,r>} = 1 \tag{6}$$

while binary constraint (5) ensures that $x_{<i,j,r>}$ is binary value and equality constraint (6) ensures that exactly only one temporal relation can be assigned to each event mention pair.

In addition, the reflexivity and transitivity constraints, as deployed in previous inference models

(Bramsen et al., 2006; Chambers and Jurafsky, 2008; Do et al., 2012), are also applied to our model as follows:

$$x_{<i,j,r>} - x_{<j,i,\bar{r}>} = 0 \qquad \forall r, \bar{r} \in R \tag{7}$$

$$x_{<i,j,r>} + x_{<j,k,r>} - x_{<i,k,r>} \leq 1 \qquad \forall r \in \{\underline{B}, \underline{A}, O\} \tag{8}$$

Here, **reflexivity constraint** (7) enforces the reflexive property of the event-event relationship, where relation $\bar{r}$ denotes inverse relation r with possible (r, $\bar{r}$) pairs { ($\underline{A}$,$\underline{B}$) , ($\underline{B}$,$\underline{A}$) , ($\underline{U}$,$\underline{U}$) }, and **transitivity constraint** (8) states that if both event mention pairs (e_i,e_j) and (e_j,e_k) have the same temporal relation r, temporal relation r must hold between e_i and e_k, with event mention e_j as a bridge to link e_i and e_k.

4.2 Discourse-level Constraints

Different from the TimeBank corpus which only annotates the temporal relations in the same sentence or neighboring sentences, our corpus is event-driven fully-annotated. That is, besides the temporal relations in the same sentence or neighboring sentences, our corpus also contains those in nonadjacent sentences, which occupy 56.3%. This poses the great necessity to address those temporal relations in nonadjacent sentences. Besides, although all the event types in the ACE corpus have a *Time* role, the statistics on our corpus shows that only 35.9% of event mentions have explicit *Time* arguments. This poses the great challenge to address those temporal relations in nonadjacent sentences due to the frequent lack of explicit *Time* arguments.

Motivated by the intuition that the intrinsic semantics of event mentions is helpful to reveal their temporal relations due to the semantic nature in the event definition, we propose various kinds of discourse-level constraints on time arguments, event relevance, event tense, discourse connective, and coreference to mine the temporal relations in both nonadjacent and adjacent sentences.

Argument *Time* constraint

Generally, an event can be expressed as "5W1H" (*Who*, *What*, *Whom*, *Where*, *When* and *How*). *When*, one of "5W", indicates the time an event happens. Naturally, this argument is the solid evidence to identify the temporal relation between two event mentions. For example, if the *Time* argument of one event mention e_1 is "今日" (today) and that of the other mention e_2 is "昨日" (yesterday), it is obvious that the relation between e_1 and e_2 is *After*.

For time arguments, we can obviously have the following constraint, stating that if *Time* argument at_i of event mention e_i is before *Time* argument at_j of event mention e_j, the temporal relation between e_i and e_j is $\underline{B}$, and if at_i is equal to at_j, or they have overlap part, the temporal relation between e_i and e_j is $\underline{O}$.

$$x_{<i,j,r>} = 1 \qquad \forall r \in \{\underline{B}, \underline{O}\} \wedge r = rel(at_i, at_j) \tag{9}$$

where function $rel(at_i,at_j)$ returns one of the four temporal relations between at_i and at_j. Due to the reflexivity constraint, it is unnecessary to enforce the constraint on *after* relation.

Since the ACE corpus uses *Timex2* to annotate all temporal expressions, the *Time* arguments need to be normalized. In this study, we first divide all time tags into two categories: time point and time duration. Then, we implement a simple rule-based tool based on the DCT (Document Create Time) to normalize all time points as "*year:month:day: hour:minute*" and all time durations as (*begintime, endtime*) where *begintime* and *endtime* are normalized as the style of time point. As a result, 92.7% of *Time* arguments are normalized correctly.

Event relevance constraint

In a discourse, most of event mentions are normally structured around a specific topic, which acts as a bone to link all the relevant event mentions together into a narration, via various kinds of event relations. Those semantics-based event relations, i.e. event relevance, are thus helpful to infer the temporal relations among event mentions. For example, if there is a causal relation between an *Attack* and a *Die* event mention, it is obvious to infer they have the *Before* temporal relation. That is, a *Die* event is always the result of an *Attack* event.

Specifically, we learn event relevance from the training set by counting the occurrence frequency $f_{<i,j,r>}$ for each event type pair (evt_i, evt_j) (e.g., (*Attack, Die)*) with relation r in the training set. To eliminate

the accidental factor in statistics, we modify the occurrence frequency of an event type pair to 0 when it only appears once in the training set.

Accordingly, we have the following constraint on event relevance, stating that if an event type pair (evt_i, evt_j) only has one occurrence frequency $f_{<i,j,r>}$(larger than 0), the temporal relations of all event mention pairs in the test set with event type pairs (evt_i, evt_j), are assigned with the temporal relation r according to constraint (10), and that if an event type pair (evt_i, evt_j) has two or three occurrence frequencies (i.e., larger than 0), the relations of all event mention pairs with event type pair (evt_i, evt_j), are enforced according to constraint (11).

$$x_{<i,j,r>} = 1 \qquad \forall f_{<i,j,r>} > 0 \wedge \sum_{r' \in SR_1} f_{<i,j,r'>} = 0 \tag{10}$$

$$\sum_{r \in SR_2} x_{<i,j,r>} = 1 \qquad \forall\, f_{<i,j,r>} > 0 \tag{11}$$

where SR_1 refers to the set of all the temporal relations except r and SR_2 refers to the set of all temporal relations whose occurrence frequencies are larger than 0.

Tense constraint

Event tense is also a helpful evidence to infer temporal relations. In the ACE 2005 corpus, each event mention has an annotated tense attribute, whose values are *Past(P)*, *Present(R)* and *Future(F)* and have been used in the baseline. For example, it is normal to infer the *Before* relation between two event mentions whose tense are *Past* and *Future* respectively. Accordingly, we can have the following constraint, stating that if the tense te_i of e_i is *Past* and that of e_j is *Present* or *Future*, the temporal relation of (e_i, e_j) is $\underline{B}$; 2), and that if te_i is *Present* and te_j is *Future*, the temporal relation of (e_i, e_j) is $\underline{B}$.

$$x_{<i,j,\underline{B}>} = 1 \qquad \forall te_i = P \wedge te_j \in \{R, F\} \vee te_i = R \wedge te_j = F \tag{12}$$

Connective constraint

In a discourse, the connective between two adjacent sentences or clauses can largely reveal their discourse relations. For example, the connective "because" illustrates the *Cause* relation. Likewise, the connective between two adjacent event mentions also explicitly unveils their temporal relation. For example, if the preceding event mention is the cause of the succeeding event mention, their temporal relation is *Before*. Besides, we find out that some verbs which represent the meaning of causality can indicate the temporal relation of an event mention pair. Take the following sentence as an example:

*E1: 这起炸弹攻击(EV1: Attack)事件**造成**了 2 个人死亡(EV2: Die)。(This bomb terror (EV1) **caused** two persons to death (EV2).)* *-From CBS20001120.1000.0823*

In sentence E1, the verb 造成 (cause) indicates that the temporal relation between the event mentions *EV1* and *EV2* is *Before*. Hence, we enumerate a set of Chinese verbs (e.g., 导致, 造成, 引起) whose meaning are "cause" and add them into our connective set *CS*. Besides, we find out that only causal and temporal connectives are helpful to infer temporal relations. Therefore, respective connectives are selected from Appendix B of the PDTB 2.0 annotation manual, which provides a list of classified explicit connectives. Finally, we divided all words in CS into two subsets CS_1 and CS_2, according to the statistics from the training set, where all words in CS_1 indicate that the preceding event mention occurs earlier than the succeeding one and all words in CS_2 indicate that the preceding event mention occurs later than the succeeding one.

Accordingly, we have the following constraint on discourse connective, stating that if there is a connective *con* (*con*$\in$*CS*) between two adjacent event mentions e_i and e_j in the same sentence or neighboring sentences, the temporal relation between e_i and e_j depends on whether *con* belongs to CS_1 or CS_2 as follows.

$$\begin{aligned} x_{<i,j,\underline{B}>} &= 1 \qquad \forall con \in CS_1 \\ x_{<i,j,\underline{A}>} &= 1 \qquad \forall con \in CS_2 \end{aligned} \tag{13}$$

Coreference constraint

An event may have more than one mention in a document and these mentions refer to the same event, called coreference events. Take the following two sentences as examples:

E2: 埃塞俄比亚与厄立特里亚 2 3 日在这里举行谈判(EV3: Meet)。(The talk (EV3) between Ethiopia and Eritrea will be held on 23rd.)

E3: 这次谈判(EV4: Meet)的目的是... (The goal of this talk (EV4) is ...) -From XIN20001024.2000.0141

It is obvious that two coreference event mentions EV3 and EV4 must have the same occurrence time and their relation is *Overlap*. Following Do et al. (2012), we also apply this constraint to our model and enforce the following constraint on event coreference, stating that if mentions e_i and e_j are coreferential event mentions, their temporal relation is *Overlap*.

$$x_{<i,j,O>} = 1 \qquad \forall\, cr(e_i, e_j) = true \tag{14}$$

where function *cr()* return true when e_i and e_j are coreferential. Besides, we use the tool described in Teng et. al. (2015) to construct those coreference event chains.

5 Experimentation

In this section, we first evaluate our model for Chinese temporal relation extraction and then report the experimental results on our event-driven fully-annotated Chinese temporal relation corpus.

5.1 Experimental Settings

All the experiments are done on the event-driven fully-annotated Chinese temporal relation corpus, annotated on the top of the ACE 2005 Chinese corpus, as described in Subsection 3.1. We conduct all evaluations with 5-fold cross-validation at document level and each fold contains about 4000 event mention pairs. Following previous studies on temporal relation extraction, we employ *Accuracy* as evaluation metric, which measures the percentage of correctly classified test instances. This metric is the same as micro F-score since each temporal relation of each event mention pair must belong to one of the four relations.

In this study, we use *lp_solve* as the ILP solver which implements the Branch-and-Bound algorithm. It takes less than 3 seconds on average to decode a document on a PC with 3.4Ghz Intel i7 CPU and 16GB memory.

5.2 Experimental Results

Performance comparison

To evaluate the performance of our discourse-level global inference model (DGIM), we compare it with two strong baselines. The first is a classifier-based system, mentioned in Subsection 3.2, originated from the top performing English systems (D'Souza and Ng, 2014; Mirza and Tonelli, 2014). The second (GIM) is a global inference model with the reflexivity and transitivity constraints following Bramsen et al. (2006), Chambers and Jurafsky (2007), and Do et al. (2012). It is worth to note that all annotated data in DGIM are also used in the first classifier-based system. Table 2 compares the performance of two baselines and our inference model DGIM.

Model	Accuracy (%)(Gold events)	Accuracy (%)(Auto events)
Baseline 1 ($C_{E\text{-}E}$)	62.17	36.21
Baseline 2 (GIM)	64.12	37.85
DGIM	68.36	40.92

Table 2. Performance comparison of different models

Table 2 shows that when all event mentions are known, i.e. with gold event mentions, DGIM significantly outperform the two baselines by 6.19% and 4.71% in accuracy respectively. All improvements from two baselines to DGIM are statistically significant ($p<0.000001$, McNemar's test, 2-tailed). Besides, GIM outperforms the classifier-based model by 2.05% in accuracy, indicating the limitation of

the conventional reflexivity and transitivity constraints in previous studies. In comparison, DGIM outperforms GIM by 4.24% in accuracy, indicating the effectiveness of our various discourse-level global constraints.

Table 2 also shows the performance comparison consistency when all the event mentions are automatically extracted, as described in (Li et al., 2013) with the F1-score of 68.2% and 53.7% in event trigger extraction and event argument extraction respectively.

Contributions of discourse-level constraints

Table 3 illustrates the contributions of different discourse-level constraints to our DGIM model with gold event mentions.

System	Accuracy (%)
Baseline 1	62.17
+Reflexivity (7)	+0.29
+Before/After Transitivity (8)	+0.54
+Argument Time (9)	+2.23
+Event relevance (10,11)	+1.26
+Tense (12)	+0.48
+Connective (13)	+0.74
+Coreference (Learned) (14)	+0.69
+Coreference (Gold) (14)	+0.86

Table 3. Contributions of different discourse-level constraints to temporal relation extraction

1) The conventional reflexivity and before/after transitivity constraints slightly improve the accuracy. This is not as effective as that on TimeBank, due to that those wrong probabilities produced by the event-event classifier will be incorrectly propagated to more temporal relations of event mention pairs since each document in our corpus is fully-annotated. Although the improvements of above two constraints are limited, they can interact with others to either improve the performance or reduce the time complexity. For example, the reflexivity constraint can simplify our discourse-level constraints, since if we have applied a constraint to an event pair, it is unnecessary to apply the opposite constraint to their inverses.
2) The argument *Time* constraint gains most with 2.23% in accuracy, while the tense constraint gains least among all constraints. Different from TimeBank, an event always has a *Time* role in the ACE 2005 corpus. If both event mentions have the *Time* arguments, we have a high confidence to determine their temporal relation. The error of the argument *Time* constraint mainly comes from those event mentions with a vague time (e.g., 最近 (recently), 日前 (a few days ago)).
3) Intuitively, tense can clearly identify the temporal relation of two event mentions if they have different tenses. However, our preliminary experiment shows that this constraint harms the accuracy if we apply it to the whole document. The reason is that the tenses annotated in the ACE 2005 corpus are relative ones based on the statement of a sentence itself. For example, although two *Transport* event mentions "他要**来**美国" (He will **come** to U.S.) and "他**来**到了美国" (He **arrive**d U.S.) have the *Future* and *Past* tenses respectively, they are coreferential events with different statement times. In this study, we only enforce this constraint on the sentence level.
4) The event relevance constraint gains an improvement of 1.26% in accuracy. This verifies that relevant events always occur in a regular order. In our experiments, we extract total 65 event type pairs to construct this constraint. For example, an *Arrest-Jail* event often occurs after an *Attack* event. Although this constraint contributes third, this is far from our expectation. Our error analysis shows that this constraint introduces lots of wrong predictions due to the lack of deep semantics, which is worth exploring in our future work.
5) Although the improvement of the connective constraint is not significant enough with a gain of 0.74% in accuracy, it achieves a high precision in predicting almost all event mention pairs enforced by this constraint, through discourse connective like "因为" (because), "后" (after) and "造成" (cause).
6) The conference constraint gains an improvement of 0.69% and 0.86% in accuracy with automatically learned (with F1-score of 61.7% using the tool described in Teng et. al. (2015)) and gold conference respectively. These figures are much smaller than those in Do et al. (2012) (2.33% for

learned 9.91% for gold). This is largely due to that although 40% of event mentions in our corpus are coreferential, the accuracy of the temporal relation among two coreferential event mentions, produced by the baseline classifier-based model, is already very high (86.2%). In comparison, the baseline in Do et al. (2012) only achieves ~40% in accuracy. Besides, Do et al. (2012) employed a much smaller corpus of only 20 documents, in comparison with 163 documents in our study.

Performance of different temporal relations

Table 4 shows the accuracy on four temporal relations with gold event mentions. From Table 4, the performance of temporal relations *Before*, *After* and *Overlap* is higher than that of *Unknown*, much due to the low recall of the *Unknown* relation, caused by its low percentage (7.1%). Compared to the two baselines, our DGIM improves the F1-scores for all temporal relations, with the highest improvement on the *Before* and *After* relations and the lowest improvement on the *Unknown* relation, much due to the fact that almost all discourse-level constraints focus on relations *Before*, *After* and *Overlap*.

Relation	Baseline 1	Baseline 2	DGIM
Before	63.43	65.30	72.21
After	63.44	65.30	72.21
Overlap	64.50	66.40	69.17
Unknown	45.60	47.20	47.44

Table 4 Accuracies (%) of four temporal relations

Analysis on adjacent or nonadjacent sentences

Table 5 shows the percentages and performance of event mention pairs in same sentence, adjacent sentences and nonadjacent sentences with gold event mentions. We can find out that 56.3% of event mention pairs are in nonadjacent sentences. Those event mention pairs in the same sentence achieve the highest accuracy while those in nonadjacent sentences gains least among all three types. Table 5 also proves that our DGIM outperforms two baselines in all three sentence levels significantly.

Distance	Rate(%)	Baseline 1	Baseline 2	DGIM
Same	18.6	68.13	69.13	72.25
Adjacent	25.1	64.54	65.47	69.09
Nonadjacent	56.3	59.15	61.87	66.75

Table 5. Accuracies (%) of event mention pairs in same sentence (Same), adjacent sentences (Adjacent) and nonadjacent sentences (Nonadjacent)

6 Conclusion

This paper first annotates an event-driven fully-annotated Chinese temporal relation corpus and then presents a novel discourse-level global inference model, enforced by various kinds of discourse-level constraints derived from event semantics, to recognize temporal relations of Chinese events in document-level, especially in nonadjacent sentences. Evaluation on an event-driven fully-annotated Chinese temporal relation corpus justifies the effectiveness of our discourse-level global inference model over two strong baselines.

Although our model focuses on Chinese, it can be naturally applied to other languages (e.g., English). Our future work will focus on how to introduce more linguistics-driven knowledge to boost our model and construct a joint modelling of temporal event relation extraction and event extraction on both Chinese and English.

Abstract

Nowadays, neural networks play an important role in the task of relation classification. By designing different neural architectures, researchers have improved the performance to a large extent in comparison with traditional methods. However, existing neural networks for relation classification are usually of shallow architectures (e.g., one-layer convolutional neural networks or recurrent networks). They may fail to explore the potential representation space in different abstraction levels. In this paper, we propose deep recurrent neural networks (DRNNs) for relation classification to tackle this challenge. Further, we propose a data augmentation method by leveraging the directionality of relations. We evaluated our DRNNs on the SemEval-2010 Task 8, and achieve an F_1-score of 86.1%, outperforming previous state-of-the-art recorded results.[1]

1 Introduction

Classifying relations between two entities in a given context is an important task in natural language processing (NLP). Take the following sentence as an example: "Jewelry and other smaller [valuables]$_{e_1}$ were locked in a [safe]$_{e_2}$ or a closet with a deadbolt." The marked entities *valuables* and *safe* are of relation Content-Container(e_1, e_2). Relation classification plays a key role in various NLP applications, and has become a hot research topic in recent years.

Nowadays, neural network-based approaches have made significant improvement in relation classification, compared with traditional methods based on either human-designed features (Kambhatla, 2004; Hendrickx et al., 2009) or kernels (Bunescu and Mooney, 2005; Plank and Moschitti, 2013). For example, Zeng et al. (2014) and Xu et al. (2015a) utilize convolutional neural networks (CNNs) for relation classification. Xu et al. (2015b) apply long short term memory (LSTM)-based recurrent neural networks (RNNs) along the shortest dependency path. Nguyen and Grishman (2015) build ensembles of gated recurrent unit (GRU)-based RNNs and CNNs.

We have noticed that these neural models are typically designed in shallow architectures, e.g., one layer of CNN or RNN, whereas evidence in the deep learning community suggests that deep architectures are more capable of information integration and abstraction (Graves et al., 2013; Hermans and Schrauwen, 2013; Irsoy and Cardie, 2014). A natural question is then whether such deep architectures are beneficial to the relation classification task.

In this paper, we propose the deep recurrent neural networks (DRNNs) to classify relations. The deep RNNs can explore the representation space in different levels of abstraction and granularity. By visualizing how RNN units are related to the ultimate classification, we demonstrate that different layers indeed learn different representations: low-level layers enable sufficient information mix, while high-level layers are more capable of precisely locating the information relevant to the target relation between

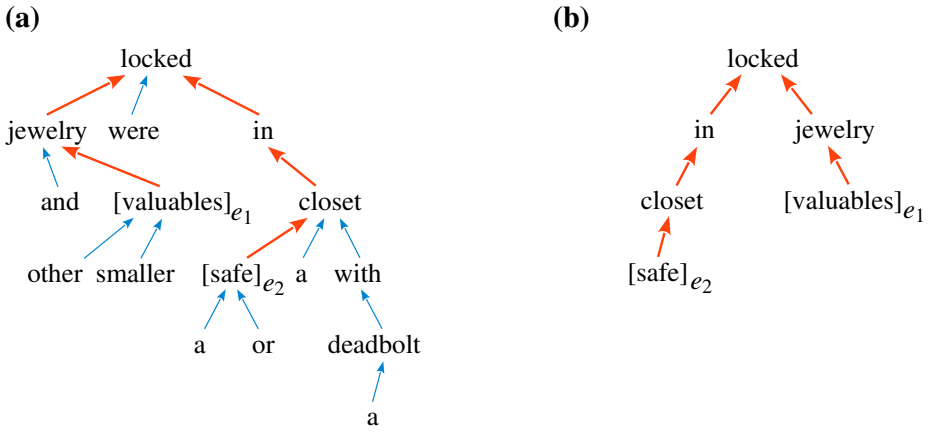

Figure 1: (a) The dependency parse tree corresponding to the sentence "Jewelry and other smaller [valuables]$_{e_1}$ were locked in a [safe]$_{e_2}$ or a closet with a deadbolt." Red arrows indicate the shortest dependency path between e_1 and e_2. (b) The augmented data sample.

two entities. Following our previous work (Xu et al., 2015b), we leverage the shortest dependency path (SDP, Figure 1) as the backbone of our RNNs.

We further observe that the relationship between two entities are directed. Two sub-paths, separated by entities' common ancestor, can be mapped to `subject-predicate` and `object-predicate` components of a relation. By changing the order of these two sub-paths, we obtain a new data sample with the inversed relationship (Figure 1b). Such data augmentation technique can provide additional data samples without using external data resources.

We evaluated our proposed method on the SemEval-2010 relation classification task. Even if we do not apply data augmentation, the DRNNs model has achieved a high performance of 84.2% F_1-score with a depth of 3, but the performance decreases when the depth is too large. This is because the deep RNN is a large model, which necessitates more data samples for training. Applying data augmentation can alleviate the problem of data sparseness and sustain a deeper RNN to improve the performance to 86.1%. The results show that both our deep networks and the data augmentation strategy have contributed to the relation classification task, and that they are coupled well together for further performance improvement.

The rest of this paper is organized as follows. Section 2 reviews related work; Section 3 describes our DRNNs model in detail. Section 4 presents in-depth experimental results. Finally, we have conclusion in Section 5.

2 Related Work

Traditional methods for relation classification mainly fall into two groups: feature-based or kernel-based. The former approaches extract different types of features and feed them into a classifier, e.g., a maximum entropy model (Kambhatla, 2004). Various features, including lexical, syntactic, as well as semantic ones, are shown to be useful to relation classification (Hendrickx et al., 2009). By contrast, kernel-based methods do not have explicit feature representations, but require predefined similarity measure of two data samples. Bunescu and Mooney (2005) design a kernel along the shortest dependency path (SDP) between two entities by observing that the relation strongly relies on SDPs. Plank and Moschitti (2013) combine structural information and semantic information in a tree kernel.

Neural networks have now become a prevailing technique in this task. Socher et al. (2011) design a recursive neural network along the constituency parse tree. Hashimoto et al. (2013), also on the basis of recursive networks, emphasize more on important phrases; Ebrahimi and Dou (2015) restrict recursive networks to SDP. In our previous study (Xu et al., 2015b), we introduce SDP-based recurrent neural network to classify relations.

Zeng et al. (2014), on the other hand, apply CNNs to relation classification. Along this line, dos Santos et al. (2015) replace the common softmax loss function with a ranking loss in their CNN model. Xu et

al. (2015a) design a negative sampling method for SDP-based CNNs.

Besides, representative hybrid models of CNNs and recursive/recurrent networks include Liu et al. (2015) and Nguyen and Grishman (2015).

3 The Proposed Methodology

In this section, we describe our methodology in detail. Subsection 3.1 provides an overall picture of our DRNNs model. Subsections 3.2 and 3.3 describe deep recurrent neural networks. The proposed data augmentation technique is introduced in Subsection 3.4. Finally, we present our training objective in Subsection 3.5.

3.1 Overview

Figure 2 depicts the overall architecture of the DRNNs model. Given a sentence and its dependency parse tree,[1] we follow our previous work (Xu et al., 2015b) and build DRNNs on the shortest dependency path (SDP), which serves as a backbone. In particular, an RNN picks up information along each sub-path, separated by the common ancestor of marked entities. Also, we take advantage of four information channels, namely, word embeddings, POS embeddings, grammatical relation embeddings, and WordNet embeddings.

Different from Xu et al. (2015b), we design deep RNNs with up to four hidden layers so as to capture information in different levels of abstraction. For each RNN layer, max pooling gathers information from different recurrent nodes. Notice that the four channels (with eight sub-paths) are processed in a similar way. Then all pooling layers are concatenated and fed into a hidden layer for information integration. Finally, we have a softmax output layer for classification.

3.2 Recurrent Neural Networks on Shortest Dependency Path

In this subsection, we introduce a single layer of RNN based on SDP, serving as a building block of our deep architecture.

Compared with a raw word sequence or a whole parse tree, the shortest dependency path (SDP) between two entities has two main advantages. First, it reduces irrelevant information; second, grammatical relations between words focus on the action and agents in a sentence and are naturally suitable for relation classification. Existing studies have demonstrated the effectiveness of SDP (Ebrahimi and Dou, 2015; Liu et al., 2015; Xu et al., 2015b; Xu et al., 2015a); details are not repeated here.

Focused on the SDP, an RNN keeps a hidden state vector $\boldsymbol{h}$, changing with the input word at each step accordingly. Concretely, the hidden state $\boldsymbol{h}_t$, for the t-th word in the sub-path, depends on its previous state $\boldsymbol{h}_{t-1}$ and the current word's embedding $\boldsymbol{x}_t$. For the simplicity and without loss of generality, we use vanilla recurrent networks with perceptron-like interaction, that is, the input is linearly transformed by a weight matrix and non-linearly squashed by an activation function, i.e.,

$$\boldsymbol{h}_t = f(W_{\text{in}}\boldsymbol{x}_t + W_{\text{rec}}\boldsymbol{h}_{t-1} + \boldsymbol{b}_h) \tag{1}$$

where W_{in} and W_{rec} are weight matrices for the input and recurrent connections, respectively. $\boldsymbol{b}_h$ is a bias term, and f is a non-linear activation function (ReLU in our experiment).

3.3 Deep Recurrent Neural Networks

Although an RNN, as described above, is suitable for picking information along a sequence (a subpath in our task) by its iterative nature, the machine learning community suggests that deep architectures may be more capable of information integration, and can capture different levels of abstraction.

A single-layer RNN can be viewed that it is deep along *time steps*. When unfolded, however, the RNN has only one hidden layer to capture the current input, as well as to retain the information in its previous step. In this sense, single-layer RNNs are actually shallow in information processing (Hermans and Schrauwen, 2013; Irsoy and Cardie, 2014).

[1] Parsed by the Stanford parser (de Marneffe et al., 2006).

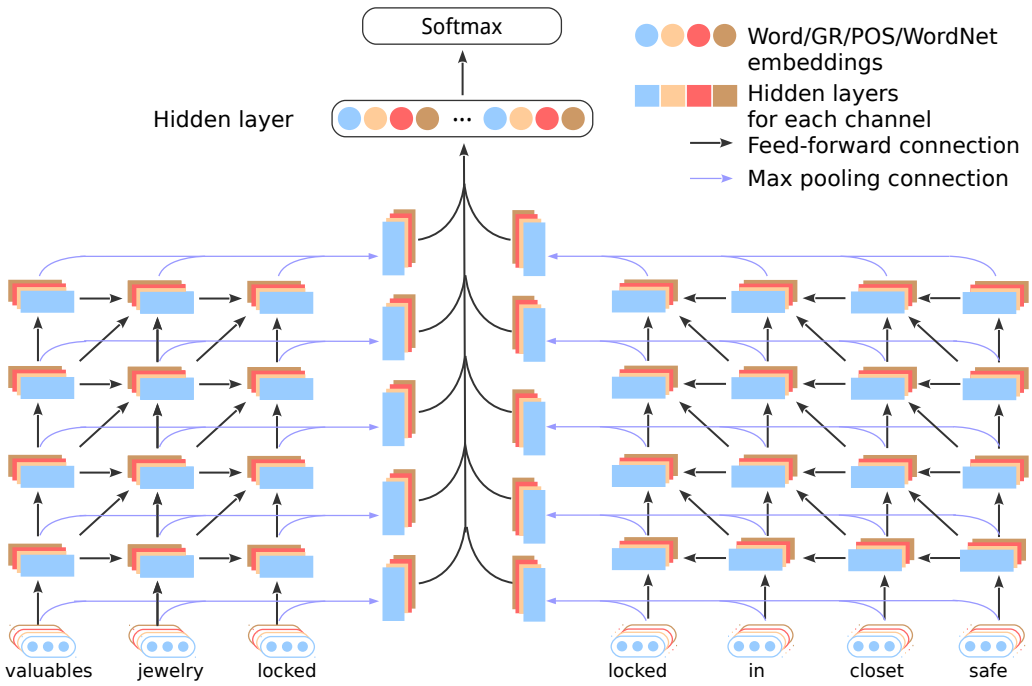

Figure 2: The overall architecture of DRNNs. Two recurrent neural networks pick up information along the shortest dependency path, separated by its common ancestor. We use four information channels, namely words, part-of-speech tags, grammatical relations (GR), and WordNet hypernyms.

In the relation classification task, words along SDPs provide information from different perspectives. On the one hand, the marked entities themselves are informative. On the other hand, the entities' common ancestor (typically verbs) tells how the two entities are related to each other. Such heterogeneous information might necessitate more complex machinery than a single RNN layer.

Following such intuition, we investigate deep RNNs by stacking multiple hidden layers on the top of one another, that is, every layer treats its previous layer as input, and computes its activation similar to Equation 1. Formally, we have

$$\boldsymbol{h}_t^{(i)} = f(W_{\text{in}}^{(i-1)}\boldsymbol{h}_t^{(i-1)} + W_{\text{rec}}^{(i)}\boldsymbol{h}_{t-1}^{(i)} + W_{\text{cross}}^{(i-1)}\boldsymbol{h}_{t-1}^{(i-1)} + \boldsymbol{b}^{(i)}) \tag{2}$$

where the subscripts refer to time steps, and superscripts indicate the layer number. To enhance information propagation, we add a "cross" connection for hidden layers ($i \geq 2$) from the lower layer in the previous time step, given by $W_{\text{cross}}^{(i-1)}\boldsymbol{h}_{t-1}^{(i-1)}$ in Equation 2. (See also $\nearrow$ and $\nwarrow$ arrows in Figure 2).

3.4 Data Augmentation

Neural networks, especially deep ones, are likely to be prone to overfitting. The SemEval-2010 relation classification dataset, we use, comprises only several thousand samples, which may not fully sustain the training of deep RNNs.

To mitigate this problem, we propose a data augmentation technique for relation classification by making use of the directionality of relationships.

The two sub-paths

$[\text{valuables}]_{e_1} \rightarrow \text{jewelry} \rightarrow \text{locked}$

$\text{locked} \leftarrow \text{in} \leftarrow \text{closet} \leftarrow [\text{safe}]_{e_2}$

in Figure 1, for example, can be mapped to the `subject-predicate` and `object- predicate` components in the relation `Content-Container`(e_1, e_2). If we change the order of these two sub-paths, we obtain

$[\text{safe}]_{e_1} \rightarrow \text{closet} \rightarrow \text{in} \rightarrow \text{locked}$
$\text{locked} \leftarrow \text{jewelry} \leftarrow [\text{valuables}]_{e_2}$

Then the relationship becomes `Container-Content`(e_1, e_2), which is exactly the inverse of `Content-Container`(e_1, e_2). In this way, we can augment the dataset without using additional resources.

3.5 Training Objective

For each recurrent layer and embedding layer (over each sub-path for each channel), we apply a max pooling layer to gather information. In total, we have 40 pools, which are concatenated and fed to a hidden layer for information integration.

Finally, a softmax layer outputs the estimated probability that two sub-paths (s^{left} and s^{right}) are of relation r. For a single data sample i, we apply the standard cross-entropy loss, denoted as $J(s_i^{\text{left}}, s_i^{\text{right}}, r_i)$. With the data augmentation technique, our overall training objective is

$$J = \sum_{i=1}^{m} J(s_i^{\text{left}}, s_i^{\text{right}}, r_i) + J(s_i^{\text{right}}, s_i^{\text{left}}, r_i^{-1}) + \lambda \sum_{i=1}^{\omega} \|W_i\|_F$$

where r^{-1} refers to the inverse of relation r. m is the number of data samples in the original training set. ω is the number of weight matrices in DRNNs. λ is a regularization coefficient, and $\|\cdot\|_F$ denotes Frobenius norm of a matrix.

For decoding (predicting the relation of an unseen sample), the data augmentation technique provides new opportunities, because we can use the probability of $r(e_1, e_2)$, $r^{-1}(e_2, e_1)$, or both. Section 4.3 provides detailed discussion.

4 Experiments

In this section, we present our experiments in detail. Subsection 4.1 introduces the dataset; Subsection 4.2 describes hyperparameter settings. We discuss the details of data augmentation in Subsection 4.3 and the rationale for using RNNs in Subsection 4.4. Subsection 4.5 compares our DRNNs model with other methods in the literature. In Subsection 4.6, we have quantitative and qualitative analysis of how the depth affects our model.

4.1 Dataset

We evaluated our DRNNs model on the SemEval-2010 Task 8 dataset, which is an established benchmark for relation classification (Hendrickx et al., 2009). The dataset contains 8000 sentences for training, and 2717 for testing. We split 800 samples out of the training set for validation.

There are 9 directed relations and an undirected default relation `Other`; thus, we have 19 different labels in total. However, the `Other` class is not taken into consideration when we compute the official measures.

4.2 Hyperparameter Settings

This subsection presents hyperparameters of our proposed model. We basically followed the settings in our previous work (Xu et al., 2015b). Word embeddings were 200-dimensional, pretrained ourselves using `word2vec` (Mikolov et al., 2013) on the Wikipedia corpus; embeddings in other channels were 50-dimensional initialized randomly. The hidden layers in each channel had the same number of units as their embeddings (either 200 or 50); the penultimate hidden layer was 100-dimensional. An ℓ_2 penalty of 10^{-5} was also applied as in Xu et al. (2015b), but we chose the dropout rate by validation with a granularity of 5% for our model variants (with different depths).

We also chose the depth of DRNNs by validation from the set $\{1, 2, \cdots, 6\}$. The 3-layer and 4-layer DRNNs yield the highest performance with and without data augmentation, respectively. Section 4.6 provides both quantitative and qualitative analysis regarding the effect of depth.

We applied mini-batched stochastic gradient descent for optimization, where gradients were computed by standard back-propagation.

Variant of Data augmentation	F_1
No Augmentation	84.16
Augment all relations	83.43
Augment `Other` only	83.01
Augment directed relations only	86.10

Table 1: Comparing variants of data augmentation.

	Depth	
	1	2
CNN	84.01	83.78
RNN	84.43	85.04

Table 2: Comparing CNNs and RNNs (also using F_1-score as the measurement).

4.3 Data Augmentation Details

As mentioned in Section 4.1, the SemEval-2010 Task 8 dataset contains an undirected class `Other` in addition to 9 directed relations (18 classes). For data augmentation, it is natural that the inversed `Other` relation is also in the `Other` class itself. However, if we augment all the relations, we observe a performance degradation of 0.7% (Table 1). We deem the `Other` class contains mainly noise, and is inimical to our model. Then we conducted another experiment where we only augmented the `Other` class. The result verifies our conjecture as we obtained an even larger degradation of 1.1% in this setting.

The pilot experiments suggest that we should take into consideration unfavorable noise when performing data augmentation. In this experiment, if we reverse the directed relations only and leave the `Other` class intact, the performance is improved by a large margin of 1.9%. This shows that our proposed data augmentation technique does help to mitigate the problem of data sparseness, if we carefully rule out the impact of noise.

During validation and testing, we shall decode the target label of an unseen data sample (with two entities e_1 and e_2). Through data augmentation, we are equipped with the probability of $r^{-1}(e_2, e_1)$ in addition to $r(e_1, e_2)$. In our experiment, we tried several settings and chose to use $r^{-1}(e_2, e_1)$ only, because it yields the highest the validation result. We think this is probably because the `Other` class brings more noise to r than r^{-1}, as the `Other` class is not augmented (and hence asymmetric).

We would like to point out that our data augmentation method is a general technique for relation classification, which is not *ad hoc* to a specific dataset; that the methodology for dealing with noise is also potentially applicable to other datasets.

4.4 RNNs vs. CNNs

As both RNNs and CNNs are prevailing neural models for NLP, we are curious whether deep architectures are also beneficial to CNNs. We tried a CNN with a sliding window of size 3 based on SDPs, similar to Xu et al. (2015a); other settings were as our DRNNs.

The results are shown in Table 2. We observe that a single layer of CNN is also effective, yielding an F_1-score slightly worse than our RNN. But the deep architecture hurts the performance of CNNs in this task. One plausible explanation is that, when convolution is performed, the beginning and end of a sentence are typically padded with a special symbol or simply zero. However, the shortest dependency path between two entities is usually not very long ($\sim$4 on average). Hence, sentence boundaries may play a large role in convolution, which makes CNNs vulnerable.

On the contrary, RNNs can deal with sentence boundaries smoothly, and the performance continues to increase with up to 4 hidden layers. (Details are deferred to Subsection 4.6.)

4.5 Overall Performance

Table 3 compares our DRNNs model with previous state-of-the-art methods.[2] The first entry in the table presents the highest performance achieved by traditional feature-based methods. Hendrickx et al. (2009) feed a variety of handcrafted features to the SVM classifier and achieve an F_1-score of 82.2%.

Recent performance improvements on this dataset are mostly achieved with the help of neural networks. In an early study, Socher et al. (2012) build a recursive network on constituency trees, but

[2]This paper was preprinted on arXiv on 14 Jan 2016.

Model	Features	F_1
SVM (Hendrickx et al., 2009)	POS, WordNet, prefixes and other morphological features, depdency parse, Levin classes, PropBank, FanmeNet, NomLex-Plus, Google n-gram, paraphrases, TextRunner	82.2
RNN (Socher et al., 2011)	Word embeddings	74.8

	+ data augmentation	**86.1**

Table 3: Comparison of previous relation classification systems.

achieve a performance worse than Hendrickx et al. (2009). They extend their recursive network with matrix-vector interaction and elevate the F_1-score to 82.4%. Ebrahimi and Dou (2015) restrict the recursive network to SDP, which is slightly better than a sentence-wide network. In our previous study (Xu et al., 2015b), we introduce recurrent neural networks based on SDP and improve the F_1-score to 83.7%.

In the school of convolution, Zeng et al. (2014) construct a CNN on the word sequence; they also integrate word position embeddings, which benefit the CNN architecture. dos Santos et al. (2015) propose a similar CNN model, named CR-CNN, by replacing the common softmax cost function with a ranking-based cost function. By diminishing the impact of the `Other` class, they achieve an F_1-score of 84.1%. Xu et al. (2015a) design an SDP-based CNN with negative sampling, improving the performance to 85.6%.

Hybrid models of CNNs and RNNs do not appear to be very useful, achieving up to an F_1-score of 84.1% (Liu et al., 2015; Nguyen and Grishman, 2015).

Yu et al. (2014) propose a Feature-rich Compositional Embedding Model (FCM), which combines unlexicalized linguistic contexts and word embeddings. They do not use neural networks (at least in the usual sense) and achieve an F_1-score of 83.0%.

Our DRNNs model, along with data augmentation, achieves an F_1-score of 86.1%. Even if we do not apply data augmentation, the DRNNs model yields 84.2% F_1-score, which is also the highest score achieved without special treatment to the noisy `Other` class. The above results show the effectiveness of DRNNs, especially trained with a large (augmented) dataset.

4.6 Analysis of DRNNs' Depth

In this subsection, we analyze the effect of depth in our DRNNs model. We have tested the depth from the set $\{1, 2, \cdots, 6\}$, and plot the results in Figure 3. Initially, the performance increases if the depth is larger in both settings with and without augmentation. However, if we do not augment data, the performance peaks when the depth is 3. Provided with augmented training samples, the F_1-score continues to increase with up to 4 layers, and ends up with an F_1-score of 86.1%.

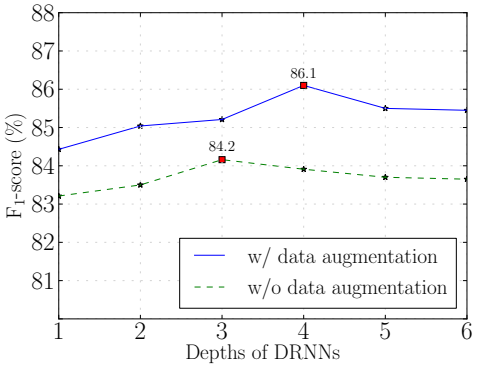

Figure 3: Analysis of the depth.[3]

We next investigate how RNN units in different layers are related to the ultimate task of interest. This is accomplished by tracing back information from pooling layers. Noticing that the pooling layer takes maximum value in each dimension, we can compute how much a hidden layer's units are gathered by pooling for further processing. In this way, we are able to demonstrate the information flow in RNN hidden units. We plot three examples in Figure 4. Here, rectangles refer to RNN hidden layers, unfolded along time. (Rounded rectangles are word embeddings.) The intensity of color reflects the ratio of the pooling proportion.

- Sample 1: "Until 1864 $[\text{vessels}]_{e_1}$ in the service of certain UK public offices defaced the Red Ensign with the $[\text{badge}]_{e_2}$ of their office" with label `Instrument-Agency`(e_2, e_1). Its two sub-paths of SDP are

  $[\text{vessels}]_{e_1} \rightarrow \text{until} \rightarrow \text{defaced}$
  $\text{defaced} \leftarrow \text{with} \leftarrow [\text{badge}]_{e_2}$

  From Figure 4a, we see that entities like *vessels* and *badge* are darker than the verb phrase *defaced with* on the embedding layer. When information is propagating horizontally and vertically, these entities are getting lighter, while the verb phrase becomes darker gradually. Intuitively, we think that, considering the relation `Instrument-Agency`(e_2, e_1), it is less informative with only two entities *vessels* and *badge*. When adding the semantic of verb phrase *defaced with*, we are more aware of the target relation.

- Sample 2: "Most of the $[\text{verses}]_{e_1}$ of the plantation songs had some reference to $[\text{freedom}]_{e_2}$" with label `Message-Topic`(e_1, e_2). Its two sub-paths of SDP are

  $[\text{verses}]_{e_1} \rightarrow \text{of} \rightarrow \text{most} \rightarrow \text{had}$
  $\text{had} \leftarrow \text{reference} \leftarrow \text{to} \leftarrow [\text{freedom}]_{e_2}$

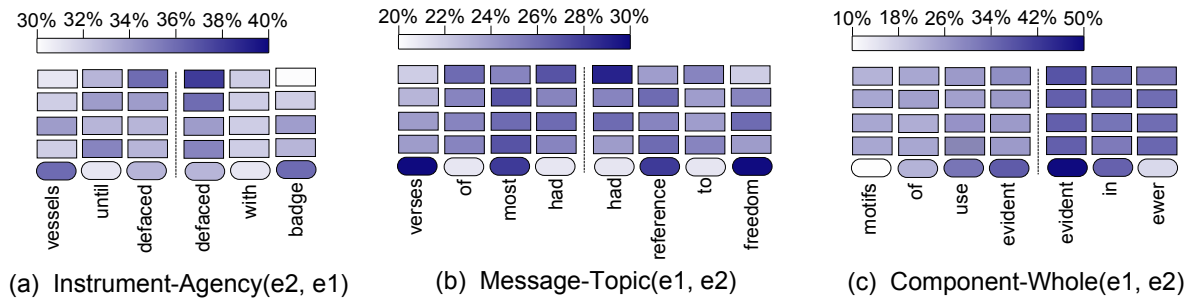
  Similar to Sample 1, we see from Figure 4b that the color of the "pivot" verb *had* is getting darker vertically, and becomes the darkest in the fourth RNN layer, indicating the highest pooling portion. This is probably because *had* links two ends of the relation, `Message` and `Topic`.

- Sample 3: "A more spare, less robust use of classical $[\text{motifs}]_{e_1}$ is evident in a $[\text{ewer}]_{e_2}$ of 1784-85" with label `Component-Whole`(e_1, e_2). Its two sub-paths of SDP are

  $[\text{motifs}]_{e_1} \rightarrow \text{of} \rightarrow \text{use} \rightarrow \text{evident}$
  $\text{evident} \leftarrow \text{in} \leftarrow [\text{ewer}]_{e_2}$

  Different from Figures 4a and 4b, higher layers pay more attention to entities rather than their ancestor. In this example, *motifs* and *ewer* appear to be more relevant to the relation `Component-Whole` than their common ancestor *evident*. The pooling proportion of entities (*motifs*, *ewer*) is increasing, while other words' proportion is decreasing.

[3] Using vanilla RNN with a depth of 1, we obtained a slightly better accuracy in this paper than Xu et al. (2015b).



(a) Instrument-Agency(e2, e1) (b) Message-Topic(e1, e2) (c) Component-Whole(e1, e2)

Figure 4: Visualization of information propagation along multiple RNN layers.

We summarize our findings as follows. (1) Pooled information usually peaks at one or a few words in the embedding layer. This makes sense because there is no information flow in this layer. (2) Information scatters over a wider range in hidden layers, showing that the recurrent propagation does mix information. (3) For a higher-level layer, the network pays more attention to those words that are more relevant to the relation, but whether entities or their common ancestor is more relevant is not consistent among different data samples.

5 Conclusion

In this paper, we proposed deep recurrent neural networks, named DRNNs, to improve the performance of relation classification. The DRNNs model, consisting of several RNN layers, explores the representation space of different abstraction levels. By visualizing DRNNs' units, we demonstrated that high-level layers are more capable of integrating information relevant to target relations. In addition, we have designed a data augmentation strategy by leveraging the directionality of relations. When evaluated on the SemEval dataset, our DRNNs model results in substantial performance boost. The performance generally improves when the depth increases; with a depth of 4, our model reaches the highest F_1-measure of 86.1%.

Abstract

Distant supervision is an efficient approach that automatically generates labeled data for relation extraction (RE). Traditional distantly supervised RE systems rely heavily on handcrafted features, and hence suffer from error propagation. Recently, a neural network architecture has been proposed to automatically extract features for relation classification. However, this approach follows the traditional expressed-at-least-once assumption, and fails to make full use of information across different sentences. Moreover, it ignores the fact that there can be multiple relations holding between the same entity pair. In this paper, we propose a multi-instance multi-label convolutional neural network for distantly supervised RE. It first relaxes the expressed-at-least-once assumption, and employs cross-sentence max-pooling so as to enable information sharing across different sentences. Then it handles overlapping relations by multi-label learning with a neural network classifier. Experimental results show that our approach performs significantly and consistently better than state-of-the-art methods.

1 Introduction

Relation extraction (RE), defined as the task of extracting binary relations from plain text, has long been a crucial task in natural language processing. Supervised methods are widely used for this task due to their relatively high performance (Zhou et al., 2005; Surdeanu and Ciaramita, 2007). Such methods, however, usually require intensive human annotation and can be time-consuming. To address this issue, distant supervision is proposed to generate labeled data automatically, by aligning facts in a knowledge base (KB) with sentences mentioning these facts (Mintz et al., 2009; Riedel et al., 2010; Riedel et al., 2013).

Traditional (distantly) supervised RE methods use as input numerous lexical and syntactic features, e.g., POS tags, dependency paths, and named entity tags (Mintz et al., 2009; Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012). These features are extracted from sentences using various NLP algorithms, thus inevitably have errors. The induced errors become more serious for long sentences (McDonald and Nivre, 2007), which is unfortunately very common in real-world relation extraction corpus (Zeng et al., 2015). Building distant supervision methods on faulty features inevitably leads to error propagation, the main culprit responsible for performance degradation. Recent studies have shown promising results on using deep neural networks for automatic feature extraction (Zeng et al., 2014; Liu et al., 2015; Xu et al., 2015). Particularly, Zeng et al. (2015) proposed a piecewise convolutional neural network (PCNN) architecture, which can build an extractor based on distant supervision. PCNN automatically extracts features with convolutional neural networks, and introduces piecewise max-pooling to better fit the RE scenario. Although PCNN achieves substantial improvements in distantly supervised relation extraction, it still has the following deficiencies.

First, PCNN uses the expressed-at-least-once assumption (Riedel et al., 2010) for labeled data generation, which states that "if two entities participate in a relation, at least one sentence that mentions

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1471–1480, Osaka, Japan, December 11-17 2016.

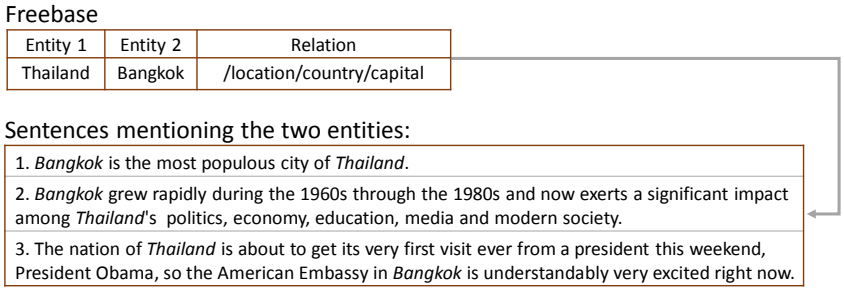

Figure 1: The new assumption states that a relation holding between two entities can be either expressed explicitly or inferred implicitly from all sentences that mention these two entities.

these two entities will express that relation". According to this assumption, PCNN selects only the most likely sentence for each entity pair in training and prediction. We argue, however, that the expressed-at-least-once assumption might be too strong, and selecting a single sentence will definitely lose rich information contained in other sentences. Actually, given two entities participating in a KB relation, it might be difficult to find from the training text the exact single sentence that expresses the relation. Aggregating information available in multiple sentences would probably make the alignment an easier task. Take Figure 1 for example. Given the KB fact (`Thailand`, `/location/country/capital`, `Bangkok`), none of the three sentences mentioning `Thailand` and `Bangkok` expresses the relation of `/location/country/capital`. But if we consider these sentences collectively, we will get more evidence supporting the fact, profiting from the relevant information available in different sentences.

Second, PCNN treats distantly supervised RE as a single-label learning problem and selects for each entity pair a single relation label, ignoring the fact that there might be multiple relations holding between the same entity pair. In fact, as pointed out by Hoffmann et al. (2011), about 18.3% of the distant supervision facts in Freebase that match sentences in the New York Times 2007 corpus have overlapping relations.

In this paper, we propose a multi-instance multi-label convolutional neural network (MIMLCNN) architecture to address the two problems described above. For the first problem, we relax the expressed-at-least-once assumption, and instead assume that "*a relation holding between two entities can be either expressed explicitly or inferred implicitly from all sentences that mention these two entities*" (see Figure 1 for a simple illustration). Therefore, after automatically extracting features within each sentence using a convolutional architecture, we employ cross-sentence max-pooling to select features across different sentences, and then aggregate the most significant features into a vector representation for each entity pair. Since the resultant representation consists of features from different sentences, we successfully make full use of all available information contained in these sentences. For the second problem, we handle overlapping relations by designing various multi-label loss functions in the neural network classifier. The overall architecture is sketched in Figure 2.

The main contributions of this paper can be summarized as follows: (1) We relax the expressed-at-least-once assumption, and propose a more realistic one that naturally enables information sharing from multiple sentences for relation extraction. (2) We propose a multi-instance multi-label convolutional neural network architecture, which handles the multi-label nature of relation extraction. (3) We evaluate our approach on a real-world dataset, and show significant and consistent improvements over state-of-the-art methods.

2 Related Work

Relation extraction is one of the most important tasks in NLP, and has been applied in many practical scenarios (Kordjamshidi et al., 2011; Madaan et al., 2016). Supervised methods has relatively high performance and better practicability, but require massive human annotation, which is both expensive and time consuming. Distant supervision solves this problem by using heuristic assumptions to align triples in a knowledge base with sentences in real-world text corpus, and has been employed in building

large-scale knowledge bases like Knowledge Vault (Dong et al., 2014). A well-known approach in distant supervision is Mintz et al. (2009), which aligns Freebase with Wikipedia articles and extracts relations with logistic regression. Follow-up studies use the feature set developed in this approach, but with deeper understanding on the nature of distant supervision. For example, Riedel et al. (2010) relaxes the assumption used in Mintz et al. (2009) and formulates distant supervision as a multi-instance learning issue; Hoffmann et al. (2011) and Surdeanu et al. (2012) consider overlapping relations between an entity pair. Further effects are also made to model missing data (Ritter et al., 2013), reduce noise (Roth et al., 2013), inject logical background knowledge (Rocktäschel et al., 2015), etc.

In recent years, deep neural network has proven its ability to learn task-specific representation automatically, so that avoiding error propagation suffered by traditional feature-based models. In particular, many neural network approaches have been proposed and shown better performance in relation classification (Zeng et al., 2014; Liu et al., 2015; Xu et al., 2015) and relation extraction (Nguyen and Grishman, 2015). However, these two tasks differ from ours in that relations are extracted at sentence-level, while annotation data is readily available. In distant supervision paradigm, Zeng et al. (2015) is a known neural network model that uses expressed-at-least-once assumption for multi-instance single-label learning. Nevertheless, it selects only one sentence as the representation of an entity pair in training phrase, which wastes the information in the neglected sentences. Besides, it also fails to consider other relations that might hold between this entity pair. The proposed method, on the other hand, leverages evidences collected from all the aligned sentences, and models overlapping relations with multi-label learning.

In traditional supervised learning, an example is usually represented by one instance and one class label. However, there are real-world issues that an example contains multiple instances and has a set of labels. This multi-instance multi-label (MIML) learning scenario was formulated in Zhou et al. (2012), and get widely employed in various tasks (Zha et al., 2008; Zhou and Zhang, 2006; Li et al., 2012). Distant supervised relation extraction is by nature a MIML learning issue, where example is entity pair, instance is sentence aligned with the pair, and label denotes relations. Among previous distant supervision methods, (Surdeanu et al., 2012) formally proposed a multi-instance multi-label framework in a Bayesian framework. In contrast, our method is constructed under a neural network architecture, with the merit of no dependency on lexical and syntactic features.

3 Our Approach

The proposed model takes as input an entity pair (e_1, e_2) as well as all the sentences aligned to this pair, and outputs a set of KB relations that hold between the two entities. As illustrated in Figure 2, our approach consists of three key steps: (1) sentence-level feature extraction, (2) cross-sentence max-pooling, and (3) multi-label relation modeling, detailed as follows.

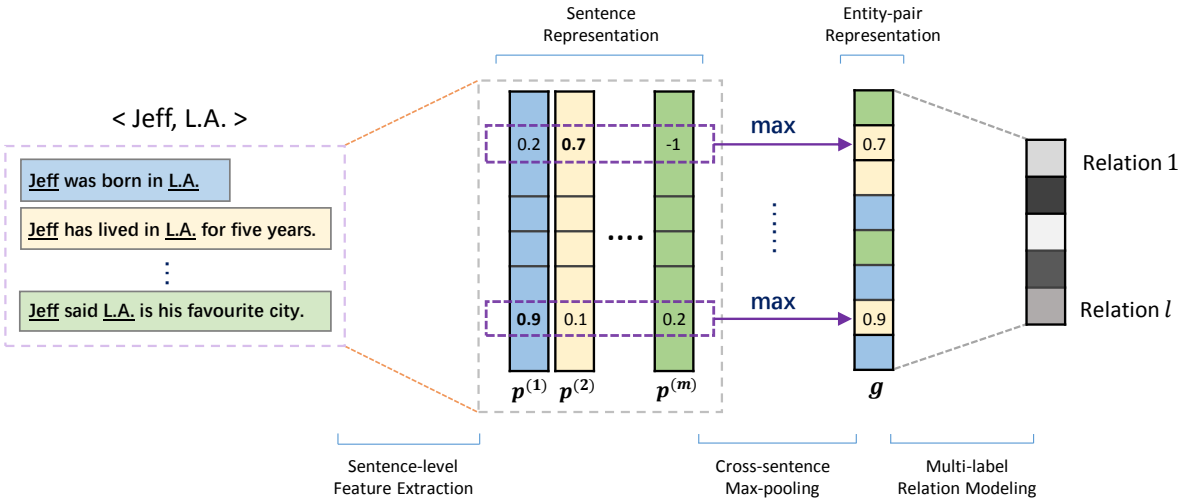

Figure 2: Overall architecture of MIMLCNN.

3.1 Sentence-level Feature Extraction

Sentence-level feature extraction aims to produce a vector feature for each of the aligned sentences. We first pad sentence length to h with zero and transform it to a matrix representation, where each row represents a word token. Convolution, piecewise max-pooling operations are then applied on the matrix to get the vector representation, as illustrated in Figure 3.

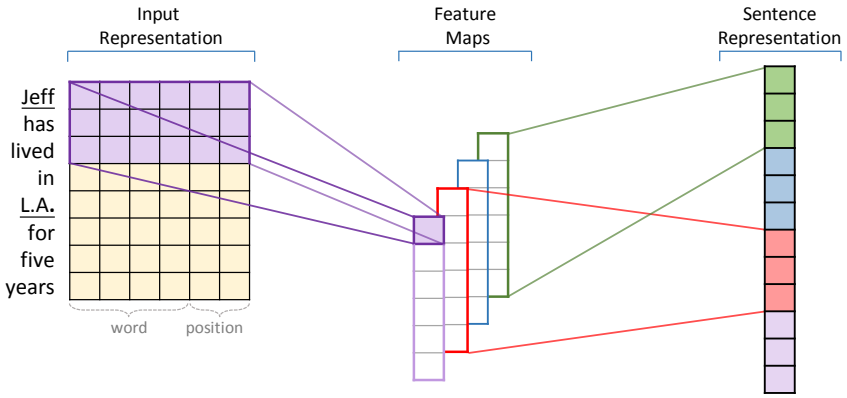

Figure 3: Sentence-level feature extraction using a convolutional architecture.

3.1.1 Input Representation

Two kinds of information are used to construct the input representation for each sentence:

- Raw tokens: We first split the sentence into a sequence of word tokens, then map each token to a d_w dimensional vector called word embedding. The embedding vectors are learned by model training.
- Position features: we use position features (Zeng et al., 2014) to point out the relative positions of a token to e_1 and e_2 in the sentence. Each token has two relative positions, and they are mapped to two different d_p dimensional vectors, separately.

We concatenate the result of these two parts and get matrix $\mathbf{X} \in \mathbb{R}^{h \times d_s}$ as input representation, where $d_s = d_w + 2 * d_p$.

3.1.2 Convolution

The convolution operation aims to extract features from input matrix $\mathbf{X}$, and can be formulated as:

$$c_i = f(\sum_{j=1}^{w_c} \sum_{k=1}^{d_s} \mathbf{W}_{j,k} \mathbf{X}_{j+i-1,k} + b) \tag{1}$$

Here $\mathbf{W} = \mathbb{R}^{w_c \times d_s}$ is a convolutional matrix, where w_c is the width of convolution window; $b \in \mathbb{R}$ is a bias; $f(\cdot)$ is a non-linear function such as Tanh, ReLU. A feature map $\mathbf{c} = [c_1, c_2, \cdots, c_{(h-w_c+1)}]$ is produced by sliding convolution window down the sentence and applying this function at each valid position. To extract n features from the sentence, we repeat the above process with different $\mathbf{W}, b$ for n times. The resultant feature maps are then stacked to construct matrix $\mathbf{C} \in \mathbb{R}^{n \times (h-w_c+1)}$.

3.1.3 Piecewise Max-pooling

To capture the most important feature, max-over-time pooling is often used to select the maximum activation value in each feature map. Piecewise max-pooling (Zeng et al., 2015) improves this idea by first dividing each feature map $\mathbf{C}_i$ into three components $\{\mathbf{c}_{i1}, \mathbf{c}_{i2}, \mathbf{c}_{i3}\}$ based on the positions of the two entities, and then applying max-over-time pooling on each component. This process is formulated as:

$$p_{ij} = max(\mathbf{c}_{ij}) \qquad 1 \le i \le n, 1 \le j \le 3 \tag{2}$$

When piecewise max-pooling is finished, the results of each feature map are concatenated to form vector $\mathbf{p} \in \mathbb{R}^{3n}$, as the feature representation for this sentence.

3.2 Cross-sentence Max-pooling

In the last subsection, we obtain a feature vector $\mathbf{p}$ for each single sentence, but how to take fully usage of the information across sentences is still worth attention. In this paper, we solve this problem by relaxing expressed-at-least-once assumption as:

Assumption: *A relation holding between two entities can be either expressed explicitly or inferred implicitly from all sentences that mention these two entities.*

That is, we relax the expressed-at-least-once assumption by not only allowing making predictions from evidences in each single sentence, but also allowing making predictions by inferring from evidences in all sentences collectively. By nature of this assumption, we skip sentence-level relation extraction and directly make prediction at entity-pair-level, which is more concerned for downstream application and beneficial for evidence aggregation, as described in Riedel et al. (2010).

We propose cross-sentence max-pooling to take the advantage of this assumption. Suppose there are m sentences aligned with the entity pair, and $p_i^{(j)}$ denotes the i^{th} component of the vector representation of the j^{th} sentence, cross-sentence max-pooling aggregates all sentence representations into an entity-pair-level representation $\mathbf{g} = [g_1, g_2, ..., g_{3n}]$, where:

$$g_i = \max(p_i^{(1)}, p_i^{(2)}, \cdots, p_i^{(m)}) \tag{3}$$

This operation brings the following benefits: First, it aggregates features from each sentence, thus supporting entity-pair-level relation extraction directly. Second, it can collect evidence from different sentences, which enables classifiers to make prediction with evidences from different sentences. Besides, compared with Zeng et al. (2015) who only selects one sentence for training at one time, we take advantage of information from all available sentences in each training iteration.

Other approaches, such as mean-pooling, can also be applied in this phrase, but we use cross-sentence max-pooling for the following reason: We consider that multiple occurrences of a feature do not supply much extra information in entity-pair-level relation extraction. That is, a discriminative signal that appears only once can also be sufficient for extracting a relation. This thinking is embodied in the cross-sentence max-pooling operation, where the maximum activation level of each feature is collected across sentences. In contrast, mean pooling averages activation signals by the number of sentences, so that predictive features may be diluted in the representation of entity-pairs that have multiple mentions. This claim is supported by the experimental results.

3.3 Multi-label Relation Modeling

In distant supervision, there are often multiple relations holding between an entity pair. Existing neural network method adopts multi-instance learning, but with single label. In this paper, we model distant supervision under neural network architecture as a multi-label learning problem.

We first calculate the confidence scores for each label by:

$$\mathbf{o} = \mathbf{W_1 g} + \mathbf{b_1} \tag{4}$$

where matrix $\mathbf{W}_1 \in \mathbb{R}^{3n \times l}$ is the collection of weight vectors for each label; $\mathbf{b}_1 \in \mathbb{R}^l$ is a bias. Afterwards, we apply sigmoid function on each element of the score vector $\mathbf{o}$ to calculate the probability of each relation:

$$p(i|M, \theta) = \frac{1}{1 + e^{-o_i}}, \quad i = \{1, 2, \cdots, l\} \tag{5}$$

where M denotes the set of the aligned sentences, and l is the number of relation labels.

A binary label vector $\mathbf{y}$ is set to indicate the set of true relations holding between the entity pair, where 1 means an relation in the set, and 0 otherwise. This way, NA (meaning there is no relation between the entity pair) is naturally represented as an all-zero vector, the complement of the combinations of positive relations.

It is worth noting that relations are often not independent. For example, if triple (A, *capital*, B) holds, another triple (A, *contains*, B) will hold as well. In our model, dependencies between relations are handled by using a shared entity-pair-level representation for all relation labels.

Following this setting, we design two loss functions for multi-label modeling:

$$Loss_{sigmoid} = -\sum_{i=1}^{l} y_i log(p_i) + (1 - y_i) log(1 - p_i) \tag{6}$$

$$Loss_{squared} = \sum_{i=1}^{l} (y_i - p_i)^2 \tag{7}$$

where $y_i \in \{0, 1\}$ is the true value on label i. In the rest sections of this paper, these two loss functions are denoted by sigmoid loss and squared loss, respectively.

The proposed method is trained in an end-to-end fashion. Loss functions are optimized with Adadelta (Zeiler, 2012), which is an robust variant of Stochastic Gradient Decent (SGD) method and features adaptive learning rate over time. Dropout (Srivastava et al., 2014) is also employed on formula (4) for regularization. Specifically, at training time, each element in $\mathbf{g}$ is randomly dropped out by multiplying a Bernoulli random variable with probability p of being 0. At test time, the learned matrix $\mathbf{W}_1$ is scaled by p (i.e. $\hat{\mathbf{W}}_1 = p\mathbf{W}_1$) before scoring. Given an entity pair, the proposed model selects relations whose probability exceeds 0.5 as predicted labels. If there is no such relation, NA is assigned to this entity pair.

4 Experiments

4.1 Dataset

We evaluate our approach on the basis of NYT10, a dataset developed by (Riedel et al., 2010) and then widely used in distantly supervised relation extraction (Hoffmann et al., 2011; Surdeanu et al., 2012; Zeng et al., 2015). NYT10 was generated by aligning Freebase relations with the New York Times (NYT) corpus, with sentences from the years of 2005 and 2006 used for training and sentences from 2007 used for testing.

We follow (Zeng et al., 2015) and use a filtered version of NYT10 released by them[1]. The filtered version prunes the original NYT10 data slightly by removing (1) duplicated sentences for each entity pair, (2) sentences which have more than 40 tokens between a pair of entities, and (3) sentences with entity names that are substrings of other entity names in Freebase. As a result, some relations with low frequency are removed. Statistics of this dataset is shown in Table 1.

	# EPs	# positive EPs	# negative EPs	# sentences	# relations
Training	65,726	4,266	61,460	112,941	26
Testing	93,574	1,732	91,842	152,416	26

Table 1: Statistics of the filtered NYT10 dataset, where EP denotes entity pair.

4.2 Evaluation Metrics

In the following experiments, we use held-out evaluation. At testing time, predicted triples are judged by comparing them with ground truth triples in the testset. We evaluate the performance of each model with Precision-Recall curve, a common used metric for the ranked retrieval results, and P@N metric.

4.3 Baseline Methods

We select three popular feature-based traditional methods as well as the CNN-based method as baselines. We briefly introduce these baselines as follows:

- PCNN: employed a convolutional neural network based method for relation extraction. In contrast to traditional methods, this method allows for automatic feature extraction from raw text, hence avoiding error propagations. Besides, it also uses piecewise max-pooling for sentence-level relation

[1] http://www.nlpr.ia.ac.cn/cip/~liukang/liukangPageFile/code/ds_pcnns-master.zip

extraction. In the following experiments, we use the PCNN code[1] published on the authors' website, along with the dataset.

- Mintz++: (Mintz et al., 2009) proposed distant supervision paradigm that aligns knowledge base entity pairs with text corpus in relation extraction, thus voiding human annotation. The method uses as input lexical and syntactic features, and multi-class logistic regression for classification. [2]
- Multir: (Hoffmann et al., 2011) pointed out that many entity pairs have more than one relation. Their method models overlapping relations by combining sentence-level relation extraction results into entity-pair-level results, with a deterministic decision.
- MIMLRE: (Surdeanu et al., 2012) proposed a novel multi-instance multi-label approach for distant supervision using a graph model. For each entity pair, this method jointly models its multiple instances and multiple labels. Besides, it also models the correlation between labels.

4.4 Implementation Details

As a common practice in neural network models, word embeddings are initialized with pre-training. We run skip-gram model (Mikolov et al., 2013) on training dataset, and use the obtained word vector to initialize the word embedding part of model input. Position features are randomly initialized with uniform distribution between [-1, 1]. For convenience of comparing with baseline methods, our model uses the same parameter settings as (Zeng et al., 2015). Specifically, At model input layer, we use a mini-batch of 50 entity pairs, set the dimension of word embedding $d_w = 50$ and the dimension of position feature $d_p = 5$. At convolutional layers, windows size w_c is set to 3, and the number of feature maps to $n = 230$. Dropout rate p is set to 0.5. Two Adadelta parameters , $\rho = 0.95$ and $\epsilon = e^{-6}$, are set with default values. For baseline models, we use the codes released by (Surdeanu et al., 2012) [3] and Zeng et al. (2015). Since PCNN and MIMLCNN are influenced by random factors when running on GPU, we run both models with the above-mentioned settings for ten times and use the averaged results in the following comparisons.

4.5 Comparison with Baseline Methods

To evaluate the performance of the proposed method, we first compare it to baseline methods. In the following experiments, we use MIMLCNN to refer to the proposed model with cross-sentence max-pooling and sigmoid loss. Figure 4 shows the resulting precision-recall curve in the most concerned area.

From the curves, we observe that MIMCNN can consistently and significantly outperform all baseline methods in the entire range of recall. Comparing neural network methods with traditional feature-based methods, we can conclude that PCNN exceeds traditional methods for its alleviation of error propagation, while MIMCNN exceeds PCNN for its usage of cross-sentence max-pooling and multi-label modeling. The result indicates that the proposed method has the best sense of exploiting the characteristic of distant supervision in a neural network framework. It is worth emphasising that the best of baseline methods can keep a reasonable precision level (larger than 0.5) when recall is less than 0.17. In contrast, our model can keep the same precision level with recall at 0.28, amounting to a 64% increase. Also note that beyond the truncated recall level (0.35), the curve of our method can extend to recall at 0.66 without any loss of precision. This brings 103% increase at the maximum recall level in comparison with the best of baseline methods.

Table 2 further presents the results using P@N metric. In accordance with our observation in precision-recall curve, MIMLCNN is still the winner at most of the entire P@N levels. It is interesting that both of the neural network methods are all good at predicting top-ranked results compared with traditional feature-based methods, especially MIMLCNN. As N gets smaller, the superiority becomes more evident. At P@10, the precision of MIMLCNN can even reach to 0.90, while neither of the baseline methods can exceed 0.84. Also, MIMLCNN is the only method whose mean value of P@N exceeds 0.7.

[2]Note that in the following experiment we use the Surdeanu et al. (2012) implemented version, which has been reported significantly better performance than the original one.

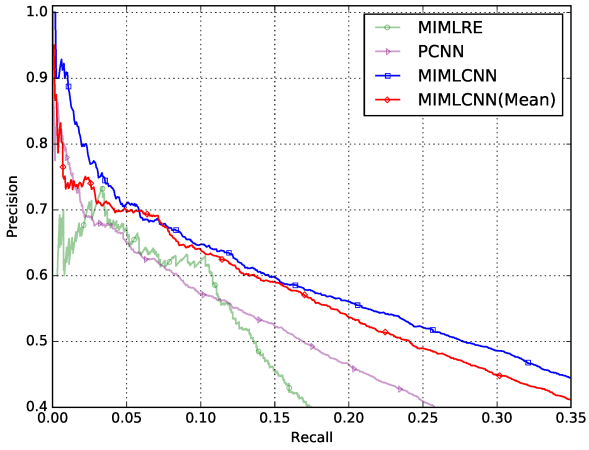
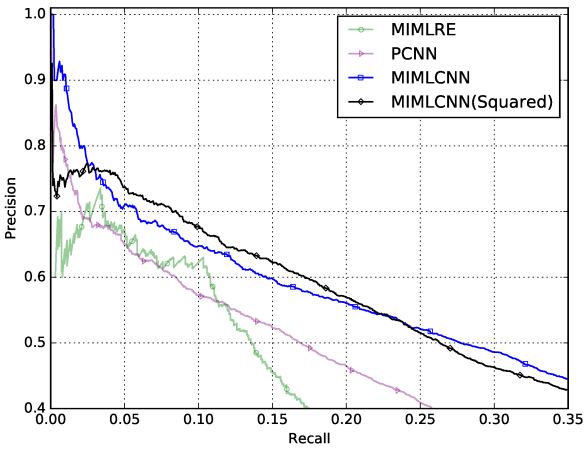
4.6 Effects of Cross-sentence Max-pooling and Multi-label Learning

In this subsection, we empirically prove the effects of cross-sentences max-pooling and multi-label learning, respectively.

In order to prove the effectiveness of cross-sentence max-pooling, we create a baseline method called MIMLCNN(Mean). Comparing with MIMLCNN, this method merely replaces cross-sentence max-pooling with the average of feature representations of all the aligned sentences. Experimental result is presented in Figure 5(b). In almost the entire curves of these two models, MIMLCNN shows better performance. The superiority is especially significant in the front and rearward part of recall levels. This observation supports our claim that cross-sentence max-pooling helps improving performance. It is also interesting that MIMLCNN(Mean) still shows improvements over the baseline methods, though not comparable with MIMLCNN.



(a) Cross-sentence max-pooling.



(b) Multi-label learning.

Figure 5: Effects of cross-sentence max-pooling and multi-label learning. PCNN and MIMLRE are used for reference.

We further compare the effect of using different loss functions in our model, as demonstrated in Figure 5(b). MIMLCNN(Squared) refers to the proposed model with cross-sentence max-pooling and squared loss. From the curves of these two models, we can see that different loss functions have diverse emphases. When we use sigmoid loss (MIMLCNN), most of the improvement resides in recall range [0.1, 0.3], but still remains competitive or slightly better in range [0, 0.1]. Compared with sigmoid loss, using

squared loss brings better performance at the middle area of the curve, but it is also less competitive with respect to the top-ranked results. In contrast with baseline methods, the superiority of MIMLCNN and MIMLCNN(Squared) indicates that multi-label modeling contributes to improving performance in distant supervision.

5 Conclusion

In this paper, we propose a novel neural network method for distant supervision with multi-instance multi-label learning. Given an entity pair, we relax the expressed-at-least-once assumption to take full usage of information from all the aligned sentences with cross-sentence max-pooling, and model multiple relations holding between the entity pair in a neural network architecture. We conduct experiments on a real-world dataset, and prove empirically (1) the proposed method has significantly and consistently better performance than state-of-the-art methods. (2) both cross-sentence max-pooling and multi-label learning take effects. In the future, we would like to further investigate how different loss functions influence performance, and enrich experiments by carrying out human evaluation as well as making detailed analysis on each relation.

Named Entity Disambiguation for little known referents: a topic-based approach

Andrea Glaser and Jonas Kuhn
Institute for Natural Language Processing
University of Stuttgart, Germany
andrea.glaser@ims.uni-stuttgart.de

Abstract

We propose an approach to Named Entity Disambiguation that avoids a problem of standard work on the task (likewise affecting fully supervised, weakly supervised, or distantly supervised machine learning techniques): the treatment of name mentions referring to people with no (or very little) coverage in the textual training data is systematically incorrect. We propose to indirectly take into account the property information for the "non-prominent" name bearers, such as nationality and profession (e.g., for a Canadian law professor named *Michael Jackson*, with no Wikipedia article, it is very hard to obtain reliable textual training data). The target property information for the entities is directly available from name authority files, or inferrable, e.g., from listings of sportspeople etc. Our proposed approach employs topic modeling to exploit textual training data based on entities sharing the relevant properties. In experiments with a pilot implementation of the general approach, we show that the approach does indeed work well for name/referent pairs with limited textual coverage in the training data.

1 Introduction

A central subtask for complex information retrieval and natural language understanding problems lies in the determination of what are the real-world entities that the proper names in a text refer to. While for some proper names (e.g., *Henry VIII of England*), the correct referent can be uniquely determined, the great majority of name mentions requires disambiguation. For instance, the name *Michael Jackson* can refer to the famous American singer, a British writer and beer expert, a Canadian actor, and many other people.

The corresponding technical Natural Language Processing (NLP) Task, which is known by various names – Named Entity Disambiguation (e.g., Hoffart et al. (2011)), Entity Linking (e.g., Han et al. (2011)), or Wikification (Mihalcea and Csomai, 2007) – is typically construed as determining for each textual mention of a proper name, which of (typically) several entries in a knowledge base (such as DBpedia or Wikipedia) representing unique referents is the correct one in the given context.

The standard approach to this task is to view it as a supervised classification problem, i.e., training data of textual mentions labeled with the correct disambiguation target are used to induce knowledge about indicative contextual clues for each candidate. A considerable amount of research has gone into the development of effective models (Mann and Yarowsky, 2003; Malin, 2005; Bollegala et al., 2006; Chen and Martin, 2007), and particularly into weakly supervised or distant supervision techniques, i.e., finding ways of exploiting explicit or implicit indications for the correct name references in real-life data (Cohen, 2005; Bunescu and Pasca, 2006; Cucerzan, 2007; Mihalcea and Csomai, 2007; Han et al., 2011; Hoffart et al., 2011). Indeed, for medium-to-high frequency name/referent combinations, it is not hard to harvest the web for suitable training material.

The contribution that we present in this paper is motivated by a type of name/referent pairs that falls outside of the standard training scenario and has so far received little attention from the research com-

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1481–1492, Osaka, Japan, December 11-17 2016.

Entity	Wikipedia
American singer	✓
British writer	✓
Canadian actor	✓
...	
Canadian law professor	×

Table 1: Examples for *Michael Jackson*.

munity[1]: besides the "prominent" bearers of a name, there are almost always others for whom little or no training material can be found by web harvesting, and who will often not even appear in the major reference knowledge bases (DBpedia, Wikipedia etc.). Table 1 shows examples of entities with the proper name *Michael Jackson* and whether or not they have a Wikipedia article. Persons need to be "worthy of notice" to be included in Wikipedia. There is a *Michael Jackson* who is a Canadian law professor, but is not among the 35 or so Michael Jacksons with their own Wikipedia articles. Still, the reference for many of these people *could* be uniquely identified by the name authority files curated by national libraries (e.g., the German Integrated Authority File; "Gemeinsame Normdatei") or other lists that provide unique identification from a specific application perspective, such as staff lists on institutional websites or listings of sportspeople.

Under the established approaches, a trained Named Entity Disambiguation system will incorrectly map those mentions which actually refer to the less known name bearers to the contextually most similar prominent person. In a standard evaluation, these false positives are often negligible since the "non-prominent" mentions are orders of magnitude less frequent. In practice however, any system that is systematically missing out on theoretically identifiable people is problematic (e.g., search engines and Question Answering (QA) systems would return more unwanted or incorrect results, or not find results about the person at all because of an incorrect mapping to a similar, more well-known person).

The purpose of this paper is (i) to propose a general approach for dealing with these cases systematically, and (ii) to present a pilot implementation of this idea using topic modeling. For evaluation, we "simulate" the situation of non-prominent name bearers by leaving documents about them out of the actual training data; this allows us to perform comparative experiments on a manageable collection. As test data we actually use texts containing explicit links to Wikipedia entries, which allows us to circumvent costly manual annotation of the name disambiguation (we call this resource our "silver standard" corpus).

The approach rests on the idea that for non-prominent name bearers, for which no or very little training material containing real mentions is available, we will nevertheless know some characteristic properties – namely, the ones mentioned in a name authority file (typically profession and nationality, as well as age and place of birth, plus possibly institutional affiliation), or similarly properties derivable from other listings. So, while we have no textual training data for the specific person (say, the Canadian law professor *Michael Jackson*), we can use some aggregate of the textual material about different people with the same properties as a proxy (i.e., mentions of all Canadians, of all law scholars, professors etc.).

For our pilot implementation, we conducted several experiments with different parameters (context size around the proper name, number of topics, different corpora) to analyze and evaluate how to the prediction quality is affected. Our results indicate that our approach is indeed very helpful for disambiguating (i) entities for which not much training material is available, and (ii) also for entities with little surrounding context, both of which are useful for many applications.

In Section 2 we discuss related work. In Section 3 we describe our approach and how we extract properties and apply them to new unknown proper names in a document. Section 4 presents the data we use and describes how we create a silver standard corpus for evaluating our system. In Section 5 we describe our experiments and discuss our experimental results and the effects of different parameters. We give our conclusions and future work plans in Section 6.

[1]Sarmento et al. (2009) address the high skewness of distribution of mentions by developing a scalable approach that can cluster a billion mentions.

2 Related Work

Topic models have been used for named entity disambiguation in previous work. Bhattacharya and Getoor (2006) look at data with authors and try to determine the number of individual authors and link them to their corresponding entities. They do not make pairwise decisions of whether two names refer to the same entity, but look at all names in the collection and make a collective decision. For this they use a Latent Dirichlet Allocation (LDA) Model and introduce a hidden variable that captures relationships between entities. With their work they extend work done by Rosen-Zvi et al. (2004) and propose a solution to the duplicate authors problem. Shu et al. (2009) extend the LDA model to include global information from documents to identify authors. All of these approaches look at author data only, they cannot be applied to people in general which we do in our work.

Some work has been done using topic models on knowledge bases. Zhang et al. (2011) train a topic model on a knowledge base, then incorporate the information as a semantic feature by mapping documents with the name mention to the hidden topic space. They use Wikipedia pages to train their model on the first parts of the pages and to test it on the second parts of the pages. Sen (2012) use topic models to learn context information and relations between co-occurring entities. They train their model on only those Wikipedia articles which describe the entities they are dealing with. Yet, to use their model for other entities they would have to use an expanded version of the knowledge base. This would require the knowledge base to contain information about these entities. Han and Sun (2012) combine context compatibility of a referent entity and its context and topic coherence of the entity and the document's main topics. Kataria et al. (2011) use a hierarchical variant of LDA that incorporates information from Wikipedia (words, annotations, and category information) and have a separate topic for each Wikipedia entry in their model. They report results on precision while we also look at the recall and F_1 score, and compare different parameters.

All of these approaches are limited to the entities that occur in the knowledge bases. To apply the approaches to other entities, the knowledge base would have to be extended or data about these entities would have to be collected otherwise. While our approach also uses Wikipedia as a collection to train some of our models, the information we obtain is independent from specific entities and can be applied to any new entity, even if there is no information about them available in Wikipedia.

Li et al. (2013) use information from Wikipedia and an external source (websites referring to entities in Wikipedia obtained by crawling the web). They conduct experiments on two datasets, TAC-KBP 2009 and twitter data about 25 ambiguous and randomly picked entities, however they filter this data to only include entities that occur in Wikipedia, because their approach is also limited to entities in Wikipedia.

Bamman et al. (2013) extend a topic model to learn character types (e.g., {*dark, major, henchman*} or {*shoot, aim, overpower*}) in movies. In subsequent work, Bamman et al. (2014) apply an extended topic model to learn character types in English novels of the 18th and 19th century. They do not identify and link the individual names to their real world entities.

Topic models have also been used in named entity recognition (NER). Guo et al. (2009) use LDA for NER in query. Ritter et al. (2011) extend LDA and take information from Freebase for NER on twitter data. They have a similar problem with ambiguous expressions which they need to solve to determine the correct class (e.g., *China* can belong to several classes such as LOCATION or PERSON). However, they do not identify the actual real world entity of the expression (e.g., there are several cities called *China* in the US and other countries, but they all belong to the class LOCATION).

3 Approach

Our system does not rely on having textual training data for a specific person (e.g., the Canadian law professor *Michael Jackson*). Instead, it uses some aggregate of the textual material about different people that have the same properties (i.e., mentions of all Canadians, of all law scholars, and all professors etc.). This means that our system is independent from existing training data or obtaining training data through other means (e.g., web scraping), and can be applied to any text without the preliminary step of extracting specific information about the entities in the text.

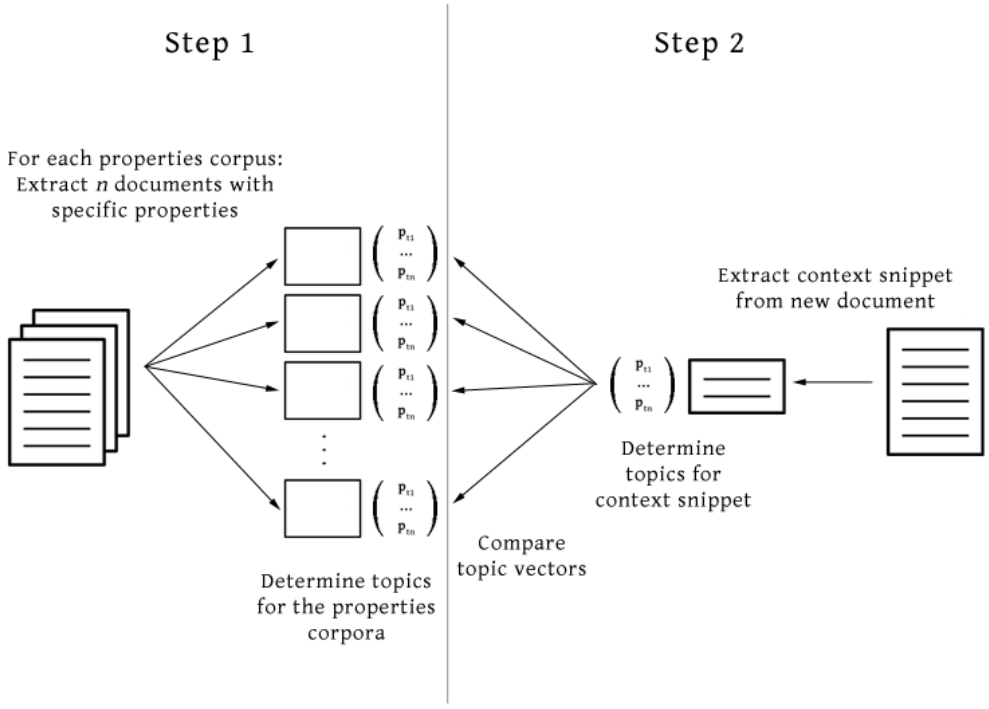

Figure 1: System that learns characteristics of people and uses them to disambiguate unknown people.

Figure 1 shows our system, which is divided into two steps. In the first step, we take a collection of documents and extract documents with specific properties, e.g., documents about singers, authors, and other professions, and documents about Americans, Canadians, and other nationalities. We then concatenate these extracted documents to individual corpora (e.g., a *singer corpora*), which we call "properties corpora". After this, the topics for these properties corpora are determined by using a topic model. In the second step, our system is applied to new unknown proper names. This is done by determining the topics for the proper name based on the chosen context and then comparing these topics with the topics of our properties corpora to find the ones with the most similarity. We describe both steps in more detail in the next two subsections.

3.1 Learning Properties of Persons

In the first step (left side of Figure 1), our system learns characteristic properties that people can have. Properties that can be learned are for example:

- Professions (singer, author, president, tennis player, ...)
- Nationalities (American, Canadian, German, Irish, Japanese, ...)
- Affiliations (university, company, ...)
- Engagements (organization, charity, ...)

In our pilot implementation of the approach we investigate the usefulness of professions and nationalities as properties. We chose these properties because they are the most prominent properties people have and can be obtained without much effort. Our system can be easily expanded with other properties in the future. Helpful properties are ones that are mentioned with the entity, for example, affiliations or engagements.

We first extract documents from a collection (e.g., Wikipedia) with the specific properties. For example, we extract documents about singers, authors, and other professions, and documents about people whose nationality is American, Canadian etc. We then concatenate randomly n of the extracted documents of one category into one corpus. After this we have many small corpora consisting of documents

with certain properties, e.g., a *singer corpus* and an *American corpus*. We call these concatenated documents "properties corpora". These properties corpora are the basis for disambiguating new entities. For example, *Michael Jackson, the American singer* has properties of the corpora *singer* and *American*.

The properties corpora are not very helpful in this form yet because the extracted documents contain a lot of information about many specific people which might not be helpful for disambiguating a new person. To obtain the relevant information from these corpora we use topic models. In natural language processing, topic models can be used to extract and explore topics from a collection of documents. Every topic consists of certain words that characterize this topic. In our work we use Latent Dirichlet Allocation (LDA) (Blei et al., 2003).

Using the topic model consists of two steps. First, we need to train the topic model. For this we use different training collections which we describe in Section 4.1. After the topic model is trained, we apply it to our properties corpora to obtain topic information from them. For example, the singer corpus will have a topic with words related to a singer, e.g., album, music, concert etc. with a high probability given the corpus.

3.2 Using Properties to Disambiguate Persons

In the second step (right side of Figure 1), our system is applied to new unknown proper names. To disambiguate a new person, we need to extract some context around the person (e.g., a sentence or a paragraph). We call the extracted text "context snippet". We use the same trained topic models as in Section 3.1 and apply them to the context snippet to obtain topic information from it.

The topic information we obtain from a document (i.e., a properties corpus or a context snippet) can be represented as a vector of length n, where n is the number of topics used by the topic model. Each entry p_{t_i} in the vector corresponds to the probability of the topic t_i given the document.

We then compare the topic vector of the new person with the topic vectors of each properties corpora to find the corpus that is most similar to the context the person occurs in. For this comparison we use cosine similarity. Let $\mathbf{x}$ be the vector of the new person and $\mathbf{y}_c$ be the vector of the properties corpus c. The cosine similarity between these two vectors is defined as:

$$\cos(\theta) = \frac{\mathbf{x} \cdot \mathbf{y}_c}{||\mathbf{x}|| \cdot ||\mathbf{y}_c||} = \frac{\sum_{i=1}^{n} x_i y_i}{\sqrt{\sum_{i=1}^{n} x_i^2}\sqrt{\sum_{i=1}^{n} y_i^2}} \qquad \text{with } \mathbf{x} = \begin{pmatrix} p_{t_1} \\ \vdots \\ p_{t_n} \end{pmatrix} \text{ and } \mathbf{y}_c = \begin{pmatrix} p_{t_1} \\ \vdots \\ p_{t_n} \end{pmatrix}$$

where p_{t_i} is the probability of topic t_i given the document.

4 Data

We use two collections in this work: (i) the English Wikipedia[2] (February 2014 version) and (ii) the English Gigaword corpus (Graff and Cieri, 2003).

4.1 Corpora for Training Topic Models

We have trained different topic models on different collections and parts of collections to study the effects of different sources.

- **Wikipedia - all ($\mathbf{W}_{all}$):** Wikipedia is an internet encyclopedia which provides a great variety of articles. For this model we used all articles without any restrictions.
- **Wikipedia - living people ($\mathbf{W}_{lp}$):** Wikipedia articles are classified into different categories. We built a model that only uses articles from the category *living people* to see if the properties we can learn from articles about people are more helpful for identifying new people than the properties we can learn from the entire Wikipedia.

[2]wiki dump enwiki-20140203

- **Wikipedia - living people - individual sections (W_{lps}):** Many Wikipedia articles are very long and separated into several sections that are often very different with respect to their topics (e.g., *early life, career*). We want to investigate if we can obtain more helpful topics by using individual sections that are about specific topics as opposed to taking entire articles that consist of many different topics.
- **English Gigaword - nyt (G_{nyt}):** The English Gigaword corpus consists of newswire text data in English. With this model we want to analyze if a newswire corpus provides different topics than an encyclopedia. We only use one part of the English Gigaword corpus for this model, newswire data from the source *The New York Times Newswire Service* (nyt).

		Topics					
Corpus	Docs	100	1000	2500	5000	7500	10000
W_{all}	4.3m	✓	✓	×	×	×	×
W_{lp}	650k	✓	✓	✓	✓	✓	✓
W_{lps}	1.7m	✓	✓	×	×	×	×
G_{nyt}	1.3m	✓	✓	✓	×	×	×

Table 2: Used models.

We experiment with different numbers of topics for each of these collections, ranging from 100 (more coarse-grained topics) to 10000 (more fine-grained topics). Table 2 shows the numbers of topics we used for the different collections. We restrict the larger collections to a maximum of 1000 topics (Wikipedia) and 2500 topics (English Gigaword) due to efficiency reasons. The approximate number of used documents for each collection is listed in the second column of Table 2.

By experimenting with different numbers of topics we want to investigate if more fine-grained topics will give us better results when disambiguating new people, or if a smaller number of topics is enough for the task.

4.2 Properties Corpora

We created properties corpora by extracting Wikipedia articles about people that share these properties. To determine whether a person has certain properties we used metadata in Wikipedia. For our purpose the `short description` field in `Persondata` provides the information we need about nationalities and professions, such as *American singer*. For example, we created a corpus with the property *American* by extracting articles that contain the word *American* in this field, and created a corpus with the property *singer* by extracting articles that contain *singer* in this field.

For each properties corpus we concatenated n random articles with this property. We chose $n = 500$. Some properties are rare in Wikipedia and we extracted less than 500 articles. In these cases we concatenated all articles we could find.

For the experiments in our pilot implementation we created a total of 15 nationalities corpora and 83 professions corpora. Choosing which nationalities and professions to use was done manually, extracting and concatenating documents to the properties corpora was done automatically. To apply the system to entities that are not included in our test system, more properties corpora need to be created. This can be done automatically, for example, by using lists of nationalities and professions.

4.3 Silver Standard Test Corpus

For our experiments we need data about persons that share the same name. Since collecting and manually annotating data is expensive, we automatically created a dataset by exploiting the link structure in Wikipedia.

We chose 14 people with the same names for which we show statistics in Table 3. All names refer to different people found in Wikipedia, with the number of different real world entities for each name ranging from 2 to 38, which can be seen in the second column (Ent).

We then went through all Wikipedia articles and every time we found one of these names linked to another article, we extracted the name, the link, and the context around the name. We experimented

Proper name	Ent	All	Max	Avg
David Mitchell	9	201	111	22.56
David Thomas	9	85	47	9.44
Jack Johnson	8	427	230	53.38
John Edwards	7	418	400	59.71
John Smith	38	466	107	12.11
John Williams	30	852	650	28.37
Michael Collins	7	443	364	63.29

Proper name	Ent	All	Max	Avg
Michael Jackson	12	3968	3899	330.67
Michael Moore	9	566	532	62.89
Paul Williams	13	385	149	29.62
Peter Müller	2	15	10	7.50
Richard Burton	4	606	592	151.50
Roger Taylor	3	79	39	26.33
Tony Martin	13	275	91	21.15

Table 3: Statistics for extracted entities. Numbers are counts.

with three different context sizes: (i) the sentence around the entity, (ii) the paragraph around the entity, (iii) the section around the entity. The third column in Table 3 (All) shows the overall numbers of context snippets we extracted for each name, the fourth column (Max) shows the maximum numbers of snippets for one entity with the name, i.e., the numbers of snippets used for the majority class baseline. For example, we extracted a total of 3968 snippets for the name *Michael Jackson* (All). 3899 of these snippets (Max) belong to the entity *Michael Jackson, the American singer*. The remaining 69 snippets belong to the other 11 entities with the same name. We have some extreme cases like this one in our dataset, with one entity having many more snippets than the others because it is a very famous person. In other cases the number of snippets is more evenly distributed over all entities with the same name. The last column in Table 3 (Avg) lists the average numbers of snippets that were extracted for each entity.

We use the extracted link information as gold labels to disambiguate the person. For example, if we find the link *Michael_Jackson_(English_singer)* in an article, we know that the extracted name and context around it refers to *Michael Jackson, the English singer*. By using this link information we do not have to annotate a dataset manually. Similar datasets have been created before (Nothman et al., 2008; Nothman et al., 2013; Hahm et al., 2014).

5 Experiments and Discussion

For obtaining topic information we use the MALLET toolkit (McCallum, 2002) which contains several machine learning applications, for example, document classification, clustering, and information extraction. For topic modeling it provides implementations of Latent Dirichlet Allocation (LDA), Pachinko Allocation, and Hierarchical LDA. We use the ParallelTopicModel class which is a simple parallel threaded implementation of LDA based on Newman et al. (2009) and Yao et al. (2009). We trained different topic models using the corpora and topic parameters we described in Section 4.1.

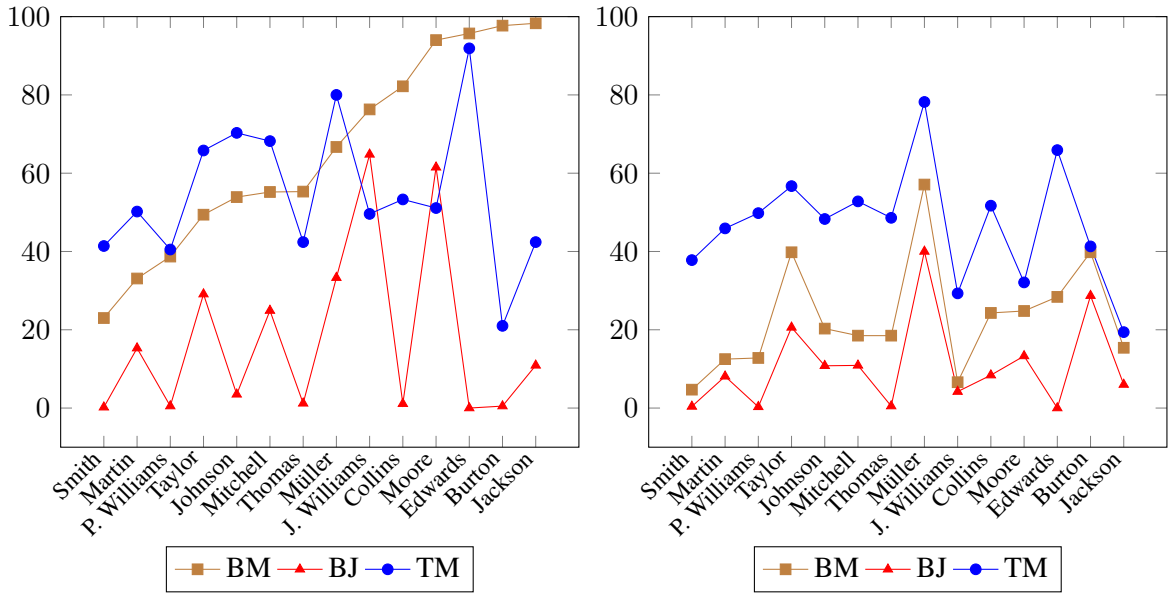
For every entity in our test set we created a corpus consisting of the properties of this entity (e.g., for *Michael Jackson, the American singer* we created a corpus with the properties *American* and *singer*) as described in Section 4.2. We then apply our trained topic models to obtain topic information from these corpora, as well as from the test snippets of our silver standard corpus. The vector representing the topic information from each new entity is then compared to each vector consisting of topic information from the properties corpora as we showed in Section 3.2.

We use two baselines. The **Baseline Majority (BM)** simply predicts the majority class. The **Baseline Jaccard (BJ)** uses the Jaccard index to compare the similarity between the context of the new unknown entity and the corpora we created. The Jaccard index is defined as the size of the intersection divided by the size of the union of two sample sets A and B:

$$J(A,B) = \frac{|A \cap B|}{|A \cup B|}$$

5.1 Results and Discussion

We conducted a total of 546 experiments with different parameters (context size, number of topics, corpus used to train the topic model). Due to limited space we show results only for one setting of parameters. We chose parameters which had an average performance in the experiments to give an estimate of how the approach works. Using other parameters can improve the results.



(a) micro-averaged F_1

(b) macro-averaged F_1

Figure 2: F_1 score of BM, BJ, and TM with parameters: context size=paragraphs, topics=1000, corpus=W_{all}.

Figure 2 shows the F_1 score for all experiments with the following parameters: context size = paragraphs, topics = 1000, corpus = W_{all}. The names are ordered by the micro-averaged F_1 score of the Baseline Majority (BM). In subsequent graphs we use the same ordering for better comparison. We present both the micro-averaged F_1 score (2a) and the macro-averaged F_1 score (2b), which give quite different results. Micro-averaged F_1 score weights each classification decision equally, i.e., it favors large classes, while macro-averaged F_1 score weights each class equally, i.e., it shows the effectiveness of small classes better (Manning et al., 2008).

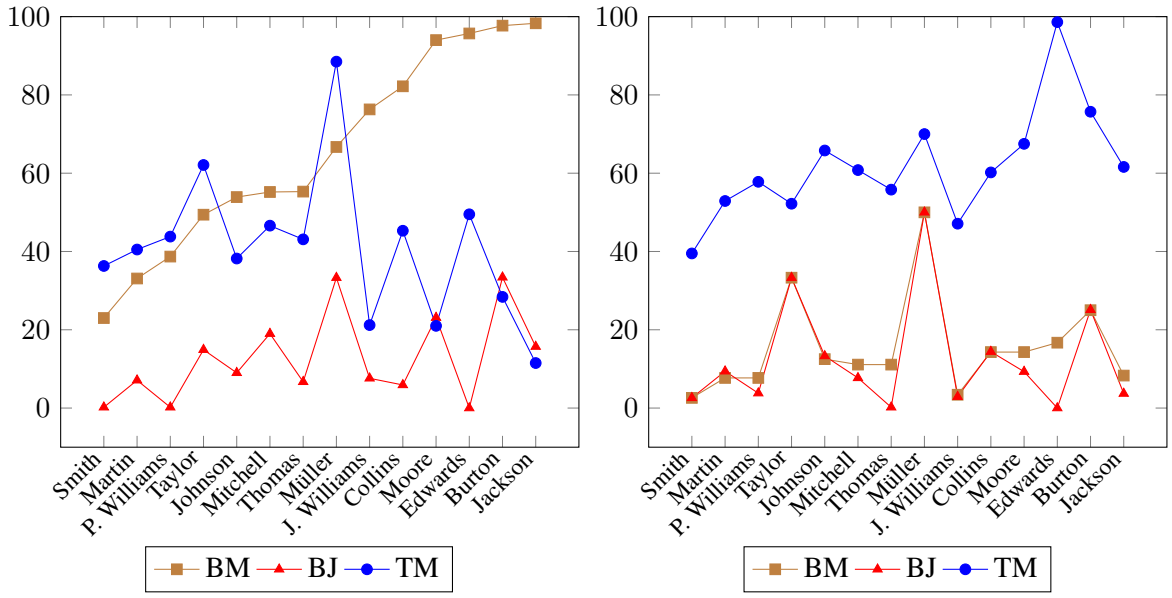
Figure 2a shows that when using micro-averaging, in some cases the majority baseline is better than our topic model approach. This is the case when there is one famous name-bearer who has many more examples than the other persons with the same name in the test set, e.g., *Edwards, Burton, Jackson*, which results in one class that is much larger than the others. For example, our test set contains 3968 snippets for *Michael Jackson*, with 3899 of the snippets belonging to the majority class (*Michael Jackson, the American singer*), which results in a micro-averaged F_1 score of 98.26% for BM.

The macro-averaged results in Figure 2b give a better sense of how well our approach works on smaller classes. It can be seen that our approach performs better than both baselines in all cases. Since we are interested in the not well-known entities, which have smaller classes in our test set, the macro-averaged results show that our approach works well for these entities.

The Baseline Jaccard (BJ) stays even below the Baseline Majority in most cases. It generally does not work well for persons that are rather unknown. One reason is that the contexts extracted for these entities are often smaller and do not provide as much information as is needed for this baseline approach. The main advantage of our TM approach is that it works well for unknown entities which usually have little or no available training material, and for entities which have little surrounding context.

In Figure 3 we give more insight into the macro-averaged results of Figure 2b and show the macro-averaged precision (3a) and macro-averaged recall (3b) with the same parameters as before. Precision-wise, the Baseline Majority does better in cases with large classes. This is expected because if most examples in the test set belong to the majority class, the number of false positives is small, which leads to higher precision.

Figure 3b shows that the recall for our approach outperforms both baselines by far in all cases. In one case (*Edwards*) we even achieve a recall of 98.6%. The reason for this is that the baseline approaches do not work well for the not well-known people with small classes in our test set. BM does not work well



(a) macro-averaged precision

(b) macro-averaged recall

Figure 3: Precision and Recall of BM, BJ, and TM with parameters: context size=paragraphs, topics=1000, corpus=W$_{all}$.

because it incorrectly tags the small classes with the majority class and BJ does not work well because the information in the context snippets is not sufficient for this approach. Measuring the similarity between words, n-grams, or similar approaches suffers from sparsity problems. Our TM approach makes better use of smaller context snippets because it extracts and uses relevant information (i.e., the topic information) about a person more effectively. This leads to higher recall results in most cases. In some cases with different parameters, we even achieve a recall of 100% for some entities (not shown in Figure 3). Obtaining a high recall is important in applications that aim for high recall results (e.g., in search engines or QA systems; the system returns more correct results instead of returning results of similar persons which are more well-known).

We have investigated how the context size, number of topics, and the corpus used for training the topic model influences the results of our TM approach. Figure 4 shows results for the different context sizes (sentence, paragraph, section), when using the same parameters for the topic model as in the previous figures (topics = 1000, corpus = W$_{all}$). In most cases, taking more context gives better results (i.e., paragraphs are better than sentences and sections are better than paragraphs). In some cases, a larger context introduces more noise which leads to worse results than when taking a smaller context (e.g., *Moore* in Figure 4a). Generally, taking a smaller context does not worsen the results a lot and in some cases gives nearly the same results as when taking a larger context. This shows that our TM approach works well if there is only little context available for a person. This is important because often the context for a person is rather limited, for example, when a document is mainly about another person there might be only one relevant sentence as context, or when the document is very short.

When we investigated the usefulness of the number of topics, we found that taking a small number of topics (like 100) works best. Using a higher number results in more fine-grained topics, which makes finding the most similar corpus harder. An advantage of using fewer topics is that it takes less time for the topic model to determine the topics of a new document. In a real application it is important to reduce the time needed as much as possible because a user of the application does not want to wait for several minutes or even hours for results.

There is no clear preference for which corpus is the most useful one for the task and it also depends on the context size. Overall, using the entire Wikipedia seems to be the least helpful and it is better to use a more specific collection which produces better topics for the task. We also found that when using different collections, the results can change a lot. While the results for using different parts of the

Wikipedia collection all followed the same trend, the results for using the Gigaword corpus were very different and often worse than Wikipedia's results.

6 Conclusion and Future Work

We presented work on a new system for Named Entity Disambiguation which does not need specific textual training data to disambiguate unknown persons. Instead, it uses some aggregate of the textual material about different people that share the same properties (e.g., nationalities and professions). The system learns which properties people can have, then uses these properties to disambiguate new proper names in documents.

To learn properties we extracted documents about people sharing the same properties from a collection, then applied topic models on the data to obtain topic information. The topic models were trained on different collections and with different numbers of topics to investigate which parameters are most useful. To disambiguate a new unknown person in a text document, we obtained topic information from the context of the person, then compared this topic information with the information from the extracted material to find out which properties are closest to the person.

In our pilot implementation of the approach, we conducted 546 experiments on 14 ambiguous names using different parameters (context size, number of topics, corpus used for training the topic model). For evaluating our system we created a silver standard corpus that does not need any manual annotation, and compared our approach to two baselines. We showed that our system outperforms the baselines in many cases, especially for (i) entities for which not much training material is available, and (ii) entities with little surrounding context. We also showed that with our approach we can achieve high recall results, which is important for many applications, e.g., search engines and QA systems.

The approach can be expanded with more properties in the future. For example, it could include properties like age, place of birth, and affiliation (university, company etc.) and properties about what people are doing besides their profession (e.g., working in organizations or for charity).

Abstract

In Natural Language Generation (NLG), one important limitation is the lack of common benchmarks on which to train, evaluate and compare data-to-text generators. In this paper, we make one step in that direction and introduce a method for automatically creating an arbitrary large repertoire of data units that could serve as input for generation. Using both automated metrics and a human evaluation, we show that the data units produced by our method are both diverse and coherent.

1 Introduction

In Natural Language Generation, one important limitation is the lack of common benchmarks on which to train, evaluate and compare data-to-text generators. In this paper, we make one step in that direction and introduce a method to automatically create an arbitrary large repertoire of data units which could serve as input for data-to-text generation. We focus on generation from RDFS data where the communicative goal is to describe entities of various categories (e.g., astronauts or monuments).

RDF data consists of (subject property object) triples (e.g., `(Alan_Bean occupation Test_pilot)`) – as illustrated in Figure 1, RDF data can be represented by a graph in which edges are labelled with properties and vertices with subject and object resources. To construct a corpus of RDF data units which could serve as input for NLG, we introduce a content selection method which, given some DBPedia entity, retrieves DBPedia subgraphs that encode relevant and coherent knowledge about that entity.

Our approach differs from previous work on content selection in that it leverages the categorial information provided by large scale knowledge bases about entities of a given ontological type. Based on this ontological knowledge, we learn two types of category-specific bigram models: one model (S-Model) for bigrams occurring in sibling triples (triples with a share subject) and one model (C-Model) for bigrams occurring in chained triples (the object of one triple is the subject of the other). The intuition is that these two models capture different types of coherence, namely, topic-based coherence for the S-Model and discourse-based coherence for the C-Model.

Using these bigram models of RDF properties, we formulate the content selection task as an Integer Linear Programming problem and select for a given entity of category C, subgraphs with maximal probability that is, subgraphs which contain properties that are true of that entity, that are typical of that category and that support the generation of a coherent text.

We evaluate the impact of our n-gram models on content selection (how well do they help support the selection of a coherent and diverse set of data units?) using quantitative metrics, a human evaluation and a qualitative analysis.

2 Related Work

Our approach has similarity with approaches on entity summarisation, content planning from DBpedia data and ILP (Integer Linear Programming) approaches for content planning. There is also a vast literature on using ILP for natural language processing.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1493–1502, Osaka, Japan, December 11-17 2016.

Entity Summarisation (Cheng et al., 2015) presents an approach which focuses on a task very similar to ours, namely the task of selecting, for a given entity e, a subgraph of the knowledge graph whose root is e. The goal is to generate entity summaries that is, sets of facts which adequately summarise a given entity. The method used extends a standard random surfer model navigating the knowledge graph based on metrics indicating (i) the informativeness of a fact and (ii) the relatedness between two facts. In this way, the selected subgraphs are both coherent (solutions which maximise relatedness are preferred) and informative (facts that helps distinguishing the entity to be summarised from others are preferred).

We depart from (Cheng et al., 2015) both in terms of goals and of methods.

In terms of goals, while (Cheng et al., 2015) aim to produce entity summaries, our goal is to produce a large set of content units that are varied both in terms of content and in terms of structure. In particular, one important difference is that we produce trees of varying shapes and depths while the graphs produced by (Cheng et al., 2015) are restricted to trees of depth one i.e., set of DBpedia triples whose subject is the entity to be described. As discussed in Section 5.1, this allows us to produce knowledge trees which, because they vary in shape, will give rise to different linguistic structures and will therefore better support the creation of a linguistically varied benchmark for Natural Language Generation.

Our approach also departs from (Cheng et al., 2015)'s in that the methods used are very different. While we use Integer Linear Programming and language models to select DBpedia subgraphs that are both discourse- and topic-coherent, (Cheng et al., 2015) use a random surfer model, pointwise mutual information and probabilistic estimates to measure relatedness and informativeness. Generally, the two methods are complementary using different resources, algorithms and metrics thereby opening interesting possibilities for combination. It would be interesting for instance, to investigate how modifying our ILP formulation to integrate the relatedness metrics used by (Cheng et al., 2015) would impact results.

Content Planning (Biran and McKeown, 2015) describes a discourse planning approach applied to the generation of comparison stories from DBpedia data. Given two DBpedia entity e_1 and e_2, they first select all DBpedia triples whose subject is either e_1 or e_2. Based on the shape of the triples (shared entities or predicates) and on the property they include, they then enrich this set of DBpedia triples with discourse relations. For instance, if two triples share the same predicate and object, an expansion relation is added between the two triples (e.g., "John has a ball. Mary also has a ball"). Discourse planning then consists in finding a path through the resulting multigraphs of potential relations between DBpedia triples using an bigram model over discourse relations. Good discourse plans are those which maximise the probability of a sequence of discourse relations. In this way, the proposed approach determines both the order of the events and the discourse relation holding between them.

(Lampouras and Androutsopoulos, 2013) present an Integer Linear Programming model of content selection, lexicalisation and aggregation for generating text from OWL ontologies. The objective function used in their ILP model maximises the total importance of selected facts and minimizes the number of distinct elements mentioned in each sentence thereby favouring aggregated sentences i.e., sentences where repeated elements are avoided through e.g., ellipsis or coordination.

(Bouayad-Agha et al., 2011) introduces an ontology driven content selection procedure in which a base domain ontology is used to infer new facts. For instance, given the numerical scores of two teams playing in the same game, a result event will be inferred between the winner and the loser and a causal relation will be inferred between the number of goals of a given team and this result event. Content selection proceeds in three steps. First, a set of hand written rules is used to select a subset of the knowledge base. Second, relevance scores learned from a parallel data/text corpus are used to select the most relevant individual and relation instances. Third, hand-written templates are used to determine the content to be included in the generated text.

Our approach differs from these proposals in that it focuses on content selection from typed RDF data. Using bigram models whose basic units are DBpedia triples, we maximise global coherence by favouring content where DBpedia properties that often co-occur are selected together. In contrast, (Lampouras and Androutsopoulos, 2013) assumes that the relevance scores are given. Moreover, while they focus on selecting content that leads to maximally aggregated content, we focus on selecting content that is discourse coherent. Like us, (Biran and McKeown, 2015) focus on DBpedia data and use bigram

models. However their approach investigate discourse planning not content selection and relatedly, the basic units of their bigram models are discourse relations rather than triples. Our approach also differs from (Barzilay and Lapata, 2005) in that it is unsupervised and does not require an aligned data-text corpus.

Finally, the work presented here is closely related to a simpler proposal we introduced in (Mohammed et al., 2016). It differs from it in that it defines the notions of chain, sibling and mixed models for n-grams of DBpedia properties; relate them to the notion of topic- and discourse-coherence; and provide a comparative evaluation of their impact on content selection.

Integer Linear Programming and NLP. Finally, there has been much work in recent years on using ILP for natural language processing. In particular, (Kuznetsova et al., 2012) proposes an ILP formulation for the generation of natural image descriptions from visual and text data and (Filippova and Strube, 2008) uses ILP to model sentence compression. The ILP formulation of our content selection method is most similar to that proposed for sentence compression in (Filippova and Strube, 2008). One important difference though is both the application (content selection rather than sentence compression) and the way in which relevance is computed. While (Filippova and Strube, 2008) uses weights derived from a treebank to determine the relative importance of an edge, we use bigram models over DBpedia properties to estimate the relative importance of DBpedia triples.

3 Task and Method

Given an entity e of category C and its associated DBpedia *entity graph* G_e, our task is to select a (target) subgraph T_e of G_e such that:

- T_e is *relevant*: the DBpedia properties contained in T_e are commonly (directly or indirectly) associated with entities of type C
- T_e maximises *topic-based coherence*: DBpedia triples that often co-occur in type C are selected together
- T_e supports *discourse coherence*: the set of DBpedia triples contained in T_e capture a sequence of entity-based transitions which supports the generation of discourse coherent texts i.e., texts such that the propositions they contain are related through shared entities.

To implement these constraints, we first build bigram models of properties for DBpedia categories. We then use these models and Integer Linear Programming to retrieve from DBpedia, entity graphs with maximal probability.

3.1 Building Bigram Models for DBpedia Categories

For each DBpedia categories (e.g., Astronaut or University), we learn two bigram models `S` and `C`, each designed to capture different aspects of content coherence.

The `S`(ibling)-model consists of bigrams that are sibling properties in DBpedia. Two properties are sibling of each other if they occur in triples sharing the same subject. Thus, the DBpedia graph shown in Figure 1 contains 5 `S`-bigrams namely, `birthPlace-mission`, `birthDate-mission`, `birthDate-birthPlace`, `country-leader` and `crewMember-operator`[1]. The `S`-model aims to capture local coherence i.e., topic-based associations between DBpedia properties.

In contrast to the `S`-model, the `C`(hain)-model aims to capture *discourse coherence* i.e., associations between DBpedia triples that involve a shared entity other than the entity being described. It consists of DBpedia triples that are related by a shared entity. The DBpedia graph shown in Figure 1 contains 4 `C`-bigrams namely, `mission-crewMember`, `mission-operator`, `birthPlace-country` and `birthPlace-leader`.

[1]Sibling bigrams (`S`-bigrams) are normalised using alphabetical order. Thus, given the two triples `(A mission B)`, `(A nationality C)`, the associated `S`-bigram is `mission-nationality` – not `nationality-mission`.

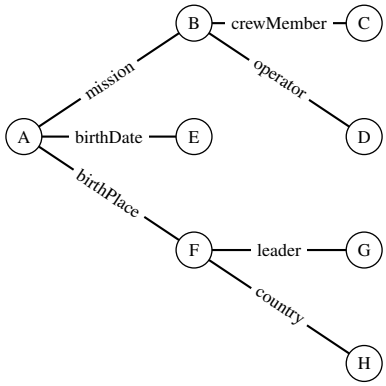

Figure 1: Example DBpedia Graph (To save space subject and object names have been replaced by capital letters).

3.2 Extracting DBpedia Subgraphs

We use the two bigram models just described and an interpolation (M-Model) of these two models to select from an entity graph subtrees whose coherence is either topic-based (S-Model), discourse-based (C-Model) or both (M-Model).

The ILP formulation of the task is as follows.

Representing triples. Given an entity graph G_e for the DBpedia entity e of category C (e.g. Astronaut), for each triple $t = (s, p, o)$ in G_e, we introduce a binary variable $x^p_{s,o}$ such that:

$$x_t = x^p_{s,o} = \begin{cases} 1 & \text{if the triple is preserved} \\ 0 & \text{otherwise} \end{cases}$$

Because we use bigrams to capture local and discourse coherence (properties that often co-occur together), we also have variables y_{t_1,t_2} for bigrams of triples such that:

$$y_{t_1,t_2} = \begin{cases} 1 & \text{if the pair of triples is preserved} \\ 0 & \text{otherwise} \end{cases}$$

For the S-Model, these binary variables capture pairs of triples which share the same subject. That is, for each bigram of triples $t_1 = (s1, p1, o1)$ and $t2 = (s2, p2, o2)$ in G_e such that $s1 = s2$, we introduce a binary variable y_{t_1,t_2}.

Similarly, for the C-Model, we introduce a binary variable y_{t_1,t_2} for each pair of triples such that the object of one is the subject of the other. That is, $(t_1,\ t_2)$ is a C-bigram iff $t_1 = (s1, p1, o1)$, $t2 = (s2, p2, o2)$ and $o1 = s2$.

Maximising Relevance and Coherence. To maximise relevance and coherence, we seek to find a subtree of the input graph G_e which maximises the S-bigram probability (S-Model), the C-bigram probability (C-Model) or an interpolation of both (M-Model).

For the S- and the C-Model, we maximise the following objective function over the set of all bigrams Y from the set of triples X:

$$S(X) = \ \sum_Y y_{t_i,t_j}\ .\ P(t_i, t_j) \tag{1}$$

where y_{t_i,t_j} is the ILP binary variable for (t_i, t_j) and $P(t_i, t_j)$ is the bigram probability for category C. Let B_c be the set of property bigrams occurring in the entity graphs of all DBPedia entities of category C. Let *count(b,C)* be the number of time b occurs in B_c, then the bigram probability $P(b)$ of b for category C is defined as follows:

$$P(b) = \frac{\textit{count(b,C)}}{\sum_{b_i \in B_C} \textit{count(b}_i\textit{,C)}} \tag{2}$$

For the S-Model, only S-bigrams are included in the counts while for the C-Model, only C-bigram counts. For the M-Model, the objective function to be maximised is defined as:

$$S(X) = \quad \gamma * \sum_Y y_{t_i,t_j} \ . \ P(t_i,t_j) + (1-\gamma) \sum_Z z_{t_k,t_l} \ . \ P(t_k,t_l) \tag{3}$$

where y_{t_i,t_j} is restricted to S-bigrams and z_{t_k,t_l} to C-bigrams and γ is a parameter to balance the contribution of local- or discourse- probabilities.

Consistency Constraints. We ensure consistency between the triple and the bigram variables so that if a bigram is selected then so are the corresponding triples (eq. 5). Conversely, eq. 6 requires that if two triples t_i and t_j are selected then so is the corresponding bigram y_{t_i,t_j}[2]

$$\forall i,j \ (y_{i,j} \leq x_i \textit{ and } y_{i,j} \leq x_j) \tag{5}$$

$$y_{i,j} + (1-x_i) + (1-x_j) \geq 1 \tag{6}$$

Ensuring Discourse Coherence (Tree Shape). Solutions are constrained to be trees by requiring that each object has at most one subject (eq. 7) and all triples are connected (eq. 8).

$$\forall o \in X, \sum_{s,p} x^p_{s,o} \quad \leq \quad 1 \tag{7}$$

$$\forall o \in X, \sum_{s,p} x^p_{s,o} \quad - \quad \frac{1}{\mid X \mid} \quad \sum_{u,p} x^p_{o,u} \geq \quad 0 \tag{8}$$

where X is the set of triples that occur in the solution (except the root node). This constraint makes sure that if o has a child then it also has a head.

Restricting the size of the resulting tree. Solutions are constrained to contain α triples:

$$\sum_x x^p_{s,o} \quad = \quad \alpha \tag{9}$$

4 Experimental Setup

We test our approach on 3 DBPedia categories chosen to be diverse in that they represent different levels of animacy namely, *Monument, University* and *Astronaut*. These provide with different sets of DBPedia properties for the evaluation.

Building bigram models of DBpedia properties. To build the bigram models, we extract from DBpedia the graphs associated with all entities of those categories up to depth 5 and separately extract C-bigrams and S-bigrams. Table 1 shows some statistics for these graphs. We build the C-Model and the S-Model using the SRILM toolkit.

Building Entity Graphs. For each of the three categories, we take 5 randomly chosen entities and extract their DBpedia graph up to depth 2[3]. Table 2 shows some statistics for these entities.

[2]Note that these constraints do not require that every selected triple be part of at least one bigram containing that triple. We have only recently added this constraint (eq. 4) to further improve topic coherence.

$$\forall i,j \ s.t. \ i = t \ or \ j = t, \ x_t <= \sum y_{i,j} \tag{4}$$

[3]It would of course be possible to extract deeper graphs using but this would required building higher order n-gram models and data sparsity might degrade results. Here, we leave this point open for further research.

Category	Entities	Triples	Properties
Astronaut	110	1664033	4167
Monument	500	818145	6521
University	500	969541	7441

Table 1: Category Graphs

Entity	A		M		U	
	d1	d2	d1	d2	d1	d2
e1	14	24	13	18	6	20
e2	21	32	20	21	13	21
e3	16	28	7	14	6	10
e4	12	24	6	14	9	16
e5	15	22	4	11	27	34

Table 2: Size in number of triples for each Entity Graph for each category (A = Astronaut, M = Monument, U = University) and depth (d1 = Depth 1 and d2 = Depth 2).

Selecting Data Units. To ensure that our content selection procedure produces varied data with respect to both form and content, we run the ILP program on entities belonging to three DBPedia categories (Astronaut, University, Monument) and using each of the bigram models (S-Model and C-Model) and their combination (M-Model). Using different DBPedia categories ensures that the selected data units vary in terms of RDF resources (entities and properties). Using the different bigram models permit producing data units exhibiting different levels of topic- and discourse-coherence. The intuition is that the S-Model will yield data units where topic-based coherence dominates, the C-Model discourse data units emphasizing transition-based, discourse coherence and M-Model data units which display a balance between topic-based and discourse coherence. We set γ to 0.4 (eq.3), after running several experiments we observed that this weight balanced the solutions favouring C-bigrams which in general have smaller probability values than S-bigrams.

We run the ILP with α (the number of triples occurring in the solution) ranging from 3 to 10 and input entity graphs with depth 1 and 2.

5 Evaluation

Our goal is to generate a large corpus of data units which could be used as a basis to build a data-to-text benchmark for training, testing and comparing data-to-text generators. In the evaluation, we therefore focus on assessing (i) the diversity and (ii) the coherence of the selected data units.

5.1 Diversity

As discussed in the preceding sections, the three ILP models generate solutions with slightly different properties. This can be viewed as a controlled *sampling* procedure. Using the different ILP models, we can sample subgraphs of the same entity graph which have the same size but are markedly distinct.

To better assess the degree to which the solutions generated by our models differ from each other, we compute two metrics designed to capture both the overlap between the solutions produced and the number of distinct shapes found.

Number of Distinct Solution Shapes. The shape of the trees extracted from an entity graph will impact the possible syntactic structure of the corresponding text. For instance, trees such as (1a) where the subject entity is shared by two triples, will naturally induce the use of an adjective modifier (1b). In contrast, trees such as (1d) where the object entity of a triple is the subject of another triple naturally suggests the use of a participial or a relative clause (1d-e).

(1) a. `(Alan_Bean occupation Test_pilot) (Alan_Bean nationality USA)`
b. *Alan Bean was an **American** test pilot*
c. `(Alan_Bean mission Apollo_12) (Apollo_12 operator NASA)`
d. *Alan Bean flew on the Apollo 12 mission **operated by** NASA*
e. *Alan Bean flew on the Apollo 12 mission **which was operated by** NASA*

More generally, to ensure a good linguistic coverage, a benchmark should contain a large number of distinct input shapes. We approximate the shape of an input unit U_e describing the entity e by using a classification which combines (i) the number D_e of triples $t \in U_e$ whose subject is e, (ii) the number

O_e of subject entities $e' \in U_e$ other than e and (iii) the number I_e of triples $t \in U_e$ whose subject is not e. That is, an input shape is defined as a triple (D_e, O_e, I_e) indicating the number D_e of triples directly connected to the entity e being described, the number O_e of subject entities other than this entity and the number I_e of triples indirectly connected to e.

When considering the 10 best solutions produced by the M-Model on the entity graphs of the 15 entities mentioned above, the total number of distinct input shapes is 75 with a minimum, a maximum and an average number of instances per input shape of 1, 24 and 5.31 respectively.

Overlap. To assess the degree to which the solutions produced by our approach differ from each other we compute the average overlap between solutions for the same configuration both within and across models. A configuration is defined by the number of triples appearing (3 to 10) in the solution, the depth of the input graph (1 or 2) and the model used (S-Model, C-Model or M-Model). For each configuration, the average overlap is defined as $\frac{\sum_{i,j} O(s_i,s_j)}{N}$ where s_i, s_j are solutions produced in that configuration, N is the number of distinct pairs produced by that configuration and the overlap, $O(s_i, s_j)$, between two solutions is the ratio between the number of property they share and the number of triples contained in (s_i, s_j)[4].

Table 6 (left) shows the results for the three models given 16 configurations and 3 DBpedia categories. The 16 configurations correspond to solutions of size 3 to 10 on graphs of depth 1 and 2.

With an average overlap within and across models ranging from 0.18 to 0.31, these results indicate a good level of diversity whereby the C-Model and the M-Model are found to be slightly better at providing solutions with small overlap (avg. 0.24 and 0.26 respectively) than the S-Model (avg. 0.31).

Similarly, Table 6 (right) shows that the overlap across models is relatively low (Min: 0.18, Max: 0.24) indicating that solutions produced for the same configuration by different models are usually markedly distinct (no more than a quarter or a small half of the triples are shared between any two solutions).

In sum, by modifying the ILP parameters to select various numbers of triples, we can generate solutions of different sizes whilst the 3 ILP models permit producing solutions with relatively small overlap both within and across models. That is, our content selection method can be used to automatically create a graduated benchmark for natural language generation in which the inputs are of increasing size and exhibit a good level of semantic variability. Using crowdsourcing, these RDF input could be associated with appropriate verbalisations whereby annotators could be gradually trained to verbalise the data by exposing them to input of gradually increasing length.

5.2 Coherence

Because they are retrieved from DBpedia, the data units selected by our approach are semantically coherent overall. In particular, the triples that are directly connected to the entity being described are all relevant. However when selecting a subtree of the input entity graph, the coherence between siblings and between chained triples may decrease. For instance, given the entity graph shown in Figure 1, subgraph (2a) is more topically-coherent that subgraph (2b). Similarly, subgraph (2c) is more discourse-coherent that subgraph (2d).

(2) a. `(A birthDate E) (A birthPlace F)`

b. `(A birthDate E) (A mission B)`

c. `(A mission B) (B crewMember C)`

d. `(A birthPlace F) (F leader G)`

We compare our approach with a baseline where a subtree of DBpedia triples is randomly selected from the entity graph using an automatic metric and a human evaluation.

[4]Since the S-Model is designed to favour sibling or topically related triples but not triples related by a shared entity, we disregard in all evaluation counts the solutions of depth 2 produced by the S-Model. Conversely, we exclude from the evaluation counts the solutions of depth 1 produced by the C-Model.

		Min	Max	Avg	# Solns
d1	BL	0	2	0.44	400
	S-Model	0	1.75	**0.31**	271
d2	BL	0	2	0.73	218
	C-Model	0	1.94	0.59	382
	M-Model	0	1.25	**0.43**	152
	S-Model	0.07	1.29	0.54	123

Table 3: Averaged number of irrelevant property descriptions for solutions of depth 1 (d1) and 2 (d2) on the Astronaut category.

	BL	S-Model	C-Model	M-Model
C (3)	6	18	1	2
M (2)	15	11	20	13
L (1)	10	2	9	15
Avg	1.87	2.52	2.27	2.43

Table 4: Coherence scores for the different models (C = Coherent, M = Medium, L = Less coherent).

Number of Irrelevant Triples. We quantify the number of irrelevant triples contained in solutions produced by the different models by first, manually labelling each property present in the Astronaut graph as relevant or irrelevant and second, counting the number of irrelevant properties occurring in the solutions produced by the baseline and the 3 ILP models. In practice, irrelevant properties are properties that are indirectly related to the entity being described. For instance, the `leader` property shown in Figure 1 is much less relevant when describing an astronaut than the `crewMember` or the `mission` property.

Table 3 shows the results. The baseline consistently shows a higher number of irrelevant properties indicating that our method is efficient in filtering them out. For depth 2, the M-Model shows the best results. The lower score (higher number of irrelevant properties) of the S-Model shows that selecting triples based on sibling bigrams only, fails to eliminate indirectly related triples which are irrelevant to the entity being described. Sibling properties are selected for entities related to the entity being described which are not relevant in context. For instance, in Figure 1, the S-bigram `leader-country` has little relevance when describing the target entity A. For the C-Model, examination of the distribution per solution size shows that the number of irrelevant properties increases with the solution size. This is explained by the fact that as the number of triples in the solution increases, the number of C-bigrams to be selected increases leading to the selection of bigrams (e.g., `birthPlace-leader`) with lower probability.

Human Evaluation. Using the Crowdflower platform, we ran a human evaluation to compare the coherence of the solutions produced by the different models. The annotators were shown two data units of the same size but produced by different content selection models and were asked to rate the coherence of each dataset as coherent (3), medium (2) or less coherent (1).

To assess the impact of the S-Model on topic-based coherence, we compared the S-Model with the baseline. The evaluation was carried out on 23 pairs of data units ranging from size 3 to 10 and describing entities of all three categories. We collected 10 judgements for each pair (230 judgements total). Similarly, we compare the M-Model and the C-Model to assess the extent to which the M-Model is successful in combining discourse- and topic-based coherence. Table 4 summarises the results. For all models, the scores are much higher than for the baseline indicating that the bigrams we learn successfully model coherence. The S-Model has the highest coherence, which is unsurprising as only graphs of depth 1 are considered and properties that are directly related to the entity being described are by definition relevant. The C-Model and M-Model also achieve relatively high scores thereby confirming the good results obtained with the other metrics (number of irrelevant properties)[5].

Qualitative Analysis. Table 5 shows some example output produced by the variants of our model which illustrate the main differences between the baseline and the three ILP models.

The baseline model tends to generate solutions with little cohesion between triples. Facts are enumerated which range over distinct topics. BL solutions also often include properties such as "source" which are generic rather than specific to the type of entity being described.

In contrast, S-Model solutions often contain sets of topically related properties (e.g., birth date and birth place) while C-Model solutions enumerate facts (affiliations, mascot, president, battle) about related

[5]The average confidence score produced by Crowdflower for the ratings is 0.63. Running a Fisher's exact test we obtain that the difference between the BL and the S-Model is statistically significant with p-value < 0.002. In contrast, C-Model and M-Model models are not significantly different, p-value < 0.1674.

6 Conclusion

We presented a method for selecting content from DBpedia data which leverages the n-gram information provided by large scale knowledge bases about entities of distinct ontological type. Based on the DBpedia graphs associated with entities of a given ontological type, we learn domain- specific n-gram models of DBpedia properties. To capture both discourse and topic-based coherence, we derive these n-grams either from chain or from sequence configurations of triples. As a result, we can extract content units based either on topic similarity, on elaboration-based discourse transition or on both. Using various metrics, we showed that our method supports the selection of content units that are both coherent and diverse.

We are currently working on exploiting this content selection procedure to semi-automatically construct a large data-to-text resource for training and testing RDF verbalisers. To associate the RDF subtrees we produce with the verbalisations required by supervised learning and evaluation, we plan to explore different methods including, the automatic generation of output using existing symbolic generators, the manual and semi-automatic validation of these automatically generated texts and the verbalisation of data units by humans, using crowdsourcing.

Abstract

Sentence compression is a way to perform text simplification and is usually handled in a monolingual setting. In this paper, we study ways to extend sentence compression in a bilingual context, where the goal is to obtain parallel compressions of parallel sentences. This can be beneficial for a series of multilingual natural language processing (NLP) tasks. We compare two ways to take bilingual information into account when compressing parallel sentences. Their efficiency is contrasted on a parallel corpus of News articles.

1 Introduction

Text simplification is a well studied application of Natural Language Processing (NLP) techniques. Its main goal is to reduce the complexity of a text without degrading the informational content. This task proves useful for a wide range of applications, be they human-oriented (e.g. text adaptation for language learning purposes, for people with reading disabilities etc. (Siddharthan, 2014; Klaper et al., 2013)) or machine-oriented, serving as a basis to improve the efficiency of other NLP downstream components (e.g., parsing (Jonnalagadda et al., 2009), semantic role labeling (Vickrey and Koller, 2008) etc.). Simplification can be performed at different linguistic levels: lexical (Paetzold and Specia, 2016), syntactic (Siddharthan, 2011), or both (Paetzold and Specia, 2013).

Sentence compression is a way to perform simplification at the level of sentences, by reducing the sentence length without sacrificing important information. Many works only consider purely syntactic simplifications, though lexical changes are also possible, especially in language learning scenarios (Cohn and Lapata, 2008; Napoles et al., 2011a).

By and large, the motivations that have been put forward for monolingual sentence compression can be also used to motivate bilingual sentence compression, understood here as the generation of parallel compressions of parallel sentences. Bilingual Sentence Compression can be used, for instance, to produce simpler versions of a parallel text for learning purposes, or to generate summaries and subtitles in different languages, or even to build simplified parallel corpora for training a Machine Translation (MT) system.

Parallel sentence compression can be approached in many ways: it is first possible to compress independently each side of a bitext using monolingual simplification, an approach which however runs the risk of breaking the parallelism of the resulting corpus. Compression could also be performed in a symmetric manner by generalizing monolingual algorithms to the case of parallel sentences. We focus here on an **asymmetrical scenario**, where the target compression is a translation of a previously simplified source sentence.

In this context, our main contribution consists in studying various bitext compression methodologies that should **ensure the parallelism of the simplified bitext**, which, to our knowledge, is the first attempt of this kind. Two compression methods are developed and compared in Section 2 : (1) a dynamic programming (DP) approach, considering the final compression

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1503–1513, Osaka, Japan, December 11-17 2016.

as a result of a series of local optimal decisions and (2) an integer linear programming (ILP) method, capable to handle global constraints. These methods are used to compress texts in the News domain (see Section 3); we experiment there with data distributed in the context of the WMT'15 translation task (English-French, automatic compression attempted on French).

2 Bilingual and Monolingual Methods for Sentence Compression

In our asymmetrical bilingual context, we formulate the compression problem as follows: given a source sentence $\mathbf{e} = e_1, e_2, \ldots, e_J$, its compressed version $\mathbf{e}' = e'_1, e'_2, \ldots, e'_{J'}$ and its translation $\mathbf{f} = f_1, f_2, \ldots, f_I$, we search for $\mathbf{f}' = f'_1, f'_2, \ldots, f'_{I'}$ that translates $\mathbf{e}'$. $\mathbf{f}'$ should both **preserve the meaning** of $\mathbf{e}'$ and respect the **grammaticality** requirements of the target language. Most approaches to monolingual compression further assume that a (dependency) parse tree of $\mathbf{f}$ is available, taking the form of a set of (dependent, head) pairs. We make the same assumption here, denoting $\tau = \{(f_i, h(f_i)), 1 \leq i \leq I\}$ this dependency tree.

Recent proposals for solving this task use dynamic programming (DP) techniques (McDonald, 2006; Filippova, 2010) or integer linear programming (ILP) (Clarke and Lapata, 2008; Filippova et al., 2015), in both cases actively taking syntactic information into account. Inspired by those approaches, we propose below two methods for bilingual compression, enriched with MT-related bilingual information. We also include a description of our baseline compression system, based on two independent monolingual compressions.

2.1 Compressing with Finite-State Machines and Dynamic Programming (DPbi)

Our first approach to compression (DPBI) uses finite-state techniques. Recall that a weighted finite-state automaton (WFSA) over a set of weights $\mathbb{K}$ is represented by a 7-tuple $A = (\Sigma, Q, B, F, E, \lambda, \rho)$, where Σ is a finite alphabet, Q is a finite set of states, $B \subseteq Q$ contains the initial states and $F \subseteq Q$ the final states; $E \subseteq Q \times \Sigma \times \mathbb{K} \times Q$ is a set of weighted transitions, $\lambda : B \to \mathbb{K}$ and $\rho : F \to \mathbb{K}$ are respectively the initial and final weight functions (Mohri, 1997).

Given $\mathbf{f}$, the search space for compression is built as follows: assuming $\mathbf{f}$ conventionally starts (respectively ends) with `<s>` at index f_0 (resp. `</s>` at index f_{I+1}), we first build the standard automaton $A_{\mathbf{f}}$ for $\mathbf{f}$, the states of which correspond to the prefixes of $\mathbf{f}$.

We then add "skip" transitions $(q_k, f_l, w, q_l,)$, $\forall l > k+1$. In this step, we make sure to preserve the syntactic dependency relationships so as to ensure that the subgraph induced by words in the compression is a subtree of the complete dependency tree. To this end, skip transitions $(q_k, f_l, w, q_l,)$ are created subject to the condition that $\forall m, k < m < l$, f_m is neither an ancestor of f_k nor an ancestor of f_l.

When the dependency trees are projective, these conditions are sufficient to ensure that compressions will be grammatical: if a compression contains a word f_i, it will also contain its head. To see why, assume with no loss of generality that $h(f_i) < f_i$ for some i. If f_i is in the compression, the incoming arc in $A_{\mathbf{f}}$ either starts in node f_k with $k < l$, or $h(f_i)$ precedes f_k (it cannot be skipped). Either $f_k = h(f_i)$, which is what we seek; or f_k is a descendant of $h(f_i)$. We can then repeat the same argument with the arc labeled f_k. It is also routine to check that all possible grammatical compressions can be obtained in this way.

Transitions $(q_k, f_l, w, q_l,)$, with $l > k + 1$, are weighted according to a score w aggregating:

- S_{LM} - a 2-gram language model (LM) score : $S_{LM}(f_l|f_k) = \log P(f_l|f_k)$. The generalization to higher-order n-grams is straightforward. In our implementation, we have used a POS-based LM, as we believe it will provide a better generalization than a word-based LM;
- $S_{IBM}(f_l|\mathbf{e}')$ - the posterior log-probability of f_l in the IBM model 1 of Brown et al. (1993):

$$S_{IBM}(f_l|\mathbf{e}') = \log\big(\frac{1}{(J'+1)}\sum_{j=1}^{J'} t(f_l|e'_j)\big). \quad (1)$$

These scores are summed along a path and yield the total IBM score: $IBM_1(\mathbf{f}'|\mathbf{e}')$.

- $S_{ali}(f_l)$ - this score approximates the contribution of f_l to the posterior log-probability of the $IBM_1(\mathbf{e}'|\mathbf{f})$ at the sentence level:

$$S_{ali}(f_l) = \sum_{i=1}^{J'} \mathbb{1}\{f_l = \operatorname*{argmax}_f t(e'_i|f)\} t(e'_i|f_l), \tag{2}$$

  where $\mathbb{1}\{T\}$ is the indicator function for predicate T. This approximation is required due to the impossibility to decompose the inverse IBM model 1 score over the arcs of $A_{\mathbf{f}}$.

The use of IBM model 1 scores is meant to ensure the preservation of the meaning of the provided source compression $\mathbf{e}'$, hence the parallelism of the resulting sentence pair. Each arc is additionally weighted with a word penalty, which should ensure that short paths are not improperly given preference over longer ones.

The score of a path generating a target string $\mathbf{f}'$ is finally computed as a summation of all arcs in the path:

$$S(\mathbf{f}'|\mathbf{e}') = \alpha \cdot S_{LM}(\mathbf{f}') + \beta \cdot S_{IBM}(\mathbf{f}'|\mathbf{e}') + \gamma \cdot S_{ali}(\mathbf{f}') + \delta \cdot l_{\mathbf{f}'}, \tag{3}$$

where α, β, γ and δ are tunable parameters. The optimal target compression is computed via standard shortest path techniques. Note that this approach can be generalized in many ways, notably including additional costs, subject to *locality constraints*: scoring functions evaluating properties of the compressed sentence should decompose over the arcs of the automaton. This restriction warrants a more generic approach to the problem, relying on Integer Linear Programming.

2.2 Compressing with Integer Linear Programming (ILPbi)

Integer Linear Programming (ILP) (Dantzig and Thapa, 1997) is an optimization approach to solving combinatorial problems that can be expressed as linear programs and in which some or all of the variables are restricted to be non-negative integers. In the following, we heavily rely on the work of Clarke and Lapata (2008), who develop an approach based on ILP for monolingual sentence compression.

The formulation of an ILP problem requires the definition of:

- decision variables, they will be binary in our case;
- an objective function, corresponding to the compression score we wish to maximize;
- constraints, i.e. linguistic or consistency conditions restricting the possible values of decision variables.

The main decision variables in our problem indicate whether a target word f_i initially in $\mathbf{f}$ also occurs in the compressed text:

$$\forall i \in [1 \dots I], x_i = \begin{cases} 1 & \text{if } f_i \text{ is in the compression} \\ 0 & \text{otherwise} \end{cases}$$

Following again Clarke and Lapata (2008), we define additional decision variables for the 2-gram LM scores (again, the generalization to higher-order n-grams is straightforward):

$$\forall i \in [1 \dots I], y_i = \begin{cases} 1 & \text{if } f_i \text{ starts the compression} \\ 0 & \text{otherwise} \end{cases}$$

$$\forall i \in [1 \dots I], p_i = \begin{cases} 1 & \text{if } f_i \text{ ends the compression} \\ 0 & \text{otherwise} \end{cases}$$

$$\forall i \in [1 \dots I-1], \forall k \in [i+1 \dots I], z_{ik} = \begin{cases} 1 & \text{if the pair } (f_i, f_k) \text{ is in the compression} \\ 0 & \text{otherwise} \end{cases}$$

Our ILPBI model is again integrated with IBM model 1 scores, which help ensure the preservation of meaning in $\mathbf{e}'$. For our approximation of the $IBM_1(\mathbf{e}'|\mathbf{f})$ score described in Section 2.1, we introduce a new variable:

$$\forall i \in [1 \dots I], \forall m \in [1 \dots J], a_{im} = \begin{cases} 1 & \text{if } g(t(\mathbf{e}'_m|f_i)) > 0 \\ 0 & \text{if } g(t(\mathbf{e}'_m|f_i)) = 0 \end{cases}, \tag{4}$$

where $g(t(\mathbf{e}'_m|f_i)) = \mathbb{1}_{f=\text{argmax}_f\, t(\mathbf{e}'_m|\mathbf{f})}(t(\mathbf{e}'_m|f_i))$ tests whether f_i is the best alignment for $\mathbf{e}'_m$.

Our objective function models 2-gram LM scores, as well as bilingual $IBM_1(\mathbf{f}|\mathbf{e}')$ and our approximation of $IBM_1(\mathbf{e}'|\mathbf{f})$:

$$\begin{aligned} S(\mathbf{f}'|\mathbf{e}') \; =& \alpha \sum_{i=1}^{I} x_i \cdot \log\big(\frac{1}{(I+1)} \sum_{i=1}^{I} t(f_l|e'_i)\big) + \gamma \sum_{i=1}^{I} y_i \cdot \log P(f_i|\text{<s>}) \\ &+ \gamma \sum_{i=1}^{I-1} \sum_{k=i+1}^{I} z_{ik} \cdot \log P(f_k|f_i) + \beta \sum_{m=1}^{J} \sum_{i=1}^{I} a_{i,m} \cdot \log t(\mathbf{e}'_m \mathbf{f}_i) + \gamma \sum_{i=1}^{I} p_i \cdot \log P(\text{</s>}|f_i) \end{aligned} \tag{5}$$

subject to: $x_i, y_i, z_{ik}, p_i, a_{i,m} \in \{0, 1\}$. The following constraints are also applied for generation of valid n-gram sequences without word repetition:

Constraint 1 Exactly one word can start a compression.

$$\sum_{i=1}^{I} y_i = 1 \tag{6}$$

Constraint 2 If a word is in the compression it must either start it, or must follow another word.

$$\forall k : k \in [1 \dots I], x_k - y_k - \sum_{i=1}^{k-1} z_{ik} = 0 \tag{7}$$

Constraint 3 If a word is in the compression it must either be followed by another word or end the sentence.

$$\forall i : i \in [1 \dots I], x_i - (\sum_{k=i+1}^{I} z_{ik}) - p_i = 0 \tag{8}$$

Constraint 4 Exactly one word can end a compression.

$$\sum_{i=1}^{I} p_i = 1 \tag{9}$$

Constraint 5 A dependent f_i cannot be included in a compression without its head $h(f_i)$ from the dependency tree $\tau_{\mathbf{f}}$, the constraint that ensures the grammaticality of $\mathbf{f}'$. This is a simplified version of constraints (20)-(24) of (Clarke and Lapata, 2008).

$$\forall i, x_{h(i)} - x_i \geq 0 \tag{10}$$

Constraint 6 If a compression contains a left bracket/quote mark it should contain the right bracket/quote mark.

$$x_{left} - x_{right} = 0 \tag{11}$$

Constraint 7 A compression is to be at least b tokens long. This constraint controls the compression length and prevents the model to generate too short compression preferred by LM.

$$\sum_{i=1}^{I} x_i \geq b \tag{12}$$

Constraint 8 If a word is in the compression it can have a best alignment in $\mathbf{e}'$.

$$x_i - a_{im} >= 0 \tag{13}$$

To complete this section, we now present our tools for monolingual compression, that will be used in our baseline system.

2.3 Monolingual Compression (DPmono and ILPmono)

In the monolingual scenario, we are given a target sentence $\mathbf{f} = f_1, f_2, \ldots, f_I$. The goal is to produce a target compression $\mathbf{f'} = f'_1, f'_2, \ldots, f'_{I'}$ by removing any subset of words in $\mathbf{f}$, given the dependency tree τ. Here we also assume to be given the lemmas corresponding to the words in $\mathbf{f}$: $m(f)$ denotes the lemma associated with word f. Here again, we look for $\mathbf{f'}$ that should be grammatical and preserve the main aspects of the meaning of $\mathbf{f}$.

We introduce grammaticality constraints in our compressions in a way similar to our bilingual methods. To help meaning preservation we introduce the following semantic importance score for the sense-bearing words of $\mathbf{f}$, namely nouns, verbs, adjectives and adverbs, inspired again by Clarke and Lapata (2008):

$$S_{sem} = \frac{1}{D_{f_{sb}}} fr_{m(sb)} \log \frac{F}{F_{m(sb)}} \tag{14}$$

This score is a `TD-IDF` measure for the lemma $m(f)$ of each sense-bearing word, weighted proportionally to its depth in the dependency tree $D_{f_{sb}}$, where $fr_{m(sb)}$ and $F_{m(sb)}$ are respectively the frequency of the lemma in the news article and in the corpus, and F is the count of all sense-bearing lemmas in the corpus.

1. DPmono For the DPmono approach, we construct an WFSA in a way similar to the one described in 2.1. We weight each arc in the automaton with S_{LM} and S_{sem}. The score of a path generating a target string $\mathbf{f'}$ is computed as:

$$S(\mathbf{f'}|\mathbf{e'}) = \alpha \cdot S_{LM}(\mathbf{f'}) + \beta \cdot S_{sem}(\mathbf{f'}) + \gamma \cdot l_{\mathbf{f'}}, \tag{15}$$

where α, β and γ are tunable parameters.

2. ILPmono The objective function for ILPmono similarly models $S_{sem}(f_i)$ and 2-gram LM scores:

$$S(\mathbf{f'}|\mathbf{e'}) = \sum_{i=1}^{I} x_i \cdot \theta S_{sem}(f_i) + \eta \sum_{i=1}^{I} y_i \cdot \log P(f_i|\text{<s>}) + \eta \sum_{i=1}^{I-1} \sum_{k=i+1}^{I} z_{ik} \cdot \log P(f_k|f_i) + \eta \sum_{i=1}^{I} p_i \cdot \log P(\text{</s>}|f_i),$$

subject to: $x_i, y_i, z_{ik}, p_i \in \{0, 1\}$, with θ and η as tunable parameters. Constraints 1-7 of ILPbi are applied.

3 Experimental Setup

In our evaluation experiments we were guided by the following questions: (1) Does the proposed bilingual compression methodology ensure **the resulting corpus parallelism** (compressed target text succeeds in preserving the meaning of the input compressed source text)? (2) Which of the proposed bilingual compression methods is more **efficient**?

3.1 Metrics

To answer the above questions, we compared the results of our bilingual methods DPBI and ILPBI to the results of our monolingual methods DPMONO and ILPMONO (baselines) using the compression rate (COMPR) estimation, F-SCORE metric for the relations in grammatical dependency parse trees (Chen and Manning, 2014), as well as the standard MT metric BLEU (Papineni et al., 2002; Clarke and Lapata, 2008; Napoles et al., 2011b). F-SCORE measures how much meaning is preserved in the compression using the grammatical-functional information, BLEU measures the fluency of the produced compressions.

We also computed the confidence score (CS) of the parallelism between the produced compressions and the compressed source. We used a Logistic Regression model trained on the parallel sentences extracted from a corpus of manual alignments. The model exploits such features as the length difference ratio, IBM model 1 scores, the cosine similarity of the distributional representations for source and target etc. Details regarding the model are in (Xu et al., 2015).

3.2 Data and Translation Models

Our experiments used the News data provided by the organizers of the WMT'15 news translation task (English-French) [1]. Details regarding data preparation are in (Marie et al., 2015).

We randomly chose around 60 articles from the News 2014 test set to be used as our development and test sets. The compressed source and reference data were created manually by three annotators. Two of them were native French speakers, all the three annotators were fluent in both English and French. The annotators were given the instruction to delete any quantity of words without disturbing the meaning and the grammaticality of a source English sentence. Target French words "translating" deleted source words were deleted accordingly under the condition that a sentence stays grammatical. This resulted in the small compression rate of COMPR = 79.74 at the source side and of COMPR = 84.45 at the target side [2].

In our experiments, we used the French 3-gram POS LMs trained with Witten-Bell smoothing on a part of the target side of the parallel Giga corpus (≈14% of the available corpus) using the SRILM (Stolcke, 2002) toolkit. The same parallel data and the uncompressed development and test sets were used to compute the IBM1 scores in both directions with the help of MGIZA++ (Gao and Vogel, 2008), and to estimate the lemma frequencies for the semantic importance scores (Schmid, 1995). The dependency parse trees were produced using the Stanford parser (Chen and Manning, 2014).

The statistics of the development and test data, as well as the data used for model estimation are in Table 1.

		Full		Compression	
	lines	tok., en	tok., fr	tok., en	tok., fr
development set	504	11K	13K	9K	11K
test set	489	12K	14K	10K	12K
Giga	3M	71M	86M		

Table 1: Data Statistics

For the WFSA experiments, we mostly used the SRILM toolkit (Stolcke, 2002). The ILP

[1] http://www.statmt.org/wmt15/translation-task.html

[2] The traces of compression operations for the corpus are available at http://perso.limsi.fr/ive.

experiments were performed with the GLPK toolkit.[3] All the tunable parameters were tuned to optimize BLEU. In our implementation of ILPBI, we slightly modified constraint 5 to take into account the negation relations: when the head of such relation are included in the compression, then their immediate dependent must also be selected. This is because the preservation of such relation is crucial for the overall meaning of a sentence. Finally, constraint 7 is parametrized by a preset compression ratio, rather than a preset target length; in our experiments this compression ratio was set to match the compression ratio of DPBI so as to make our results more comparable.

3.3 Evaluation

Results of our experiments comparing bilingual and monolingual methods are in Table 2.

model	COMPR	F-SCORE	BLEU	CS
DPMONO	82.58	80.37	73.37	0.94
DPBI	84.63	81.71	**76.09**	0.96
ILPMONO	85.10	80.18	62.59	0.95
ILPBI	85.06	**82.72**	69.85	**0.97**
Ref.	83.59			0.99

Table 2: Evaluation results

As reflected by the automatic metrics, the bilingual methods produce compressions that better preserve the meaning of the source sentence than the corresponding monolingual methods, hence improving the parallelism of the resulting compressions (average ΔF-SCORE = 1.94, ΔBLEU = 4.99 and ΔCS = 0.02, between the ILP and DP monolingual and bilingual methods) (see Table 3).

	'The city of New York is considering.'
ILPBI	Ville de New York en envisage **un**.
	'City of New York is considering **one**.'

Table 3: Examples of compressions produced by the monolingual and bilingual methods

F-SCORE and CS estimations suggest that ILPBI is a slightly more efficient method than DPBI in terms of preserving parallelism (+1.01 F-SCORE, +0.01 CS). Due to the global constraints, ILPBI tends to include more sense-bearing words in the compression (see Table 4, first example). Our example shows that ILPBI kept the word "cour" 'court'. This noun is more important for understanding the meaning of the sentence than the preposition "en" 'in' following the verb "présenter" 'appear', chosen due to the local decision taken by DPBI.

At the same time the length constraint "obliges" ILPBI to compress every sentence. In our setting with the small compression rate, short sentences often stay uncompressed. In this case, DPBI is able to choose the automaton path of the maximum length (see Table 4, second example). ILPBI though in this case deletes the auxiliary words (articles in our example). This

[3] `http://glpk-java.sourceforge.net`

is reflected in the decrease of the BLEU score for ILPBI as compared to DPBI (-6.24 BLEU). BLEU here is heavily penalized by the decrease in matching n-grams of the order $n > 1$.

ILP methods can also be very convenient for a series of reasons. E.g., in the absence of development corpora ILP compressions can be obtained with minimum or without any tuning. Another advantage is the easy parameterization of the compression rate. This criteria was very important for our task with the small compression rate. Keeping it was crucial for correct evaluation of our methodology. Thus, for the DP methods we observe the compression rate variation of ΔCOMPR = 2.05, for the ILP methods this variation is insignificant (ΔCOMPR = 0.04).

4 Related Work

The deletion-based compression problem has been studied using a series of modeling paradigms. We mention first the work of Knight and Marcu (2002), who use the *noisy channel* model. This approach aims to maximize $P(\mathbf{f}'|\mathbf{f}) \propto P(\mathbf{f}')P(\mathbf{f}|\mathbf{f}')$, where $P(\mathbf{f}')$ is the source model, and $P(\mathbf{f}|\mathbf{f}')$ models the syntactic parse tree probability of the long sentence being an expansion of the compressed one. The noisy channel model is also used by approaches that consider compression as a monolingual translation problem (Napoles et al., 2016).

McDonald (2006) formulates the problem as a binary sequence labeling problem with a rich syntactic feature set, and proposes a solving procedure based on dynamic programming techniques. More recent DP solutions to the sentence compression problem use neural network architectures (Filippova et al., 2015).

The ILP approach to compression was introduced by Clarke and Lapata (2008). The main motivation was the necessity to take global features into account (e.g., the constraint to have at least one verb in the compressed sentences). This approach has been widely reused in research related to text compression with various modifications to syntactic and informativeness scores used by Clarke and Lapata (2008) (see also (Wei et al., 2015; Filippova and Altun, 2013)).

In our bilingual framework we compare the performance of DP and ILP approaches. As far as we know this is the first attempt to create compressed parallel bitext in asymmetrical setting. A closely related work is that of Aziz et al. (2012), who also exploits bilingual information. The authors propose a PBSMT solution for joint translation and compression of subtitles, which dynamically decides where it is necessary to impose a space/time constraint on the translated text.

5 Conclusions

In this paper we consider sentence compression in a bilingual setting. We adopt an asymmetrical view to the task, where we first compress the source, then look for a compressed target translating the reduced source. Based on recent research on these issues, our main contribution is to adapt

existing monolingual compression techniques to produce compressed bitext. As we know this the first attempt of the kind. We use dynamic programming (DP) and integer linear programming methods (ILP) enriched with bilingual features. Both methods improve the preservation of the compressed source meaning, hence the parallelism of the resulting bitext, as opposed to using independently monolingual methods in source and target.

In our setting, ILP was found to perform better than DP; the ILP method is more flexible and requires less resources for tuning; furthermore, it can accommodate more complex (e.g. global) constraints. Our future work includes exploring additional global constraints, experimenting with shorter compressions, as well as using basic phrase-based statistical machine translation (PBSMT) techniques, including applying the noisy channel model and beam-search decoding to find the best possible target compression.

The results of bilingual compression can be used for human-oriented (language learning, subtitles generation etc.) purposes, or in a large spectrum of natural language processing (NLP) tasks. The approach can be extended to paraphrastic compression (as opposed to deletion-based), as well as applied in the symmetric compression scenario, when source and target are compressed simultaneously.

Acknowledgements

The work of the first author is supported by a CIFRE grant from the French ANRT. We would like to thank Yong Xu for helping us with the computation of the parallelism confidence scores, as well as the annotators for their participation in the creation of the compressed corpus.

Abstract

In the age of information exploding, multi-document summarization is attracting particular attention for the ability to help people get the main ideas in a short time. Traditional extractive methods simply treat the document set as a group of sentences while ignoring the global semantics of the documents. Meanwhile, neural document model is effective on representing the semantic content of documents in low-dimensional vectors. In this paper, we propose a document-level reconstruction framework named *DocRebuild*, which reconstructs the documents with summary sentences through a neural document model and selects summary sentences to minimize the reconstruction error. We also apply two strategies, sentence filtering and beamsearch, to improve the performance of our method. Experimental results on the benchmark datasets DUC 2006 and DUC 2007 show that *DocRebuild* is effective and outperforms the state-of-the-art unsupervised algorithms.

1 Introduction

Multi-document summarization aims at capturing the important information of a set of documents related to the same topic and presenting it in a brief, representative, and pertinent summary. Most existing researches focus on extraction-based methods, in which sentences are selected from the original document set.

Typically, two kinds of unsupervised models are used for sentence selection. One is based on sentence ranking, which uses methods such as clustering (Lin and Hovy, 2002; Radev et al., 2004), PageRank (Erkan and Radev, 2004; Mihalcea and Tarau, 2005) and topic modeling (Harabagiu and Lacatusu, 2005; Wang et al., 2008), to rank the sentences. Considering that top-ranked sentences tend to convey much redundant information, additional strategies are usually applied to reduce redundancy when selecting sentences. This kind of methods usually need to weigh between relevance and redundancy, which may be hard to balance.

The other is based on sparse reconstruction (He et al., 2012; Liu et al., 2015; Yao et al., 2015), which selects a sparse subset of the sentences that can linearly reconstruct all the sentences in the original document set. This kind of methods has a good motivation but also weaknesses in their hypothesises. First, reconstructing single sentences may lose the global information of documents; Second, there are more reasonable ways than linear combination in reconstruction.

Commonly, in the above methods the document set is treated as a set of sentences and all the operations are carried out on the sentence set, losing the global information of documents. Meanwhile, neural document model (Le and Mikolov, 2014; Li et al., 2015; Lin et al., 2015) is an emerging technique which has made significant progress in capturing semantic information of documents by projecting the text into the low-dimensional continuous distributed representation. It has been applied to natural language processing tasks such as sentiment classification (Tang et al., 2015).

*Zhi-Hong Deng is the corresponding author.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1514–1523, Osaka, Japan, December 11-17 2016.

In this paper, we address the aforementioned problems of existing methods and propose a document-level reconstruction framework based on neural document model, named *DocRebuild*, for multi-document summarization.

Intuitively, a good summary is supposed to reconstruct the main content of the multi-document set. In our model, we first introduce neural document model to represent the content of each document and use averaging to obtain the main content of the document set. The main content is reconstructed by concatenating the summary sentences into a sequence and feeding the summary sequence into the document model. Hence the multi-document summarization is converted into an optimization problem via taking the reconstruction error as the objective function. Summary sentences are selected to minimize this error. Furthermore, two strategies are addressed in selecting sentence to yield a better performance. First, irrelevant sentences are filtered and only a subset of related sentences is reserved as candidate set. Second, a beamsearch algorithm is applied to get a better solution in sentence selection stage.

Our contributions can be concluded as follows:

- We introduce neural document model into multi-document summarization task. As far as we know, no such works have been presented before.
- We propose a document-level reconstruction framework *DocRebuild*, and further adopt two effective strategies to improve the performance of our method.
- The experimental results on two benchmark DUC data sets show that our method outperforms the state-of-the-art unsupervised approaches.

2 Related Work

Multi-document summarization has received widespread attention in recent years. Most existing multi-document systems use extraction-based methods, in which sentences are directly selected from the original document set.

The majority of these methods use the idea of sentence-ranking, assigning salient scores to sentences of the original document set and choosing the top sentences to form the summary. Typical methods are the centroid-based methods (Lin and Hovy, 2002; Radev et al., 2004), which score sentences basing on features such as cluster centroids, sentence position and TF-IDF. Besides, graph based models (Erkan and Radev, 2004; Mihalcea and Tarau, 2005) first measure the sentence similarity then use ranking algorithm such as PageRank on the similarity graph to estimate the importance of different sentences. Topics in documents are also discovered to be an effective feature for sentence ranking (Hardy et al., 2002; Harabagiu and Lacatusu, 2005; Wang et al., 2008). Maximum Marginal Relevance (MMR) (Goldstein et al., 1999) is widely used for greedily selecting sentences while considering the tradeoff between relevance and redundancy.

However, it is usually hard to get a good balance between relevance and redundancy. Recently, a couple of works have employed the idea of data reconstruction in the summarization task. DSDR (He et al., 2012) reconstructs each sentence in the document set by a non-negative linear combination of summary sentences then minimizes the reconstruction error. MDS-Sparse (Liu et al., 2015) introduces the diversity constraint and proposes a two-level sparse representation model to reconstruct the sentences in the document set. SpOpt (Yao et al., 2015) follows the sparse representation framework while simultaneously doing sentence selection and compression by adjusting reconstruction coefficients and compression coefficients alternately in optimization.

In this work, neural document model is involved in performing summarization task on document level. With the development of deep learning, some attempts have been made to model documents with neural networks. Le and Mikolov (2014) extends the neural network of word embedding (Mikolov et al., 2013) to learn the document embedding. Li et al. (2015) uses a hierarchical long-short term memory auto-encoder to reconstruct the original document. Lin et al. (2015) proposes a hierarchical recurrent neural network language model to consider sentence history information in word prediction. Tang et al. (2015) presents a convolutional-gated recurrent neural network and applies it to sentiment classification task.

However, few such researches have been reported on document level in multi-document summarization task.

3 Proposed Framework

We propose our framework *DocRebuild* in this section. The neural document model is introduced in Section 3.1, the objective function is formulated in Section 3.2, and summary sentences are selected with two effective strategies as shown in Section 3.3. Figure 1 illustrates the framework of *DocRebuild*.

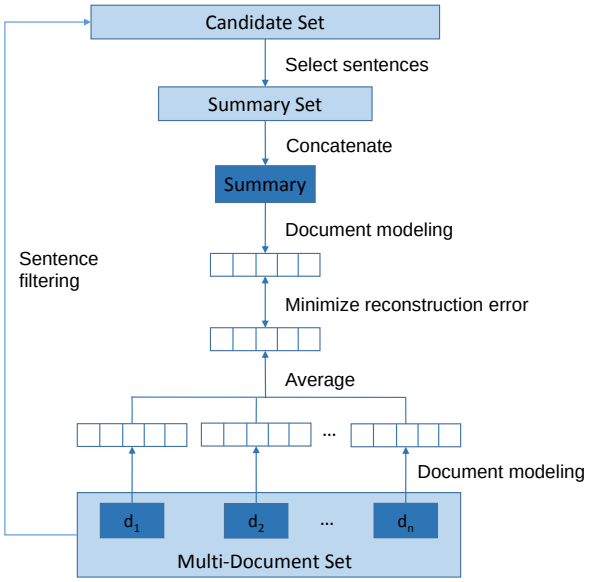

Figure 1: The framework of *DocRebuild*. Light blue boxes represent the sets of documents or sentences, deep blue boxes represent the document or summary sequences. Document modeling process projects document or summary sequences into real-valued vectors as represented by the bars.

3.1 Neural Document Model

Neural document model aims to represent the semantic content of a document with low-dimensional vector representation. As the basis of our framework, it is the key to a good performance. Here we focus on the unsupervised methods and exploit two kinds of unsupervised document models, named Bag-of-Words(BoW) model and Paragraph Vector(PV) model respectively, in our task.

In the BoW model, we simply use the bag-of-words of the document without considering the original order or relationships between neighboring words. Word embedding(Mikolov et al., 2013) has been proven of great significance in most natural language processing tasks in recent years. So we represent each word by its corresponding word embedding and the document is represented as the weighted average of all the words in the document.

Since BoW model is likely to lose the semantic information hidden in the order and composition of words, we introduce a more complex model which takes word order into consideration. PV (Le and Mikolov, 2014) is an unsupervised framework that learns distributed representations for sentences and documents. Compared with other hierarchical document models (Li et al., 2015; Lin et al., 2015) built upon sentences, PV handles texts with various length in a common way, making it possible to measure sentences, short summaries and long documents in the same semantic space.

Figure 2 illustrates the framework of PV model. In this model, every document is mapped to a unique vector, as a column in matrix $D \in \mathbb{R}^{n \times l}$ and every word is mapped to a unique vector, as a column in matrix $W \in \mathbb{R}^{m \times l}$. n, m, l represent document set size, vocabulary size and dimensionality of vector, respectively.

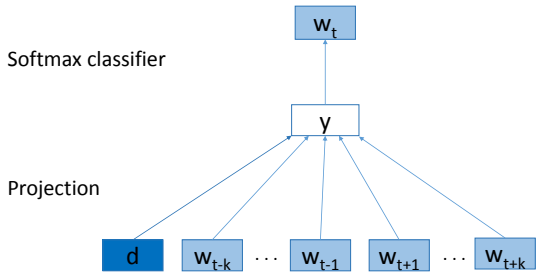

Figure 2: The framework of PV model

It employs a similar idea as the one in Mikolov et al. (2013), to predict the next word given many contexts sampled from the document. More precisely, given a document d consisting of a sequence of words $w_1, w_2, \ldots, w_T$ and the fixed window size k of context, the objective of PV model is to maximize the log-likelihood,

$$\mathcal{L} = \sum_{t=1}^{T} \log \mathbb{P}(w_t | w_{t-k} : w_{t+k}, d) \tag{1}$$

Note that $w_{t-k} : w_{t+k}$ represents the word sequence from w_{t-k} to w_{t+k} except w_t. The probability $\mathbb{P}(w_t | w_{t-k} : w_{t+k}, d)$ is defined using the softmax,

$$\mathbb{P}(w_t | w_{t-k} : w_{t+k}, d) = \frac{e^{y_{w_t}}}{\sum_{i=1}^{m} e^{y_{w_i}}} \tag{2}$$

$\mathbf{y} \in \mathbb{R}^m$ represents un-normalized log probability for all the possible words in vocabulary, computed as,

$$\mathbf{y} = Uh(w_{t-k} : w_{t+k}, d) + b \tag{3}$$

where $U \in \mathbb{R}^{m \times l}, b \in \mathbb{R}^m$ are the parameters of softmax classifier and h stands for the averaging of document vector and word vectors extracted from D and W.

During training, parameters D, W, U, b are randomly initialized and then updated to maximize equation (1) using stochastic gradient descent via backpropagation. Once the model is trained, it can further be employed in predicting representations of the documents not included in the training set.

At inference stage, a new document is fed into the PV model to do the same prediction task as the training documents. But this time only the document vector d is randomly initialized while other parameters W, U, b are fixed. Then we update the document vector d to maximize equation (1) by gradient descent as well. After convergence, d is taken as the corresponding document vector.

3.2 Objective Function

We denote the **multi-document set** as $D = \{d_1, d_2, \ldots, d_n\}$. All the documents in D are processed into a group of sentences, defined as the **candidate set** and denoted as $C = \{s_1, s_2, \ldots, s_m\}$. The sentences selected from S form the **summary set**, denoted as $S = \{s_1^*, s_2^*, \ldots, s_l^*\}$, where $S \subset C$ and $|S| \ll |C|$. Note that all the elements in the above sets are sequences of words. Let θ denote the required summary length, our task is to select the optimal subset of candidate set C that composes summary shorter than θ.

We consider the multi-document summarization task as a data reconstruction problem. We assume that a good multi-document summary is supposed to reconstruct the main content of the document set. Therefore we focus on two issues: (1) how to represent the main content of the document set, and (2) how to use the summary set to reconstruct the main content. In this work, both issues are resolved by document modeling.

As an example, we randomly choose four document sets and their corresponding human-written summaries in DUC2006 dataset, compute their vector representation with PV model and project the vectors into the two-dimensional space. As shown in figure 3, each color corresponds to a document set and four

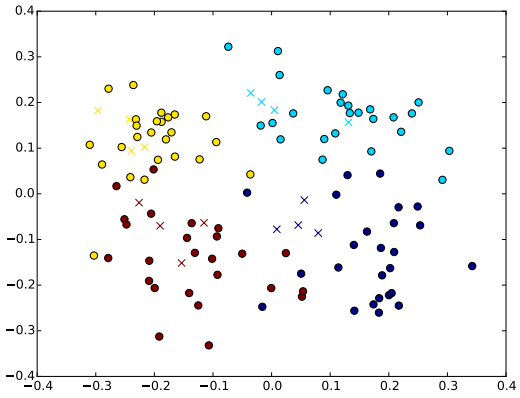

Figure 3: Visualization of document vectors and summary vectors. Documents are represented by circles and summaries are represented by crosses.

summaries, and we find that the centre of summary vectors are close to the centre of document vectors in the same color, implying the effectiveness of averaging.

Hence in our model, each document in the document set is mapped into a vector through document model, then the document vectors are averaged to represent the main content. As for the summary set, all the sentences in S are sequentially concatenated into a sequence S^* as the corresponding summary. Then the summary sequence S^* can be seen as a short document and fed into the document model to reconstruct the main content. Naturally, reconstruction error is applied as objective function and measured by distance between the summary vector and the main content vector. Summary set S is adjusted to minimize the reconstruction error.

Provided that the document modeling process is represented by DM, it takes a document or summay x as input and obtains the semantical vector representation of x, denoted as $DM(x)$. Our reconstruction model is formalized as follows:

$$\begin{aligned} &\min_{S \subset C} \quad \|DM(S^*) - \frac{1}{n}\sum_{i=1}^{n} DM(d_i)\|_2^2 \\ &s.t. \quad len(S^*) \leq \theta \end{aligned} \tag{4}$$

Where S^* denotes the corresponding summary sequence of summary set S and $len(S^*)$ denotes the length of the summary sequence.

Our formulation is similar to the intuition behind He et al. (2012), but differs from it mainly in two aspects: first, we directly reconstruct the original document set on document level; second, we introduce neural document model to represent and reconstruct documents with the summary sentences.

In addition, multi documents are usually considered to bring the redundancy problem in previous works. Contrarily, multiple documents benefit our method by helping represent documents reliably and capture the main content unbiasedly.

3.3 Sentence Selection

Our task is essentially to find the optimal subset of sentences that minimize equation (4) with length constraints, which can be seen as a generalization of knapsack problem and is NP-hard as explained in Lin and Bilmes (2011). The simple approximate approach is to select sentences sequentially from the candidate set with a greedy algorithm. Here we introduce two strategies in sentence selection stage to guarantee both efficiency and effectiveness.

Sentence filtering This strategy aims to narrow the search space by filtering the irrelevant noisy sentences and reserving the promising sentences as candidate. It also benefits the document modeling process by removing noisy sentences with rare words or in bad format. Unsurprisingly, other existing

summarization systems are suitable for this task. In the experiments, we utilize the baseline methods to rank the sentences first and reserve a subset of top-ranked sentences as candidate. Our method then selects summary sentences from the filtered candidate set.

Algorithm 1 BeamSearch

Require: Candidate set C, multi-document set D, document model DM, beam size k, summary length threshold θ

Ensure: A list L_k including top-k summary sets

$L_k, L_{old}, L_{new} \leftarrow \varnothing$
$S \leftarrow \varnothing$ and append S to L_{old}
while L_{old} is not empty **do**
  for each sentence s in C **do**
    for each summary set S in L_{old} **do**
      if $s \notin S$ **then**
        $S_{new} \leftarrow S \cup s$
        if $len(S^*_{new}) < \theta$ **then**
          $\delta \leftarrow \|DM(S^*_{new}) - \frac{1}{n}\sum_{i=1}^{n} DM(d_i)\|_2^2$
          if S_{new} can't further extend **then**
            Update L_k to reserve the top-k final summary sets with loss δ
          else
            Update L_{new} to reserve the top-k promising summary sets with loss δ
          end if
        end if
      end if
    end for
  end for
  $L_{old} \leftarrow L_{new}$
  $L_{new} \leftarrow \varnothing$
end while
return L_k

BeamSearch Algorithm Beamsearch algorithm can be seen as the extension to greedy algorithm, which traverses the entire candidate set C while limiting itself to k potential sentences at each selection step. This is similar to the algorithm used for sentence decoding in neural machine translation tasks (Bahdanau et al., 2014; Sutskever et al., 2014) except that the search space in neural machine translation is the vocabulary of words.

As shown in Algorithm 1, a list L_k is maintained to store top-k final summaries and two lists L_{old}, L_{new} are used to store the top-k promising summaries at each iteration. The algorithm iterates on the candidate set C over and over to select sentences until the required summary length is satisfied. At each iteration, all the sentences in the candidate set are added to the current promising summaries in L_{old} to calculate the reconstruction error. The new summary sets within the length restriction are reserved. The reserved summary sets that have no room for adding new sentences are used to update L_k, while the rest are used to update L_{new}. At last, the top summary set in L_k is chosen and the sentences in it are concatenated sequentially as result.

4 Experiments

In this section, we present the experimental results of our model compared with other baseline approaches and analyze the influence of sentence selection strategies.

4.1 Experimental Setup

Data Set The document understanding conference (DUC)[1] was the main forum providing benchmarks for researchers working on document summarization. We employ DUC 2006 and DUC 2007, the benchmark datasets in multi-document summarization task, for evaluation. DUC 2006 and DUC 2007 contain 50 and 45 document sets respectively. Each document set has 25 news articles for summarization and 4 human-written summaries as ground truth. The length of a result summary is limited to 250 words.

Evaluation Metric We use ROUGE toolkit (Lin, 2004) as our evaluation metric, which is adopted by DUC for automatic summarization evaluation. ROUGE measures summary quality by counting overlapping units such as the n-gram, word sequences and word pairs between the candidate summary (produced by algorithms) and the reference summary (produced by humans). Here we report the average F-measures of ROUGE-1, ROUGE-2 and ROUGE-SU4[2], which are based on uni-gram match, bi-gram match, and unigram plus skip-bigram match with maximum skip distance of 4 between the candidate summary and the reference summary, respectively.

Document Model Training DUC datasets are of small scale, making it hard to train a neural network. For BoW model, we simply use the word vectors pre-trained on GoogleNews[3] to infer the document vectors. For PV model, we employ the Thomson Reuters Text Research Collection (TRC2) in Reuters Corpora (Lewis et al., 2004) to train the PV model first, then fine-tune it on the documents in DUC2006 and DUC2007 datasets to learn more precise representation. The entire training set contains 215 million tokens, 1.3 million word types and 1.8 million documents. The python package gensim[4] is used for training PV model and the parameters are set to default.

Compared Methods Since we focus on unsupervised extractive summarization task in this work, we compare our model *DocRebuild* with several unsupervised extraction-based algorithms. As the same reason as He et al. (2012), we don't compare with supervised methods (Toutanova et al., 2007; Haghighi and Vanderwende, 2009; Çelikyilmaz and Hakkani-Tür, 2010; Lin and Bilmes, 2011) on DUC2006 and DUC2007 here.

1. **Random** randomly selects sentences from the original document set.
2. **Lead** (Wasson, 1998) sorts the documents chronologically and selects the leading sentences one by one.
3. **DSDR** (He et al., 2012) reconstructs all the sentences in the document set by linearly combining summary sentences and selects sentences to minimize reconstruction error with sparse coding.
4. **SpOpt** (Yao et al., 2015) uses a sparse representation model simultaneously selecting sentences and doing sentence compression, subject to the diversity constraint.

Among these methods, Random and Lead are weaker baselines, DSDR is the original reconstruction method, and SpOpt is a state-of-the-art summarization method which considers sentence compression at the same time. Note that we re-implement the above methods[5] to filter sentences and generate candidate sets for our method. Then we construct our reconstruction model on each candidate set. We use term BoW(*) to denote the versions with BoW model and term PV(*) for those with PV model.

4.2 Experimental Result

Overall Performance Table 1 shows the system comparison results on the two datasets. The parameters of *DocRebuild* are set as follows: the dimensionality of document model is 300 for both BoW model and PV model, the candidate sentences are the top 10% sentences[6], and the beamsize is set to

[1] `http://duc.nist.org`

[2] ROUGE version 1.5.5 with options: -a -n 2 -x -m -2 4 -u -c 95 -r 1000 -f A -p 0.5 -t 0 -d -l 250

[3] `https://code.google.com/p/word2vec/`

[4] `http://radimrehurek.com/gensim/index.html`

[5] Here we used the source code of SpOpt but failed to completely reproduce its results, which may be caused by document preprocessing and parameter setting.

[6] As for Lead, all the leading sentences are reserved as candidate.

Table 1: Average F-measure performance on DUC2006 and DUC2007.

10 (parameters are tuned in the DUC2005). Among all the systems, Random and Lead unsurprisingly show the poorest performance, for they don't consider any semantic information. DSDR performs better by introducing reconstruction framework. SpOpt improves the performance by employing diversity constraint and doing sentence compression. *DocRebuild* obtains a significant[7] improvement on most of the corresponding baselines. Both PV(over DSDR) and PV(over SpOpt) outperform all the baselines and PV(over SpOpt) achieves the best performance. The result demonstrates the rationality of document-level reconstruction and the effectiveness of neural document model.

Besides, among all the versions of *DocRebuild*, PV model performs much better than BoW model, and the gap is more obvious on DUC2006 than on DUC2007. One possible reason is that PV model takes word order into consideration and this advantage is more apparent in the case of long documents (maximal length of documents is 5407 words in DUC2006 while 2663 words in DUC2007). It also can be observed that Rouge-1 score improves more obviously than Rouge-2 and Rouge-SU4 scores. This implicates our document models are more adept at handling words than n-grams since both document models do the prediction task on word-level.

Algorithm	**Rouge-1**	**Rouge-2**	**Rouge-SU4**

+Beamsearch	**0.42193**	**0.09314**	**0.15177**

Table 2: Performance with different strategies on DUC2006.

Analysis on Sentence Selection Strategies We further discuss the separate influence of two sentence selection strategies with PV(over SpOpt) version on DUC2006. As shown in Table 2, None stands for greedily selecting sentences from all the sentences in the document set, sentence filtering and beam-search are added sequentially. We can see that sentence filtering has impressive effect on improving our method. This demonstrates that sentence filtering is necessary for making document model work well as document model may be weak in modeling noisy sentences with rare words or in bad format. In addition, beamsearch further improves the performance by considering more possible combination of sentences. The above results indicate these two strategies both work well.

[7]T-test with p-value ≤ 0.05

5 Conclusion and Future Work

In this paper, we introduced neural document model into multi-document summarization task and proposed a document-level reconstruction framework named *DocRebuild*. In this framework, we represent and reconstruct the main content of documents with summary sentences on neural document model and take the reconstruction error as objective. To obtain the summary, we use sentence filtering to generate a candidate set and select the summary sentences from the candidate set via beamsearch algorithm. The experiment results show that *DocRebuild* outperforms the state-of-the-art unsupervised algorithms and shows great potential in summarizing multiple documents. In future work, it would be of great interests to extend our model by two ways: (1) trying more complex neural networks to model the documents, and (2) designing new algorithm to improve sentence selection.

Abstract

The search space in grammar-based natural language generation tasks can get very large, which is particularly problematic when generating long utterances or paragraphs. Using surface realization with OpenCCG as an example, we show that we can effectively detect partial solutions (*edges*) which cannot ultimately be part of a complete sentence because of their syntactic category. Formulating the completion of an edge into a sentence as finding a solution path in a large state-transition system, we demonstrate a connection to AI Planning which is concerned with this kind of problem. We design a compilation from OpenCCG into AI Planning allowing the detection of infeasible edges via AI Planning dead-end detection methods (proving the absence of a solution to the compilation). Our experiments show that this can filter out large fractions of infeasible edges in, and thus benefit the performance of, complex realization processes.

1 Introduction

Surface generation is an NP-complete problem (Koller and Striegnitz, 2002). This is particularly problematic in practical terms when the sentence or text paragraph to be generated is long. Our aim in this paper is to improve the efficiency of surface realization in OpenCCG (White, 2006; White and Rajkumar, 2012), by detecting, early on during search, *infeasible* partial solutions (which can never be completed into a full sentence), through a new connection to techniques from *AI Planning*.

OpenCCG is based on *combinatory categorial grammar (CCG)*, where words from a lexicon are annotated with syntactic *categories*, and simple rules (e. g., forward/backward application) dictate category combination. The target of the realization process is a text that conveys the desired meaning, formalized as a conjunction of *elementary predicates*, where each must be covered exactly once. The search space (following a chart realization algorithm, e. g. (Kay, 1996; Cahill and van Genabith, 2006; Carroll and Oepen, 2005)) traverses collections of partial sentences (*edges*). We say that an edge is infeasible if it is not part of any complete sentence. This happens when the edge cannot be combined with other edges to a sentence in a way covering exactly the remaining semantic items. Our contribution is a new technique to automatically identify, and prune, such infeasible edges.

AI Planning (e. g. (Russell and Norvig, 1995; Ghallab et al., 2004)) is one of the oldest sub-areas of Artificial Intelligence (AI). It investigates general problem description languages, and general problem solving algorithms, where a "problem" comes in the form of an "initial state", a "goal", and a set of "actions" that can be applied to change states and thus, eventually, reach the goal. In other words, AI Planning is concerned with models of, and algorithms for, goal reachability testing in large state-transition systems. Connections between sentence generation and AI Planning were previously established for tree-adjoining grammars (Koller and Stone, 2007; Koller and Hoffmann, 2010; Koller and Petrick, 2011), showing how to formulate the entire generation problem as planning. Here we establish a new connection for combinatory categorial grammars, and we focus on the objective of identifying

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1524–1534, Osaka, Japan, December 11-17 2016.

infeasible edges, keeping the overall generation process in the hands of OpenCCG (which is better suited for surface realization as a planning compilation would be agnostic of quality measures such as n-grams).

We observe that edge feasibility in OpenCCG – the ability to complete an edge e_0 into a sentence – can be formulated in terms of a state-transition system. We design a compilation of that ability into an AI Planning task Π, where unsolvability of Π – the absence of a path to the planning goal – implies infeasibility of e_0. Applying dead-end detection algorithms from AI Planning (e. g. (Haslum and Geffner, 2000; Hoffmann and Nebel, 2001; Hoffmann et al., 2014; Steinmetz and Hoffmann, 2016)) to the compiled task Π, and doing so for every edge e_0 during the OpenCCG realization process, then allows the detection and filtering out of infeasible edges. We present two variants of the compilation, which we call optimistic and pessimistic. The optimistic compilation guarantees that every pruned edge is infeasible but it does not perform much pruning in practice. The pessimistic compilation may prune out some solutions. Our experiments show that the pessimistic compilation can filter out large fractions of infeasible edges in, and thus benefit the performance of, complex realization processes.

2 Background and State-Transition System Notation

We briefly introduce background and basic notations for OpenCCG and AI Planning, in a manner geared toward our compilation techniques.

2.1 OpenCCG

Combinatory categorial grammar (CCG) (Steedman, 2000; Steedman and Baldridge, 2011) is a grammar formalism which, in a nutshell, assigns *(syntactic) categories* to words or sequences thereof and provides a set of *combination rules* to combine these. Categories can be either atomic, e. g. noun phrase $\mathbf{NP}$, or complex, e. g. $\mathbf{NP}/\mathbf{N}$, where a slash indicates that the sequence $\mathbf{NP}/\mathbf{N}\ \mathbf{N}$ can be combined, via application of the *forward application* rule, to obtain a noun phrase. A backslash requires the combination partner, in *backward application*, to be on the left hand side. As an example, consider the sentence `Winter is coming`, where `Winter` as proper name has category $\mathbf{NP}$, `is` as verb modifier has category $\mathbf{S}\backslash\mathbf{NP}/(\mathbf{S}\backslash\mathbf{NP})$, and `coming` as intransitive verb has category $\mathbf{S}\backslash\mathbf{NP}$. We can combine `is coming` to acquire $\mathbf{S}\backslash\mathbf{NP}$, and combining that with `Winter` results in a sentence, i. e., in category $\mathbf{S}$. There are also unary rules to enable different combinations by allowing a word sequence to change its own category.

In OpenCCG's realization process, a formula in hybrid logical dependency semantics is flattened, i.e., transformed into a conjunction of elementary predications – the *semantic items* – and transformed into a sentence covering the semantic items. In this process, a *lexicon* provides entries – words associated with categories – potentially useful in terms of their semantics. Composed entries, enriched with additional information, are called *edges* during the search.

Towards our compilation, we next give notations for OpenCCG, and OpenCCG realization, already following AI Planning terminology. In doing so, we will not keep track of the word sequences in edges, and we will not incorporate any notion of word-sequence quality. This is because the purpose of our work merely is to filter out infeasible edges. We specify only those aspects relevant to that purpose.

We refer to the input of the realization process as an *OpenCCG task*, notated $\Omega = (C_0^\Omega, SI^\Omega, R^\Omega, s_I^\Omega, e_G^\Omega)$. Here, C_0^Ω is the finite set of atomic categories c_0. SI^Ω is the finite set of semantic items si. R^Ω is the set of combination rules. We will denote with C^Ω the set of *all* categories, that can be formed from C_0^Ω through applying the rules R^Ω. s^Ω is what we call a *state*, which consists of the set of *edges* already reached in that state. s_I^Ω specifically is the *initial state*. An edge e is a pair (c, σ) where $c \in C^\Omega$ is a category and $\sigma \subseteq SI^\Omega$ is the subset of semantic items *covered* by e (which we will also refer to as the edge's *coverage*). We denote the set of all edges by E^Ω. The initial state $s_I^\Omega \subseteq E^\Omega$ corresponds to the words in the lexicon that are semantically relevant for the sentence. Finally, e_G^Ω is the *goal edge*, defined as $e_G^\Omega = (\mathbf{S}, SI^\Omega)$.

Given this input, OpenCCG realization conducts a search – a chart realization process – over the possible constructions of new edges from previous ones. Each step of the search either applies a unary rule to an edge already reached, i. e., an edge contained in the current state; or applies a combination

rule to a pair of edges $e_1 = (c_1, \sigma_1)$ and $e_2 = (c_2, \sigma_2)$ from the current state, where c_1 and c_2 can be combined, and the truth value assignments have *empty overlap*, $\sigma_1 \cap \sigma_2 = \emptyset$. The resulting new edge is added into the outcome state. The details of how this search process is organized are not relevant to our purpose. Relevant to us are the states and their transitions, which we notate as Ω's *OpenCCG state space*, $\Theta^\Omega = (S^\Omega, T^\Omega, s_I^\Omega, S_G^\Omega)$. Here, $S^\Omega = \mathcal{P}(E^\Omega)$ is the set of all possible states (i.e., the powerset of all possible edges); $T^\Omega \subseteq S^\Omega \times S^\Omega$ contains the transitions over states, as just explained; s_I^Ω is the initial state; and $S_G^\Omega := \{s_G^\Omega \in S^\Omega \mid e_G^\Omega \in s_G^\Omega\}$, the *goal states*, are those containing e_G^Ω. We say that a state s^Ω is *reachable* in Θ^Ω if there is a transition path from s_I^Ω to s^Ω in Θ^Ω. The reachable states in Θ^Ω correspond to the OpenCCG search space. We say that Ω is *solvable* if Θ^Ω contains a reachable goal state.

Formulating our example above in this manner, say the semantic items SI^Ω are $\{\text{Winter}, \text{be}, \text{come}\}$. Say the lexicon contains exactly the three words needed, so that the initial state s_I^Ω contains the edges $(\mathbf{NP}, \{\text{Winter}\})$, $(\mathbf{S}\backslash\mathbf{NP}/(\mathbf{S}\backslash\mathbf{NP}), \{\text{be}\})$, and $(\mathbf{S}\backslash\mathbf{NP}, \{\text{come}\})$. A solution to Θ^Ω then is the path $s_I^\Omega \rightarrow s_1^\Omega \rightarrow s_2^\Omega$ where $s_1^\Omega = s_I^\Omega \cup \{(\mathbf{S}\backslash\mathbf{NP}, \{\text{be}, \text{come}\})\}$ and $s_2^\Omega = s_1^\Omega \cup \{(\mathbf{S}, \{\text{Winter}, \text{be}, \text{come}\})\}$.

We say that an edge e_0 is *feasible* in an OpenCCG task Ω iff, in the OpenCCG state space Θ^Ω, there is a reachable goal state $s_G^\Omega \in S_G^\Omega$ *containing a derived tree* T_0 for e_G^Ω where e_0 appears in T_0. Here, the derived tree T for an edge e is a tree combining edges to get from elements of s_I^Ω to e; and a state s^Ω contains T if all edges in T are elements of s^Ω. In other words, e_0 is feasible if it forms part of a derived tree for a complete sentence. Otherwise, e_0 is *infeasible*.

2.2 AI Planning

Many different variants of AI Planning problem variants have been devised. Here, we consider *STRIPS Planning* (Fikes and Nilsson, 1971), over Boolean variables ("facts"), extended with so-called *conditional effects* (Pednault, 1989). This planning variant is motivated by its wide-spread support in modern planning techniques, and by its match with the needs of our desired OpenCCG compilation.

A *planning task* is a tuple $\Pi = (F^\Pi, A^\Pi, s_I^\Pi, G^\Pi)$. Here, F^Π is a finite set of *facts*; $s_I^\Pi \subseteq F^\Pi$ is the *initial state* (the facts initially true); and G^Π is the *goal* (the facts we need to be true at the end). A^Π is a finite set of *actions*. Each action $a \in A^\Pi$ is a tuple $(pre_a, add_a, del_a, \mathit{CEff}_a)$ where $pre_a \subseteq F^\Pi$ is the action's *precondition*, $add_a \subseteq F^\Pi$ is the action's *add list*, $del_a \subseteq F^\Pi$ is the action's *delete list*, and CEff_a is the action's finite set of *conditional effects*. Each $e \in \mathit{CEff}_a$ is a triple (con_e, add_e, del_e) of fact sets, namely the effect's *condition*, *add list*, and *delete list* respectively.

Given a planning task Π, the task's *state space* is a tuple $\Theta^\Pi = (S^\Pi, T^\Pi, s_I^\Pi, S_G^\Pi)$. Here, $S^\Pi = \mathcal{P}(F^\Pi)$ is the set of all possible states, i. e., fact subsets interpreted as those facts currently true; s_I^Π is Π's initial state; and $S_G^\Pi := \{s_G \in S^\Pi \mid G^\Pi \subseteq s_G\}$ are the *goal states*, where Π's goal is true. The state transitions $T^\Pi \subseteq S^\Pi \times S^\Pi$ arise from action applications. Action a is *applicable* in state s if $pre_a \subseteq s$; in that case, the outcome state is defined as $s' := (s \cup add_a \cup \bigcup_{e \in \mathit{CEff}_a : con_a \subseteq s} add_e) \setminus (del_a \cup \bigcup_{e \in \mathit{CEff}_a : con_a \subseteq s} del_e)$. In other words, s' results from s by including the add lists of the action plus those effects whose condition holds in s, and afterwards removes the delete lists of the action and those effects. We say that Π is *solvable* if Θ^Π contains a reachable goal state.

3 Partial Compilation of OpenCCG Sentence Generation into AI Planning

There is a correspondence between AI Planning and OpenCCG realization – at the level of category combination rules and semantic item coverage – in that both require reaching a goal, from an initial state, in a transition system described in terms of actions/transition rules. We aim to exploit this connection, via a *compilation* from OpenCCG into AI Planning, for automatic filtering of infeasible edges.

Our compilation is *partial* in that it does not attempt to preserve OpenCCG edge reachability exactly. The compilation makes approximations – losing information – aimed at practical viability. It consists of (1) a finite approximation of the set of reachable categories; (2) a planning task capturing solvability of Ω, modulo approximation (1) plus an approximation of semantic coverage; and (3) a modified planning task capturing edge feasibility. We introduce these constructions in this order.

3.1 Finite Approximations of Reachable Categories

In CCG, combination rules specify how to create new categories from old ones. It is possible in principle to simulate this behavior in terms of AI Planning actions, designed to emulate the behavior of CCG combination rules. But this yields large and complex planning encodings, and it is not clear how to exploit those effectively. Therefore, we take a different approach here, pre-compiling all combined (non-atomic) categories that will be considered by the planning process. Our starting point is what we call the *category space*, capturing all possible categories and compositions:

Definition 1. *Let $\Omega = (C_0^\Omega, SI^\Omega, R^\Omega, s_I^\Omega, e_G^\Omega)$ be an OpenCCG task. The* category space *of Ω is the pair $(C^\Omega, \gamma^\Omega)$ where $\gamma^\Omega : C^\Omega \times C^\Omega \cup C^\Omega \mapsto \mathcal{P}(C^\Omega)$ is the partial function where $c' \in \gamma^\Omega(c)$ iff c can be transformed into c' using a unary rule from R^Ω, and $c' \in \gamma^\Omega(c_1, c_2)$ iff c_1 and c_2 can be combined into c' using a binary rule from R^Ω.*

Note that γ^Ω is a function onto subsets of possible outcome categories, rather than onto a unique outcome category, as several different rules may be applicable to the same input categories. Note further that, in the presence of unary rules (like type raising) which are always applicable in CCG, the category space is infinite. To compile it into a finite planning task, we need to restrict ourselves to a finite sub-space. We do so via a size-bound parameter k, in an optimistic vs. a pessimistic manner:

Definition 2. *Let $\Omega = (C_0^\Omega, SI^\Omega, R^\Omega, s_I^\Omega, e_G^\Omega)$ be an OpenCCG task. Let k be a natural number. For $c \in C^\Omega$, let the* degree *of c, denoted $\#(c)$, be the overall number of slashes and backslashes in c. By $C^\Omega[k] := \{c \in C^\Omega \mid \#(c) \leq k\} \cup \{*\}$, we denote the set of all categories whose degree is at most k, plus the* wildcard *symbol $*$. Two category spaces are defined as follows:*

(i) The pessimistic category space *of Ω given k is the pair $(C^\Omega[k], \gamma^{-\Omega})$ where $\gamma^{-\Omega}$ is defined like γ^Ω but replacing any category c' where $\#(c') > k$ by $*$.*

(ii) The optimistic category space *of Ω given k is the pair $(C^\Omega[k], \gamma^{+\Omega})$ where $\gamma^{+\Omega}$ is defined like γ^Ω but replacing any category c' where $\#(c') > k$ by $*$; and including $c' \in \gamma^\Omega(*)$ whenever $\gamma^\Omega(c) = c'$; and including $c' \in \gamma^\Omega(c_1, *)$ whenever $\gamma^\Omega(c_1, c_2) = c'$; and including $c' \in \gamma^\Omega(*, c_2)$ whenever $\gamma^\Omega(c_1, c_2) = c'$.*

In other words, we cut off the generation of categories once their degree exceeds a user-defined threshold k. In the pessimistic (under-approximating) variant, no further combinations are possible behind $*$. In the optimistic (over-approximating) variant, all combinations are possible behind $*$.[1]

For illustration, say in our example the lexicon contains only the words $(\mathbf{S}\backslash\mathbf{NP}/(\mathbf{S}\backslash\mathbf{NP}), \{\text{be}\})$ and $(\mathbf{S}\backslash\mathbf{NP}, \{\text{come}\})$. If we set $k := 3$, then $\gamma^{+\Omega}$ preserves γ^Ω sufficiently to determine that $\mathbf{S}$ cannot be reached from the initial state categories. For $k := 2$, however, $\mathbf{S}\backslash\mathbf{NP}/(\mathbf{S}\backslash\mathbf{NP})$ is replaced by $*$, and we can reach $\mathbf{S}$ by "pretending" that $*$ stands for $\mathbf{NP}$.

The optimistic approximation variant preserves solutions and can be used to provide guarantees, i. e., using our edge-feasibility compilation below, to prune only edges that are indeed infeasible. The pessimistic variant does not provide that guarantee, but tends to be more successful in practice as we will show in Section 5. Observe that the approximations approach γ^Ω from opposite sides, in the sense that they are coarsest for $k = 1$, and become more precise as k grows, $\gamma^{+\Omega}$ getting less optimistic and $\gamma^{-\Omega}$ getting less pessimistic. The approximations converge to γ^Ω in that, for any finite sub-space of $(C^\Omega, \gamma^\Omega)$, there is a k so that both approximations are exact. In terms of edge pruning, this means that the optimistic variant prunes more for larger k, and eventually is precise enough to find any edge that can be pruned; while the pessimistic variant prunes less for larger k, and eventually is precise enough to preserve any edge that cannot be pruned (in particular: precise enough to preserve any one solution).

[1] One can (and our implementation does) define $\gamma^{+\Omega}$ in a more fine-grained manner, replacing only the *sub*-categories behind the threshold k with $*$, and accordingly being less generous in the over-approximation of γ. As this refined version is cumbersome to spell out formally, and leads to similar results in practice, we omit this here.

3.2 Planning Compilation for Solvability

To capture solvability relative to the optimistic/pessimistic finite category space approximation, our compiled planning task combines facts keeping track of category creation with facts keeping track of semantic coverage. Here again we face a design choice: we could, in principle, keep track of the actual category/coverage pairs, i. e., of edges. This would allow us to check for empty overlap when combining two edges. However, that would (a) again yield rather large planning encodings, and (b) require the AI Planning dead-end detection method to be able to reason about delete lists. The most canonical dead-end detection method, that we employ here, does not qualify for (b), so we can just as well circumvent (a). We do so by abstracting from edges, associating a category c with a semantic item si if *at least one* reached edge has category c and covers si. We compile this into a planning task as follows:

Definition 3. *Let $\Omega = (C_0^\Omega, SI^\Omega, R^\Omega, s_I^\Omega, e_G^\Omega)$ be an OpenCCG task. Let k be a natural number. The* optimistic solvability-compilation *is the planning task $\Pi^{+\Omega}[k] = (F^\Pi, A^\Pi, s_I^\Pi, G^\Pi)$ where:*

(i) $F^\Pi = \{c \mid c \in C^\Omega[k]\} \cup \{c[si] \mid c \in C^\Omega[k], si \in SI^\Omega\}$.

(ii) $s_I^\Pi = \{c \mid e = (c, \sigma) \in s_I^\Omega\} \cup \{c[si] \mid e = (c, \sigma) \in s_I^\Omega, si \in \sigma\}$.

(iii) $G^\Pi = \{\mathbf{S}\} \cup \{\mathbf{S}[si] \mid si \in SI^\Omega\}$.

(iv) $A^\Pi = \{a[c, c'] \mid \gamma^{+\Omega}(c) = c'\} \cup \{a[c_1, c_2, c'] \mid \gamma^{+\Omega}(c_1, c_2) = c'\}$, *where:*

(a) $a[c, c'] := (\{c\}, \{c'\}, \emptyset, \{(\{c[si]\}, \{c'[si]\}, \emptyset) \mid si \in SI^\Omega\})$.

(b) $a[c_1, c_2, c'] := (\{c_1, c_2\}, \{c'\}, \emptyset, \{(\{c_j[si]\}, \{c'[si]\}, \emptyset) \mid j \in \{1, 2\}, si \in SI^\Omega\})$.

The pessimistic solvability-compilation *is the planning task $\Pi^{-\Omega}[k]$, defined like $\Pi^{+\Omega}[k]$ but using $\gamma^{-\Omega}$.*

Items (i)–(iii) should be easy to understand: in the compiled planning task, facts c indicate whether category c has been reached yet, and facts $c[si]$ indicate whether c covers si yet; in the initial state, these flags are set according to s_I^Ω, i. e., according to the words in the lexicon; the goal is to have a sentence covering the entire semantics. To understand item (iv), recall that actions have the form $(pre_a, add_a, del_a, CEff_a)$. In item (iv a), encoding unary rule applications $\gamma^{+\Omega}(c) = c'$, the precondition is $\{c\}$ and the (unconditional) add list is $\{c'\}$, effectively saying that, if c is already reached, then applying the action (the rule) yields c'. The conditional effects simply transfer, for each si, the coverage from c (if already reached) to c'. The encoding of binary rules in item (iv b) is similar.

Note that, as indicated above, the delete lists in the compilation are empty. On the one hand, this corresponds to the monotonic nature of the OpenCCG search space, where new edges are being added without removing the old ones. On the other hand, delete effects *would* be needed to capture empty coverage overlap in combination-rule applications. For example, consider that our example of Figure 1 where we have two edges with categories $\mathbf{NP}$. In case 1a, "Winter comes" and "It comes" are valid solutions. However, in case 1b it is impossible to convey all the semantics because it is not possible to use both "Winter" and "Summer" as required (assuming that there are no "and" connectives in our lexicon). Nevertheless, both cases are mapped into the same planning instance since there are edges $\mathbf{NP}$ with semantics 011. Yet, as explained, in the present approach we forsake that information as our dead-end detector would not be able to handle it anyhow.

Theorem 1. *Let Ω be an OpenCCG task. Let k be a natural number. If Ω is solvable, then so is $\Pi^{+\Omega}[k]$.*

Proof. The proof compares Ω's state space $\Theta^\Omega = (S^\Omega, T^\Omega, s_I^\Omega, S_G^\Omega)$ with that of $\Pi^{+\Omega}[k]$. Denote the latter by $\Theta = (S, T, s_I, S_G)$. Define the mapping $\alpha : S^\Omega \mapsto S$ as $\alpha(s^\Omega) := \{c \mid e = (c, \sigma) \in s^\Omega\} \cup \{c[si] \mid e = (c, \sigma) \in s^\Omega, si \in \sigma\}$. As $\alpha^{+\Omega}$ over-approximates the category combinations in α^Ω, it is easy to see that transitions are preserved by α, i. e., whenever $(s_1^\Omega, s_2^\Omega) \in T^\Omega$, we have $(\alpha(s_1^\Omega), \alpha(s_2^\Omega)) \in T$. Furthermore, goal states are preserved, i. e., whenever $s^\Omega \in S_G^\Omega$, we have $\alpha(s^\Omega) \in S_G$. Finally, $\alpha(s_I^\Omega) = s_I$. The claim follows. □

Given Theorem 1, if $\Pi^{+\Omega}[k]$ is *not* solvable, i. e., if an AI Planning dead-end detector is able to detect that this is so, then we can safely conclude that Ω is not solvable either. The pessimistic compilation $\Pi^{-\Omega}[k]$ does not give that guarantee.

String	Category	Semantics
"Winter"	**NP**	011
"It"	**NP**	011
"comes"	**S\NP**	100

(a) Case 1: Feasible

String	Category	Semantics
"Winter"	**NP**	010
"Summer"	**NP**	001
"comes"	**S\NP**	100

(b) Case 2: Unfeasible

Figure 1: Example of two cases that are compiled into the same planning task.

For illustration, consider again the example variant where the lexicon contains only the words $(\mathbf{S}\backslash\mathbf{NP}/(\mathbf{S}\backslash\mathbf{NP}), \{\text{be}\})$ and $(\mathbf{S}\backslash\mathbf{NP}, \{\text{come}\})$, so Ω is unsolvable. Then $\Pi^{+\Omega}[3]$ is unsolvable as $\mathbf{S}$ cannot be reached using $\gamma^{+\Omega}$, cf. above. $\Pi^{+\Omega}[2]$ also is unsolvable, because the semantic item "Winter" cannot be covered; but if we remove that semantic item from the OpenCCG task (and thus from $\Pi^{+\Omega}[2]$), then $\Pi^{+\Omega}[2]$ has a one-step solution combining the two initial-state categories.

3.3 Planning Compilation for Edge Feasibility

The above compilation provides a necessary criterion for an OpenCCG task to be solvable. However, our actual purpose requires a necessary criterion for an OpenCCG *edge* e_0 to be *feasible*, i. e., to form part of a solution. This can be achieved by a simple modification of the compilation, propagating markers to make sure that e_0's category is used in the solution:[2]

Definition 4. *Let $\Omega = (C_0^\Omega, SI^\Omega, R^\Omega, s_I^\Omega, e_G^\Omega)$ be an OpenCCG task, and let $e_0 = (c_0, \sigma_0)$ be an edge in Ω. Let k be a natural number. The* optimistic feasibility-compilation *is the planning task $\Pi^{+\Omega}[k, e_0] = (F^\Pi, A^\Pi, s_I^\Pi, G^\Pi)$ where:*

(i) $F^\Pi = \{c, c[0] \mid c \in C^\Omega[k]\} \cup \{c[si] \mid c \in C^\Omega[k], si \in SI^\Omega\}$.

(ii) $s_I^\Pi = \{c_0[0]\} \cup \{c \mid e = (c, \sigma) \in s_I^\Omega, \sigma \cap \sigma_0 = \emptyset\} \cup \{c[si] \mid e = (c, \sigma) \in s_I^\Omega, \sigma \cap \sigma_0 = \emptyset, si \in \sigma\}$.

(iii) $G^\Pi = \{\mathbf{S}, \mathbf{S}[0]\} \cup \{\mathbf{S}[si] \mid si \in SI^\Omega\}$.

(iv) $A^\Pi = \{a[c, c'] \mid \gamma^{+\Omega}(c) = c'\} \cup \{a[c_1, c_2, c'] \mid \gamma^{+\Omega}(c_1, c_2) = c'\}$, *where:*

(a) $a[c, c'] := (\{c\}, \{c'\}, \emptyset, \{(\{c[0]\}, \{c'[0]\}, \emptyset)\} \cup \{(\{c[si]\}, \{c'[si]\}, \emptyset) \mid si \in SI^\Omega\})$.

(b) $a[c_1, c_2, c'] := (\{c_1, c_2\}, \{c'\}, \emptyset, \{(\{c_1[0]\}, \{c'[0]\}, \emptyset), (\{c_2[0]\}, \{c'[0]\}, \emptyset)\} \cup$
$\{(\{c_j[si]\}, \{c'[si]\}, \emptyset) \mid j \in \{1, 2\}, si \in SI^\Omega\})$.

The pessimistic feasibility-compilation *is $\Pi^{-\Omega}[k, e_0]$, defined like $\Pi^{+\Omega}[k, e_0]$ but using $\gamma^{-\Omega}$.*

Relative to Definition 3, we add the $c[0]$ markers to keep track of whether an ancestor of c uses e_0's category. The initial state includes this marker only for e_0's own category c_0, the goal is for $\mathbf{S}$ to be marked. The actions propagate the markers through conditional effects, marking the outcome category c' if at least one of the input categories is already marked. The additions "$\sigma \cap \sigma_0 = \emptyset$" in (ii) introduce a limited form of empty coverage overlap reasoning, excluding in the initial state those edges whose semantics overlaps with e_0 (and that thus won't be used in a solution incorporating e_0).

Theorem 2. *Let Ω be an OpenCCG task, and let e_0 be an edge in Ω. Let k be a natural number. If e_0 is feasible in Ω, then $\Pi^{+\Omega}[k, e_0]$ is solvable.*

Proof. Say that e_0 is feasible in Ω. Then there is a solution θ to Ω using e_0, and not using any $e \in s_I^\Omega$ whose semantics overlaps with that of e_0. By Theorem 1, $\Pi^{+\Omega}[k]$ is solvable, via a transition path π corresponding to θ. By construction, π is a solution for $\Pi^{+\Omega}[k, e_0]$. □

Given Theorem 2, if an AI Planning dead-end detector proves $\Pi^{+\Omega}[k, e_0]$ to be unsolvable, then we can conclude that e_0 is infeasible. The pessimistic compilation $\Pi^{-\Omega}[k, e_0]$ does not give that guarantee.

For illustration, say in our example the lexicon contains the words $e_1 = (\mathbf{NP}, \{\text{Winter}\})$, $e_2 = (\mathbf{S}\backslash\mathbf{NP}/(\mathbf{S}\backslash\mathbf{NP}), \{\text{be}\})$, and $e_3 = (\mathbf{S}\backslash\mathbf{NP}, \{\text{come}\})$ as before, but contains also the transitive form

[2] In this definition, the modifications relative to Definition 3 are shown in red for the benefit of on-screen reading.

of "coming", $e_4 = ((\mathbf{S}\backslash\mathbf{NP})/\mathbf{NP}, \{\text{come}\})$, infeasible for our purposes. Consider the edge $e_0 = (\mathbf{S}\backslash\mathbf{NP}, \{\text{Winter}, \text{come}\})$, where we combined e_1 with e_4. Consider the compilation $\Pi^{+\Omega}[3, e_0]$: In the initial state, as e_1 overlaps e_0, e_1 is not included. But without **NP**, **S** is unreachable given $\gamma^{+\Omega}$ for $k = 3$, so $\Pi^{+\Omega}[3, e_0]$ is unsolvable and we correctly detect that e_0 is infeasible.[3]

4 Practical Compilation Use and Optimizations

Our idea is to create, and check the solvability of, the compiled planning task $\Pi^{+\Omega}[k, e_0]$ respectively $\Pi^{-\Omega}[k, e_0]$, every time a new edge e_0 is created during the OpenCCG realization process. If the compiled planning task is unsolvable, e_0 is deemed infeasible, and is discarded. This filtering method is provably sound when using $\Pi^{+\Omega}[k, e_0]$. When using $\Pi^{-\Omega}[k, e_0]$, it is a practical heuristic, and converges to sound pruning – eventually preserving the best solution – as k grows.

To realize this approach, we require a method for checking solvability of planning tasks. In general, however, deciding solvability ("plan existence") is **PSPACE**-complete (Bylander, 1994). For fast solvability detection, planning research therefore concentrates on polynomial-time solvable fragments of the plan existence problem. The most wide-spread such fragment is the one where all delete lists are required to be empty (e. g. (Bylander, 1994; Haslum and Geffner, 2000; Hoffmann and Nebel, 2001)). Hence the design of our compilation, which incorporates approximations resulting in empty delete lists. For planning tasks with empty delete lists, plan existence can be decided in time low-order polynomial in the size of the task, using so-called *relaxed planning graphs* (Hoffmann and Nebel, 2001).

Though polynomial time, testing delete-free plan existence does incur a runtime overhead, especially in our context where we need to do so for every edge during realization. Efficient implementation is therefore important. One key to this is the re-use of information/computation shared across individual tests. First, every call to sentence realization based on the same lexicon shares the same category space. Hence we can build the category space approximation, $(C^{\Omega}[k], \gamma^{+\Omega})$ respectively $(C^{\Omega}[k], \gamma^{-\Omega})$, *offline*, just once for the lexicon at hand, prior to realization. Second, the feasibility compilations for individual edges e_0 during the same realization process are identical except for their initial states. So, during a realization process, we create a compiled task just once and adapt it minimally for each test.

Finally, (a) the action set in $\Pi^{+\Omega}[k, e_0]$ respectively $\Pi^{-\Omega}[k, e_0]$ is fully determined by $\gamma^{+\Omega}$ respectively $\gamma^{-\Omega}$ along with the set of semantic items SI^{Ω}; while (b) for the maintenance of semantic coverage and $c[0]$ markers, instead of the compilation via conditional effects as specified, one can implement a simple special-case handling in the standard relaxed planning graph solvability test. Taking these two observations together, we can generate the action set completely offline. Online, prior to a realization process, we merely need to read in the actions and setup the marker-maintenance data structures.

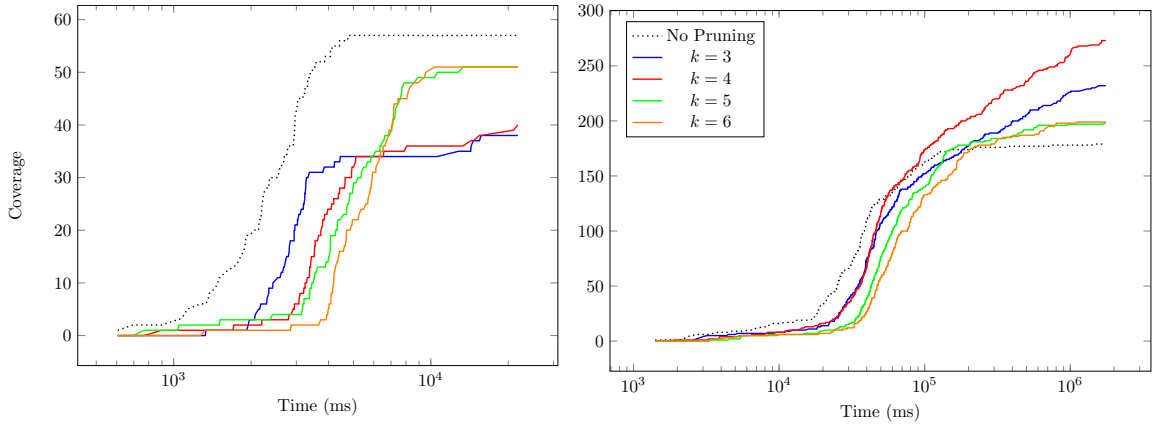
5 Experiments

As our main test base for experimentation, we used the SPaRKy Restaurant Corpus (we also ran preliminary experiments with some other test bases, which we get back to below). SPaRKy is one of the only published resources for NLG which provides intermediate representations in addition to system inputs and outputs and quality ratings for those outputs. Originally introduced by Walker et al. (2007), Nakatsu and White (2010) developed a CCG grammar for this dataset which spans both the sentence and the discourse levels. The domain of the corpus is restaurant descriptions, including prices, kind of food, decor, service, etc. In this work we use the a set of 431 test instances developed for the contrast-enhanced version of the grammar presented in Howcroft, Nakatsu, & White (2013). The lexicon in this testbed includes 193 words and the grammar is capable of producing a wide variety of texts of varying lengths. Of the 431 OpenCCG realization tasks, 61 *recommendation tasks* require generating a text recommending a single restaurant, while 370 *comparison tasks* require generating a text comparing two or more restaurants with each other. As these instances correspond to the generation of entire text paragraphs, they are complex enough to be interesting use cases for our techniques. This pertains in particular to

[3]Note that the same is not true for $k = 2$; and neither for e_4 because, there, ignoring overlap in rule applications means that e_1 could be used twice. These are weaknesses of our current approach, which could potentially be tackled by more informed compilations. We get back to this in the conclusion.

the comparison tasks, where the required text is longer (an average of 60 words with respect to 38 for recommendation tasks).

In preliminary tests with the optimistic approximation variant, the pruning was too weak to pay off, i. e., too few edges were pruned to get a benefit. We therefore concentrate here on pruning with the pessimistic approximation variant, where small values of k may prune too aggressively, while large values of k yield more reliable pruning yet incur a larger runtime overhead. All experiments were run on a cluster of machines with Intel Xeon E5-2660 processors running at 2.2 GHz. The runtime/memory limit was set to 30 minutes/4 GB for each sentence generation task, i. e., for each benchmark instance.



(a) Recommendation tasks (b) Comparison tasks

Figure 2: Coverage, i. e., the number of sentence generation tasks to which a solution was found, as a function of runtime on SPaRKy (a) recommendation tasks and (b) comparison tasks. A data point (x, y) means that y tasks are solved within a time limit of x milliseconds. "No pruning" is the baseline OpenCCG search without pruning; "$k = n$" considers our pessimistic pruning with parameter k, i. e., the $\Pi^{-\Omega}[k, e_0]$ compilation, on every edge e_0 during search, pruning e_0 if $\Pi^{-\Omega}[k, e_0]$ is unsolvable.

As a simple measure of performance, we focus on the runtime spent by the OpenCCG chart realization process until the first solution – the first edge of category **S** covering all semantic items – is generated. Figure 2 shows coverage, i. e., the number of benchmark instances where a solution was found, as a function of runtime. We distinguish between (a) recommendation vs. (b) comparison tasks as these are different in nature and yield very different performance profiles.

Regarding (a), we see that these tasks are essentially too easy for our pruning method to pay off: the runtime overhead of repeatedly checking the solvability of $\Pi^{-\Omega}[k, e_0]$ outweighs the gain from pruning, so that fewer tasks are solved within the same runtime limits. The restaurant comparison tasks (b), however, are more challenging (notice the different x-axis scales in (a) and (b)), and the picture is different: in the much larger search spaces, the pruning impact is stronger. For runtime limits > 56 seconds, the coverage of $k = 4$ pruning exceeds that without pruning. For runtime limits > 206 seconds, all settings of k exceed the baseline. Note here that the value of k controls the trade-off between accuracy (better with large k) and runtime overhead (better with small k). In SPaRKy restaurant comparison tasks, $k = 4$ is the sweet spot of that trade off. At our maximum time limit of $x = 30$ minutes, $k = 4$ pruning increases coverage from 179 instances without pruning, to 273 with pruning, an increase of 52%.

As the pessimistic compilation does not guarantee that pruned edges are actually infeasible, the pruning may adversely affect the quality of the sentences generated. As k gets larger, this danger decreases as the pruning becomes more accurate. In SPaRKy, it turns out that $k = 4$ is not only best in terms of runtime performance, but is also enough to avoid any deterioration in sentence quality. Of the 215 instances solved by both the baseline and $k = 4$ (across recommendation and comparison tasks), in 137 cases the two realizations are identical. In the remainining 78 cases, the realizations differ only in using the word "just" vs. the word "only", so that the version with pruning does exactly as well as the baseline.

Going beyond solutions, there also are cases where OpenCCG produces a *partial solution*, an edge of

category S that covers only a subset of the semantic items. This can still be useful if, e. g., four instead of five restaurants are being compared. Our $k = 4$ pruning has clear advantages in terms of the ability to find such partial solutions. Of the 97 cases where neither $k = 4$ nor the baseline find a complete solution, $k = 4$ provides a partial solution in 81 cases, the baseline in 52 cases. In all 21 cases where only the baseline finds a complete solution, $k = 4$ finds a partial solution. In contrast, of the 98 cases where only $k = 4$ finds a complete solution, in 59 cases the baseline does not manage to find a partial solution.

We also ran experiments on some other test bases (Vancoppenolle et al., 2011; Racioppa, 2011; Kruijff et al., 2010), yet as the text paragraphs to be generated were comparatively small, similarly to SPaRKy recommendation tasks our pruning methods generally did not pay off. Conversely, in the CCGBank (Hockenmaier and Steedman, 2007), our category space approximations consumed excessive amounts of memory. For practical viability in such large bases, either additional implementation tricks, or more intelligent abstractions (not just enumerating all categories up to a fixed degree), would be required.

6 Related Work

There are a number of approaches in the literature to speed-up sentence realization. The closest approach is *polarity filtering* for generation with Tree-Adjoining Grammar (TAG), proposed by Gardent and Kow (2005). The polarity filter avoids the combination of those sets of elementary trees that cannot possibly lead to a full solution, by making sure that the numbers and types of substitution nodes and elementary trees fit together. Compared to the approach of compiling into planning in general, this differs in that it specifies a concrete dead-end detector, rather than a connector to another area offering a rich set of potential such detectors. Compared to our particular compilation here, polarity-based filtering uses a different kind of abstraction, of CCG categories as input/output signatures, instead of the finite category space approximation we make based on bounded degree.

Within CCG-based surface realization approaches, there are several suggestions to reduce the size of the search space:

- *Chunking* (White, 2006) divides the semantic input into subproblems that are solved independently and then combined into a full sentence. This approach is different to ours since we remove edges that are deemed as infeasible due to the syntactic structure of the grammar, while *chunking* exploits the structure of the semantics in order to simplify the problem.

- *Hypertagging* (Espinosa et al., 2008) uses text-body statistics in order to select the relevant words from the lexicon and assign them a syntactic category. This may filter out irrelevant edges but it does not reason over category/semantic combinations.

- *Glue rules* (White, 2011) can be activated whenever the search fails to find a grammatically correct sentence, in order to relax the constraints imposed by the grammars. In our case, we try to speed-up search to be able to find correct sentences according to the grammar rules provided.

Besides OpenCCG, other surface realization approaches have been successfully used to for broad-coverage language generation. These include TAG-based structure-driven surface realization (Narayan and Gardent, 2012), head-driven phrase structure grammar approaches (Carroll and Oepen, 2005), and statistical approaches trained on the surface realization shared task data (Bohnet et al., 2010). Some of these approaches, in which certain grammar rules must be followed, may also benefit from detecting infeasible partial solutions. Hence, adapting our planning compilation to other grammar formalisms is an interesting line for future research.

Previous connections between sentence generation and AI Planning were previously established for tree-adjoining grammars (Koller and Stone, 2007; Koller and Hoffmann, 2010; Koller and Petrick, 2011). Our compilation, apart from starting from CCG rather than TAG, has a quite different purpose and properties. While the TAG-PDDL is an equivalent compilation whose size is "the same as" that of the TAG input, whereas here we have an over/under-approximation whose size grows exponentially in category space with the our size limit k.

7 Conclusion

Sentence generation as search relates deeply to AI Planning in that, at least as far as grammatical and semantic correctness is concerned, it is essentially a reachability problem in a large discrete transition system. This connection has been made before, and we herein propose a new variant and application, detecting infeasible edges in OpenCCG. Our empirical results show promise, though much remains to be done. In our view, the most interesting question is *how much information we can efficiently capture and exploit* in this kind of compilation. Our present approach is (a) inflexible in precomputing a category space approximation, and (b) conservative in targeting delete-free planning which is easy to handle. Both design choices sacrifice information, and both may be lifted through more intelligent compilations/abstractions, paired with more advanced dead-end detection on the AI Planning side.

From a broader point of view, we believe that planning/search techniques can be an important part of the quest for practical sentence generation with complex optimization objectives (Demberg et al., 2016).

The Next Step for Multi-Document Summarization: A Heterogeneous Multi-Genre Corpus Built with a Novel Construction Approach

Abstract

Research in multi-document summarization has focused on newswire corpora since the early beginnings. However, the newswire genre provides genre-specific features such as sentence position which are easy to exploit in summarization systems. Such easy to exploit genre-specific features are available in other genres as well. We therefore present the new ***h***MDS corpus for multi-document summarization, which contains heterogeneous source documents from multiple text genres, as well as summaries with different lengths. For the construction of the corpus, we developed a novel construction approach which is suited to build large and heterogeneous summarization corpora with little effort. The method reverses the usual process of writing summaries for given source documents: it combines already available summaries with appropriate source documents. In a detailed analysis, we show that our new corpus is significantly different from the homogeneous corpora commonly used, and that it is heterogeneous along several dimensions. Our experimental evaluation using well-known state-of-the-art summarization systems shows that our corpus poses new challenges in the field of multi-document summarization. Last but not least, we make our corpus publicly available to the research community at the corpus web page https://github.com/AIPHES/hMDS.

1 Introduction

Multi-document summarization (MDS) is the task of creating a summary from a topically related document collection. Existing corpora for the evaluation of MDS systems, most notably from the Document Understanding Conference (DUC) (Over et al., 2007) and from the Text Analysis Conference (TAC),[1] cover mostly MDS of news documents (Nenkova et al., 2011). While research on MDS has also considered genres other than newswire (e.g., opinionated blog posts in TAC 2008 or biomedical research papers in TAC 2014), MDS has almost exclusively focused on *homogeneous* document collections that belong to the same genre.

However, this homogeneous nature of the existing MDS benchmark corpora does not reflect application scenarios where topically related documents from different genres need to be summarized. An exemplary scenario of increasing importance is MDS on the web, where a user retrieves multiple online documents for a particular topic (cf. Rosner and Camilleri (2008), Nenkova and McKeown (2011)). These online documents may comprise news articles, blog posts, encyclopedic texts, or even scientific articles.

A related issue is the very high effort needed to create a new MDS corpus. Summarizing a set of documents is a demanding task for humans and requires expert abstractors, e.g., information analysts as in the DUC competitions. Attempts to obtain human-written summaries via crowdsourcing have failed (Lloret et al., 2013). When the set of documents to be summarized grows, the summarization task even becomes infeasible for humans.

We address these gaps and present (i) a large heterogeneous MDS corpus in English as a new challenging benchmark for summarization systems, and (ii) a novel approach for constructing such a corpus

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1535–1545, Osaka, Japan, December 11-17 2016.

at a large scale. Our methodology combines summaries from Wikipedia featured articles with human-retrieved source documents and can thus be generally applied in all languages where Wikipedias exist. Our detailed analysis and evaluation of the new MDS corpus shows that MDS from heterogeneous genres poses a new challenge and calls for future research.

2 Related Work

Related to our work are methods to create MDS corpora, i.e., pairs of topically related documents and reference summaries. In this section, we focus on the particular aspect of obtaining summaries of a given set of documents. We summarize the traditional approaches used in DUC and TAC, and previous work on alternative approaches.

Approach in DUC and TAC How have multi-document summaries been written in DUC and TAC? For example, the 2005 DUC Summary-Writing Task states that a human should first read the topic and all the 25 - 50 documents in the topic cluster. While reading the documents, information relevant for the topic should be highlighted and then used in a second step to write a 250-word summary of the documents. As observed in early DUC competitions, the agreement between different reference summaries for the task of generic summarization was low (cf. Harman and Over (2004)). Therefore, DUC 2005 offered 10 reference summaries for a subset of the 50 topics in order to cover a more representative sample of the diverging reference summaries.

Another approach to reduce the high variation between reference summaries was taken in TAC 2010, where the summarization task was made more specific and accompanied by guidelines describing a list of required aspects to be covered, e.g., summaries in the category accidents should cover aspects such as what, when, where why (Owczarzak and Dang, 2011).

Alternative Approaches Having trained humans, e.g., professional abstractors, write multidocument summaries is expensive, and for laymen, the task is highly demanding and time-consuming. Therefore, a recent project on the construction of a MDS corpus for European Portuguese took a semi-automatic approach where the documents within a topic were first filtered for relevance using a summarization system and then processed by human annotators who only had to remove sentences until the summary length was reached (Almeida et al., 2014). However, this approach is problematic in our context, because existing summarization systems have not been developed and evaluated on heterogeneous text types.

Crowdsourcing is another approach to reduce the effort for creating annotated data and it has been increasingly used in NLP for a range of different tasks. However, for multidocument summaries, it has been shown to lead to poor results (Lloret et al., 2013).

Exploiting user generated content on the web as a source of reference summaries is another option. For example, Aker and Gaizauskas (2010) used content available on the VirtualTourist platform to construct reference summaries for the task of summarizing location-related images. Even more appealing are collaboratively edited platforms such as Wikipedia where the content is refined and consolidated over time through a well-documented discussion and revision process. Recently, Wikipedia featured articles[2] have been used to create an evaluation dataset for the task of multilingual single-document summarization (Giannakopoulos et al., 2015). In Wikipedia featured articles, the first paragraph constitutes a summary of the article; hence Giannakopoulos et al. (2015) used it as a reference summary for the body of the Wikipedia article.

While Giannakopoulos et al. (2015) address the issue in DUC and TAC datasets of topic bias towards news-specific content, they consider only single-document summarization and sources from a single text type (i.e., encyclopedic text). In contrast to the DUC and TAC datasets, their multilingual SDS dataset provides only a single reference summary for each source document. Although the use of featured articles ensures a certain quality level of the summaries, there might be important aspects of the topic which are missing, in particular for topics that are discussed differently in different languages and cultures. For example, Filatova (2009) suggests to combine the Wikipedia articles across multiple languages for a specific topic in order to obtain a comprehensive summary.

[2] https://en.wikipedia.org/wiki/Wikipedia:Featured_articles

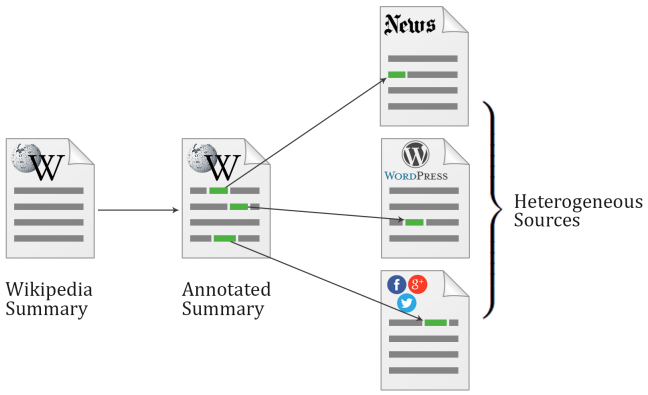

Figure 1: Illustration of the novel corpus construction approach. Left: already available Wikipedia summary; middle: Wikipedia lead with annotated information nuggets; right: a set of heterogeneous source documents which contain the information nuggets.

Our new corpus construction method addresses the bottleneck of human summary creation and the limitation of Giannakopoulos et al. (2015) to be restricted to the single-document summarization task.

3 Reversing Corpus Construction

Previous approaches for constructing MDS corpora start with specifying topics and collecting topic-related source documents; in a second step humans write a summary of the source documents for each of the topics. This approach has several disadvantages, in particular, the reading effort (a human has to read all source documents), the writing effort (the summary has to be written), and the subjectivity of the resulting summary (since the summary is written by only one human). Furthermore, good topics and suitable source documents that cover the topics have to be found in the first place, which can be a laborious and expensive task.

To address these issues, we propose to build MDS corpora by reversing the usual process: Instead of writing a summary for previously gathered source documents, we propose to use an already available high-quality summary and just search for suitable source documents which contain information about the topic. This simplifies the corpus construction process and reduces the effort to create pairs of source documents and summaries. The process is illustrated in Figure 1. In the rest of this section, we describe our novel methodology in detail.

3.1 Methodology

We propose to use the first section of Wikipedia featured articles (the so called *lead*) for this purpose. According to the Wikipedia featured article criteria,[3] these articles are (i) well-written, (ii) comprehensive, (iii) well-researched, (iv) neutral, and (v) stable. In particular, the lead of a featured article is supposed to summarize the topic (according to the guidelines). Since Wikipedia articles are written by many authors, we can consider the lead of a featured article as the consensus of many people regarding the important information about a particular topic. We can therefore consider the leads as high-quality summaries which are representative, because they combine contributions from many authors.

It is important to emphasize that our approach can easily be transferred to other languages where the respective Wikipedias contain featured articles, or even to completely different sources of already existing high-quality summaries.

Given a particular topic (i.e., Wikipedia article), the corpus construction process consists of two steps. First, we annotate topic-specific information nuggets in the summary, in order to be able to retrieve source documents in a systematic way. The information nuggets are supposed to represent atomic information units, i.e., omitting words would change the meaning of the nugget significantly. In the second

[3] https://en.wikipedia.org/wiki/Wikipedia:Featured_article_criteria

step, we search for heterogeneous source documents given the information nuggets. For each annotated information nugget, we search for one source document, which contains the information represented by the nugget, and we keep the text genre as document metadata (the set of possible text genres has been defined in advance, see section 3.2 for details). During our search for source documents, we try to find sources from as many text genres as possible, since we aim to build a heterogeneous corpus. Furthermore, we collect only source documents which are not too similar to the summary. This means that the sources should (i) not contain all information nuggets about the topic, and (ii) contain information which is irrelevant to the topic.

The first property enforces a *content distribution* across all source documents, which means that a summarization system has to consider all source documents to create a proper summary. This is different from previous corpora consisting of documents from a single text type (e.g., newswire), where each individual source document already provided most of the relevant information. In particular, this property reduces the redundancy in the source documents which is often used by multi-document summarization systems to detect important information. Consider as an example homogeneous newswire corpora where documents on a given topic typically have a high degree of redundancy due to the way journalists write news articles: in a typical hard news report, the reported news is first summarized in the lead section, and then specified and elaborated on in the body of the article (Thomson et al., 2008), which creates redundancy even in a single article. As a further consequence of the low redundancy in our collected source documents, the heuristics that the most frequent information is also the most important information (making frequency usually a strong feature in newswire MDS corpora (Nenkova et al., 2006)) is weakened.

The second property, the *presence of unimportant information*, is also different from prior corpora, where the sentences provide usually at least some information about the topic. Selecting the right sentences becomes therefore even more important in order to achieve a good scoring.

Our corpus construction approach is valid, since it is reasonable to assume that the retrieved documents do not introduce new important information about the topic. Wikipedia featured articles already contain the most important information related to a topic, and are furthermore continuously updated by the Wikipedia community. We therefore retrieve the version timestamp of each article and store it in the corpus metadata; the manual retrieval of sources for this version of the Wikipedia article was performed within a short time frame.

3.2 Corpus Construction

We applied our new corpus construction methodology to build ***h***MDS, a new, heterogeneous, multi-genre corpus for MDS. In this section, we describe details of the actual corpus construction process.

Since Wikipedia provides a large number of featured articles, we first selected a subset of the articles for our project. Based on the featured article overview page,[4] we selected the three broad domains

- *Art, Architecture, and Archaeology* (D1),
- *History* (D2), and
- *Law, Politics, and Government* (D3).

We asked three annotators to perform the steps described in the previous section. As part of the first step, they should tag and extract roughly 10 to 20 information nuggets from the lead of each Wikipedia article. For the topic *California Gold Rush*, examples of extracted nuggets are *1848-1855*, *period in American history*, *Sutter's mill*, *gold was found by James W. Marshall*, and *300,000 gold-seekers*.

In the second step, the annotators searched for source documents as described above, using well-known web search engines. Since they tried to find the nugget text verbatim in the source documents, ROUGE scoring is assumed to perform well in our corpus, which is confirmed in our experiments in section 5. The retrieved documents were archived in the Wayback Machine.[5] We provide more detailed

[4] `https://en.wikipedia.org/wiki/Wikipedia:Featured_articles`
[5] `http://archive.org/web/`

corpus information as well as the annotator guidelines and download scripts to retrieve the documents at the corpus web page `https://github.com/AIPHES/hMDS`. For the retrieval step, we used a predefined set of 10 text genres, which are shown in Table 1 along with short descriptions.

Since the source documents are web pages and not ready-to-use raw text documents, we asked the annotators to extract and store the relevant part of the web page, which leads to rather compact source documents. We also generate two larger versions of the corpus by performing boilerplate content removal with Boilerpipe (Kohlschütter et al., 2010). A second version contains all visible web page content. We use the shorthand notation ***h***MDS-M, ***h***MDS-A, and ***h***MDS-V to denote the manually extracted, the automatically extracted and the version with all the visible content, respectively. We also provide a version of the corpus where sentence splitting has already been applied, because most extractive summarizing systems extract sentences. This improves the reproducibility of summarization experiments since it removes one noisy preprocessing step. We use version 1.7.0 of the Stanford segmenter in the DKPro Core software (Eckart de Castilho and Gurevych, 2014) to produce the sentence segmentation.

Although the main purpose of our corpus is MDS, it can also be used for various other tasks. Since we store the genre of each source document, it can be used for text genre classification, or as dataset for training and evaluating boilerplate removal systems. Research in automatic source document retrieval can also use our new corpus.

4 Corpus Analysis

In the following, we summarize and analyze the result of our corpus construction effort. In particular, we analyze whether our corpus actually is as heterogeneous as we designed it to be via our corpus construction methodology. For this, we also compared the ***h***MDS corpus with two common MDS corpora, namely DUC2004[6] and TAC2008A.[7]

The ***h***MDS corpus contains 91 summary-source documents pairs (topics). In total, the annotators retrieved 1,265 source documents. We obtained 13.90 ± 3.09 (where $\pm$ indicates the standard deviation) source documents per topic in comparison to DUC2004 and TAC2008A which both have exactly 10 source documents per topic (i.e. 10 ± 0).

4.1 Text Genres

Since we asked the annotators to classify each source document according to the text genre it belongs to, we are able to provide a detailed analysis of the distribution of texts genres in our corpus. Table 1 provides an overview of the text genres which are present in our corpus, as well as their distributions.

		across domains			
Text Genre – Description (Example)	Count	D1	D2	D3	Avg. length (in words)
article – well-written text (high-quality blog post, news article)	524	0.37	0.42	0.47	1452.70 ± 1751.28
forum post – lack text structure (QA site, Youtube comment)	115	0.10	0.08	0.09	964.10 ± 1726.89
microblog – short, contains abbreviations (Twitter)	33	0.03	0.03	0.02	53.61 ± 14.44
organization – announcement, press release (any org./company)	99	0.11	0.06	0.06	749.29 ± 1119.21
encyclopedic short – encyc. source (Urban Dictionary, IMDB)	115	0.12	0.07	0.08	400.45 ± 362.88
encyclopedic long – encyc. source (Wikipedia)	137	0.11	0.14	0.07	3434.15 ± 5077.32
social media – post in social network (Facebook, Google+)	11	0.01	0.01	0.01	270.45 ± 250.67
scientific – contain citations and bibliography	119	0.07	0.08	0.14	5394.03 ± 9118.11
education – text book, tutorial	79	0.05	0.09	0.05	1568.76 ± 3020.62
dialogues – opinionated (interview, transcript, discussion)	33	0.02	0.03	0.03	3759.79 ± 4897.97
Total	1265	0.36	0.35	0.28	1863.59 ± 3928.91

Table 1: List of genres present in the ***h***MDS corpus along with their fractions in the different domains. The length details are computed for the M-version of our corpus.

We obtained a large amount of source documents for the "article" genre. The distribution of the other genres is rather uniform with most documents belonging to the encyclopedic, scientific, and forum post categories. The fraction of microblog documents, dialogues, and social media is considerably smaller.

[6] `http://duc.nist.gov/duc2004`
[7] `https://tac.nist.gov/2008`

On average, we obtained 5.39 $\pm$ 1.54 different genres per topic with a minimum of 3 and a maximum of 9 different genres per topic. These results substantiate our claim that the ***h***MDS corpus contains sources from very diverse genres. We also observe variations of the distributions of text genres across the three different domains.

4.2 Length of Source Documents and Summaries

Another property which we analyze is the length of both source documents and summaries. Table 1 provides information about the distribution of lengths across the different genres. We see that we obtained a wide variety of different lengths across the genres. Since Table 1 only provides information for ***h***MDS-M, we provide more details of the source document lengths in Table 2 where we can see that the variation of lengths increases strongly in the versions A and V of the ***h***MDS corpus. Compared to DUC2004 and TAC2008A, we obtained much longer source documents, as well as a much higher variance in length.

Corpus	Avg. length (in words)	Relative std
hMDS-M	1863.59 $\pm$ 3928.91	2.11
hMDS-A	2192.53 $\pm$ 8196.75	3.74
hMDS-V	2973.06 $\pm$ 8429.32	2.84
DUC2004	672.14 $\pm$ 506.32	0.75
TAC2008A	589.20 $\pm$ 480.33	0.82

Table 2: Length comparisons of source documents.

Corpus	Avg. length (in words)	Relative std
hMDS	245.55 $\pm$ 132.94	0.54
DUC2004	118.11 $\pm$ 6.38	0.05
TAC2008A	109.33 $\pm$ 7.01	0.06

Table 3: Length comparisons of summaries.

Regarding the summaries, we achieved a large difference to prior work as well, see Table 3. Our summaries are on average about twice as long as the summaries in DUC2004 and TAC2008A. The major difference, however, is the huge variance of lengths in our corpus which can be observed by both standard- and relative standard deviation. The minimum length of a summary in our corpus equals 72 words and the maximum length equals 657 words.

4.3 Textual Heterogeneity

The heterogeneity of our corpus also results from other textual properties. Heterogeneous documents are expected to use different wording and to have some topics shifts. In order to measure this textual heterogeneity, we use information theoretic metrics on word probability distributions.

In our experiments, we use the Jensen-Shannon (JS) divergence, which is a symmetric and always defined version of the Kullback Leibler (KL) divergence (Kullback and Leibler, 1951). It incorporates the idea that the distance between two distributions cannot be very different from the average of distances from their mean distribution. Its expression is $JS(P\|Q) = \frac{1}{2}KL(P\|A)+\frac{1}{2}KL(Q\|A)$ where $A = \frac{P+Q}{2}$ is the mean distribution of P and Q. Based on the JS divergence, we can define a measure of textual heterogeneity TH for a topic T composed of documents $d_1, \cdots, d_n$ as

$$TH_{JS}(T) = \frac{1}{n}\sum_{d_i \in T} JS(P_{d_i}, P_{T\setminus d_i}) \quad (1)$$

where P_{d_i} is the probability distribution of words in document d_i and $P_{T\setminus d_i}$ is the probability distribution of words in all other documents of the topic except d_i. TH_{JS} is the average divergence of documents with all the others and provides therefore a measure of diversity among documents of a given topic.

	DUC2004	TAC2008A	***h***MDS-M	***h***MDS-A	***h***MDS-V
TH_{JS}	0.3019	0.3188	0.3815	0.3358	0.3252

Table 4: Average TH_{JS} scores of classical corpora and our new datasets.

Table 4 shows the results of the analysis according to the TH metric. DUC2004 and TAC2008A have similar source documents in comparison to ***h***MDS-M according to TH. ***h***MDS-A and ***h***MDS-V are closer to the classical datasets than ***h***MDS-M. This is due to the fact that these versions contain much more boilerplate content compared to ***h***MDS-M, which makes them more similar again. Nevertheless, the heterogeneity of the main content in the source documents is verified by TH.

4.4 Distribution of Content

	ROUGE-1 Recall				ROUGE-2 Recall			
Corpus	full	n-1	n/2	1	full	n-1	n/2	1
hMDS-M	0.68	0.67 ± 0.03	0.63 ± 0.06	0.42 ± 0.12	0.48	0.46 ± 0.04	0.40 ± 0.07	0.17 ± 0.09
DUC2004	0.43	0.43 ± 0.01	0.43 ± 0.02	0.36 ± 0.05	0.16	0.15 ± 0.01	0.15 ± 0.01	0.09 ± 0.03
TAC2008A	0.46	0.46 ± 0.02	0.44 ± 0.02	0.35 ± 0.05	0.20	0.19 ± 0.01	0.17 ± 0.02	0.10 ± 0.03

Table 5: Results of the content distribution experiment. We present results of using all, n-1, n/2, and only 1 source document. The omitted documents were selected randomly.

As mentioned in section 3.1, our corpus construction aims for a distribution of content across all source documents. To evaluate this property, we conduct an experiment in which we use different fractions of the source documents as input for a greedy optimal summarization systems. Since we use a greedy optimal summarizer due to performance reasons, the optimal results differ slightly from the results in Table 6. We observe in Table 5 that the omission of one document has already an effect in our corpus, whereas the optimal performance stays nearly constant in DUC2004 and TAC2008A. The effect increases when only half of the source documents is considered. A rather large difference can be observed when only one source document is available to the summarizer. In DUC2004 and TAC2008A, the summarizer is still able to achieve 83.7% and 76.1% of the optimal score, whereas in our corpus, only 61.8% can be achieved according to ROUGE-1. For ROUGE-2, we observe 56.3% and 50.0% in DUC2004 and TAC2008A, compared to 35.4% in our corpus.

As we did not manually annotate the information nuggets in the source documents (due to the high annotation effort), we can investigate the differences in content distribution only regarding the ROUGE scores, which also considers high-frequent function words in the default setup. This might explain why the variation is not even higher.

4.5 Distribution of ROUGE Scores

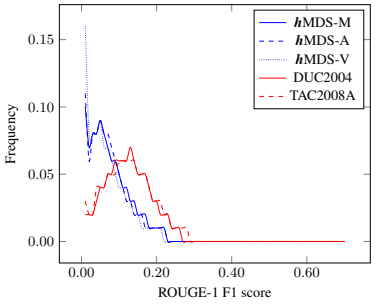

Figure 2: F1 score

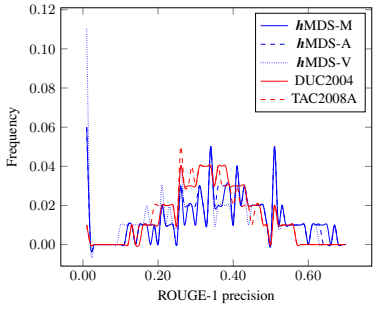

Figure 3: Precision

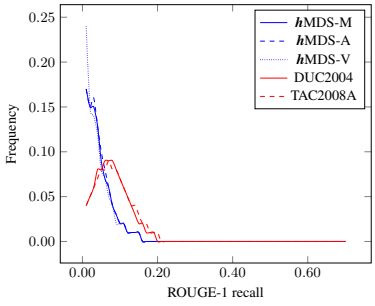

Figure 4: Recall

In this section, we investigate the distribution of ROUGE-1 scores of single sentences in our corpus compared to the DUC2004 and TAC2008A corpora. Figures 2, 3, and 4 provide the distribution of ROUGE-1 F1 measure, ROUGE-1 precision, and ROUGE-1 recall, respectively. The evaluation shows that the distribution according to ROUGE-1 precision is not much different, except for a large number of sentences with very low precision in our corpora. The ROUGE-1 recall curve shows that single sentences in DUC2004 and TAC2008A on average provide a higher recall compared to ***h***MDS. In combination, we see that there are a lot of sentences in ***h***MDS with both very low precision and very low recall. Thus, we can conclude that we indeed constructed a corpus containing sentences which do not contribute much to a good summary (see section 3.1, *presence of unimportant information*).

5 Summarization Experiments

In this section, we conduct experiments with well-known baselines and summarization systems to analyze our new corpus further. As evaluation metric, we apply the commonly used ROUGE scoring (Lin,

2004). All experiments were evaluated with ROUGE version 1.5.5 with standard parameters `-a -m -n 2 -x -c 95 -r 1000 -f A -p 0.5 -t 0 -l` l, which includes stemming without removing stopwords. Since our summaries have different length, we use a variable length parameter l for the evaluation, where l denotes the length of the reference summary. For the DUC2004 and TAC2008A datasets, we use $l = 100$. All results are averaged across all topics.

5.1 Summarization Systems

First, we describe several well-known extractive summarization approaches. By applying them to both the classical datasets and to our new corpus, we can test whether or not we succeeded in creating a new challenge for this research area. Furthermore, we can investigate different properties of our corpus in more detail, such as the strength of the sentence position and centrality features which are used by different summarizers.

Measure	Dataset	Optimal	Random	Lead	LexRank	ICSI	LSA	TF-IDF
ROUGE-1	DUC 2004	0.4535	0.2955	0.3424	0.3450	0.3778	0.2904	0.3318
	TAC 2008A	0.5067	0.2963	0.3315	0.3466	0.3675	0.3154	0.3236
	hMDS-M	0.6992	0.3754	0.4069	0.4192	0.5401	0.3447	0.3671
	hMDS-A	0.6962	0.3242	0.1041	0.4083	0.5370	0.3391	0.3439
	hMDS-V	0.7019	0.2847	0.0050	0.3133	0.5033	0.3228	0.3302
ROUGE-2	DUC 2004	0.1876	0.0435	0.0766	0.0715	0.0900	0.0430	0.0657
	TAC 2008A	0.2540	0.0458	0.0765	0.0773	0.1107	0.0696	0.0572
	hMDS-M	0.4960	0.0732	0.1237	0.1273	0.2293	0.0689	0.0939
	hMDS-A	0.4845	0.0594	0.0318	0.1192	0.2267	0.0652	0.0805
	hMDS-V	0.5018	0.0450	0.0018	0.0797	0.2082	0.0603	0.0766

Table 6: Performance according to ROUGE recall of various summarization approaches for DUC 2004 and our new MDS corpus.

Optimal provides an upper bound for the performance of the summarization systems by searching for the best combination of sentences that achieves the highest ROUGE score. It is no competitive summarization system, since it uses oracle knowledge (i.e. the reference summaries) to generate the best possible summary with an ILP solver. **Random** selects sentences randomly. Although it is a quite simple approach, it helps to compare the absolute ROUGE scores in different datasets. **Lead** is a simple, but quite strong baseline in newswire documents. It iteratively selects the first sentences of the source documents until the desired summary length is reached. Its strength in classical datasets derives from the fact that most important information are usually written first in news articles.

TF-IDF was introduced by Luhn (1958). It uses the typical word frequency assumption as a proxy for importance, which is a very strong feature in multi-document newswire corpora (Nenkova et al., 2006). In **LexRank** (Erkan and Radev, 2004), a similarity graph is constructed with sentences as nodes and the Cosine similarity between them as edge weights. Sentences are scored according to their PageRank score. LexRank relies on centrality to measure relevance. **LSA** performs single value decomposition on a terms-sentences matrix weighted by TF-IDF scores. The summary is made up of the sentences that represent well the most important topics. LSA is a topic-model approach which relies on frequency of co-occuring patterns. **ICSI** (Gillick and Favre, 2009) treats summarization as global linear optimization problem. It extracts a summary by solving a maximum coverage problem considering the most important bi-grams. The importance of bi-grams is estimated via their frequency in the source documents.

In our experiments, we use our own implementations of Optimal, Random, and Lead and implementations of TF-IDF, LexRank, and LSA provided by the sumy package.[8] We use the Python implementation of ICSI released by Boudin et al. (2015).

5.2 Results

The results of the summarization experiment are displayed in Table 6. We first observe that the optimal achievable score is much higher in our corpus, which means that a better fit of source documents and summary is possible. This might be due to the fact that we asked the annotators to search for documents

[8] `https://github.com/miso-belica/sumy`

containing the information nuggets verbatim. Having only one reference summary compared to multiple reference summaries in DUC2004 and TAC2008A might also have an impact. Since we observe different optimal scores, we present in the following relative ROUGE-1 scores according to the respective optimum. For ***h***MDS-V and ***h***MDS-A, we use the optimal score of ***h***MDS-M, which is a lower bound for the true score.

Selecting sentences randomly yields lower results in ***h***MDS compared to DUC2004 and TAC2008A in terms of the maximal possible result (e.g. in DUC2004, selecting sentences randomly yields 65.2% of the optimal score, in ***h***MDS-M we only achieve 54.7%). The lead baseline, which is strong in newswire, does not perform well in ***h***MDS-M (58.2%) and particularly bad in ***h***MDS-A (14.9%) and ***h***MDS-V (0.7%). Sentence position is therefore no longer a good feature in these corpora. ROUGE-2 scores support this result even stronger.

TF-IDF, LSA, LexRank, and ICSI use different approaches to model centrality. We observe that the performance of all approaches decreases when more noise is added to the corpus (versions A and V compared to M). ICSI, a strong state-of-the-art approach (Hong et al., 2014), performs best in our new corpus. We observe, similarly to Random, that it is better suited to summarize DUC2004 (83.3%) than ***h***MDS-M (77.2%), ***h***MDS-A (76.8%), and ***h***MDS-V (72.0%). LSA and TF-IDF have the lowest performance across the four non-baseline systems, and the LexRank results are between them and ICSI.

Our results show that the relative difference to the optimum is quite large in our corpora compared to the classical datasets.

6 Conclusion

In this paper, we presented ***h***MDS: a new, heterogeneous, multi-genre MDS corpus which provides new challenges for summarization systems and is therefore suited to drive research in new directions. To build the corpus, we proposed a novel corpus construction approach which reverses the classically applied approach and reduces the construction effort.

We provide detailed analyses of ***h***MDS which verify that our corpus is inherently different from DUC2004 and TAC2008A in various ways. ***h***MDS contains topics from three broad domains, the reference summaries and source documents have varying lengths, and the source documents belong to different genres, which results in the important information being distributed across all source documents. Thus, a system has to be able to deal with this high degree of heterogeneity in order to generate a proper summary. Furthermore, summaries in the corpus are not only written by one person, but are the consensus of a whole community and therefore provide a representative view of the importance of information. We provide results of several baselines and well-known summarization systems which indicate that our corpus poses new challenges for summarization systems. Last but not least, we make our corpus publicly available to the research community.

In future work, we are going to add another dimension of heterogeneity to the corpus by adding pairs of summary and source documents in German, based on German Wikipedia featured articles. Furthermore, we want to investigate if we can generate a very large corpus based on the proposed construction approach by automatically retrieving source documents instead of manually collecting them. The corpus built manually would then serve as a gold standard.

Acknowledgments

This work has been supported by the German Research Foundation (DFG) as part of the Research Training Group "Adaptive Preparation of Information from Heterogeneous Sources" (AIPHES) under grant No. GRK 1994/1, and via the German-Israeli Project Cooperation (DIP, grant No. GU 798/17-1). We thank Kamel Chelly, Matthias Hanreich, and Hannah Wieland for their contributions to the corpus construction.

Abstract

In this paper, we introduce the task of targeted aspect-based sentiment analysis. The goal is to extract *fine-grained* information with respect to entities mentioned in user comments. This work extends both *aspect-based* sentiment analysis that assumes a single entity per document and *targeted* sentiment analysis that assumes a single sentiment towards a target entity. In particular, we identify the sentiment towards each aspect of one or more entities. As a testbed for this task, we introduce the SentiHood dataset, extracted from a question answering (QA) platform where urban neighbourhoods are discussed by users. In this context units of text often mention several aspects of one or more neighbourhoods. This is the first time that a generic social media platform in this case a QA platform, is used for fine-grained opinion mining. Text coming from QA platforms is far less constrained compared to text from review specific platforms which current datasets are based on. We develop several strong baselines, relying on logistic regression and state-of-the-art recurrent neural networks.

1 Introduction

Sentiment analysis is an important task in natural language processing. It has received not only a lot of interest in academia but also in industry, in particular for identifying customer satisfaction on products and services. Early research in the field (Das and Chen, 2001; Morinaga et al., 2002) of sentiment analysis only focused on identifying the overall sentiment or polarity of a given text. The underlying assumption of this work was that there is one overall polarity in the whole text.

Aspect-based sentiment analysis (ABSA) (Jo and Oh, 2011; Pontiki et al., 2015; Pontiki et al., 2016) relates to the task of extracting fine-grained information by identifying the polarity towards different aspects of an entity in the same unit of text, and recognizing the polarity associated with each aspect separately. The datasets for this task were mostly based on specialized review platforms such as Yelp where it is assumed that only one entity is discussed in one review snippet, but the opinion on multiple aspects can be expressed. This task is particularly useful because a user can assess the aggregated sentiment for each individual aspect of a given product or service and get a more fine-grained understanding of its quality.

Another line of research in this field is *targeted* (a.k.a. target-dependent) sentiment analysis (Jiang et al., 2011; Vo and Zhang, 2015). Targeted sentiment analysis investigates the classification of opinion polarities towards certain target entity mentions in given sentences (often a tweet). For instance in the sentence "People everywhere love Windows & vista. Bill Gates", polarity towards Bill Gates is "Neutral" but the positive sentiment towards Windows & vista will interfere with identifying it if the usual methods for sentiment analysis task are employed. However this task assumes only the *overall* sentiment for each entity. Moreover, the existing corpora for this task so far has contained only a single target entity per unit of text.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1546–1556, Osaka, Japan, December 11-17 2016.

Both settings are obviously limited, and there exists many scenarios in which sentiments towards different aspects of several entities are discussed in the same unit of text. As a running example, we use urban areas: choosing which area to live or to visit is an important task when moving or visiting a new city. Currently there are no dedicated platforms for reviewing and rating aspects of neighbourhoods of a city. However we can find many discussions and threads on several blogs and question answering platforms that discuss aspects of areas in many cities around the world. In general, these conversations are very comprehensible: they often contain specific information about several aspects of several neighbourhoods. One example is the following (area names are highlighted in bold and aspect related terms are underlined):

"*Other places to look at in South London are* ***Streatham*** *(good range of shops and restaurants, maybe a bit far out of central London but you get more for your money)* ***Brixton*** *(good transport links, trendy, can be a bit edgy)* ***Clapham*** *(good transport, good restaurants/pubs, can feel a bit dull, expensive) ...*"

The example above does not perfectly fit into the existing tasks in sentiment analysis mentioned earlier. In this work, we introduce a new task that not only subsumes the existing sub-fields of *targeted* and *aspect-based* sentiment analysis but it also makes less assumptions on the number of entities that can be discussed in the unit of text.

To compare with the existing aspect-based sentiment analysis task, take the following example from the restaurant dataset used by SemEval shared ABSA (Pontiki et al., 2016) task. "*The design of the space is good but the service is horrid!*". The ABSA task aims to identify that a positive sentiment towards the *ambiance* aspect is expressed (opinion target expression is "space"). Moreover, a negative sentiment is expressed towards the *service* aspect (opinion target expression is "service"). In this example, it is assumed that both of these opinions are expressed about a single restaurant which is not mentioned explicitly. However, take the following *synthetic* example that ABSA is not addressing:

"*The design of the space is good in* ***Boqueria*** *but the service is horrid, on the other hand, the staff in* ***Gremio*** *are very friendly and the food is always delicious.*"

In this example, more than one restaurant are discussed and restaurants for which opinions are expressed, are explicitly mentioned. We call these target entities. Current ABSA task can only recognise that positive and negative opinions towards aspect "service" are expressed. But it can not identify the target entity for each of these opinions (i.e. Germio and Boqueria respectively). Targeted aspect-based sentiment analysis handles extracting the target entities as well as different aspects and their relevant sentiments.

In the following, we argue that this task is both very relevant in practice, and raises interesting modelling questions. To facilitate research on this task we introduce the SentiHood dataset. SentiHood is based on the text from a QA platform in the domain of neighbourhoods of a city. Table 2 shows examples of input sentences and annotations provided.

Sentence	**Labels**
The cheap parts of London are **Edmonton** and **Tottenham** and they are all poor, crime ridden and crowded with immigrants	(Edmonton,price,Positive) (Tottenham,price,Positive) (Edmonton,safety,Negative) (Tottenham,safety,Negative)
Hampstead area, more expensive but a better quality of living than in **Tufnell Park**	(Hampstead,price,Negative) (Hampstead,live,Positive)

Table 1: Examples of input sentences and output labels in the system.

Our contributions in this paper can be summarised as follows:

- We introduce the task of *targeted aspect-based* sentiment analysis as a further step towards extracting more fine-grained information from more complex text in the field of sentiment analysis.
- We use the text from social media platforms, in particular QA, for fine-grained opinion mining. So far, all datasets in this field have utilised text from review specific platforms where certain assumptions can be made and data is more constrained and less noisy.
- We propose SentiHood, a benchmark dataset that is annotated for the task of targeted aspect-based sentiment analysis in the domain of urban neighbourhoods.
- We show that despite the fact that the texts in QA were not written with the goal of writing a review in mind, question answering platforms and online forums are in general rich in information.
- We provide strong baselines for the task using both logistic regression and Long Short Term Memory (LSTM) networks and analysis of the results.

2 SentiHood

SentiHood is a dataset for the task of *targeted aspect-based* sentiment analysis. It is based on the text taken from question answering platform of Yahoo! Answers that is filtered for questions relating to neighbourhoods of the city of London. In this section we explain the data collection and annotation process and summarise properties of the dataset.

2.1 Data Collection Process

Entities in the dataset are locations or neighbourhoods. Yahoo! Answers was queried using the name of each neighbourhood of the city of London. Location (entity) names were taken from the gazetteer GeoNames[1] and restricted to those within the boundaries of London. This list includes names of areas and boroughs and therefore entities are not always geographically exclusive (a borough contains several areas or neighbourhoods). The content of each question-answer pairs was aggregated and split into sentences. We keep only sentences that have a mention of a location entity name and discard other sentences.

2.2 Categories

The Number of location mentions in a single sentence in our dataset varies from one to over 50. To simplify the task, we only annotate sentences that contain one or two location mentions. These sentences were divided into two groups: sentences containing one location mention — Single, and sentences containing two location mentions — Multi. This is to observe the difficulty of annotating two groups by human annotators and by the models.

2.3 Aspects

Like existing work in the aspect-based sentiment analysis task (Brychcın et al., 2014), a pre-defined list of aspects is provided for annotators to choose from. These aspects are: *live*, *safety*, *price*, *quiet*, *dining*, *nightlife*, *transit-location*, *touristy*, *shopping*, *green-culture* and *multicultural*. Adding an additional aspect of *misc* was considered. However in the initial round of annotations, we realised that it had a negative effect on the decisiveness of annotators and it led to a lower overall agreement. Aspect *general* refers to a generic opinion about a location, e.g. "I love **Camden Town**".

2.4 Sentiment

For each selected aspect, annotators were required to select a polarity or sentiment. Most work in this area considers three sentiment categories of "Positive". "Negative" and "Neutral". In our annotation however, we only provided "Positive" and "Negative" sentiment labels. This is because in our data we rarely come across cases where aspects are discussed without a polarity.

[1] http://www.geonames.org/

2.5 Target Entity

Target entity is a location entity in which an opinion (aspect and sentiment) is expressed for. We also refer to target entity as target location.

2.6 Out of scope

For the sentences that do not comply with our schema, we define the two following special labels. Sentences marked with one of the these labels are removed from the dataset.

1. **Irrelevant**: When the identified name does not refer to a location entity: for example in the sentence "**Notting Hill** (1999) stars Julia Roberts and Hugh Grant use the characteristic features of the area as a backdrop to the action", "Notting Hill" refers to the movie and not the area.

2. **Uncertain**: When two contradicting sentiments are expressed for the same location and aspect, e.g. "Like any other area, **Camden Town** has good and bad parts". Moreover, when the opinion is expressed for an area without a direct mention in the sentences, e.g. "**It**'s a very trendy area and not too far from **King's Cross**".

2.7 Procedure:

We use the BRAT annotation tool (Stenetorp et al., 2012) to simplify the annotation task. Three annotators were initially selected for the task. None of the annotators are experts in linguistics. Annotators began by reading the guidelines and examples. Each annotator was then required to annotate a small subset of the data. After each round of annotation, agreements between annotators were calculated and discussed and this procedure continued until they reached a reasonable agreement. 10% of the whole dataset was randomly selected and annotated by all the three annotators. The annotator with the highest inter-annotator agreement was selected to annotate all the dataset.

Agreements: Cohen's Kappa coefficient(K) (COHEN, 1960) is often used for measuring the pairwise agreement between each two annotators for the task of aspect-based sentiment analysis (Gamon et al., 2005; Ganu et al., 2009) and other tasks (Liakata et al., 2010). The Kappa Coefficient is calculated over aspect-sentiment pairs per each location. Pairwise inter-annotator agreement for aspect categories measured using Cohen's Kappa is 0.73, 0.78 and 0.70, which is deemed of sufficient quality. It is worth mentioning that agreements on different aspect categories varied, with some aspects having a higher agreement rate. Agreements for aspect expressions are 0.93, 0.94, 0.93. These agreements indicate reasonably high inter-annotator agreements (Pavlopoulos, 2014).

Disagreements: Main disagreements between annotators occurred in detecting the aspect rather than detecting the sentiment, aspect expression or the target location. For instance, some annotators associated the expression "residential area" with a "Positive" sentiment for aspect "quiet" or "live" and others did not agree that "residential" implies quietness or desirable for living. In the case of disagreements, the vote of the majority was considered as the correct annotation.

Some ambiguity was also observed with respect to detecting the target location. This occurred mainly when a location is confined in another location. For instance the sentence "**Angel** in **Inslington** has many great restaurants for eating out" expresses a "Positive" sentiment for the aspect "dining" of area **Angel** which is within the borough of **Islington**. Some annotators suggested that the sentence also implies the same opinion for **Islington**. However at the end all annotators agreed that in such cases no implicit assumptions should be made and only confined area should be labeled.

2.8 Dataset

SentiHood currently contains annotated sentences containing one or two location entity mentions.[2] SentiHood contains 5215 sentences with 3862 sentences containing a single location and 1353 sentences containing multiple (two) locations. Figure 1 shows the number of sentences that are labeled with each aspect, breaking down on the sentiment "Positive" or "Negative". "Positive" sentiment is dominant for

[2]SentiHood data can be obtained at `http://annotate-neighborhood.com/download/download.html`

aspects such as dining and shopping. This shows that for some aspects, people usually talk about areas that are good for it as oppose to areas that are not. The *general* aspect is the most frequent aspect with over 2000 sentences while aspect *touristy* has occurred in less than 100 sentences. Notice that since each sentence can contain one or more opinions, the total number of opinions (5920) in the dataset is higher than the number of sentences.

Location entity names are masked by **location1** and **location2** in the whole dataset, so the task does not involve identification and segmentation of the named entities. We also provide the dataset with the original location entity names.

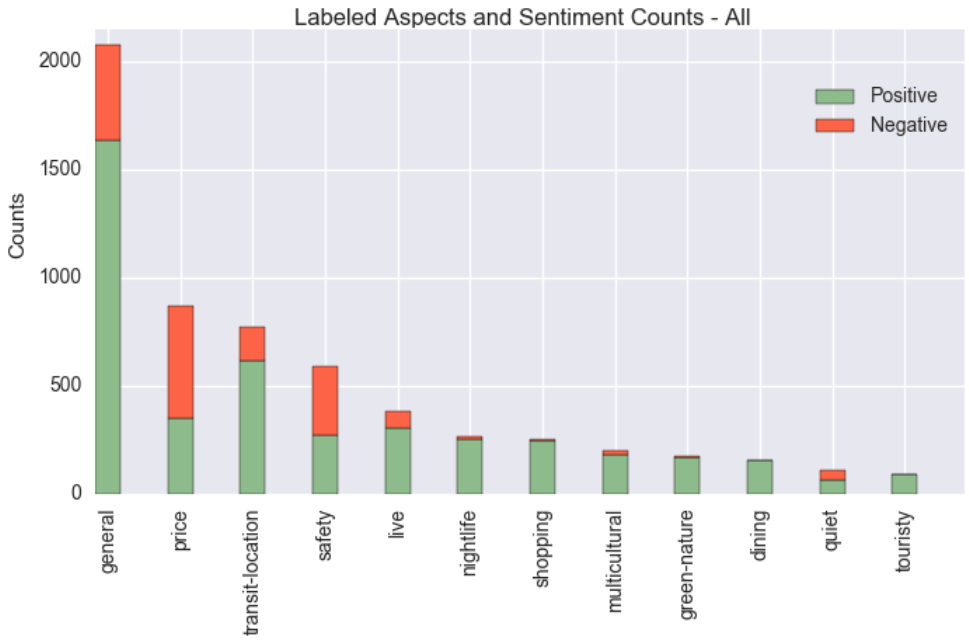

Figure 1: Number of annotated aspects and their sentiments.

3 Task

We define the task of targeted aspect-based sentiment analysis as follows: given a unit of text s (for example, a sentence), provide a list of tuples (labels) $\{(l, a, p)\}_{t=0}^{T}$, where p is the polarity expressed for the aspect a of entity l. Each sentence can have zero to T number of labels associated with it.

Within the current aspect-based sentiment analysis work, three tasks are defined (Brychcın et al., 2014): detecting the aspect, detecting the opinion target expression and detecting the sentiment, with detecting the opinion target expression being an intermediary task for identifying the sentiment of the aspect.

Here we focus on identifying only the aspect and sentiment for each entity. We identify each aspect, its relevant sentiment and the target location entity jointly by introducing a new polarity class called "None". "None" indicated that a sentence does not contain an opinion for the aspect a of location l. Therefore the overall task can be defined as a three-class classification task for each (l, a) pair with labels "Positive", "Negative", "None". Table 2 shows an example of the input sentence and output labels.

Sentence	**Labels**
location1 is very safe and **location2** is too far	(location1,safety,Positive) (location1,transit-location,None) (location2,safety,None) (location2,transit-location,Negative)

Table 2: Example of an input sentence and the output labels.

4 Evaluation

Most existing work in aspect-based sentiment analysis field, report F_1 measure for aspect detection task, and accuracy for sentiment classification. The scores can be calculated over 2-class or 3-class sentiments (Pontiki et al., 2015). In our results, F_1 score is calculated with a threshold that is optimized on validation set.

We also propose the AUC (area under the ROC curve) metric for both aspect and sentiment detection tasks. AUC captures the quality of the ranking of output scores and does not rely on a threshold.

5 Baseline

Here we propose baselines for the task. In all our methods, we treat the task as a three-class classification for each aspect and use a softmax function as follows:

$$p(y_{l,a} = c) = \text{softmax}(c) = \frac{exp(w_c.e_l + b_c)}{\sum_{c'=1}^{C} exp(w_{c'}.e_l + b_{c'})} \quad (1)$$

where $y_{l,a}$ is the sentiment label of aspect a for location l. w_c and b_C are the weights and the bias specific to each sentiment class c, respectively. e_l is a representation of location l. This representation can be a BoW or a distributional representation. Each method that we propose here define their own specific representation for e_l.

5.1 Logistic Regression

Many existing works in the aspect-based sentiment analysis task,[3] use a classifier, such as logistic regression or SVM, based on linguistic features such as n-grams, POS information or more hand-engineered features. We can think of these features as a sparse representation e_l that enter the softmax in equation 1. More concretely, we define the following sparse representations of locations:

Mask target entity n-grams: For each location, we define an n-gram representation over the sentence and mask the target location using a special token. This can help to differentiate between representations of two locations present in the same sentence.

Left-right n-grams: we create an n-gram representation for both the right and the left context around each location mention. We then concatenate these two representations to obtain one single feature vector.

Left right pooling: Previously embedding representations over the left and right context have been used for automatic feature detection in the targeted sentiment analysis task (Vo and Zhang, 2015). Inspired by this approach, we obtain max, min, average and standard deviation pooling over all the word embeddings for left and right context separately. We then combine the pooled embeddings of the left and right context to obtain a single feature vector. Word embeddings are obtained by running word2vec tool on a combination of our Yahoo! Answers corpus and a substantially big corpus from the web.[4]

5.2 Long Short-Term Memory (LSTM)

Inspired by the recent success of applying deep neural networks on language tasks, we use a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) to learn a classifier for each of the aspects. Representations for a location (e_l) are obtained using one of the following two approaches:

Final output state (LSTM - Final): e_l is the output embedding of the bidirectional LSTM.

Location output state (LSTM - Location): e_l is the output representation at the index corresponding to the location entity as illustrated in Figure 2.

[3] including participants of SemEval ABSA tasks

[4] http://ebiquity.umbc.edu/redirect/to/resource/id/351/UMBC-webbase-corpus

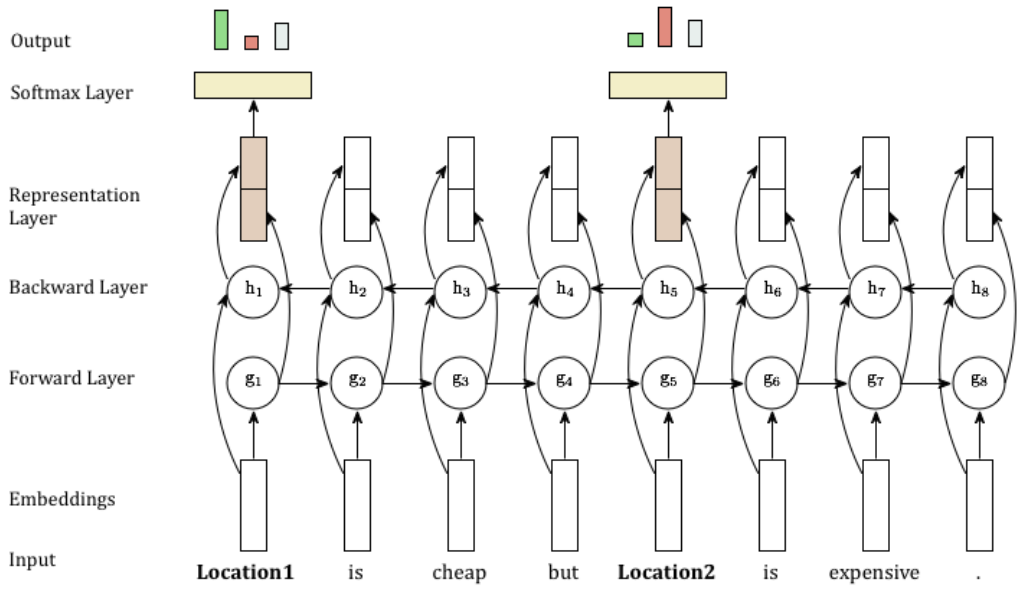

Figure 2: Bidirectional LSTM outputs a representation for each token in the sentence. The output state at the index of each location is then fed into a softmax layer to identify the sentiment class for the corresponding aspect. In this figure, LSTM is trained to identify the sentiment of aspect "price". Model should predict "Positive" for **location1** and "Negative" for **location2**

6 Experiments

In this paper, we select the four most frequent aspects from the dataset which are: "price", "safety", "transit-location" and "general" but the same approach can be applied to the remaining aspects. We divide each collection of single and multiple location mentions into train, dev and test set, with each having 70%, 10% and 20% of data respectively. We choose the best model with respect to the dev set.

In the case of the LSTM, we evaluate the loss on both training set and dev set after each iteration. We save the best model which has the lowest loss on the dev set over all the iterations. We then run this model on the test set and report the results. We report results separately on both categories of single location sentences and sentences with two locations and over all the data in the test set. Results on single location sentences mainly show the ability of the model to detect the correct sentiment for an aspect. On the other hand, results on two location sentences demonstrate the ability of the system not only on detecting the relevant sentiment of an aspect but also on recognising the target entity of the opinion.

Training LSTMs We implement our LSTM models using tensorflow (ten, 2015). To tackle the problem of having an unbalanced dataset (i.e. too many "None" instances), we train the LSTM model in batches with every batch having the same number of sentences selected randomly from each sentiment class. We tune the hyper parameters of the model on the dev set. The best model uses hidden units of size 50 and batch sizes of size 150. The Adam optimizer is used for optimization with a starting learning rate of 0.01 which is tuned to be the best performing on the dev set. Dropout is used both on initial word embeddings and on LSTM cells with the probability of 0.001. Tensorflow (ten, 2015) is used for the implementation of LSTM.

Training Logistic Regression Logistic regression models were based on implementations from scikit-learn.[5] Since we have an unbalanced dataset, we use a weighted logistic regression. To obtain the best weights, we cross-validate them on the development set. Weights inversely proportional to the size of each class result in the best performance.

[5] `http://scikit-learn.org/`

7 Results

Table 3 shows the results (averaged over all selected aspects) in terms of both F_1/accuracy and AUCs. It also shows the results of logistic regression based models versus LSTM models.

As we can see, the n-gram representation with location masking achieves slightly better results over the left-right context. N-grams include unigrams and bigrams. Also, by adding POS information, we gain an increase in the performance. We also experimented with adding tri-grams but it did not have a positive effect on the overall scores. Separating the left and the right context (LR-Left-Right) for BoW representation, does not improve the performance. Left-right pooling of dense embeddings performed weakly in comparison with other representations and therefore their results were omitted.

Amongst the two variations of LSTM, the model with final state embeddings does slightly better than the model where we use the embeddings at the location index, however they are not significantly different (with a p value less than 0.01). It is interesting to note that the best LSTM model is not superior to logistic regression model, especially in terms of AUC. This can be due to the fact that the amount of training data is not sufficient for LSTM to perform well. Moreover, while we provide some grammar information to logistic regression model through POS tags, such information is not incorporated into LSTM models. Another interesting observation is that the F_1 measure for logistic regression model with n-grams and POS information is very low while this model's performance is superior to other models in terms of AUC. This is because in general, it is easier to rank prediction scores than to assign predicted labels to instances by choosing a hard threshold.

Model	Aspect (F_1)	Sentiment (Accuracy)	Aspect (AUC)	Sentiment (AUC)
LR-Left-Right	0.683	0.847	0.903	0.875
LR-Mask(ngram)	**0.697**	0.853	0.918	0.885
LR-Mask(ngram+POS)	*0.393*	**0.875**	**0.924**	**0.905**
LSTM-Final	0.689	0.820	0.898	0.854
LSTM-Location	**0.693**	0.819	0.897	0.839

Table 3: Results of best logistic regression (LR) models and LSTM models.

Table 4 shows the average AUC (over aspect and sentimentclassification tasks) for two categories of data: Single — sentences that contain one location entity and Multi — sentences that contain two location entities. While logistic regression can perform slightly better on son Single location sentences, LSTM performs slightly better on Multi location sentences.

Model	Single	Multi
LR - Mask (n-gram + POS)	**0.916**	**0.907**
LSTM - Final	0.872	0.890

Table 4: Results of best logistic regression (LR) and LSTM models on sentences with a single location (Single) and multiple locations (Multi). AUC scores are averaged over aspect and sentiment classification tasks.

Table 5 shows the break down of average AUC scores for each aspect. We can see that aspects such as "safety" can be predicted with a better AUC score than aspect "general".

Model	Price	Safety	Transit	General
LR - Mask (n-gram + POS)	**0.940**	**0.960**	**0.879**	0.864
LSTM - Final	0.875	0.932	0.836	**0.869**

Table 5: LR and LSTM performance breakdown on aspects. AUC scores are averaged over aspect and sentiment detection.

Table 6 shows examples of correct and incorrect predictions using the best logistic regression model. The top part of the table contains examples that each contain a single location entity. At the bottom of the table, a sentence with two location entities is provided. The system correctly identifies that a "Positive" sentiment is expressed for the *general* aspect about **location2**. However, no sentiment is expressed for this aspect for **location1**.

Sentence	Aspect	Predicted	Label
location1 is not a nice cheap residential area to live trust me i was born and raised there	Price	Positive	Negative
I think you'd find it tough to find something affordable in **location1**	Price	Positive	Negative
I can't recommend **location1** for affordability	Price	Negative	Negative
I only know about **location1**, most people prefer location2	General	None	None
I only know about location1, most people prefer **location2**	General	Positive	Positive

Table 6: Examples of input sentences and predicted labels using the best system (LR - Mask (n-gram + POS). Target entity locations are highlighted in bold.

8 Related Work

The term sentiment analysis was first used in (et al, 2003). Since then, the field has received much attention from both research and industry. Sentiment analysis has applications in almost in every domain and it raised many interesting research questions. Furthermore, the availability of a huge volume of opinionated data on social media platforms has accelerated the development in this area.

In the beginning work on sentiment analysis mainly focused on identifying the overall sentiment of a unit of text. The unit of text varied from document (Pang et al., 2002; Turney, 2002), paragraph or sentences (Hu and Liu, 2004). However, only considering the overall sentiment fails to capture the sentiments over the aspects on which an entity can be reviewed or sentiment expressed toward different entities. Two remedy this, two new tasks have been introduced: *aspect-based* sentiment analysis and *targeted* sentiment analysis.

Aspect based sentiment analysis assumes a *single entity* per a unit of analysis and tries to identify sentiments towards different aspects of the entity (Lu et al., 2011; Lakkaraju et al., 2014; Alghunaim, 2015; Bagheri et al., 2013; Somprasertsri and Lalitrojwong, 2008; Alghunaim, 2015; Lu et al., 2011; Titov and McDonald, 2008; Brody and Elhadad, 2010). This task however does not consider more than one entity in the given text.

Targeted (target dependent) sentiment analysis is another task that identifies polarity towards a target entity (as opposed to over entire unit of text) (Mitchell et al., 2013; Jiang et al., 2011; Dong et al., 2014; Vo and Zhang, 2015; Zhang et al., 2016). (Jiang et al., 2011) was the first to propose targeted sentiment analysis on Twitter and demonstrates the importance of targets by showing that 40% of sentiment errors are due to not considering them in classification. However this task only identifies the *overall sentiment* and the existing corpora for the task consist only of text with one single entity per unit of analysis.

The task of targeted aspect-based sentiment analysis caters for more generic text by making fewer assumptions while extracting fine-grained information.

9 Conclusion

In this paper, we introduced the task of *targeted aspect-based* sentiment analysis and a new dataset. We also provide two strong baselines using logistic regression and LSTM. Ways to improve the baselines can involve using parse trees for identifying the context of each location. Data augmentation can be used

to make the models and especially LSTM more robust to variations in the data. We also like to provide more detailed analysis of what each system can achieve.

Abstract

Sentiment polarity lexicons are key resources for sentiment analysis, and researchers have invested a lot of efforts in their manual creation. However, there has been a recent shift towards automatically extracted lexicons, which are orders of magnitude larger and perform much better. These lexicons are typically mined using bootstrapping, starting from *very few* seed words whose polarity is given, e.g., 50-60 words, and sometimes even just 5-6. Here we demonstrate that much higher-quality lexicons can be built by starting with hundreds of words and phrases as seeds, especially when they are in-domain. Thus, we combine (*i*) mid-sized high-quality manually crafted lexicons as seeds and (*ii*) bootstrapping, in order to build large-scale lexicons.

1 Introduction

The recent rise of social media has greatly democratized content creation. Facebook, Twitter, Skype, WhatsApp and LiveJournal are now commonly used to share thoughts and opinions about anything in the surrounding world. This proliferation of social media content has created new opportunities to study public opinion, with Twitter being especially popular for research due to its scale, representativeness, variety of topics discussed, as well as ease of public access to its messages.

Naturally, this abundance of data has attracted business and research interest from various fields including marketing, political science, and social studies, among many others, which are interested in questions like these: *Do people like the new Apple Watch? What do they hate about iPhone6? Do Americans support ObamaCare? What do Europeans think of Pope's visit to Palestine? How do we recognize the emergence of health problems such as depression? Do Germans like how Angela Merkel is handling the refugee crisis in Europe? What do republican voters in USA like/hate about Donald Trump?* Answering these questions requires studying the sentiment of opinions people express in social media, which has given rise to the fast growth of the field of sentiment analysis in social media.

Initially, sentiment analysis was addressed as a text classification problem, but it was soon realized that sizable performance gains can be obtained from using carefully built sentiment polarity lexicons as a source of external knowledge. Thus, researchers have invested a lot of efforts in the manual creation of such lexicons, which were typically of small to moderate size, e.g., less than 10,000 words. Recently, there has been a shift towards using automatically extracted lexicons, which are orders of magnitude larger and perform much better. These lexicons are typically mined using bootstrapping, starting from *very few* seed words whose polarity is given, e.g., 50-60 words, and sometimes even just 5-6.

Here, we demonstrate that sizable further performance gains can be observed by starting with mid-sized seeds (hundreds of words and phrases), thus getting the best of both worlds: (*i*) using high-quality mid-sized manually crafted lexicons as seeds, and (*ii*) extending them automatically using bootstrapping.

The remainder of the paper is organized as follows: Section 2 presents some related work. Section 3 describes our training and testing datasets. Section 4 presents the various lexicons we created for Macedonian. Section 5 gives details about our system, including the pre-processing steps and the features used. Section 6 describes our experiments and discusses the results. Section 7 concludes with possible directions for future work.

2 Related Work

In this section, we first present work on sentiment analysis in general: methods used, work on sentiment analysis on Twitter, and relevant tasks at SemEval. Then, we present work on sentiment polarity lexicon induction, and finally, we discuss sentiment analysis for Macedonian.

2.1 Sentiment Analysis

Research in sentiment analysis started in the early 2000s. Initially, it was regarded as standard document classification into topics (Pang et al., 2002). However, researchers soon realized that it was quite different from standard document classification (Sebastiani, 2002), e.g., into categories such as business, sport and politics, and that sentiment analysis crucially needs external knowledge in the form of sentiment polarity lexicons. See for example the surveys by Pang and Lee (2008) and Liu and Zhang (2012) for more detail about research in sentiment analysis.

Around the same time, other researchers realized the importance of external sentiment lexicons, e.g., Turney (2002) proposed an unsupervised approach to learn the sentiment orientation of words/phrases: positive vs. negative. Later work studied the linguistic aspects of expressing opinions, evaluations, and speculations (Wiebe et al., 2004), the role of context in determining the sentiment orientation (Wilson et al., 2005), of deeper linguistic processing such as negation handling (Pang and Lee, 2008), of finer-grained sentiment distinctions (Pang and Lee, 2005), of positional information (Raychev and Nakov, 2009), etc. Moreover, it was recognized that in many cases, it is crucial to know not just the polarity of the sentiment, but also the topic towards which this sentiment is expressed (Stoyanov and Cardie, 2008).

Early sentiment analysis research focused on customer reviews of movies, and later of hotels, phones, laptops, etc. Later, with the emergence of social media, sentiment analysis in Twitter became a hot research topic. Unfortunately, research in that direction was hindered by the unavailability of suitable datasets and lexicons for system training, development and testing. While some Twitter-specific resources were developed, initially they were either small and proprietary, such as the i-sieve corpus (Kouloumpis et al., 2011), were created only for Spanish like the TASS corpus (Villena-Román et al., 2013), or relied on noisy labels obtained automatically based on emoticons and hashtags (Mohammad, 2012; Pang et al., 2002; Mohammad et al., 2013).

This situation changed with the shared task on *Sentiment Analysis on Twitter*, which was organized at SemEval, the International Workshop on Semantic Evaluation, a semantic evaluation forum previously known as SensEval. The task ran in 2013, 2014, 2015 and 2016, attracting over 40+ of participating teams in all four editions. While the focus was on general tweets, the task also featured out-of-domain testing on SMS messages, LiveJournal messages, as well as on sarcastic tweets.

SemEval-2013 task 2 (Nakov et al., 2013) and SemEval-2014 Task 9 (Rosenthal et al., 2014) focused on expression-level and message-level polarity. SemEval-2015 Task 10 (Rosenthal et al., 2015; Nakov et al., 2016b) featured topic-based message polarity classification, on detecting trends towards a topic, and on determining the out-of-context (a priori) strength of association of Twitter terms with positive sentiment. SemEval-2016 Task 4 (Nakov et al., 2016a) introduced a 5-point scale, which is popular and is commonly used for human review ratings on popular websites such as Amazon, TripAdvisor, Yelp, etc.; from a research perspective, this meant moving from classification to *ordinal regression*. Moreover, some subtasks of the general task focused on *quantification*, i.e., determining what proportion of a set of tweets on a given topic are positive/negative about it. It also featured a 5-point scale *ordinal quantification* subtask (Gao and Sebastiani, 2015).

Other related (mostly non-Twitter) tasks explored aspect-based sentiment analysis (Pontiki et al., 2014; Pontiki et al., 2015; Pontiki et al., 2016), sentiment analysis of figurative language on Twitter (Ghosh et al., 2015), implicit event polarity (Russo et al., 2015), stance in tweets (Mohammad et al., 2016), out-of-context sentiment intensity of phrases (Kiritchenko et al., 2016), and emotion detection (Strapparava and Mihalcea, 2007). Some of these tasks featured languages other than English.

2.2 Sentiment Polarity Lexicons

Despite the huge variety of knowledge sources explored in the literature, sentiment polarity lexicons remained the only universally recognized resource for the task of sentiment analysis. Until recently, such sentiment polarity lexicons were manually crafted, and were thus of small to moderate size, e.g., LIWC (Pennebaker et al., 2001) has 2,300 words, the General Inquirer (Stone et al., 1966) contains 4,206 words, Bing Liu's lexicon (Hu and Liu, 2004) includes 6,786 words, and MPQA (Wilson et al., 2005) has about 8000. Early efforts in building them automatically also yielded lexicons of moderate sizes such as the SentiWordNet (Esuli and Sebastiani, 2006; Baccianella et al., 2010).

However, recent results have shown that automatically extracted large-scale lexicons (e.g., up to a million words and phrases) offer important performance advantages, as confirmed at shared tasks on Sentiment Analysis on Twitter at SemEval 2013-2016 (Nakov et al., 2013; Rosenthal et al., 2014; Rosenthal et al., 2015; Nakov et al., 2016a), where over 40 teams participated four years in a row.

Using such large-scale lexicons was crucial for the performance of the top-performing systems. Similar observations were made in the related Aspect-Based Sentiment Analysis task at SemEval 2014 (Pontiki et al., 2014). In both tasks, the winning systems benefitted from building and using massive sentiment polarity lexicons (Mohammad et al., 2013; Zhu et al., 2014).[1] The two most popular large-scale lexicons were the Hashtag Sentiment Lexicon and the Sentiment140 lexicon, which were developed by the team of NRC Canada for their participation in the SemEval-2013 shared task on sentiment analysis on Twitter.

The importance of building sentiment polarity lexicons has resulted in a special subtask (Rosenthal et al., 2015) at SemEval-2015 (part of Task 4), and an entire task (Kiritchenko et al., 2016) at SemEval-2016 (namely, Task 7), on predicting the out-of-context sentiment intensity of words and phrases.[2]

These large-scale automatic lexicons are typically built using bootstrapping, starting with a small set of seeds of, e.g., 50-60 words, and sometimes even just two emoticons (Mohammad et al., 2013).

Here, we demonstrate that sizable further performance gains can be observed by starting with mid-sized seeds (i.e., hundreds of words and phrases), thus getting the best of both worlds: (*i*) using high-quality mid-sized manually crafted lexicons as seeds, and (*ii*) further extending them automatically using bootstrapping.

2.3 Sentiment Analysis for Macedonian

In our experiments below, we focus on Macedonian (tweets), for which we only know two publications on sentiment analysis, none of which is about Twitter.

Gajduk and Kocarev (2014) experimented with 800 posts from the Kajgana forum (260 positive, 260 negative, and 280 objective), using SVM and Naïve Bayes classifiers, and features such as bag of words, rules for negation, and stemming.

Uzunova and Kulakov (2015) experimented with 400 movie reviews[3] (200 positive, and 200 negative; no objective/neutral), and a Naïve Bayes classifier, using a small manually annotated sentiment lexicon of unknown size, and various preprocessing techniques such as negation handling and spelling/character translation.

Unfortunately, the datasets and the generated lexicons used in the above work are not publicly available, and/or are also from a different domain (i.e., not Twitter). As we are interested in sentiment analysis of Macedonian tweets, we had to build our own datasets. We have described these datasets and initial experiments with them in an earlier publication (Jovanoski et al., 2015), where the focus was on the datasets and on the classifier; in contrast, here we focus on assessing the impact of our proposed lexicon generation method. Below we will describe these datasets in detail, for the sake of self-containment of the present paper.

[1] Such lexicons proved useful for other tasks at SemEval, e.g., for SemEval-2016 Task 3 on Community Question Answering (Balchev et al., 2016).

[2] We should note though that the utility of using sentiment polarity lexicons for sentiment analysis probably needs to be revisited, as the best system at SemEval-2016 Task 4 could win without using any lexicons (Deriu et al., 2016).

[3] There have been also experiments on movie reviews for the closely related Bulgarian language (Kapukaranov and Nakov, 2015), but there the objective was to predict user rating, which was addressed as an ordinal regression problem.

3 Data

We downloaded half a million tweets in Macedonian, which we collected over a six-month period spanning from November 2014 to April 2015. We tried to download all Macedonian tweets based on the Twitter language classification. However, it turned out that in many cases, the returned tweets were in Bulgarian or Russian, which are also Slavic languages and share the same alphabet with Macedonian. Thus, we trained and used our own Naïve Bayes classifier, which achieved over 95% accuracy.[4] We used part of these tweets as training and testing data, and the rest for building automatic lexicons.

Table 1 shows statistics about the training and the testing datasets. We can see that they are somewhat balanced between positive and negative tweets, and that there is smaller proportion of neutral tweets.[5]

The *testing data* was annotated for sentiment at the tweet level (using *positive*, *negative*, and *neutral/objective* as labels[6]) by two annotators, both native speakers of Macedonian. The Cohen's Kappa statistics (Cohen, 1960) for the inter-annotator agreement was 0.64, which corresponds to *substantial* agreement (Landis and Koch, 1977). Our follow-up analysis has shown that the main disagreement was about distinguishing between negative and neutral tweets. In the final testing dataset, we discarded all tweets with disagreement (a total of 482 tweets).

The *training data* was annotated by a single annotator, one of those who annotated the testing dataset. In addition to producing tweet-level sentiment polarity annotations, the annotator further marked the positive and the negative phrases inside each tweet. We will use the set of these words and phrases, together with their polarities, as a sentiment lexicon, and also as seeds when bootstrapping a large-scale automatic sentiment lexicon from the remaining unannotated tweet messages.

Dataset	Positive	Neutral	Negative	Total
Train	2,610 (30%)	1,280 (15%)	4,693 (55%)	8,583
Test	431 (38%)	200 (18%)	508 (44%)	1,139
No annot.	–	–	–	0.5M

Table 1: Statistics about the datasets.

4 Sentiment Lexicons

A sentiment lexicon contains words and phrases annotated with positive and negative sentiment, sometimes with numerical intensity, e.g., *spectacular* could have positive strength of 0.91, while for *okay* that might be 0.3. Below we describe the sentiment lexicons we built and experimented with.

4.1 Manually-Crafted Lexicon

As we mentioned above, our training dataset was annotated with sentiment words and phrases, a total of 1,088: 459 positive and 629 negative. These terms form our manually-crafted lexicon.

4.2 Translated Lexicons

As no sentiment polarity lexicons are publicly available for Macedonian, we translated some popular English manually-crafted lexicons such as Bing Liu's lexicon (2,006 positive and 4,783 negative), and MPQA (2,718 positive and 4,912 negative), and a Bulgarian lexicon (5,016 positive and 2,415 negative), extracted from a movie reviews website (Kapukaranov and Nakov, 2015), which includes 694 positive and 2,966 negative English words. We used Google Translate, and we further manually corrected some of the results: we removed some bad translations and we corrected the grammar.

[4] At the 2015 Discriminating between Similar Languages (DSL) shared task (Zampieri et al., 2015), the participating systems distingushed Macedonian from Bulgarian with 100% accuracy, which shows that this is an easy task; as a result, this language pair was not included in the 2016 edition of the task (Malmasi et al., 2016). Our Naïve Bayes classifier achieved slightly lower accuracy as we deal with tweets, which are short and harder to categorize than the newswire texts in the DSL task.

[5] It was previously reported that most tweets are neutral, but this was for English, and for tweets about selected topics (Rosenthal et al., 2014). Here, we have no topic restriction. Moreover, there is an ongoing political crisis in Macedonia, and thus Macedonian tweeps express a lot of emotions rather than staying neutral.

[6] Following (Nakov et al., 2013), we merged *neutral* and *objective* as they are commonly confused by annotators.

4.3 Bootstrapped Lexicons

Various approaches have been proposed in the literature for bootstrapping sentiment polarity lexicons starting from a small set of seeds: positive and negative terms (words and phrases).

A very influential approach is that of Turney (2002), which uses pointwise mutual information and bootstrapping to build a large lexicon and to estimate the semantic orientation of each word in that lexicon. The idea is to start with a small set of seed positive (e.g., *excellent*) and negative words (*bad*), and then to use these words to induce sentiment polarity orientation for new words in a large unannotated set of texts (in his case, product reviews). The idea is that words that co-occur in the same text with positive seed words are likely to be positive, while those that tend to co-occur with negative words are likely to be negative. To quantify this intuition, Turney defines the notion of sentiment orientation (SO) for a term w as follows:

$$SO(w) = pmi(w, pos) - pmi(w, neg)$$

where PMI is the pointwise mutual information, pos and neg are placeholders standing for any of the seed positive and negative terms, respectively, and w is a target word/phrase from the large unannotated set of texts (here tweets).

A positive/negative value for $SO(w)$ indicates positive/negative polarity for w, and its magnitude shows the corresponding sentiment strength. In turn, $pmi(w, pos) = \frac{P(w,pos)}{P(w)P(pos)}$, where $P(w, pos)$ is the probability to see w with any of the seed positive words in the same tweet,[7] $P(w)$ is the probability to see w in any tweet, and $P(pos)$ is the probability to see any of the seed positive words in a tweet; $pmi(w, neg)$ is defined similarly.

The pointwise mutual information (PMI) is a notion from information theory: given two random variables A and B, the mutual information of A and B is the "amount of information" (in units such as bits) obtained about the random variable A, through the random variable B (Church and Hanks, 1990).

Let a and b be two values from the sample space of A and B, respectively. The *pointwise* mutual information between a and b is defined as follows:

$$pmi(a; b) = \log \frac{P(A = a, B = b)}{P(A = a) \cdot P(B = b)} = \log \frac{P(A = a|B = b)}{P(A = a)} \quad (1)$$

$pmi(a; b)$ takes values between $-\infty$, which happens when $P(A = a, B = b) = 0$, and $\min\{-\log P(A = a), -\log P(B = b)\}$, when $P(A = a|B = b) = P(B = b|A = a) = 1$.

In his experiments, Turney (2002) used five positive and five negative words as seeds. His PMI-based approach further served as the basis for the creation of the two above-mentioned large-scale automatic lexicons for sentiment analysis in Twitter for English, initially developed by NRC for their participation in SemEval-2013 (Mohammad et al., 2013). The *Hashtag Sentiment Lexicon* uses as seeds hashtags containing 32 positive and 36 negative words, e.g., `#happy` and `#sad`. Similarly, the *Sentiment140* lexicon uses smileys as seed indicators for positive and negative sentiment, e.g., `:)`, `:-)` and `:))` as positive seeds, and `:(` and `:-(` as negative ones.

Recently, Severyn and Moschitti (2015) proposed an approach to lexicon induction, which, instead of using PMI **(SO)**, assigns positive/negative labels to the unlabeled tweets (based on the seeds), and then trains an SVM classifier on them, using word n-grams as features. These n-grams are then used as lexicon entries with the learned classifier weights as polarity scores.

In our experiments below, we calculate $SO(w)$ using PMI or LR (Logistic Regression[8]), and we experiment with different seeds:

- the 1+1 seeds of Turney (2002), translated to Macedonian ("excellent" and "poor");
- the 7+7 seeds of Turney and Littman (2003), translated to Macedonian;

[7] Here we explain the method using tweets as this is how we are using it, but Turney (2002) actually used page hits in the AltaVista search engine.

[8] LR worked better than SVM in our experiments.

- our 5+5 seeds, manually selected words in Macedonian with strong sentiment;
- 30+30 seeds, which we obtained by translating the 32+36 seeds[9] used for the *Hashtag Sentiment Lexicon* lexicon (but we used these seeds as regular words, not as hashtags);
- the 3+2 smileys from above;
- the 459+629 terms from our manually-crafted lexicon (we further experiment with random proportional positive/negative subsets of 100, 200, and 500 words thereof).

Table 2 shows some statistics about the lexicons we built (unigrams + bigrams) on the unanotated 0.5M tweets. We can see that the larger the seed, the larger the bootstrapped lexicons. Note that the lexicon sizes for PMI and LR are the same as they are calculating the sentiment orientation for the exactly same terms; what differs is the way the weights are being calculated.

Type of seed	Seeds	Unigrams	Bigrams	Total
Smileys: NRC	5	128	2,163	2,291
Words: Turney	10	865	14,343	15,208
Words: NRC	60	1,669	32,459	34128
Words: MCL	100	1,926	40,242	42,168
Words: MCL	200	3,752	60711	64,463
Words: MCL	500	7,219	124,977	132,196
Words: MCL	1,088	9,746	160,526	170,272

Table 2: Statistics about the lexicons we built using bootstrapping with PMI and LR. MCL is the manually-crafted lexicon.

5 The System

Below we describe our baseline system: the preprocessing, and the features used.

5.1 Preprocessing

For pre-processing, we applied various algorithms, which we combined in order to achieve better performance. We used Christopher Potts' tokenizer,[10] and we had to be careful since we had to extract not only the words but also other tokens such as hashtags, emoticons, user names, etc. The pre-processing of the tweets goes as follows:

1. **URL and username removal**: tokens such as URLs and usernames (i.e., tokens starting with `@`) were removed.
2. **Stopword removal**: stopwords were filtered out based on a word list (146 words).
3. **Repeating characters removal**: consecutive character repetitions in a word were removed, e.g., 'какоооо' became 'како' ('what' in English); also were removed repetitions of a word in the same token, e.g., 'дададада' became 'да' ('yes' in English).
4. **Negation handling**: negation was addressed using a predefined list of negation tokens, then the prefix `NEG_CONTEXT_` was attached to the following tokens until a clause-level punctuation mark, in order to annotate it as appearing in a negated context, as suggested in (Pang et al., 2002). A list of 45 negative phrases and words was used to signal negation.

[9] We lost some terms in the process of translation, e.g., because some English words translated to the same Macedonian word.

[10] http://sentiment.christopherpotts.net/tokenizing.html

Seeds for bootstrapping	Source	PMI			LR			PMI + LR
		B	B+S	B+S+M	B	B+S	B+S+M	B+S+M
–	–	–	61.99	78.18	–	61.99	78.18	78.18
1+1 words	(Turney, 2002)	51.48	62.29	78.40	59.82	63.57	78.51	78.89
2+3 smileys	(Mohammad et al., 2013)	61.12	63.81	78.69	65.18	68.99	78.95	79.62
5+5 words	manually-selected	62.55	64.59	79.25	66.70	69.73	80.13	80.87
7+7 words	(Turney and Littman, 2003)	63.02	66.27	79.71	66.98	69.82	80.54	81.99
30+30 words	(Mohammad et al., 2013)	63.47	68.51	79.84	67.28	70.01	80.68	81.33
50+50 words	our MCL	67.11	72.48	80.89	69.79	74.15	81.96	82.73
100+100 words	our MCL	70.94	76.30	82.76	71.41	77.47	84.72	85.45
250+250 words	our MCL	72.25	84.72	92.23	73.76	85.89	93.47	93.55
459+629 words	our MCL	73.82	90.91	94.12	75.29	91.02	94.32	94.44

Table 3: Sentiment classification results (F-score) using lexicons bootstrapped with PMI, LR, or both to calculate $SO(w)$: B = using the bootstrapped lexicon only, B+S = also using non-lexicon features, B+S+M = also using our MCL. The first line shows results when no bootstrapped lexicon is used.

5. **Non-standard to standard word mapping**: non-standard words (slang) were mapped to an appropriate form, according to a manualy crafted predefined list of mappings.

6. **PoS tagging**: rule-based, using a dictionary.

7. **Tagging positive/negative words**: positive and negative words were tagged as `POS` and `NEG`, using sentiment lexicons.

8. **Stemming**: rule-based stemming was performed, which removes or replaces some prefixes and suffixes.

In sum, we started the transformation of an input tweet by converting it to lowercase, followed by removal of URLs and user names. We then normalized some words to Standard Macedonian using a dictionary of 173 known word transformations, and we also removed the stopwords (from a list of 146 words). As part of the transformation, we marked the words in a negated context.

We further created a rule-based stemming algorithm with a list of 65 rules for removing/replacing prefixes and suffixes, inspired by the Porter stemmer (Porter, 1980). We used two groups of rules: 45 rules for affix removal, and 20 rules for affix replacement. Developing a stemmer for Macedonian was challenging as this is a highly inflective language, rich in both inflectional and derivational forms.

5.2 Features

In order to evaluate the impact of the sentiment lexicon, we defined features that are fully or partially dependent on the lexicons. When using multiple lexicons at the same time, there are separate instances of these features for each lexicon. Here are the features we used: number of positive terms, number of negative terms, ratio of the number of positive terms to the number of positive+negative terms, ratio of the number of negative terms to the number of positive+negative terms, sum of all positive scores, sum of all negative scores, sum of all scores, both positive and negative.

For classification, we used logistic regression. Our basic features were TF.IDF-weighted unigrams and bigrams, and also emoticons. We further included additional features that focus on the positive and on the negative terms that occur in the tweet together with their scores in the lexicon. In case of two or more lexicons being used together, we had a copy of each feature for each lexicon.

6 Experiments and Evaluation

Our evaluation setup follows that of the SemEval 2013-2016 task on Sentiment Analysis on Twitter (Nakov et al., 2013; Rosenthal et al., 2014; Rosenthal et al., 2015; Nakov et al., 2016a), and uses an F-score that is the average of the F_1 score for the positive, and the F_1 score for the negative class. Note that, even though implicit, the neutral class still matters in this score. Note also that our focus here is on assessing the impact of our proposed lexicon generation method, and not the classifier itself.

Table 3 shows the results when using each of the bootstrapped lexicons from Table 2. The upper part of the table shows experiments with translations of the seeds used in related work, as described above, while the lower part shows results with (a random subset) of our manually crafted lexicon. We can see that all lexicons outperform the *no bootstrapped lexicons* baseline. The results indicate that our manual lexicon is more useful than the bootstrapping lexicons built using small seeds: it improves over the baseline by 16 points absolute, while the NRC-style or Turney-style lexicons only improve by 2-8 points.

Moreover, using our manually crafted lexicon as a seed for bootstrapping works better than using it as a lexicon: 90.91 vs. 78.18 (with PMI). Moreover, combining it with a bootstrapped lexicon built using all 1,088 words as seeds yields an F-score of 94.12 (with PMI). Note that LR performs better than PMI, by up to four points. Yet, as the last column shows, there is also gain when combining them.

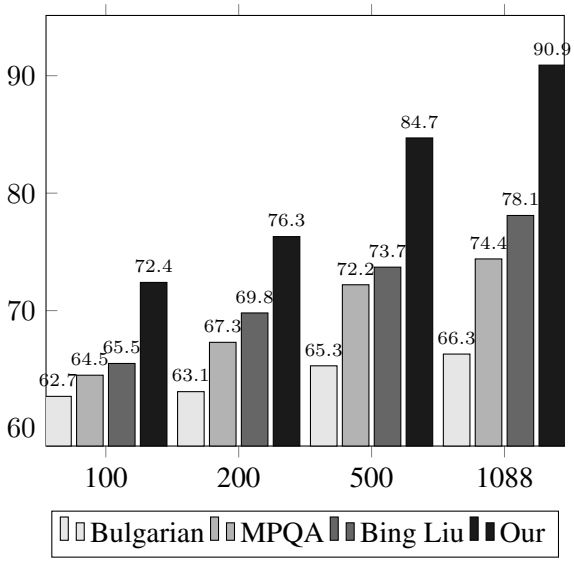

Figure 1: Sentiment polarity classification results (F-score) using different translated bootstrapped lexicons and numbers of seeds with PMI for $SO(w)$, and using B+S as features.

The B+S+M columns in Table 3 show results when using our manually-crafted 1,088-word lexicon as an additional lexicon in each experiment. We can see consistent improvement ranging from 3 to 15 points of F-score absolute on top of the performance of the bootstrapped lexicons. Most interestingly, the bigger the size of the seed, the better the performance of the resulting lexicon (improvement of up to 28 points). So, is it all about the size of the resulting lexicon (as Table 2 shows, bigger seeds yield bigger bootstrapped lexicons)? In order to test this hypothesis, we built bootstrapping lexicons with 100, 200, 500, and 1,088 seeds, with the seeds coming from our lexicons and from the three translated lexicons above. The results are shown in the Figure 1. There are consistent gains as the number of seeds increases, and this is true for seeds coming from our lexicon and also from translations of MPQA, Bing Liu's lexicon, and the Bulgarian lexicon.

However, not all seeds are created equal, even when they are of equal size, and we can see that it is much better to use our manually crafted lexicon as a source of seeds. Yet, if only using 100 seeds from our lexicon, the resulting bootstrapped lexicon would not be able to compete against one built using 1,088 seeds from MPQA or Bing Liu's lexicon. Next, we computed what proportion of each translated lexicon is contained in our lexicon – Bulgarian: 25%, MPQA: 37%, Bing Liu: 43%. We can see that the larger the overlap the better the lexicon, i.e., closer to our domain.

Thus, we can conclude that it is preferable to use (*i*) a *manually-crafted/in-domain lexicon* for the seeds, and (*ii*) a *mid-sized set of seeds*.

7 Conclusion and Future Work

We have presented experiments with different seeds for bootstrapping sentiment polarity lexicons. We have shown that it is best to use (*i*) a *mid-sized seed*, contrary to what is common practice, and (*ii*) a *manually-crafted/in-domain lexicon*, and (*iii*) a classifier such as LR rather than PMI. We have released all our Macedonian lexicons freely for research use.[11]

In future work, we plan experiments for other languages, other sets of seeds, other lexicons, and other learning methods. We further want to study the impact of the raw corpus size, e.g., we could only collect half a million tweets for Macedonian, while Mohammad et al. (2013) used 135 million English tweets. Also, we are interested not only in quantity but also in quality, i.e., in studying the impact of the quality of the individual words when used as seeds. An interesting work in that direction, even though in a different domain and context, is that of (Kozareva and Hovy, 2010).

Abstract

This work investigates whether the development of ideas in writing can be captured by graph properties derived from the text. Focusing on student essays, we represent the essay as a graph, and encode a variety of graph properties including PageRank as features for modeling essay scores related to quality of development. We demonstrate that our approach improves on a state-of-the-art system on the task of holistic scoring of persuasive essays and on the task of scoring narrative essays along the development dimension.

1 Introduction

Development, elaboration and exemplification are important writing skills that come into play in many different genres of writing. In a persuasive essay, to produce good arguments, it is important to substantiate a stance. Similarly, in a story, it is important to develop plot, character and events. Consequently, skill in development is evaluated in essay writing tasks at all levels of education, from primary school to the graduate level. For example, on the Graduate Record Examination (GRE), the scoring guidelines recommend that the top score be assigned to persuasive essays that "develop the position fully with compelling reasons and/or persuasive examples"[1]. Primary school assessments of narrative writing (i.e., stories and personal experiences, real or imagined) also test this skill. For instance, the scoring rubric for one of the U.S. Common Core State Standards tests[2] has a dimension for "elaboration and development", where top scores are given to essays where "experiences, characters, settings and/or events are clearly developed".

Previous research has investigated techniques for the automated assessment of essays by evaluating aspects of writing such as grammar, fluency, and coherence (Shermis and Burstein, 2013; Miltsakaki and Kukich, 2004; Attali and Burstein, 2006; Rus and Niraula, 2012; Stab and Gurevych, 2014b; Somasundaran et al., 2014; Rahimi et al., 2015; Song et al., 2014; Farra et al., 2015). In this work, we investigate how to evaluate the development of ideas and exemplification. Specifically, we explore whether development is reflected in the structure of graphs constructed from the discourse proximity of essay concepts. We construct graphs for each essay where the essay's concepts comprise the nodes and links are formed from concepts occurring in adjacent sentences. We then use properties of each graph, such as PageRank, to predict essay quality, including the quality of development. Our hypothesis is that this novel graph representation can help distinguish essays with well-developed ideas from essays lacking development and elaboration.

We test the effectiveness of our approach on two different essay datasets: holistically scored persuasive essays and trait-scored narrative essays. Our results demonstrate that graph-based features are useful across genres for essay scoring, and improve the performance of models for both holistic scoring and trait scoring. With the addition of these features, we are able to improve on the state of the art in essay scoring.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1568–1578, Osaka, Japan, December 11-17 2016.

The rest of the paper is organized as follows. Section 2 presents our intuitions, methods for graph construction, and features for scoring. Section 3 introduces our data. Experiments and analyses are in Sections 4 and 5, respectively. We discuss related work in Section 6 and conclude in Section 7.

2 Graphs for capturing development

In the process of developing a story or an argument, experienced writers provide detailed, illustrative examples. For example, consider a persuasive essay from Stab and Gurevych (2014a) responding to the prompt "In order to become integrated into society in their adopted countries, immigrants should abandon their old ways and adapt to local customs and codes of behavior. Do you agree or disagree?" The essay, a portion of which is shown in Example 1, takes a stance that immigrants should maintain their cultural identity.

Example 1. The last 50 years have seen an increasing number of immigrants to other countries... However I strongly believe that they are able to sustain their cultural identities and doing so help they keep their origin values.

Firstly, maintaining one's cultural identity is a key important rule to help individuals emerge in the new multicultural environments. Take Australia for example, ...

Secondly, it is crucial to keep ones identity for they need a connection back to their country as well as teach their children their value of origin. For instance, children immigrated to a new country will face social troubles ...

To conclude, ...

The writer first takes a stance that immigrants should sustain their identities. He then presents a claim ("maintaining one's cultural identity is a key important rule...") and then develops this idea ("Take Australia for example, ..."). Once this example is discussed, the writer moves on to another claim and example. The writer concludes by reiterating the main stance.

Intuitively, the linguistic correlates of development are new words related to sub-topics and allied topics that writers introduce into the discourse to support or illustrate their main points. Rather than repeating the same vocabulary over and over, writers enrich the vocabulary of the essay as they develop examples. The discourse flow is also affected by development – when claims and examples are developed, vocabulary associated with the main topic or stance is suspended, then revived when the discussion of the example is complete. In more detail, as the reader moves from sentence to sentence in an essay, he encounters concepts that either have been previously introduced or that are new to the discourse. When there is a repetition of ideas across the essay, the reader encounters the same concepts over and over again. On the other hand, when an example is introduced (e.g., to support a claim or to develop an idea), the reader encounters new concepts. As the example is developed further in successive sentences, the reader continues to move between concepts pertaining to this example and tends not to encounter concepts from the main topic of the essay. When the example is complete, the reader again encounters words pertaining to the main topic or stance. In a typical essay, this process repeats as the writer moves between presenting the main topic claims and detailed examples to develop the claims.

This type of development structure is also often evident in skillful narrative storytelling. After a character or situation is introduced, it may be described or fleshed out (via background information, vivid descriptions, etc.) before the writer returns to the main story line. The writer may briefly digress from the main goal of the story to add plot, character, and situation details.

2.1 Essay as a Graph

We construct graphs from essays by representing each content word in a sentence as a node in the graph. Content words are found by filtering out all words less than 4 characters long. This filtering removes function words such as "a" and "the" as well as punctuation. Other than this filtering, we use all the words in the essay, as is, to construct nodes. That is, we do not use lemmatization or synonymy to collapse similar words. Links are created from all nodes in one sentence to nodes in the following sentence to simulate the reader's movement from sentence to sentence. At this point, the nodes in the graph correspond to tokens in the essay, and any given node has as its neighbors all nodes from the previous and next sentence. Next, the nodes corresponding to the same word token are collapsed to a single node representing the word type, converting the graph of word tokens to a graph of word types. All links from collapsing nodes are added to their respective collapsed nodes. This collapsing process gives words that are repeated multiple times in the essay many more neighbors than words that occur

just once. Finally, multiple links between two nodes are collapsed into a single weighted link, where the weight is equal to the number of links between the two nodes.

We hypothesize that the structure of graphs constructed in this way can distinguish essays where there is no development from essays where ideas are developed in detail. For instance, if a writer repeats the same idea over and over, the corresponding graph will have nodes (corresponding to repeated ideas) that are heavily linked to other nodes. When an idea is not developed, the nodes corresponding to this idea will tend to have very few neighbors.

2.2 Graph Characteristics

Node degree The number of neighbors that a node has can indicate how it is connected to other concepts in the discourse. If a node has high degree, it is connected to more concepts, indicating that it has occurred in more contexts. Similarly, a node with low degree is sparsely connected to other nodes, corresponding to a concept that is mentioned in passing, without being developed. A large number of such sparsely connected nodes in an essay might indicate underdeveloped ideas.

PageRank PageRank (Brin and Page, 1998) emulates a "random surfer" on a graph. In our graph, this random surfer will move from concept to concept. PageRank is influenced by both the number of nodes and by the structure of the graph.

The number of nodes in the graph is influenced by the number of unique concepts in an essay. When an essay is characterized by development, we expect that more concepts get introduced into the discourse. On the other hand, mere repetition will not increase the number of nodes in the graph. The larger the graph, the lower the PageRank value assigned to individual nodes (if link characteristics remain constant).

Node count (i.e., unique concepts) remaining constant, the link structure of the graph is influenced by both development and repetition. When an example is well developed, the nodes corresponding to this development will form a well connected sub-graph. Consequently, there will be a shift in the distribution of PageRank values to reflect the fact that the random surfer is likely to visit these nodes with comparable probabilities as the nodes of the main theme or stance. When there is little development, PageRank values will be skewed and concentrated on a few nodes. Similarly, if an idea is repeated many times in the essay, the corresponding set of nodes will have very high connectivity, thus obtaining high PageRank values.

2.3 Graph Features

With the goal of encoding the graph characteristics described above, we developed 19 features: 6 features based on degree, one feature designed to capture the basic connectivity of the graph, and 12 features based on PageRank.

Features based on degree: We use three features to capture underdeveloped ideas: percentage of nodes in the graph with degree one (*perNodesDeg1*), percentage of nodes in the graph with degree two (*perNodesDeg2*), and percentage of nodes in the graph with degree three (*perNodesDeg3*). A node can get one neighbor if everything in the previous and next sentence (except for one word type) gets filtered out. Recall that, during graph construction, words with fewer than 4 characters are filtered out as non-content. For example, the sentence "I can say in the end it may be all good" will have only one resulting node in the graph.

Two features encode the degree of the two top most connected nodes in the graph: *degreeTop1* and *degreeTop2*. A third feature, *degreeMed*, is the median degree and encodes the general connectivity structure of the graph. Finally, the *starScore* feature aims to capture the extent to which the graph has a star-like appearance: the number of links from the node with the highest degree divided by the total number of links in the graph.

Features based on PageRank We have three features corresponding to the top three PageRank values in the graph (*prTop1*, *prTop2* and *prTop3*), and one feature, *prMed*, corresponding to the median PageRank value. As PageRank values tend to be very small numbers, we create negative log versions of the features: *prTop1Log*, *prTop2Log*, *prTop3Log* and *prMedLog*. Finally, the size of the graph can influence PageRank values. Specifically, given two nodes with the same type of linking structure, the node in a

larger graph (i.e., a graph with more nodes) will receive a smaller PageRank value. To mitigate this effect, we create a new set of PageRank-based features in which the values of the original PageRank features are multiplied by the total number of nodes in the graph, producing node count-normalized features. These features are: *prTop1NodeNorm*, *prTop2NodeNorm* and *prTop3NodeNorm* and *prMedNodeNorm*. While the 12 proposed features are correlated, in our experiments we use an Elastic Net learner (Zou and Hastie, 2005), which is designed for the case of groups of correlated features and performs automatic feature selection.

3 Data

To test our hypotheses, we carried out experiments in two different genres using two different datasets.

The first dataset, *persuasive*, is comprised of 1000 persuasive essays written by test takers from a high stakes assessment. The essays are holistically scored on an integer scale from 1 to 6 (with score point 6 assigned to excellent essays). The data distribution for each score point is as follows: score 0 = 0.3%; score 1 = 2%; score 2 = 12.3%; score 3 = 42.3%; score 4 = 33.6%; score 5 = 8.4%; score 6 = 1.1%. Essays were scored by expert human annotators trained in operational essay scoring. Holistic scores were assigned based on writing proficiency displayed in analyzing an issue topic. Scores take into account a number of factors such as organization, development, language fluency, use of proper grammar, mechanics, and language conventions. With this dataset, we investigate if and how development in the form of developing a persuasive stance is captured by our approach.

The second dataset, *narrative*, is obtained from the Criterion® writing evaluation system[3] and is comprised of 590 narrative essays written by middle and high school students. These essays were scored based on a rubric developed by the Smarter Balanced Assessment Consortium[4] for assessing narrative essays[5]. The rubrics assign three separate "trait" scores to each essay for the dimensions of Organization, Development, and Conventions. The scores for the Organization and Development traits are on an integer scale from 0 ("non-scorable") to 4 ("excellent"), and the score for Conventions is on a 3 point scale from 0 ('little or no command of conventions") to 2 ("excellent"). The data distribution is as follows:
Organization: score 0 = 4.9%; score 1 = 5.4%; score 2 = 27.3%; score 3 = 32.0%; score 4 = 30.4%.
Development: score 0 = 4.9%; score 1 = 6.6%; score 2 = 34.1%; score 3 = 28.5%; score 4 = 25.9%.
Conventions: score 0 = 9.7%; score 1 = 47.1%; score 2 = 43.2%.

Inter-annotator agreement is calculated using quadratic weighted kappa (QWK) (Cohen, 1968). QWK for the three dimensions was: Organization = 0.726; Development = 0.741; Conventions = 0.459. Correlation between the dimension scores (Pearson's r) are: Conventions and Organization = 0.41; Conventions and Development= 0.43; Organization and Development = 0.89. This dataset allows us to test if the proposed features work across different genres of writing. Additionally, as this data is scored separately along the development dimension, it allows us to test if our approach indeed captures development.

4 Experiments

We performed 10-fold cross validation experiments on the *persuasive* and *narrative* datasets to evaluate whether our proposed graph-based features help predict scores of essay quality and development. We used Gephi (Bastian et al., 2009) for generating the graph features listed in Section 2.3. All default parameters were used (epsilon, probability and number of iterations). We compared our proposed features with two baseline feature sets. Performance was measured with Quadratic Weighted Kappa (QWK) (Cohen, 1968), a common metric for measuring essay scoring performance. QWK scores are averaged across the 10 folds. We used a bootstrap significance test (Berg-Kirkpatrick et al., 2012; Zhang et al., 2004) to test if improvements over baselines are significant. We used the Elastic Net implementation from scikit-learn (Pedregosa et al., 2011)[6].

[6]Results using Lasso and ridge regression were similar.

4.1 Baselines

e-rater Features (eRaterFeat) E-rater (Attali and Burstein, 2006), a state-of-the-art system for automatic essay scoring, uses a comprehensive set of features covering many aspects of writing quality, such as grammar, language use, mechanics, fluency, style, organization, and development. We use the e-rater feature set as a baseline and compare with our proposed features by employing the same learning algorithm over both feature sets. Development in eRaterFeat is captured by a feature that sums up the counts of the thesis, main points, supporting ideas, and conclusion elements in the essay, where the individual elements (e.g., supporting ideas) are identified in a separate step as described in Burstein et al. (2003).

We investigate how our graph-based features perform in comparison to the eRaterFeat feature set and in combination with it. Specifically, for holistic scoring, we hypothesize that graph features will improve over eRaterFeat performance by improving construct coverage. For trait scoring of development, we hypothesize that the graph-based features will perform as well or better than eRaterFeat since the graph-based feature set is designed to capture this trait.

Lexical Diversity Baseline (lexdiv) As discussed in Section 2, development and exemplification introduce new concepts into the discourse. A simple measure of lexical diversity is the type-token ratio, the ratio of the count of unique word types to the count of word tokens in the essay. To ascertain whether the graph features do more than capture lexical diversity in the essay, we employ the type-token ratio as a baseline. We refer to this feature as *lexdiv*. While we do not expect this single feature to perform well by itself for holistic scoring, our goal is to test if its combination with eRaterFeat produces similar or better performance to that achieved by the combination of graph features to eRaterFeat.

4.2 Results

All features (baseline and proposed) are extracted for all essays in both datasets. For the *persuasive* dataset, the features are used to predict the target holistic score. For the *narrative* dataset, the features are used to train three separate systems, one for predicting each trait score.

Table 1 reports the results of the feature sets (individually and in combination) for holistic scoring of persuasive essays. Statistically significant improvements over eRaterFeat (E) are indicated with * for $p < 0.05$ and ** for $p < 0.005$. All feature sets significantly outperform the lexdiv baseline ($p < 0.005$); to reduce clutter, we omit these significance results in the tables. At the level of individual feature sets, eRaterFeat is the best performer. This is expected, as eRaterFeat uses a suite of features capturing a variety of language proficiency measures that the holistic score represents, while the graph-based (and lexdiv) features capture only one aspect of writing. The lexdiv baseline is a poor performer, not substantially improving the performance of any system or system combination to which it is added.

Notably, when graph features are added to eRaterFeat features (eRaterFeat+graph), there is a significant boost in performance of 4 percentage points. This result is promising, as it indicates that graph features capture a part of the construct previously not covered in the state of the art.

Feature set	Holistic
Combinations	
all	0.73 (E**)
eRaterFeat+graph	0.73 (E**)
eRaterFeat+lexdiv	0.69 (E**)
graph+lexdiv	0.64
Individual	
graph	0.63
eRaterFeat	0.69
lexdiv	-0.01

Table 1: Performance (QWK) of feature sets on holistic scoring on the persuasive dataset. "all" = eRaterFeat+graph+lexdiv.

Feature set	Conv.	Org.	Dev.
Combinations			
all	0.34	0.50	0.57 (E**)
eRaterFeat+graph	0.36	0.51	0.57 (E**)
eRaterFeat+lexdiv	0.37	0.50	0.54
graph+lexdiv	0.23	0.51	0.55
Individual			
graph	0.24	0.51	0.56 (E*)
eRaterFeat	0.36	0.49	0.52
lexdiv	-0.01	0.11	0.12

Table 2: Performance (QWK) of feature sets on trait scoring (Conventions, Organization, Development) on the narrative dataset. "all" = eRaterFeat+graph+lexdiv.

Table 2 reports the performance of the different feature sets and their combinations on trait scoring of narrative essays. In general, the QWK values are lower than those in Table 1, suggesting that scoring of stories is a much harder task. As expected, eRaterFeat is the best performing individual feature set for Conventions; graph and lexdiv features are not designed to score this aspect of writing. There is a slight improvement in eRaterFeat performance when lexdiv is added (eRaterFeat+lexdiv), but this improvement is not significant over eRaterFeat individually.

For Organization the graph features are the best performing individual feature set. In combination with eRaterFeat (eRaterFeat+graph), QWK remains the same. However, in neither case is there a statistically significant improvement. Nevertheless, this result is interesting, as it shows that graph features, while intended to capture development, are able to predict Organization scores at least as well as a well-established system. We believe this is presumably because the Organization and Development traits are correlated.

Confirming our hypothesis, the graph feature set is the best performer for scoring Development. The graph feature set individually improves on eRaterFeat by 4 percentage points, a significant difference ($p < 0.05$). This result is notable as it shows that the graph features indeed capture the Development construct much more effectively than the features in eRaterFeat. When graph and eRaterFeat features are combined (eRaterFeat+graph), there is an additional 1 point improvement over eRaterFeat alone.

5 Analysis

Our results provide strong evidence that the graph-based feature set is useful for essay scoring. In this section, we examine in more detail how the graph features are related to the Development score from the *narrative* dataset.

5.1 Correlation Analysis

We employed correlation analysis to study the relationship of each of our graph features with Development trait scores. Table 3 lists the correlation (Pearson's *r*) between each degree-based graph feature and its correlation with Development scores. All features except *perNodeDeg1* and *perNodeDeg3* have medium (> 0.3) to low (between 0.1 and 0.3) correlation with scores (significant at $p < 0.005$). The features encoding values of the higher degree of nodes, *degreeTop1* and *degreeTop2*, are positively correlated with scores. This indicates that the higher the connection of central ideas to other concepts, the better the development of the essay. Interestingly, *starScore* is negatively correlated with Development scores, suggesting that essays where most of the links represent connections to a single idea have little or no development.

Feature set	Corr.	Partial Corr.
degreeTop1	0.41*	0.00
degreeTop2	0.39*	0.01
degreeMed	0.24*	0.09
perNodesDeg3	-0.04	0.05
perNodesDeg1	-0.07	-0.03
perNodesDeg2	-0.12*	-0.03
starScore	-0.31*	-0.12 *

Table 3: Correlation and partial correlation (controlling for length) of node degree-based features with Development trait scores. * = significant at $p < 0.005$.

Feature set	Corr.	Partial Corr.
prMedLog	0.63 *	0.35 *
prTop3Log	0.57 *	0.31 *
prTop2Log	0.56 *	0.30 *
prTop1Log	0.52 *	0.27 *
prTop3NodeNorm	0.49 *	0.09
prTop2NodeNorm	0.44 *	0.07
prTop1NodeNorm	0.41 *	0.05
prMedNodeNorm	0.06	0.10
prTop1	-0.33 *	-0.20 *
prTop2	-0.41 *	-0.22 *
prTop3	-0.48 *	-0.23 *
prMed	-0.48 *	-0.26 *

Table 4: Correlation and partial correlation (controlling for length) of PageRank-based features with Development trait scores. * = significant at $p < 0.005$.

In Table 4 we see that all features based on PageRank, with the exception of *prMedNodeNorm*, are moderately or highly correlated with development ($p < 0.005$). All of the raw PageRank features show a negative correlation with Development scores, which implies that the lower the highest PageRank values, better the development of the essay. This happens when: (1) there are more nodes in the graph (indicating a large number of concepts in the essay); (2) the links for a graph are more distributed. Such decentralization indicates that the writer emphasizes the detailed development of multiple concepts and tends not to repeat a single concept. The negative log and nodeNorm counterparts of the raw features are naturally positively correlated with the scores.

Indeed, it is impossible to develop an idea or character without using additional words. As a result, longer essays may receive higher scores. The graph-based features are also naturally affected by essay length. Nevertheless, it is informative to investigate if a feature has predictive value even after the effect of essay length is removed. Looking at the partial correlations (accounting for length) in Tables 3 and 4 (Partial Corr. column), the node degree-based *starScore* feature and all PageRank-based features with the exception of *nodeNorm features retain their respective correlations with Development scores ($p < 0.005$), albeit to a smaller degree.

5.2 Qualitative Analysis

To explore whether the graph features indeed encode the intuitions discussed in Section 2, we modified the contents of the sample essay discussed in Example 1 in various ways to simulate a lack of development and repetition of ideas. This essay is very similar to the persuasive essays in our dataset[7]. In each simulated essay, we maintained the length of the original as much as possible so that we could see the effect of the parameters we varied. We simulated different scenarios:

No development (no-dev): This simulates a scenario where the writer does not expand beyond the main stance or theme. We replaced the second and third paragraphs of the essay with the first paragraph (which contains the main stance).

Vague development (vague-dev): This simulates a scenario where the writer provides vague development for the main stance, but does not fully elaborate on the main claims. We deleted the examples in the second and third paragraphs (i.e., the text spans "Take Australia ..." and "For instance ...", respectively). Note that this results in an essay that is smaller than the original.

Vague development with repetition (vague-dev-rep): This simulates a scenario where the writer reiterates an idea multiple times, without substantially developing it. Similar to vague-dev, the text of the examples are deleted, but in this case they are replaced by the first sentence of the corresponding paragraph ("Firstly, ..." and "Secondly, ...", respectively). The number of words approximately matches the original, so that the simulated essay is similar in length to the original.

essay	length	degreeTop1	degreeTop2	starScore	prTop1Log	prTop2Log	prTop3Log	prMedLog
original	2025	67	65	0.073	3.460	3.485	3.813	4.742
vague-dev-rep	2033	34	29	0.102	3.093	3.373	3.400	3.862
vague-dev	1005	33	28	0.115	3.031	3.204	3.218	3.929
no-dev	2026	24	24	0.155	2.697	2.697	3.200	3.200

Table 5: Graph-based feature values under different simulated conditions of essay development. *length* = number of characters.

Table 5 shows several graph features computed from the different scenarios (we reproduce only a subset of features due to space limitations). Notice that all features show sensitivity to the type of development. The degree-based features (*degreeTop1*, *degreeTop2*) and PageRank-based features (*prTop1Log*, *prTop2Log*, *prTop3Log*) rank the essays from worst to best in the order: no-dev, vague-dev, vague-dev-rep, original. These features rank the vague development (vague-dev) essay higher than no development (no-dev) essay, even though the latter is a longer essay. The *starScore* feature ranks the essays in the same order, keeping in mind that this feature is negatively correlated with Development scores. The *prMedLog* feature, which is most highly correlated Development scores in Table 4, ranks vague develop-

[7]Due to the proprietary nature of our datasets, we are not able to reproduce actual essays.

ment (vague-dev) higher than vague development with additional repetition (vague-dev-rep), penalizing repetition that contains the same amount of development.

6 Related Work

Entity-based approaches to discourse coherence focus on the distribution of entities in discourse, under the assumption that a patterned focus on discourse entities is indicative of greater topic continuity. Barzilay and Lapata (2008) formalize these intuitions to predict coherence. Their work has been extended in a number of ways, such as adding sentence-to-sentence sequences based on predicted discourse relations (Lin et al., 2011; Feng et al., 2014), adding information about topics (Elsner and Charniak, 2011), and incorporating other linguistic features (Eisner and Charniak, 2011). Burstein et al. (2010) employ this idea for evaluating coherence in student essays. Morris and Hirst (1991) connect highly related words in the discourse to create chains, which indicate cohesion of ideas in text. This idea is employed in the context of essay evaluation by Somasundaran et al. (2014) to capture discourse coherence quality. Our approach does not evaluate discourse coherence and does not employ cohesion-based relations. Rather, we use discourse-based proximity relations to evaluate the development of ideas.

Hearst's TextTiling algorithm (Hearst, 1997) captures some elaboration of subtopics by measuring the differences of word profiles between discourse segments. Our work also captures the use of subtopics, but we do not address the issue of text segmentation.

Guinaudeau and Strube (2013) build a graph representation of entities and sentences to predict sentence ordering, summary coherence, and readability. Mesgar and Strube (2015) extend this graph representation by adding rhetorical relations, and use subgraph mining techniques improve readability classification accuracy. Petersen et al. (2015) leverage the graph representation of Guinaudeau and Strube to compute a variety of graph-based metrics to measure coherence, including PageRank, and show that these features improve the relevance of IR results. In contrast with these lines of work, our graph structure only contains nodes for words, not sentences, and edges are inserted for words in consecutive sentences. Additionally, our goal is to predict essay scores, focusing on capturing the development trait.

In argumentative writing, it has been observed that support and elaboration plays an important role in overall comprehensibility (Garing, 2014; Duterte-Angeles, 2005). Miltsakaki and Kukich (2004) developed the concept of "rough shifts" in discourse and found that more rough shifts and less elaboration negatively correlated with essay score. In related work, O'Rourke et al. (2011) develop a method to measure the semantic or topic flow of essays. Rahimi et al. (2015) tie together the concepts of discourse coherence, essay organization, and argumentation for scoring short answers. Farra et al. (2015) evaluate whether a given opinion is topically relevant to the persuasive goal in student essays. These works are complementary to ours: while these approaches do not penalize repetition and lack of development, our approach is not sensitive to topicality and organization.

Stab and Gurevych (2014b) propose methods for identifying argumentation components in persuasive essays, including claims and premises. Peldszus and Stede (2015) demonstrate how the resulting graphs of argument components and their relations can be parsed into discourse structure. Song et al. (2014) as well as Ghosh et al. (2016) explore features specific to argumentation and argumentation schemes. While our features capture elaboration in persuasive essays, they are not tied to the specifics of argumentation, and we demonstrate the applicability of these features across genres. Along similar lines, previous work in narrative evaluation (Evanini and Wang, 2013; Hassanali et al., 2013; Somasundaran et al., 2015) explores features that are complementary to ours.

Within the area of predicting text quality more generally, researchers have focused on readability and text complexity using a variety of features such as entity grid features (Pitler and Nenkova, 2008), language model-based features (Kate et al., 2010; Feng et al., 2010), grade-level features (Qumsiyeh and Ng, 2011). Jiang et al. (2015) uses a graph representation to predict readability.

7 Conclusion

Evaluation of development is a relatively less investigated aspect in writing evaluation. In this work, we examined whether writing development can be represented in the properties of simple graphs computed

from the structure of essays. From our graph representation of word types and sentence-adjacency links, to capture development, we computed both graph structural features based on node degree and PageRank features. To the best of our knowledge, this is the first work on employing graphs to capture this aspect of writing.

We performed experiments to show that our approach complements previously established features in essay scoring. Specifically, we demonstrated that our feature set significantly improves on the state of the art for holistic essay scoring. For trait scoring, we showed that our features are more effective in capturing writing development than existing feature sets. As part of this investigation, we also explored automated scoring of narratives, a relatively less explored genre of student writing. Results across genres (persuasive and narrative) and scoring granularity (holistic and trait) demonstrated that graph-based features are effective at capturing development in writing.

In future work we plan to explore ways to incorporate and represent more information in the graphs, such as discourse relations, morphological variants, equivalence classes of semantically similar words and synonyms, as well as examine performance trends on publicly available essay datasets.

Selective Co-occurrences for Word-Emotion Association

Ameeta Agrawal and Aijun An
Department of Electrical Engineering and Computer Science
York University, Toronto, Canada
{ameeta,aan}@cse.yorku.ca

Abstract

Emotion classification from text typically requires some degree of word-emotion association, either gathered from pre-existing emotion lexicons or calculated using some measure of semantic relatedness. Most emotion lexicons contain a fixed number of emotion categories and provide a rather limited coverage. Current measures of computing semantic relatedness, on the other hand, do not adapt well to the specific task of word-emotion association and therefore, yield average results. In this work, we propose an unsupervised method of learning word-emotion association from large text corpora, called **Se**lective **Co**-occurrences (SECO), by leveraging the property of mutual exclusivity generally exhibited by emotions. Extensive evaluation, using just one seed word per emotion category, indicates the effectiveness of the proposed approach over three emotion lexicons and two state-of-the-art models of word embeddings on three datasets from different domains.

1 Introduction

Emotion detection from text is the task of identifying emotions from natural language data such as user reviews, blogs, news articles, etc. (Alm et al., 2005; Aman and Szpakowicz, 2007). Although there is no strict definition for emotion, most researchers agree that it is a particular feeling that characterizes the state of mind such as happiness, anger, sadness and so on. Emotion analysis is extremely popular in the field of market research, where brands tap into their customer base by analyzing user-generated data, readily available nowadays due to the rapid growth of social media (De Bondt et al., 2013; Shrum et al., 2013). Mohammad and Turney (2013) present a more extensive list of applications.

Emotion detection from text typically requires some degree of *word-emotion association*, i.e., knowing which words are more appropriately associated with which emotions. For example, the word *"accident"* can be considered associated with the emotion SADNESS. This association can be obtained from a pre-compiled emotion lexicon or calculated using some measure of semantic relatedness. The currently available manually annotated emotion lexicons tend to be restricted in size due to the expensive process of human annotation. This limited coverage leads to the undesirable effect of leaving too many words unassociated with any emotion category. Moreover, most lexicons contain a small fixed set of emotions which is unsuitable for a larger (Du et al., 2014) or a newly defined set of emotions (Facebook, 2016). On the other hand, while automatically computing word-emotion association scores from text corpora possibly provides a better coverage and more flexibility, the current techniques are ill-suited to the task of emotion detection and therefore, tend to yield average results.

To address these issues, in this work, we propose an unsupervised method of learning word-emotion association scores from text corpora, which we call **Se**lective **Co**-occcurences (SECO). By modifying conventional co-occurrence-based methods, we compute a uni-directional asymmetric association between a given word and an emotion seed word. The proposed approach is found to be better at capturing the association between words and emotions than general purpose measures. Extensive evaluation of word-emotion association scores derived from two large text corpora, Wikipedia and Amazon reviews,

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1579–1590, Osaka, Japan, December 11-17 2016.

on three emotion datasets from very diverse domains demonstrates the effectiveness of employing selective co-occurrences. The proposed approach is particularly interesting as it requires no training data and can be applied to a flexible number of emotion categories.

The remainder of this paper is organized as follows. In Section 2, we survey the related work. In Section 3, we describe the learning of the word-emotion association scores and their use in the task of emotion classification. Section 4 describes the evaluation setup, while Section 5 analyzes the experimental results. Lastly, Section 6 concludes the paper with a brief look at future work.

2 Related Work

In this section, we present the existing emotion lexicons, manually annotated as well as those created using supervised machine learning, and also discuss the measures of semantic relatedness that have been previously employed to derive word-emotion association for emotion classification.

2.1 Emotion Lexicons

2.1.1 Manually Annotated Lexicons

One of the earliest and most popular emotion resources is the WordNet Affect (Strapparava and Valitutti, 2004), developed by manually labelling about 1,314 synsets with one or more of Ekman's (1992) six basic emotions. Using crowd-sourcing, one of the largest manually annotated emotion lexicons created to date is the NRC Emotion Lexicon (EmoLex) (Mohammad and Turney, 2010; Mohammad and Turney, 2013). It contains about 14,200 unigrams annotated with one or more of Plutchik's eight emotions (Plutchik, 2001). Another manually created lexicon, the Affect database (Neviarouskaya et al., 2007), contains a total of 2,440 entries (emoticons, acronyms, words and modifiers) annotated by three annotators using nine emotion labels as well as their intensities. Considering the fundamental role played by lexical resources in the task of emotion detection, the current options available due to manual lexicons seem rather limited in their coverage. Human annotation, including crowd-sourcing, requires considerable lexicographic expertise, time and effort. An alternative approach involves creating such lexical resources automatically.

2.1.2 Automatically Acquired Lexicons

More recently, DepecheMood (Staiano and Guerini, 2014), was created using supervised training by applying distributional semantics to a dataset of crowd-annotated news articles. This lexicon consists of 37,000 words and their emotion scores across seven emotions. A different approach of generating an emotion lexicon (18,000 words and 8 emotions) involves using the Google n-grams corpus to expand an existing, smaller human-annotated lexicon such as the EmoLex (Perrie et al., 2013). Although these approaches cover a larger vocabulary, they are limited to the emotion categories of the source corpus or the lexicon which they use for training.

2.2 Measures of Semantic Relatedness

Statistical approaches that leverage large text corpora provide an alternative way of acquiring word-emotion association scores, which can remedy the problem of unseen vocabulary to a large extent. As these approaches employ just a handful of emotion seed words to initialize the process, they are also applicable to a flexible number of emotion categories. Many models of computing word semantic relatedness exist, from the traditional count-based methods such as Pointwise Mutual Information (PMI) to the more recent neural-network inspired models of word embeddings such as Continuous Bag of Words (CBOW). While the models differ in their algorithms, they are fundamentally based on the intuitive assumption that co-occurring words tend to be related to each other.

Previously, PMI has been used to classify emotions in news headlines, where the probabilities of words were calculated using statistics collected from three search engines (Kozareva et al., 2007). Wikipedia has also proven a useful resource for calculating word frequencies using PMI to obtain word-emotion association scores (Agrawal and An, 2012). Alternatively, PMI has been used to first build an emotion lexicon which is then used for classification (Yang et al., 2007). Latent Semantic Analysis (LSA)

(Deerwester et al., 1990), which analyzes the statistical relationships among words in a corpus using Singular Value Decomposition (SVD) dimensionality reduction technique, was used to calculate word-emotion association scores to classify news headlines (Strapparava and Mihalcea, 2008).

Despite, and perhaps because of, its simplicity, PMI (Church and Hanks, 1990) has long been a popular measure of semantic relatedness. It estimates the similarity between two terms x and y as $PMI\,(x,y) = \log\left(\frac{p(x,y)}{p(x)p(y)}\right)$, where $p\,(x,y)$ is the probability that words x and y co-occur within a window of specific length, and $p\,(x)$ and $p\,(y)$ are the individual probabilities of word x and word y, respectively, in the corpus. To overcome a few well-known shortcomings of PMI (i.e., low frequency events receiving relatively high scores, lack of a fixed upper bound), Bouma (2009) proposed a normalized version of PMI (NPMI), where $NPMI\,(x,y) = \frac{PMI(x,y)}{-\log\,p(x,y)}$, with fixed orientation values: when two words only occur together, NPMI$(x,y) = 1$; when they are distributed as expected under independence, NPMI$(x,y) = 0$; and, when they occur separately but not together, NPMI$(x,y) = -1$.

More recently proposed neural-network based approaches, such as Continuous Bag-of-Words (CBOW) and Skip-Gram (SG) (Mikolov et al., 2013b; Mikolov et al., 2013a) output word embeddings which can then be used to compute the similarity between two words by calculating their cosine similarity. These methods implicitly factorize a word-context matrix whose cell values are in fact shifted PMI (Levy and Goldberg, 2014) and have outperformed traditional count-based methods such as PMI on many similarity-oriented tasks (Marco Baroni, Georgiana Dinu, 2014).

While these measures of semantic relatedness provide promising results on most word similarity tasks, they do not adapt well to emotion detection. We build upon these latest advancements by proposing a variant that is more suitable to the task at hand.

3 Word-emotion Association for Emotion Classification

Given a sentence s and a set $E = \{e_1, e_2, \ldots, e_g\}$ of g emotion categories, the objective is to label s with the best possible emotion $e \in E$. We first discuss our proposed method for deriving the word-emotion association scores between a word and an emotion category, and then use these scores to obtain an emotion label for each sentence.

3.1 Learning Word-emotion Association

Let $W = \{w_1, w_2, \ldots, w_n\}$ be a set of n cue words in an input sentence s, where $W \subset s$. A cue word is defined as any word within a sentence that could have some emotional connotation. Usually, these are the nouns, adjectives, verbs and adverbs. Let $E = \{e_1, e_2, \ldots, e_g\}$ be a set of g emotion categories. Each emotion category $e_j \subset E$ is represented by one or more emotion seed words. Let T be the set of all the seed words for all the emotion categories, $T_j \subset \mathrm{T}$ and $T_j = \{t_{j_1}, t_{j_2}, \ldots, t_{j_m}\}$ be the set of m emotion seed words for each emotion category $e_j \subset E$.

As an illustration, consider the sentence "*We are going to a party tonight*". Here, the set of cue words includes $W = \{going, party, tonight\}$. If the classification scheme follows, for example, Ekman's (1992) model of emotions, then $E = \{anger, disgust, fear, happiness, sadness, surprise\}$. The set of seed words for HAPPINESS could be $T_{happiness} = \{happy, joy, ...\}$ and ANGER's seed words could be $T_{anger} = \{angry, mad, \ldots\}$.

We adopt the $\rightarrow$ symbol to denote the association between a cue word w and an emotion seed word t. The first step is to derive the association scores between a cue word and every seed word, e.g., $Assoc.\,(party \rightarrow joy)$, $Assoc.\,(party \rightarrow angry)$. Since our main goal is to acquire *association scores for emotion classification*, the design choices for our proposed measure of learning word-emotion association scores, SECO, are largely motivated by the following observations:

- The intrinsic process of annotating an emotion dataset as well as that of classifying it is uni-directional, i.e., given a word or a sentence, the task is to label it with the emotion it evokes the most.
- Although expressions of emotions can sometimes be fuzzy, most words primarily evoke only one emotion in a particular context, i.e., the emotion categories are, for the most part, mutually exclusive.

In fact, in the emotion lexicon WordNet Affect (Strapparava and Valitutti, 2004), which has words annotated with more than one emotion, about 98.7% of the terms are labelled with just one emotion.

- Most importantly, unlike other word relatedness tasks, the second half of the association pair (i.e., emotion seed words) in this particular task are known in advance.

These observations lead us to hypothesize that an asymmetric measure of association, where a word's association with an emotion seed word (and therefore by extension, with an emotion category) may be more meaningful than trying to achieve a symmetric bi-directional association between the two. In fact, as Tversky (1977) notes, certain linguistic relationships are characteristically asymmetric . In one experiment to list the first meaningfully related word that comes to mind, for the cue word *fear*, 24% of the participants answered *scared*, while only 9% of them recalled *fear* when given the cue word *scared*, suggesting an inherent asymmetry in word associations (Altarriba et al., 1999).

As noted earlier, traditional co-occurrence based models of semantic relatedness consider two words as co-occurring when both the words appear within a specific window of text, no matter how far they are from each other. In reality, nearer words have been found to exhibit stronger relationships (Beeferman et al., 1997).

In similar essence, emotions generally exhibit the property of mutual exclusivity and therefore, we propose the concept of selective co-occurrences (SECO), where a cue word is considered as co-occurring with only one emotion's seed words within any particular window of text. Consider Fig. 1 containing an example window of text, the cue word "*party*", and two seed words "*angry*" and "*happy*", representing the two different emotion categories respectively. To apply selective co-occurrences, the cue word "*party*" is considered co-occurring with either "*angry*" or "*happy*", not both.

> Theater critic Michael Riedel (playing himself) also shows up, uninvited. Ivy is put out by this and gets **angry** at Michael about it. We hear but don't see Ivy singing "Bittersweet Symphony" at her **party**. Derek then walks in and gives her a present and wishes her **happy** birthday.

Figure 1: Sample window of text containing cue and seed words

When a context window contains multiple seed words from multiple emotion categories, three possible settings for selecting the most appropriate seed word as co-occurring with the cue word can be explored:

- *nearest* (SECO-NEAR): This is the most intuitive option, where the nearest seed word to the cue word is selected. For example, "*happy*" is counted as co-occurring with "*party*"; "*angry*" is ignored.
- *preceding* (SECO-PREC): To account for any positional predisposition, this variant considers only the closest preceding seed word to the cue word. For example, "*angry*" is considered as co-occurring with "*party*"; "*happy*" is ignored.
- *following* (SECO-FOLL): Similarly, this variant considers only the closest seed word that follows the cue word as co-occurring together. For example, "*happy*" is considered as co-occurring with "*party*"; "*angry*" is ignored.

The selective counting of the seed word's co-occurrence frequency with the cue word is what essentially makes our association measure asymmetric and therefore, the order of the cue and seed word in the association equation cannot be interchanged. That is, $Assoc.(w \rightarrow t)$ denotes the association between a cue word w and a seed word t, and $Assoc.(w \rightarrow t) \neq Assoc.(t \rightarrow w)$. Technically, SECO is applicable to any traditional co-occurrence-based word association measure that estimates the relatedness between two words by computing some function of the words' frequencies. To this end, we adopt three popular co-occurrence association measures, namely NPMI (Bouma, 2009), Dice (1945) and Jaccard (1912), into their SECO counterparts, SECO-NPMI, SECO-Dice and SECO-Jaccard, respectively.

When applying SECO, in a corpus of M words, $\#(w, t)$ denotes the number of times a cue word w co-occurs mutually exclusively with any one emotion seed word $t \subset \mathrm{T}$ within a context window of size

k, where k is the maximum distance between those two words; $\#(w)$ and $\#(t)$ denote the frequencies of w and t, respectively.

SECO-NPMI The normalized SECO-NPMI between w and t, within the range of $[-1, 1]$, is:

$$SECO\text{-}NPMI(w \rightarrow t) = \frac{\log\left(M \frac{\#(w,t)}{\#(w)\#(t)}\right)}{\log\left(\frac{M}{\#(w,t)}\right)}. \quad (1)$$

SECO-Dice Similarly, SECO-Dice between w and t is computed as:

$$SECO\text{-}Dice(w \rightarrow t) = \frac{2 \times \#(w,t)}{\#(w) + \#(t)}. \quad (2)$$

SECO-Jaccard Lastly, one of the earliest co-occurrence associations measures, Jaccard, can be transformed as follows:

$$SECO\text{-}Jaccard(w \rightarrow t) = \frac{\#(w,t)}{\#(w) + \#(t) - \#(w,t)}. \quad (3)$$

Empirical data shows that the association between words decays exponentially (Beeferman et al., 1997) and this property has been successfully exploited by adding a decaying factor which allows words that co-occur nearer to each other to be more related (Gao et al., 2002; Sahlgren, 2006; Brosseau-Villeneuve et al., 2010; Mikolov et al., 2013a). Drawing from previous research, we also apply a context weighting scheme whereby a seed word is linearly weighted according to its distance from the cue word as follows: in a window of size k, the n^{th} word from the cue word is weighted by the function $\frac{k-n+1}{k}$. For example, in a window of 5, the first word next to the cue word is weighted by $\frac{5}{5}$, while the fourth word away is of weight $\frac{2}{5}$. In other words, as the distance between two words increases, their weighted association score decreases.

Finally, the word-emotion association between w and an emotion category e_j is obtained by calculating the average mean of the association scores between w and all the seed words of e_j as:

$$Assoc.(w \rightarrow e_j) = \frac{1}{m} \sum_{k=1}^{m} Assoc.(w \rightarrow t_{j_k}) \quad (4)$$

where $Assoc.$ is any association measure such as SECO-NPMI.

3.2 Classifying Sentence Emotion

For each word w, its emotion vector ϕ_w is denoted as:

$$\phi_w = \langle Assoc.(w \rightarrow e_1), Assoc.(w \rightarrow e_2), \ldots, Assoc.(w \rightarrow e_g) \rangle$$

and the emotion vector ϕ_s of sentence s is obtained by averaging the emotion vectors of all its n cue words as $\phi_s = \frac{1}{n} \sum_{i=1}^{n} \phi_{w_i}$. Finally, the sentence is labelled with the emotion category $e \subset E$ with the maximum value in ϕ_s.

4 Evaluation Setup

In this section we describe the evaluation datasets, the text corpus used for learning the word-emotion association scores and the evaluation metric for this task.

4.1 Evaluation Datasets

Below described are the three popular emotion evaluation datasets, with some sample sentences presented in Table 1 and their summarized statistics in Table 2.

Aman: Consisting of highly informal blog data, this dataset includes 1290 sentences annotated with one of six emotions: *anger, disgust, fear, joy, sadness and surprise* (Aman and Szpakowicz, 2007).

Alm: Emotions are particularly significant in the literary genre of fairy tales and this dataset contains 1207 high-agreement sentences (i.e., all four annotators agreed with the same label) marked with one of five emotions: *angry-disgusted, fearful, happy, sad and surprised* (Alm, 2008).

Aman	Do you people not listen to the news or what? I had a blast in california hanging out with my family and friends.	*anger* *happiness*
Alm	Oh! cried the devil, "what are you doing?" Ha! what are you doing? cried the devil angrily.	*surprised* *angry-disgusted*
ISEAR	When I saw a ghost. Slaughtering of animals.	*fear* *disgust*

Table 1: Sample sentences from evaluation datasets

	ag	***dg***	***fr***	***hp***	***sd***	***sp***	**total**
Aman	179	172	115	536	173	115	1290
Alm	218		166	445	264	114	1207
ISEAR	1085	1072	1086	1089	1080	-	5412

Table 2: Details of evaluation datasets

ISEAR: Developed for studying the relationships among emotions and cultures, this corpus contains experiences evoking seven emotions: *anger, disgust, fear, joy, sadness, shame* and *guilt*, resulting in a total of 5412 sentences[1]. To the best of our knowledge, no existing lexicon contains *shame* or *guilt* categories, and therefore methods that depend on emotion lexicons cannot correctly classify sentences belonging to these emotions. However, unsupervised approaches such as ours, which can be initialized with as little as one seed word per emotion category, are easily applicable to such datasets.

4.2 Text Corpora

We derive the word-emotion association scores from two large text corpora of different domains, which are pre-processed by: a) converting to lowercase; b) stripping off all non-alphanumeric characters; c) removing stopwords; d) stemming, and e) removing words that occur less than 5 times in the corpus.

Wikipedia[2]: The large publicly available corpus of Wikipedia mainly consists of formal language structured text articles considered to be more "objective" in nature. Our clean corpus contains approximately 918.5 million tokens, with each article on one line.

Amazon: The text of all the product reviews, mostly consisting of informal language makes up our second corpus, considered to be of more "emotional" type. This data was extracted from the aggressively deduplicated dataset (McAuley et al., 2015), which contains 82.83 million product reviews from Amazon, spanning May 1996 - July 2014. Our clean corpus contains more than 3 billion tokens (three times the size of Wikipedia corpus), with one review per line.

4.3 Evaluation Metric

Following prior studies, we calculate the F-score for each emotion class e, where F-score is the harmonic mean of *precision* and *recall*, defined as $2\left(\frac{precision \times recall}{precision + recall}\right)$. *Precision* is the number of sentences correctly labeled as belonging to the class e divided by the total number of sentences labeled as belonging to e, and *recall* is the number of sentences correctly labeled as belonging to e divided by the total number of sentences that actually belong to e. We report the average F-score over all the classes.

5 Experiments and Analysis

In what follows, we evaluate the performance of the proposed approach in several experiments and discuss their results.

5.1 How effective is selective co-occurrence?

We test the performance of the three proposed variants, `SECO-NEAR`, `SECO-PREC` and `SECO-FOLL`, against regular as well as weighted versions (where the same context weighting scheme as described in Section 3.1 is applied to regular association measures) in order to analyze the effect of selective co-occurrence in particular, and not just the advantage obtained using weighted contexts.

(a) NPMI (b) Dice (c) Jaccard

Figure 2: Selective co-occurrences and regular co-occurrences on Alm dataset

As observed from Figure 2, tested for context window sizes 1 to 20 and trained on the Wikipedia corpus, our proposed approach, *preceding* selective co-occurrences (SECO−PREC), where only the nearest seed word that precedes a given cue word within a context window is considered, exhibits the best performance when applied to all the three association measures (NPMI, Dice and Jaccard), on the Alm dataset[3]. In fact, the best average F-score from SECO−NPMI−PREC is almost 10% better than that of Wt-NPMI, leading us to conclude that the gain in performance is due to selective co-occurrences and not just weighted contexts. As expected, the weighted versions, Wt-NPMI, Wt-Dice and Wt-Jaccard perform much better than their regular unweighted counterparts, NPMI, Dice and Jaccard, respectively. SECO−NEAR has slight advantage over weighted association measures while SECO−FOLL and regular association measures (i.e., NPMI, Dice, Jaccard) are nearly always the poorest performing. Since SECO−PREC−NPMI (Figure 2a) yielded better average F-score than SECO−PREC−Dice or SECO−PREC−Jaccard, we further evaluate its performance in the next experiment.

5.2 How effective is SECO−PREC−NPMI?

In this experiment, we evaluate the performance of unsupervised SECO−PREC−NPMI against five baselines (in **bold**) described next.

5.2.1 Baselines

WordNet Affect (**WNA**), NRC Emotion Lexicon (**EmoLex**) and DepecheMood (**DM**) (Section 2.1) contain words and their association with various emotions. For each emotion category, WNA contains a simple list of words, which we interpret as a binary association; if a word exists in an emotion category, we assign $+1$ for that emotion. EmoLex and DM, on the other hand, contain association scores between a word and all the emotion categories. For instance, EmoLex lists the association between the word "*awful*" and 8 emotions (anger, anticipation, disgust, fear, joy, sadness, surprise, trust) as: $1, 0, 1, 1, 0, 1, 0, 0$. In DM, each word is associated with a different set of emotions by a real valued score, summing upto 1. For instance, the word "*awe*" and 8 emotions (afraid, amused, angry, annoyed, dont_care, happy, inspired, sad) is listed as: $0.08, 0.12, 0.04, 0.11, 0.07, 0.15, 0.38, 0.05$. We use these emotion lexicons as a baseline by applying a keyword matching algorithm, to obtain $Assoc.(w \rightarrow e)$. For example, $Assoc.(awe \rightarrow sad) = 0.05$ from DM. Note that, since DM does not contain two of the emotions found in our evaluation datasets, i.e., disgust and surprise, we report its results on a subset of the datasets. Instead of directly comparing our word-emotion association scores with those of emotion lexicons, we extrinsically evaluate them in the task of emotion classification as there are significant differences between the various emotion lexicons and none can be considered to be a perfect benchmark.

Semantic similarity computed from two state-of-the-art word embedding algorithms, **CBOW** and **SG** (Mikolov et al., 2013b; Mikolov et al., 2013a) (Section 2.2), provide another baseline as they can be used to obtain unsupervised word-emotion association scores, which is closer in spirit to our goal. We

[3]Consistent results were obtained on Aman and ISEAR datasets, not included here due to limited space.

used the algorithms' recommended default parameter settings: *dimension size of feature vectors* = 300; *negative sampling* = 5. We present a comparison against only unsupervised methods as the focus of this paper is on unsupervised emotion detection methods.

Since the context window size can have a significant impact on the performance of an algorithm, we run each method of semantic relatedness on 20 different window sizes (1 to 20) on both the corpora (Wikipedia and Amazon) and report the average result with standard deviation for each setting in Table 3. To keep the process as unsupervised as possible, in this study only one seed word per emotion category is used to derive the association scores. The seed words "*angry, disgust, happy, scared, sad, surprise*" represent the six emotion categories "*anger, disgust, happiness, fear, sadness, surprise*", respectively.

	Aman	**Alm**	**ISEAR**
SG_{wiki}	0.242 ± 0.04	0.209 ± 0.05	0.259 ± 0.08
$CBOW_{wiki}$	0.382 ± 0.02	0.426 ± 0.03	0.446 ± 0.03
SECO-PREC-NPMI$_{wiki}$	**0.410** ± 0.01**	**0.443** ± 0.01**	0.488 ± 0.02**
SG_{amazon}	**0.410** ± 0.02*	0.406 ± 0.02	0.438 ± 0.04
$CBOW_{amazon}$	0.393 ± 0.02	0.373 ± 0.02	0.484 ± 0.03
SECO-PREC-NPMI$_{amazon}$	0.403 ± 0.01	0.409 ± 0.01**	**0.498** ± 0.02**

Table 3: Average F-scores (of windows 1 to 20) for three evaluation datasets. SG, CBOW and SECO-PREC-NPMI were run on Wikipedia and Amazon corpora for windows 1 to 20. The best average result for each dataset is in **bold**. $^{**}p < .00001$, $^{*}p < .01$ (one-way ANOVA test for each dataset results using the same training corpus, i.e., wiki or amazon)

5.2.2 Results

Usually it is difficult to determine the best window size in advance, and therefore, for window sizes 1 to 20, we summarize the average F-scores over all 20 window sizes in Table 3. The best results obtained using any particular window are presented in Table 4 and the details of different emotion category results are further shown in Table 5. Finally, Figure 3 presents the window sensitivity graphs.

i) The average F-score results summarized in Table 3 indicate that on average, SECO-PREC-NPMI yields better overall results, with SG_{amazon}obtaining competitive results on one dataset (Aman), suggesting the effectiveness of selective co-occurrences in this task. Interestingly, contrary to popular intuition, the "objective" text from Wikipedia training corpus yields better F-scores on average than the "subjective" Amazon reviews corpus for two out of the three evaluation datasets.

	Aman	**Alm**	**ISEAR**
WNA	0.286	0.362	0.343
EmoLex	0.316	0.341	0.318
DM	0.324	0.340	0.290
SG_{wiki}	0.338 (2)	0.345 (1)	0.433 (1)
$CBOW_{wiki}$	0.410 (15)	0.456 (11)	0.481 (19)
SECO-PREC-NPMI$_{wiki}$	0.422 (10)	**0.464** (8)	0.497 (10)
SG_{amazon}	**0.435** (6)	0.440 (1)	0.490 (5)
$CBOW_{amazon}$	0.411 (6)	0.399 (18)	0.510 (19)
SECO-PREC-NPMI$_{amazon}$	0.412 (11)	0.422 (15)	**0.512** (20)

Table 4: Details of best results for three evaluation datasets. The best result for each dataset is in **bold**. The window size is shown in parentheses.

ii) The results of Table 4 indicate that, on all three evaluation datasets, with just one seed word per emotion category used to derive the word-emotion association scores, all the unsupervised measures of semantic relatedness (SECO-PREC-NPMI, SG and CBOW) outperform all the emotion lexicons (WNA, EmoLex and DM) that were created using considerable human input and training data, indicating that semantic similarity approaches provide an effective unsupervised way of extracting meaningful word-emotion association scores. Within the emotion lexicons, WNA provides the best performance on two out

of the three datasets despite being the smallest in size. Unsupervised association measures demonstrate two significant advantages over emotion lexicons: firstly, association measures are able to provide a wider coverage by exploiting the inherent associations between words that are present in text corpora; and secondly, while lexicons have fixed pre-determined emotion categories, association measures can be flexibly extended to any number and types of emotions. As for the recommended window settings for each approach, it seems that SG works well with window size $= 1$ on Wikipedia corpus and around 5 on Amazon; CBOW usually does well on windows larger than 15 and `SECO-PREC-NPMI` is recommended to be used with window 10 on Wikipedia and larger than 15 on Amazon.

Table 5: Details of emotion category results for best window size/training corpus combination for three evaluation datasets. *ag* = anger, *dg* = disgust, *fr* = fear, *hp* = happy, *sd* = sad, *sp* = surprise. P = precision, R = recall, F = F-score.

iii) To analyze the individual emotion category results, we present the results of the best approach/training corpus combination in Table 5. In general, the *happiness* category obtains the highest results in two datasets while *fear* does best on the third. On the other hand, the most difficult category to be classified correctly seems to be *surprise*. One avenue of future work could include experimenting with various seed words to increase the accuracy of such emotions.

iv) Figure 3 summarizes the results of sensitivity of the three algorithms, SG, CBOW and `SECO-PREC-NPMI`, to different window parameter settings. On Wikipedia corpus, `SECO-PREC-NPMI` is consistently better than the others, whereas SG takes better advantage of the Amazon corpus. While `SECO-PREC-NPMI` and CBOW get better with bigger context windows, SG depicts the opposite trend, best on windows less than 5.

To summarize the results:

- Initialized using one seed word per emotion category, the measures of semantic relatedness yield better results than the emotion lexicons.
- When the window size is not known, in general, `SECO-PREC-NPMI` yields consistent promising results on all the evaluation datasets, while SG provides competitive results on one dataset.
- `SECO-PREC-NPMI` and CBOW yield better results with larger window sizes, whereas SG is best on windows less than 5.

6 Conclusion

Emotion detection from text requires the degree of word-emotion association which is generally obtained from emotion lexicons or measures of semantic relatedness. While manual lexicons require considerable human time and effort, automatic techinques provide average performance. In this paper, we described a novel approach to automatically learning word-emotion association scores. Using just one seed word per emotion category, our proposed approach `SECO-PREC-NPMI` significantly outperformed three emotion lexicons and two state-of-the-art word embeddings models when trained using the Wikipedia text corpus.

As future work, we plan to further improve the accuracy of emotion classification by experimenting with a variety of seed words and also adapt `SECO` to other tasks that require association between two words.

Abstract

NBSVM is one of the most popular methods for text classification and has been widely used as baselines for various text representation approaches. It uses Naive Bayes (NB) feature to weight sparse bag-of-n-grams representation. N-gram captures word order in short context and NB feature assigns more weights to those important words. However, NBSVM suffers from sparsity problem and is reported to be exceeded by newly proposed distributed (dense) text representations learned by neural networks. In this paper, we transfer the n-grams and NB weighting to neural models. We train n-gram embeddings and use NB weighting to guide the neural models to focus on important words. In fact, our methods can be viewed as distributed (dense) counterparts of sparse bag-of-n-grams in NBSVM. We discover that n-grams and NB weighting are also effective in distributed representations. As a result, our models achieve new strong baselines on 9 text classification datasets, e.g. on IMDB dataset, we reach performance of 93.5% accuracy, which exceeds previous state-of-the-art results obtained by deep neural models. All source codes are publicly available at https://github.com/zhezhaoa/neural_BOW_toolkit.

1 Introduction

Text representation is a core technology for many NLP tasks. Most text representation approaches fall into one of the two classes: sparse and distributed (dense) representations. One of the most popular sparse representations is bag-of-words (BOW), where each dimension represents the number of occurrences of a word in a text. Though simple, BOW enjoys the advantages of being efficient and surprisingly effective. Until now, BOW representation still serves as baselines on a range of NLP tasks.

In distributed representation, texts are represented by low-dimensional real vectors. Recently, there has been a surge of work proposing to learn distributed text representation through neural networks. There exists two lines of researches in neural models. The first is order/syntax-aware models, such as Convolutional Neural Networks (CNNs) (Kim, 2014; Kalchbrenner et al., 2014; Zhang et al., 2016), Recurrent Neural Networks (RNNs) (Dai and Le, 2015) and Recursive Neural Networks (RecNNs) (Socher et al., 2011; Socher et al., 2012). In these models, words are firstly embedded into low-dimensional real vectors (word embeddings) as the input, and then order/syntax-aware compositions upon words are learned by neural networks (Goldberg, 2015). Another line is neural bag-of-words models, where unordered compositions are learned upon word embeddings (Iyyer et al., 2015). The simplest neural bag-of-words model is word embeddings average. Compared to order/syntax-aware models, they are much more efficient in training (Iyyer et al., 2015) but lose the accuracies due to the ignorance of the order/syntax information.

To the best of our knowledge, most of the neural models map isolated words (uni-grams) to embeddings. Sometimes, consecutive words (n-grams), such as 'not like' and 'as good as' can convey semantics that are difficult to be obtained by simple compositions of individual words (Mikolov et al., 2013b). A natural extension is to embed n-grams into low-dimensional real vectors, e.g. the embedding of bi-gram

*Equal contribution. † Corresponding author.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1591–1600, Osaka, Japan, December 11-17 2016.

'not like' should be close to the embedding of word 'dislike'. The introduction of the n-gram embeddings takes the word order in short context into consideration, and can further enrich the semantics of text representations.

A distinct characteristic of neural models is their automatic feature extraction ability. Most neural models directly learn compositions upon word embeddings, and are reported to be powerful enough to learn high-quality distributed representations without human intervention. However, in sparse case, heuristic weighting techniques designed by humans are shown to be able to bring significant improvements over raw BOW representation (Wang and Manning, 2012; Martineau and Finin, 2009). For example, in sentiment classification, word 'amazing' is much more important than words like 'movie' and 'of', and should be given more weight in sparse BOW representation. Weighting technique has been successfully applied to sparse representation, but is still seldom used in neural models. Intuitively, neural models can also benefit a lot from knowing the importance of words in advance to guide the training processes.

In this paper, both n-grams and weighting techniques are introduced into the neural bag-of-words models. In fact, our models can be regarded as a neural or distributed counterparts of NBSVM (Wang and Manning, 2012). In NBSVM, these two techniques are shown to be very useful for sparse representations and strong baselines are achieved on a range of text classification tasks. In our work, we show how to transfer these two techniques to distributed representations, and discover that they are also very effective in distributed case.

We evaluate our models on 9 text classification tasks. Significant improvements are witnessed when n-gram and weighting techniques are introduced into neural bag-of-words models. As a result, new strong baselines are achieved on 5 document-level datasets and 4 sentence-level datasets. Most recently, state-of-the-art results on NLP tasks are dominated by deep neural models: CNNs exploit convolutional filters to extract n-grams features from texts; RNNs are reported to be able to capture long-distance patterns from natural languages. RecNNs even take syntactic information into consideration. In theory, these models are very powerful since complex compositionalies are learned upon word embeddings. However, experimental results in this paper give us further insights: though n-gram features have been studied in the NLP literature for decades and are usually viewed as baselines, they can still outperform features learned by the newly proposed deep neural models in many datasets if we can make use of them correctly. At least in text classification tasks, complex deep neural models do not show obvious superiority over our n-grams models on accuracies. What is more, deep neural models always require much more computational resources compared to bag-of-words (n-grams) models.

2 Related Work

Bag-of-words (n-grams)

Bag-of-words (n-grams) models treat a text as a set of words (n-grams), which ignore the fact that texts are essentially sequential data (Pang et al., 2002). Though the order information contained in word sequences is discarded, bag-of-words (n-grams) models are surprisingly effective, and also enjoy the advantages of being efficient and robust. They have been widely used in various kinds of NLP tasks such as information retrieval, question answering and text classification. Usually, sparse BOW features require weighting techniques to achieve better performance, where important words are given more weights while unimportant words are given less weights. For example, NBSVM (Wang and Manning, 2012) uses the ratio of the number of words in positive texts and negative texts to weight words, and achieves competitive results on a range of text classification tasks. However, traditional sparse BOW representations take each word or n-gram as a unit and ignore the internal semantics of them. As a result, they tend to generalize poorly compared with the newly proposed distributed representations.

Recently, distributed text representations are widely used in NLP tasks. The most fundamental work in the distributed representation literature is word embedding. In word embedding algorithms, syntactic and semantic information of words is encoded into low-dimensional real vectors and similar words tend to have close vectors (Bengio et al., 2003; Collobert et al., 2011; Mikolov et al., 2013a; Mikolov et al., 2013b). To obtain text embedding from word embedding, the simplest way is word embeddings

(vectors) average (VecAvg). This method belongs to neural bag-of-words models based on the fact that VecAvg also treats text as a set of words and discards order information totally. Other popular neural bag-of-words models include Deep Average Network (DAN) (Iyyer et al., 2015) and Paragraph Vector (PV) (Le and Mikolov, 2014). DAN constructs multiple neural layers upon the average of word vectors in the text. They show that more discriminative features can be extracted by deepening the layers of the neural networks. In PV, text embedding are trained to be useful to predict the words in the text. These neural bag-of-words models are reported to perform better than sparse BOW representations, and inherit the advantages of BOW models of being efficient and robust.

Complex Compositionality

Recently, many deep neural models are proposed on the basis of compositionality: the meanings of the expressions depend on their constituents. These models can learn complex compositionality upon words and achieve state-of-the-art results on a range of NLP tasks. Kim (2014) proposes to use convolutional neural networks (CNNs) to extract text features. N-grams information is extracted by convolutional layers and the most distinct features are selected by max pooling layers. Recurrent Neural Networks (RNNs) are sequential models and are suitable for texts data in nature. Hidden layers of RNNs can preserve the historical sequential information, and can be used as the representations of the texts (Dai and Le, 2015). However, both CNNs and RNNs are essentially 'flat' models, where structural information (e.g. syntactic parse tree) from texts are generally ignored. Socher et al. (2011) propose to use Recursive Neural Networks (RecNNs) to learn syntactic-aware compositionality upon words. They recursively combine neighbor nodes on parse trees in a bottom-up fashion until the root is reached.

Most recently, many researchers have focused on using the combinations of neural networks to achieve better text representations. Sutskever et al. (2014) propose to use multi-layer LSTM networks for text representation and significant improvement is achieved on machine translation when more layers of neural networks are added. Lai et al. (2015) use RNN-CNN for text representations, where RNN layer is used for extracting word sequences information and the most distinct features are selected by max-pooling layer. Tai et al. (2015) model the texts through tree-structured LSTM, which can be viewed as the combination of RecNN and RNN. To take the relationships among sentences in a document into consideration, some works have been done to learn document representation hierarchically (Kiros et al., 2015). For example, in (Li, 2014), RecNN is used for learning sentence embedding from word embedding, and RNN is used for learning document embedding from sentence embedding. Denil et al. (2014), Lin et al. (2015), Li et al. (2015b) and Tang et al. (2015) respectively propose to use CNN-CNN, RNN-RNN, LSTM-LSTM and CNN-LSTM to represent documents hierarchically.

These models are very powerful in theory since they exploit extensive information of texts such as word order, syntax and even relations among sentences. However, for text classification, a relatively simple task in the NLP community, deep neural models do not show their superiority over our n-grams models according to our experimental results. It still requires further explorations to demostrate if deep neural models can really exploit complex information beyond n-grams, or if complex information is really useful for text classification. What is more, most deep neural models require intensive training resources and usually need careful hyper-parameter tuning for specific datasets.

3 Models

In the following subsections, we present the framework of exploiting n-grams and weighting techniques for neural bag-of-words models. We use Paragraph Vector (PV) model (Le and Mikolov, 2014)[1] as a concrete case to illustrate the way of introducing these two techniques. Our method can be applied to other neural bag-of-words models straightforwardly.

Paragraph Vector (PV) is a popular method for text representation. In PV, text embedding is trained to be useful to predict words in the text. Formally, the objective is to maximize the conditional probabilities of words given their texts:

[1]Concretely, PV-DBOW (a variant of PV) is used in our paper.

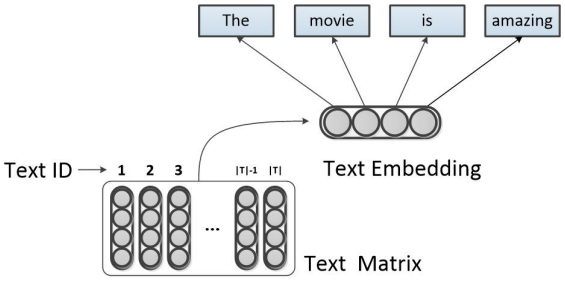

Figure 1: Illustration of the original Paragraph Vector model. The model only considers the uni-grams and they are equally treated in the model.

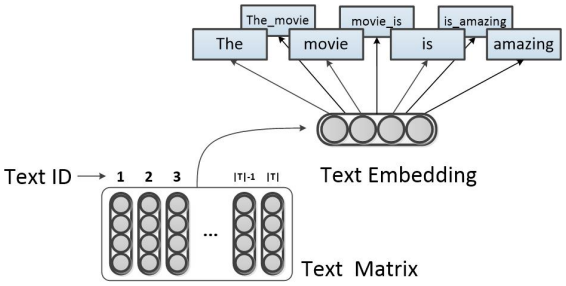

Figure 2: Illustration of n-gram PV model, where n-grams are predicted by the text embedding.

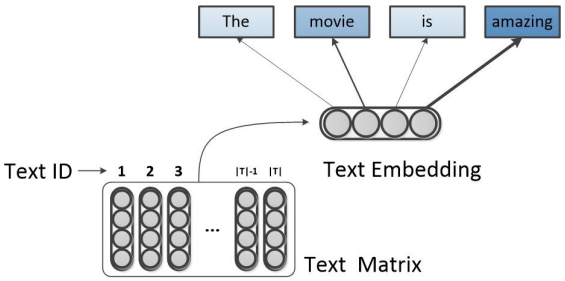

Figure 3: Illustration of weighted PV model, where important words are given more attention during the training process.

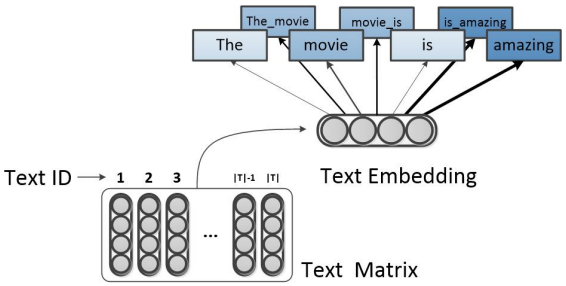

Figure 4: Combination of n-gram and weighting techniques. Text embeddings are trained to be useful to predict important n-grams during the training process.

$$\sum_{i=1}^{|T|}\sum_{j=1}^{|t_i|} logP(w_{i,j}|t_i) \tag{1}$$

where t_i=$\{w_{i,1},w_{i,2},.....,w_{i,|t_i|}\}$ denotes the i_{th} text and T=$\{t_1,t_2,.....,t_{|T|}\}$ denotes the whole dataset. In this paper, the conditional probability is defined by negative sampling (Mikolov et al., 2013b), which speeds up the training process significantly. Figure 1 clearly shows that, in PV, each word is predicted separately and the words in a text are equally treated.

3.1 N-gram Embedding

As we have mentioned above, n-grams can reflect semantics that can not be captured by looking at words individually. To introduce n-grams information into the neural models, a natural extension is to train n-gram embeddings (Li et al., 2015a). Each text is regarded as a set of n-grams (e.g. n = 1, 2, 3) and each n-gram is assigned a randomly initialized vector. The length of the text t is denoted by $|t|$. Obviously, text t consists of $|t|$ uni-grams, $|t|$-1 bi-grams and $|t|$-2 tri-grams.

During the training process, text embeddings are trained to be useful to predict n-grams in the text (as shown in figure 2). The following objective is optimized:

$$\sum_{i=1}^{|T|}\sum_{n=0}^{N-1}\sum_{j=1}^{|t_i|-n} logP(w_{i,j\sim j+n}|t_i) \tag{2}$$

where N denotes the number of consecutive words considered. When N equals to 3, uni-grams, bi-grams and tri-grams are predicted by the text. $w_{i,j\sim j+n}$ denotes *n+1* consecutive words $w_{i,j}, w_{i,j+1}, ..., w_{i,j+n}$. Word order in short context is captured by including n-grams information.

3.2 Naive Bayes Weighting

Intuitively, some n-grams are more important and should be paid more attention during the training process. In this paper, we only consider calculating weights of n-grams for binary classification. Without loss of generality, we use 'positive' and 'negative' to denote the name of two classes. Following works done by Wang and Manning (2012) and Martineau and Finin (2009), we use Naive Bayes feature to assign weight for each word. The weight of word *w* is calculated as follows:

$$(\frac{(\#POS(w)+\alpha)/|POS|}{(\#NEG(w)+\alpha)/|NEG|})^{\beta * \lfloor \#POS(w)/|POS| > \#NEG(w)/|NEG| \rfloor} \tag{3}$$

$$where \quad \lfloor \cdot \rfloor = \begin{cases} 1 & \cdot is True \\ -1 & \cdot is False \end{cases}$$

where ***#POS(w)*** denotes the number of positive texts that contain n-gram *w*, and ***#NEG(w)*** denotes the number of negative texts that contain n-gram *w*. α and β are two hyper-parameters for smoothing ratios (both of them are set to be 0.5 in this paper). $|POS|$ and $|NEG|$ denote the number of positive and negative texts respectively (including pseudo count α). To this end, words that have uneven distributions over classes are given more weights. Naive Bayes weighting is shown to be effective in sparse representation. To introduce weighting techniques into distributed case, weighted objective function is optimized to train text embeddings:

$$\sum_{i=1}^{|T|} \sum_{n=0}^{N-1} \sum_{j=1}^{|t_i|-n} Weight(w_{i,j\sim j+n}) logP(w_{i,j\sim j+n}|t_i) \tag{4}$$

where ***Weight(•)*** denotes the weight of n-gram •. As a result, text embeddings are trained to predict those important n-grams in larger probabilities rather than those words that have little discriminative information for classification. Figure 3 and 4 respectively demonstrate the overview of introducing weighting techniques into uni-gram and n-gram Paragraph Vector. The way we exploit n-grams and weighting information can be easily used in other neural bag-of-words models. For example, we can use the weighted average of n-gram embeddings as the input of the DAN neural networks (Iyyer et al., 2015).

In summary, this section introduces n-grams and NB weighting into neural bag-of-words models. These two techniques have shown their effectiveness on sparse representation in NBSVM. In the following Experiment Section, we demonstrate the effectiveness of n-grams and NB weighting for distributed representations.

4 Experiments

4.1 Datasets and Training Protocols

We evaluate our models on five document-level and four sentence-level text classification datasets. The details of the datasets are shown in table 1. The pre-processing of texts and the train/test, cross-validation splits strictly follow the implementation in NBSVM[2].

Our models are trained by stochastic gradient descent (SGD). The hyper-parameter setting follows the implementation in (Mesnil et al., 2014) [3] except that the training iterations are determined by validation set. When the training process is finished, the text representations are fed into a logistic regression classifier. Following the work done by Mesnil et al. (2014), we also combine the outputs of logistic classifiers (for sparse and dense representations) via linear interpolation. The weights are determined by validation set.

It is common to use pretrained vectors (Kim, 2014) and additional unlabeled texts (Mesnil et al., 2014; Li et al., 2015a)[4] to assist the training when size of the dataset is small. IMDB is a relatively large-scale

[2]https://github.com/sidaw/nbsvm

[3]https://github.com/mesnilgr/iclr15

[4]Mesnil et al. use the unlabeled data in their published implementation.

dataset and does not require pretrained vectors. For the rest of eight tasks, we use word2vec vectors to initialize the uni-grams. The additional unlabeled texts are added to RT-2k and RTs datasets, the details of which will be discussed in the following subsections.

Unless otherwise noted, we don't perform any data specific hyper-parameter tuning.

Type	Dataset	$\#(train+, train-, test+, test-)$	CV	$\lvert\bar{t}\rvert$	|V|
document-level	IMDB	(12500,12500,12500,12500)	N	231	392K
	RT-2k	(1000,1000)	10	787	51K
	AthR	(399,315,400,313)	N	345	22K
	Xgraph	(491,486,489,487)	N	261	32K
	BbCrypt	(497,496,497,495)	N	269	25K
sentence-level	RTs	(5331,5331)	10	21	21K
	CR	(2406,1366)	10	20	5713
	MPQA	(3316,7308)	10	3	6229
	Subj.	(5000,5000)	10	24	24K

Table 1: Datasets statistics. #(train+,train-,test+,test-): the number of positive and negative samples in train, test set respectively. For datasets that use cross-validation to evaluate models, column 3 only lists the number of positive and negative samples. CV: the number of cross-validation splits. N denotes train/test split. $|\bar{t}|$ denotes the average length of text samples. $|V|$ denotes the vocabulary size.

4.2 Comparison of Models on IMDB Dataset

IMDB dataset is one of the most popular benchmarks in text classification. A large amount of models are evaluated and compared on this dataset. In table 2, we compare our neural bag-of-words models with NBSVM. We can observe that dense representations consistently outperform their sparse counterparts. The n-grams and NB weighting are effective for both sparse and dense representations. Four percent improvement in accuracies is witnessed when n-grams and NB weighting are considered in dense representation. The best result is achieved by the ensemble of dense and sparse represntations (Mesnil et al., 2014).

In table 3, we compare our models with state-of-the-art methods which are dominated by deep neural models. To better compare different methods, we divide the existing models into three groups according to how they exploit information in the texts. Models in the first group treat a text as a bag of words or n-grams. Models in the second group treat texts as sequential data. In the third group, structural information such as syntactic parse tree and relationships among sentences is taken into consideration. In theory, accuracy should benefit from the sequential and structural information of texts. However, we surprisingly find that our models outperform other approaches, even though only n-gram information is exploited in our models.

Models	**Sparse**	**Dense**
Unigram	86.95	88.97
Unigram+NB	88.29	**90.10**
Bigram	89.16	91.27
Bigram+NB	91.22	**92.20**
Trigram	91.4	92.14
Trigram+NB	91.87	**92.95**
Ensemble	**93.51**	

Table 2: Comparison of sparse and dense representations. Dense representations consistently outperform sparse representations. N-grams and NB weighting are effective in both sparse and dense cases

Group	**Model**	**Accuracy**
bag-of-words	NBSVM-tri(Mesnil et al., 2014)	91.87
	Paragraph Vector(Mesnil et al., 2014)	88.73
	DAN(Iyyer et al., 2015)	89.40
	DV-tri(Li et al., 2015a)	92.14
	our model	92.95
	our ensemble	**93.51**
sequential	word2vec-LSTM(Dai and Le, 2015)	90.00
	SA-LSTM(Dai and Le, 2015)	92.76

4.3 Comparison of Models on Document-level Datasets

In this subsection, we continue evaluating our methods on document-level datasets. RT-2k dataset contains 2000 movie reviews. Texts in RT-2k and IMDB are both movie reviews and are classified according to whether they are positive or negative. Consequently, texts in IMDB are suitable alternative as additional unlabeled texts for RT-2k. AthR, XGraph and BbCrypt are classification pairs from 20-newsgroups. In these datasets, pretrained word2vec vectors are used to initialize uni-gram embeddings. N-gram embeddings are initialized randomly. To the best of our knowledge, state-of-the-art results on these four document-level datasets are still achieved by NBSVM. In table 4, we compare our models with their sparse counterparts NBSVM. We discover that dense representations benefit a lot from n-gram and weighting techniques. However, dense representations do not perform consistently better than sparse representations.

Not surprisingly, ensemble of the dense and sparse models achieves the best results.

Models	RT2k		AthR		XGraph		BcCrypt	
	Sparse	Dense	Sparse	Dense	Sparse	Dense	Sparse	Dense
Unigram	86.3	87.6	82.6	79.0	85.1	89.2	98.3	98.9
Unigram+NB	87.8	**88.7**	**87.9**	84.0	**91.2**	90.2	**99.7**	99.2
Bigram	87.4	89.2	83.7	81.1	86.2	90.5	97.7	99.1
Bigram+NB	89.5	**90.5**	**87.7**	86.1	90.7	**90.8**	99.5	**99.7**
Ensemble	**91.4**		**88.0**		**92.0**		**99.7**	

Table 4: Comparison of sparse and dense representations on document-level datasets.

4.4 Comparison of Models on Sentence-level Datasets

In this subsection, we demonstrate the effectiveness of our models on four sentence-level datasets: RTs, MPQA, CR and Subj. Pretrained word2vec vectors are used to initialize uni-gram embeddings. For RTs, data in IMDB dataset are used as additional unlabeled texts. From table 5, it can be observed that comparable results are achieved by dense and sparse representations. Similar with the conclusions obtained in above subsections: both n-grams and NB weighting improve the accuracies significantly. Ensemble of dense and sparse representations gives the best results.

In table 6, we make comparisons of state-of-the-art models, which are grouped according to their ways of exploiting text information. From the first row of table 6, we can observe that traditional PV performs poorly on sentence-level datasets compared to other state-of-the-art models. When n-grams, NB weighting and pretrained word embeddings are introduced, decent accuracies are achieved by PV. We can also observe that deep neural models show their superiority over bag-of-words models. Since n-grams information contained in sentence-level texts is limited, sequential and structural information is important for achieving better accuracies on these datasets. Nevertheless, most deep neural models in table 6 can not be extended to document-level texts. In contrast, our models can be used for texts of variable length.

Models	RTs		MPQA		CR		Subj.	
	Sparse	Dense	Sparse	Dense	Sparse	Dense	Sparse	Dense
Unigram	76.2	77.3	**86.1**	81.7	79.0	79.1	90.8	90.5
Unigram+NB	78.1	**78.7**	85.3	81.1	**80.5**	80.3	**92.4**	92.0
Bigram	77.7	78.5	**86.7**	82.0	80.8	80.1	91.7	91.2
Bigram+NB	79.4	**79.5**	86.3	82.1	**81.8**	81.1	**93.2**	92.8
Ensemble	**80.8**		**86.8**		**82.5**		**93.6**

4.5 Further Discussions

From tables in the above subsections, we can observe that n-gram features are still competitive if we can take full advantages of them. For document-level datasets, the ensemble of dense and sparse representation even outperforms the complex deep neural models which take complex compositions into consideration. For sentence-level datasets, competitive results are achieved by our models when pre-trained vectors or additional unlabelled data is added.

When taking efficiency and robustness into consideration, our n-gram models are better choices. Since our models are essentially bag-of-n-grams models, they only require a fraction of time compared to deep neural models. Our models are also robust for both sentence and document level datasets. In contrast, many deep neural models can not be extended to document-level datasets. Besides that, they usually require careful dataset-specific hyper-parameter tuning for better performance. While in our models, experimental setting is universal to all datasets except that the number of iterations are determined by validation set.

5 Conclusion

In this paper, we propose a framework of introducing n-grams and Naive Bayes weighting into neural bag-of-words models. These two techniques are effective for neural models and new strong baselines are achieved when they are used together. Though many state-of-the-art results in NLP tasks are achieved by deep neural models, we discover that for text classification, n-grams information is sufficient to achieve state-of-the-art accuracies. Moreover, our models inherit efficiency and robustness from bag-of-words representations: they only require a fraction of computational resources compared to deep neural models, and at the same time perform consistently well on a range of datasets without specific hyper-parameter tunings. Our source codes are organized as a text classification toolkit at `https://github.com/zhezhaoa/neural_BOW_toolkit`. We recommend to use the ensemble of dense and sparse representations implemented in our toolkit in real-world challenges.

Abstract

Sarcasm detection is a key task for many natural language processing tasks. In sentiment analysis, for example, sarcasm can flip the polarity of an "apparently positive" sentence and, hence, negatively affect polarity detection performance. To date, most approaches to sarcasm detection have treated the task primarily as a text categorization problem. Sarcasm, however, can be expressed in very subtle ways and requires a deeper understanding of natural language that standard text categorization techniques cannot grasp. In this work, we develop models based on a pre-trained convolutional neural network for extracting sentiment, emotion and personality features for sarcasm detection. Such features, along with the network's baseline features, allow the proposed models to outperform the state of the art on benchmark datasets. We also address the often ignored generalizability issue of classifying data that have not been seen by the models at learning phase.

1 Introduction

Sarcasm is defined as "a sharp, bitter, or cutting expression or remark; a bitter gibe or taunt". As the fields of affective computing and sentiment analysis have gained increasing popularity (Cambria, 2016), it is a major concern to detect sarcastic, ironic, and metaphoric expressions. Sarcasm, especially, is key for sentiment analysis as it can completely flip the polarity of opinions. Understanding the ground truth, or the facts about a given event, allows for the detection of contradiction between the objective polarity of the event (usually negative) and its sarcastic characteristic by the author (usually positive), as in "*I love the pain of breakup*". Obtaining such knowledge is, however, very difficult.

In our experiments, we exposed the classifier to such knowledge extracted indirectly from Twitter. Namely, we used Twitter data crawled in a time period, which likely contain both the sarcastic and non-sarcastic accounts of an event or similar events. We believe that unambiguous non-sarcastic sentences provided the classifier with the ground-truth polarity of those events, which the classifier could then contrast with the opposite estimations in sarcastic sentences. Twitter is a more suitable resource for this purpose than blog posts, because the polarity of short tweets is easier to detect (as all the information necessary to detect polarity is likely to be contained in the same sentence) and because the Twitter API makes it easy to collect a large corpus of tweets containing both sarcastic and non-sarcastic examples of the same event.

Sometimes, however, just knowing the ground truth or simple facts on the topic is not enough, as the text may refer to other events in order to express sarcasm. For example, the sentence "*If Hillary wins, she will surely be pleased to recall Monica each time she enters the Oval Office :P :D*", which refers to the 2016 US presidential election campaign and to the events of early 1990's related to the US president Clinton, is sarcastic because Hillary, a candidate and Clinton's wife, would in fact not be pleased to recall her husband's alleged past affair with Monica Lewinsky. The system, however, would need a considerable amount of facts, commonsense knowledge, anaphora resolution, and logical reasoning to draw such a conclusion. In this paper, we will not deal with such complex cases.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1601–1612, Osaka, Japan, December 11-17 2016.

Existing works on sarcasm detection have mainly focused on unigrams and the use of emoticons (González-Ibánez et al., 2011; Carvalho et al., 2009; Barbieri et al., 2014), unsupervised pattern mining approach (Maynard and Greenwood, 2014), semi-supervised approach (Riloff et al., 2013) and n-grams based approach (Tsur et al., 2010; Davidov et al., 2010; Ptácek et al., 2014; Joshi et al., 2015) with sentiment features. Instead, we propose a framework that learns sarcasm features automatically from a sarcasm corpus using a convolutional neural network (CNN). We also investigate whether features extracted using the pre-trained sentiment, emotion and personality models can improve sarcasm detection performance. Our approach uses relatively lower dimensional feature vectors and outperforms the state of the art on different datasets. In summary, the main contributions of this paper are the following:

- To the best of our knowledge, this is the first work on using deep learning for sarcasm detection.
- Unlike other works, we exploit sentiment and emotion features for sarcasm detection. As user profiling is also an important factor for detecting sarcastic content, moreover, we use personality-based features for the first time in the literature.
- Pre-trained models are commonly used in computer vision. In the context of natural language processing (NLP), however, they are barely used. Hence, the use of pre-trained models for feature extraction is also a major contribution of this work.

The rest of the paper is organized as follows: Section 2 proposes a brief literature review on sarcasm detection; Section 4 presents the proposed approach; experimental results and thorough discussion on the experiments are given in Section 5; finally, Section 6 concludes the paper.

2 Related Works

NLP research is gradually evolving from lexical to compositional semantics (Cambria and White, 2014) through the adoption of novel meaning-preserving and context-aware paradigms such as convolutional networks (Poria et al., 2016a), recurrent belief networks (Chaturvedi et al., 2016), statistical learning theory (Oneto et al., 2016), convolutional multiple kernel learning (Poria et al., 2016b), and commonsense reasoning (Cambria and Hussain, 2015). But while other NLP tasks have been extensively investigated, sarcasm detection is a relatively new research topic which has gained increasing interest only recently, partly thanks to the rise of social media analytics and sentiment analysis.

An early work in this field was done by (Tsur et al., 2010) on a dataset of 6,600 manually annotated Amazon reviews using a kNN-classifier over punctuation-based and pattern-based features, i.e., ordered sequence of high frequency words. (González-Ibánez et al., 2011) used support vector machine (SVM) and logistic regression over a feature set of unigrams, dictionary-based lexical features and pragmatic features (e.g., emoticons) and compared the performance of the classifier with that of humans. (Reyes et al., 2013) described a set of textual features for recognizing irony at a linguistic level, especially in short texts created via Twitter, and constructed a new model that was assessed along two dimensions: representativeness and relevance. (Riloff et al., 2013) used the presence of a positive sentiment in close proximity of a negative situation phrase as a feature for sarcasm detection. (Liebrecht et al., 2013) used the Balanced Window algorithm for classifying Dutch tweets as sarcastic vs. non-sarcastic; n-grams (uni, bi and tri) and intensifiers were used as features for classification.

(Buschmeier et al., 2014) compared the performance of different classifiers on the Amazon review dataset using the imbalance between the sentiment expressed by the review and the user-given star rating. Features based on frequency (gap between rare and common words), written spoken gap (in terms of difference between usage), synonyms (based on the difference in frequency of synonyms) and ambiguity (number of words with many synonyms) were used by (Barbieri et al., 2014) for sarcasm detection in tweets. (Joshi et al., 2015) proposed the use of implicit incongruity and explicit incongruity based features along with lexical and pragmatic features, such as emoticons and punctuation marks. Their method is very much similar to the method proposed by (Riloff et al., 2013) except (Joshi et al., 2015) used explicit incongruity features. Their method outperforms the approach by (Riloff et al., 2013) on two datasets.

(Ptácek et al., 2014) compared the performance with different language-independent features and pre-processing techniques for classifying text as sarcastic and non-sarcastic. The comparison was done over three Twitter dataset in two different languages, two of these in English with a balanced and an imbalanced distribution and the third one in Czech. The feature set included n-grams, word-shape patterns, pointedness and punctuation-based features.

In this work, we use features extracted from a deep CNN for sarcasm detection. Some of the key differences between the proposed approach and existing methods include the use of a relatively smaller feature set, automatic feature extraction, the use of deep networks, and the adoption of pre-trained NLP models.

3 Sentiment Analysis and Sarcasm Detection

Sarcasm detection is an important subtask of sentiment analysis (Cambria et al., 2015). Since sarcastic sentences are subjective, they carry sentiment and emotion-bearing information. Most of the studies in the literature (Joshi et al., 2016; Bosco et al., 2013; Joshi et al., 2015; Farías et al., 2016) include sentiment features in sarcasm detection with the use of a state-of-the-art sentiment lexicon. Below, we explain how sentiment information is key to express sarcastic opinions and the approach we undertake to exploit such information for sarcasm detection.

In general, most sarcastic sentences contradict the fact. In the sentence "I love the pain present in the breakups" (Figure 1), for example, the word "love" contradicts "pain present in the breakups", because in general no-one loves to be in pain. In this case, the fact (i.e., "pain in the breakups") and the contradictory statement to that fact (i.e., "I love") express sentiment explicitly. Sentiment shifts from positive to negative but, according to sentic patterns (Poria et al., 2015b), the literal sentiment remains positive. Sentic patterns, in fact, aim to detect the polarity expressed by the speaker; thus, whenever the construction "I love" is encountered, the sentence is positive no matter what comes after it (e.g., "I love the movie that you hate"). In this case, however, the sentence carries sarcasm and, hence, reflects the negative sentiment of the speaker.

In another example (Figure 1), the fact, i.e., "I left the theater during the interval", has implicit negative sentiment. The statement "I love the movie" contradicts the fact "I left the theater during the interval"; thus, the sentence is sarcastic. Also in this case the sentiment shifts from positive to negative and hints at the sarcastic nature of the opinion.

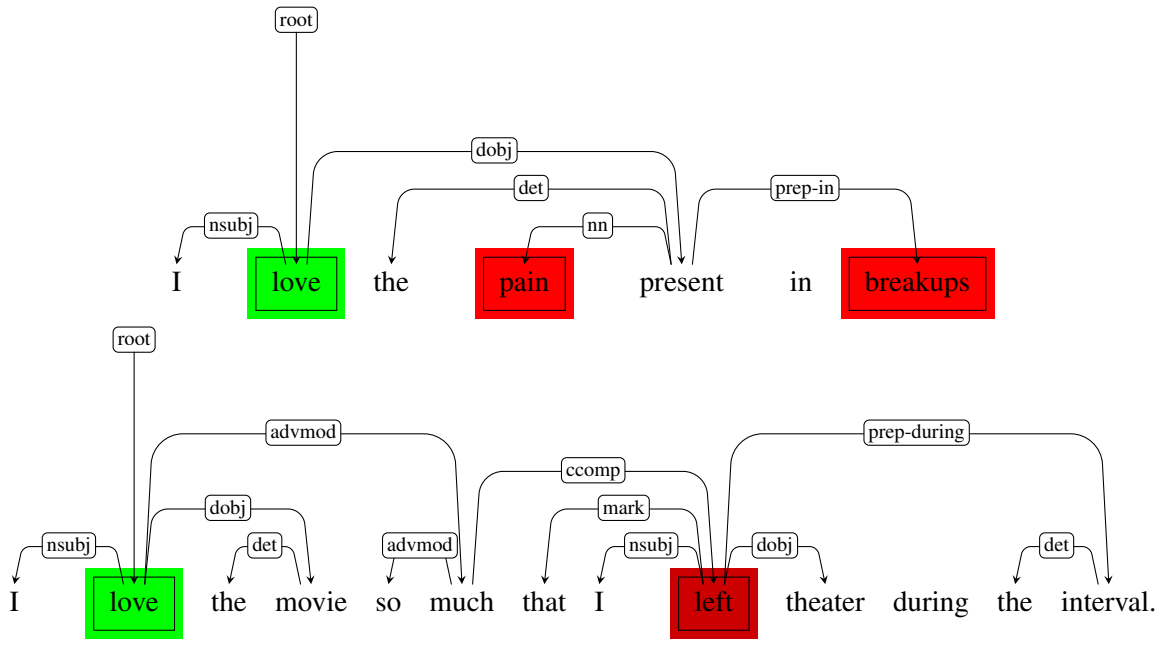

Figure 1: Sentiment shifting can be an indicator of sarcasm.

The above discussion has made clear that sentiment (and, in particular, sentiment shifts) can largely help to detect sarcasm. In order to include sentiment shifting into the proposed framework, we train a sentiment model for sentiment-specific feature extraction. Training with a CNN helps to combine the local features in the lower layers into global features in the higher layers. We do not make use of sentic patterns (Poria et al., 2015b) in this paper but we do plan to explore that research direction as a part of our future work. In the literature, it is found that sarcasm is user-specific too, i.e., some users have a particular tendency to post more sarcastic tweets than others. This acts as a primary intuition for us to extract personality-based features for sarcasm detection.

4 The Proposed Framework

As discussed in the literature (Riloff et al., 2013), sarcasm detection may depend on sentiment and other cognitive aspects. For this reason, we incorporate both sentiment and emotion clues in our framework. Along with these, we also argue that personality of the opinion holder is an important factor for sarcasm detection. In order to address all of these variables, we create different models for each of them, namely: sentiment, emotion and personality. The idea is to train each model on its corresponding benchmark dataset and, hence, use such pre-trained models together to extract sarcasm-related features from the sarcasm datasets.

Now, the viable research question here is - Do these models help to improve sarcasm detection performance?' Literature shows that they improve the performance but not significantly. Thus, do we need to consider those factors in spotting sarcastic sentences? Aren't n-grams enough for sarcasm detection? Throughout the rest of this paper, we address these questions in detail. The training of each model is done using a CNN. Below, we explain the framework in detail. Then, we discuss the pre-trained models. Figure 2 presents a visualization of the proposed framework.

4.1 General CNN Framework

CNN can automatically extract key features from the training data. It grasps contextual local features from a sentence and, after several convolution operations, it forms a global feature vector out of those local features. CNN does not need the hand-crafted features used in traditional supervised classifiers. Such hand-crafted features are difficult to compute and a good guess for encoding the features is always necessary in order to get satisfactory results. CNN, instead, uses a hierarchy of local features which are important to learn context. The hand-crafted features often ignore such a hierarchy of local features.

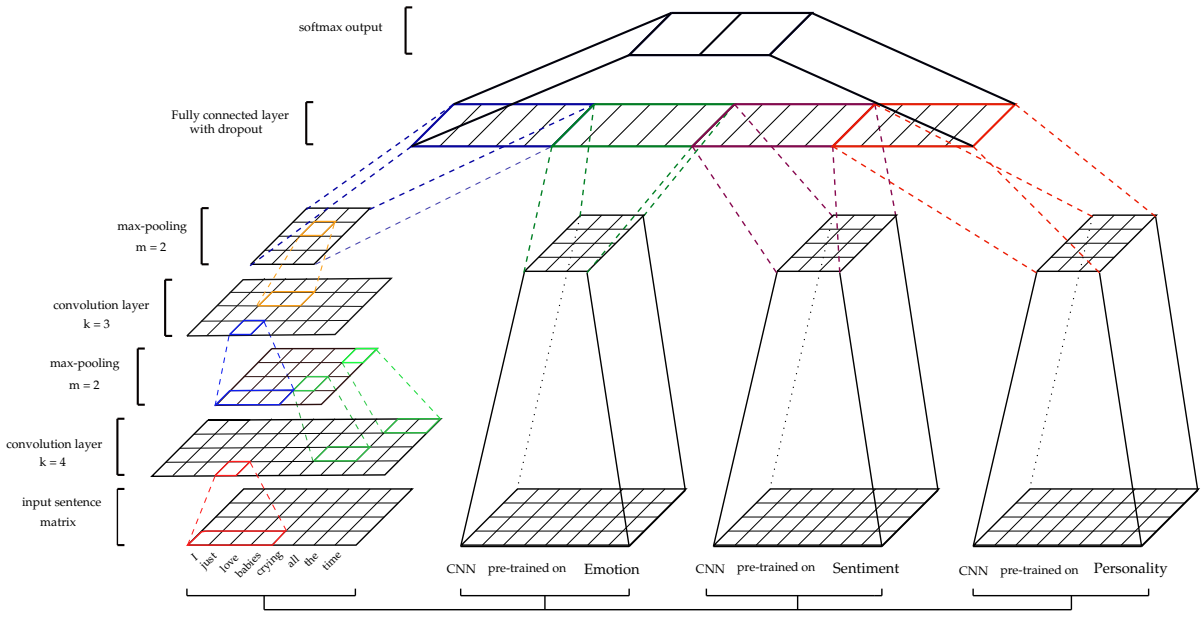

Figure 2: The proposed framework: deep CNNs are combined together to detect sarcastic tweets.

Features extracted by CNN can therefore be used instead of hand-crafted features, as they carry more useful information. The idea behind convolution is to take the dot product of a vector of k weights w_k also known as kernel vector with each k-gram in the sentence $s(t)$ to obtain another sequence of features $c(t) = (c_1(t), c_2(t), \ldots, c_{\mathrm{L}}(t))$.

$$c_j = {w_k}^T . \mathbf{x}_{i:i+k-1} \tag{1}$$

Thus, a max pooling operation is applied over the feature map and the maximum value $\hat{c}(t) = \max\{\mathbf{c}(t)\}$ is taken as the feature corresponding to this particular kernel vector. Similarly, varying kernel vectors and window sizes are used to obtain multiple features (Kalchbrenner et al., 2014). For each word x_i in the vocabulary, a d-dimensional vector representation is given in a look up table that is learned from the data (Mikolov et al., 2013). The vector representation of a sentence, hence, is a concatenation of vectors for individual words. Similarly, we can have look up tables for other features. One might want to provide features other than words if these features are suspected to be helpful. The convolution kernels are then applied to word vectors instead of individual words.

We use these features to train higher layers of the CNN, in order to represent bigger groups of words in sentences. We denote the feature learned at hidden neuron h in layer l as F_h^l. Multiple features may be learned in parallel in the same CNN layer. The features learned in each layer are used to train the next layer:

$$F^l = \sum_{h=1}^{n_h} w_k^h * F^{l-1} \tag{2}$$

where * indicates convolution and w_k is a weight kernel for hidden neuron h and n_h is the total number of hidden neurons. The CNN sentence model preserves the order of words by adopting convolution kernels of gradually increasing sizes that span an increasing number of words and ultimately the entire sentence. As mentioned above, each word in a sentence is represented using word embeddings.

Word Embeddings We employ the publicly available word2vec vectors, which were trained on 100 billion words from Google News. The vectors are of dimensionality 300, trained using the continuous bag-of-words architecture (Mikolov et al., 2013). Words not present in the set of pre-trained words are initialized randomly. However, while training the neural network, we use non-static representations. These include the word vectors, taken as input, into the list of parameters to be learned during training.

Two primary reasons motivated us to use non-static channels as opposed to static ones. Firstly, the common presence of informal language and words in tweets resulted in a relatively high random initialization of word vectors due to the unavailability of these words in the *word2vec* dictionary. Secondly, sarcastic sentences are known to include polarity shifts in sentimental and emotional degrees. For example, "*I love the pain present in breakups*" is a sarcastic sentence with a significant change in sentimental polarity. As *word2vec* was not trained to incorporate these nuances, we allow our models to update the embeddings during training in order to include them. Each sentence is wrapped to a window of n, where n is the maximum number of words amongst all sentences in the dataset. We use the output of the fully-connected layer of the network as our feature vector.

CNN-SVM We have done two kinds of experiments: firstly, we used CNN for the classification; secondly, we extracted features from the fully-connected layer of the CNN and fed them to an SVM for the final classification. The latter CNN-SVM scheme is quite useful for text classification as shown by Poria et al. (Poria et al., 2015a). We carry out n-fold cross-validation on the dataset using CNN. In every fold iteration, in order to obtain the training and test features, the output of the fully-connected layer is treated as features to be used for the final classification using SVM. Table 1 shows the training settings for each CNN model developed in this work. *ReLU* is used as the non-linear activation function of the network[1]. The network configurations of all models developed in this work are given in Table 1.

[1]We show the optimal training settings of the CNNs used in this work. Changing kernels' size or adding/removing layers does not improve results.

	Convolution Layer 1		1st Max Pooling	Convolution Layer 2		2nd Max-Pooling	FC Layer	Softmax Output
	Kernel Size	Feature Map		Kernel Size	Feature Map			
S	4,5	50	2	3	100	2	100	3
E	3,4,5	50	2	2	100	2	150	6
P	3,4,5	50	2	2	100	2	150	2
B	4,5	50	2	3	100	2	100	2

Table 1: Training settings for each deep model. Legenda: FC = Fully-Connected, S = Sentiment model, E = Emotion model, P = Personality model, B = Baseline model.

4.2 Sentiment Feature Extraction Model

As discussed above, sentiment clues play an important role for sarcastic sentence detection. In our work, we train a CNN (see Section 4.1 for details) on a sentiment benchmark dataset. This pre-trained model is then used to extract features from the sarcastic datasets. In particular, we use Semeval 2014 (Rosenthal et al., 2014) Twitter Sentiment Analysis Dataset for the training. This dataset contains 9,497 tweets out of which 5,895 are positive, 3,131 are negative and 471 are neutral. The fully-connected layer of the CNN used for sentiment feature extraction has 100 neurons, so 100 features are extracted from this pre-trained model. The final softmax determines whether a sentence is positive, negative or neutral. Thus, we have three neurons in the softmax layer.

4.3 Emotion Feature Extraction Model

We use the CNN structure as described in Section 4.1 for emotional feature extraction. As a dataset for extracting emotion-related features, we use the corpus developed by (Aman and Szpakowicz, 2007). This dataset consists of blog posts labeled by their corresponding emotion categories. As emotion taxonomy, the authors used six basic emotions, i.e., Anger, Disgust, Surprise, Sadness, Joy and Fear. In particular, the blog posts were split into sentences and each sentence was labeled. The dataset contains 5,205 sentences labeled by one of the emotion labels. After employing this model on the sarcasm dataset, we obtained a 150-dimensional feature vector from the fully-connected layer. As the aim of training is to classify each sentence into one of the six emotion classes, we used six neurons in the softmax layer.

4.4 Personality Feature Extraction Model

Detecting personality from text is a well-known challenging problem. In our work, we use five personality traits described by (Matthews and Gilliland, 1999), i.e., Openness, Conscientiousness, Extraversion, Agreeableness, and Neuroticism, sometimes abbreviated as OCEAN (by their first letters). As a training dataset, we use the corpus developed by (Matthews and Gilliland, 1999), which contains 2,400 essays labeled by one of the five personality traits each.

The fully-connected layer has 150 neurons, which are treated as the features. We concatenate the feature vector of each personality dimension in order to create the final feature vector. Thus, the personality model ultimately extracts a 750-dimensional feature vector (150-dimensional feature vector for each of the five personality traits). This network is replicated five times, one for each personality trait. In particular, we create a CNN for each personality trait and the aim of each CNN is to classify a sentence into binary classes, i.e., whether it expresses a personality trait or not.

4.5 Baseline Method and Features

CNN can also be employed on the sarcasm datasets in order to identify sarcastic and non-sarcastic tweets. We term the features extracted from this network *baseline features*, the method as *baseline method* and the CNN architecture used in this baseline method as *baseline CNN*. Since the fully-connected layer has 100 neurons, we have 100 baseline features in our experiment. This method is termed baseline method as it directly aims to classify a sentence as sarcastic vs non-sarcastic. The baseline CNN extracts the inherent semantics from the sarcastic corpus by employing deep domain understanding. The process of using baseline features with other features extracted from the pre-trained model is described in Section 5.2.

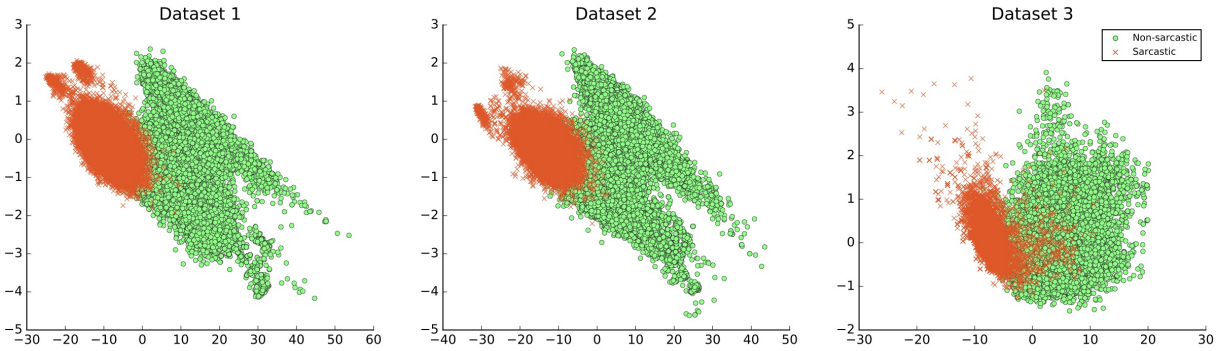

Figure 3: Visualization of the data.

5 Experimental Results and Discussion

In this section, we present the experimental results using different feature combinations and compare them with the state of the art. For each feature we show the results using only CNN and using CNN-SVM (i.e., when the features extracted by CNN are fed to the SVM). Macro-F1 measure is used as an evaluation scheme in the experiments.

5.1 Sarcasm Datasets Used in the Experiment

Dataset 1 (Balanced Dataset) This dataset was created by (Ptácek et al., 2014). The tweets were downloaded from Twitter using #sarcasm as a marker for sarcastic tweets. It is a monolingual English dataset which consists of a balanced distribution of 50,000 sarcastic tweets and 50,000 non-sarcastic tweets.

Dataset 2 (Imbalanced Dataset) Since sarcastic tweets are less frequently used (Ptácek et al., 2014), we also need to investigate the robustness of the selected features and the model trained on these features on an imbalanced dataset. To this end, we used another English dataset from (Ptácek et al., 2014). It consists of 25,000 sarcastic tweets and 75,000 non-sarcastic tweets.

Dataset 3 (Test Dataset) We have obtained this dataset from The Sarcasm Detector[2]. It contains 120,000 tweets, out of which 20,000 are sarcastic and 100,000 are non-sarcastic. We randomly sampled 10,000 sarcastic and 20,000 non-sarcastic tweets from the dataset. Visualization of both the original and subset data show similar characteristics.

Pre-processing A two-step methodology has been employed in filtering the datasets used in our experiments. Firstly, we identified and removed all the "user", "URL" and "hashtag" references present in the tweets using efficient regular expressions. Special emphasis was given to this step to avoid traces of hashtags, which might trigger the models to provide biased results. Secondly, we used *NLTK Twitter Tokenizer* to ensure proper tokenization of words along with special symbols and emoticons. Since our deep CNNs extract contextual information present in tweets, we include emoticons as part of the vocabulary. This enables the emoticons to hold a place in the word embedding space and aid in providing information about the emotions present in the sentence.

5.2 Merging the Features

Throughout this research, we have carried out several experiments with various feature combinations. For the sake of clarity, we explain below how the features extracted using difference models are merged.

- In the standard feature merging process, we first extract the features from all deep CNN based feature extraction models and then we concatenate them. Afterwards, SVM is employed on the resulted feature vector.

[2]http://thesarcasmdetector.com

- In another setting, we use the features extracted from the pre-trained models as the static channels of features in the CNN of the baseline method. These features are appended to the hidden layer of the *baseline CNN*, preceding the final output softmax layer.

For comparison, we have re-implemented the state-of-the-art methods. Since (Joshi et al., 2015) did not mention about the sentiment lexicon they use in the experiment, we used SenticNet (Cambria et al., 2016) in the re-implementation of their method.

5.3 Results on Dataset 1

As shown in Table 2, for every feature CNN-SVM outperforms the performance of the CNN. Following (Tsur et al., 2010), we have carried out a 5-fold cross-validation on this dataset. The baseline features (4.5) perform best among other features. Among all the pre-trained models, the sentiment model (F1-score: 87.00%) achieves better performance in comparison with the other two pre-trained models. Interestingly, when we merge the baseline features with the features extracted by the pre-trained deep NLP models, we only get 0.11% improvement over the F-score. It means that the baseline features alone are quite capable to detect sarcasm. On the other hand, when we combine sentiment, emotion and personality features, we obtain 90.70% F1-score. This indicates that the pre-trained features are indeed useful for sarcasm detection. We also compare our approach with the best research study conducted on this dataset (Table 3). Both the proposed baseline model and the *baseline + sentiment + emotion + personality* model outperform the state of the art (Joshi et al., 2015; Ptácek et al., 2014). One important difference with the state of the art is that (Ptácek et al., 2014) used relatively larger feature vector size (>500,000) than we used in our experiment (1,100). This not only prevents our model to overfit the data but also speeds up the computation. Thus, we obtain an improvement in the overall performance with automatic feature extraction using a relatively lower dimensional feature space.

In the literature, word n-grams, skipgrams and character n-grams are used as baseline features. According to Ptacek et al. (Ptácek et al., 2014), these baseline features along with the other features (sentiment features and part-of-speech based features) produced the best performance. However, Ptacek et al. did not analyze the performance of these features when they were not used with the baseline features. Pre-trained word embeddings play an important role in the performance of the classifier because, when we use randomly generated embeddings, performance falls down to 86.23% using all features.

5.4 Results on Dataset 2

5-fold cross-validation has been carried out on Dataset 2. Also for this dataset, we get the best accuracy when we use all features. Baseline features have performed significantly better (F1-score: 92.32%) than all other features. Supporting the observations we have made from the experiments on Dataset 1, we see CNN-SVM outperforming CNN on Dataset 2. However, when we use all the features, CNN alone (F1-score: 89.73%) does not outperform the state of the art (Ptácek et al., 2014) (F1-score: 92.37%). As shown in Table 3, CNN-SVM on the *baseline + sentiment + emotion + personality* feature set outperforms the state of the art (F1-score: 94.80%). Among the pre-trained models, the sentiment model performs best (F1-score: 87.00%).

B	S	E	P	Dataset 1		Dataset 2		Dataset 3	
				CNN	CNN-SVM	CNN	CNN-SVM	CNN	CNN-SVM
+				95.04%	97.60%	89.33%	92.32%	88.00%	92.20%
	+			-	87.00%	-	86.50%	-	73.50%
		+		-	76.30%	-	84.71%	-	72.10%
			+	-	75.00%	-	77.90%	-	74.41%
	+	+	+	-	**90.70%**	-	**90.90%**	-	**84.43%**
+	+			95.21%	97.67%	89.69%	94.60%	88.58%	93.12%
+		+		95.22%	97.65%	89.72%	94.50%	88.56%	92.63%
+			+	95.21%	97.64%	89.62%	93.60%	88.26%	92.50%
+	+	+	+	95.30%	**97.71%**	89.73%	**94.80%**	88.51%	**93.30%**

Table 2: Experimental Results. Legenda: B = Baseline, S = Sentiment, E = Emotion, P = Personality, 5-fold cross-validation is carried out for all the experiments.

Method	Dataset 1	Dataset 2	Dataset 3	D3 => D1
(Ptácek et al., 2014)	94.66%	92.37%	63.37%	53.02%
(Joshi et al., 2015)	65.05%	62.37%	60.80%	47.32%
Proposed Method (using all features)	97.71%	94.80%	93.30%	76.78%

Table 3: Performance comparison of the proposed method and the state-of-the-art approaches. Legenda: D3 => D1 is the model trained on Dataset 3 and tested on Dataset 1.

Table 2 shows the performance of different feature combinations. The gap between the F1-scores of only baseline features and all features is larger on the imbalanced dataset than the balanced dataset. This supports our claim that sentiment, emotion and personality features are very useful for sarcasm detection, thanks to the pre-trained models. The F1-score using sentiment features when combined with baseline features is 94.60%. On both of the datasets, emotion and sentiment features perform better than the personality features. Interestingly, using only sentiment, emotion and personality features, we achieve 90.90% F1-score.

5.5 Results on Dataset 3

Experimental results on Dataset 3 show the similar trends (Table 3) as compared to Dataset 1 and Dataset 2. The highest performance (F1-score 93.30%) is obtained when we combine baseline features with sentiment, emotion and personality features. In this case, also CNN-SVM consistently performs better than CNN for every feature combination. The sentiment model is found to be the best pre-trained model. F1-score of 84.43% is obtained when we merge sentiment, emotion and personality features.

Dataset 3 is more complex and non-linear in nature compared to the other two datasets. As shown in Table 3, the methods by (Joshi et al., 2015) and (Ptácek et al., 2014) perform poorly on this dataset. The TP rate achieved by (Joshi et al., 2015) is only 10.07% and that means their method suffers badly on complex data[3]. The approach of (Ptácek et al., 2014) has also failed to perform well on Dataset 3, achieving 62.37% with a better TP rate of 22.15% than (Joshi et al., 2015). On the other hand, our proposed model performs consistently well on this dataset achieving 93.30%.

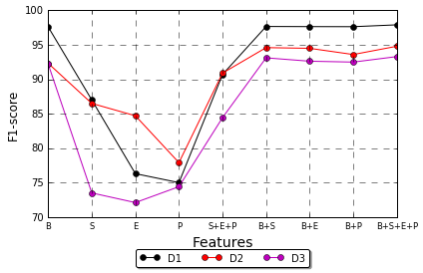
5.6 Testing Generalizability of the Models and Discussions

To test the generalization capability of the proposed approach, we perform training on Dataset 1 and test on Dataset 3. The F1-score drops down dramatically to 33.05%. In order to understand this finding, we visualize each dataset using PCA (Figure 3). It depicts that, although Dataset 1 is mostly linearly separable, Dataset 3 is not. A linear kernel that performs well on Dataset 1 fails to provide good performance on Dataset 3. If we use *RBF* kernel, it overfits the data and produces worse results than what we get using linear kernel. Similar trends are seen in the performance of other two state-of-the-art approaches (Joshi et al., 2015; Ptácek et al., 2014). Thus, we decide to perform training on Dataset 3 and test on the Dataset 1. As expected better performance is obtained[4] with F1-score 76.78%. However, the other two state-of-the-art approaches fail to perform well in this setting. While the method by (Joshi et al., 2015) obtains F1-score of 47.32%, the approach by (Ptácek et al., 2014) achieves 53.02% F1-score when trained on Dataset 3 and tested on Dataset 1. Below, we discuss about this generalizability issue of the models developed or referred in this paper.

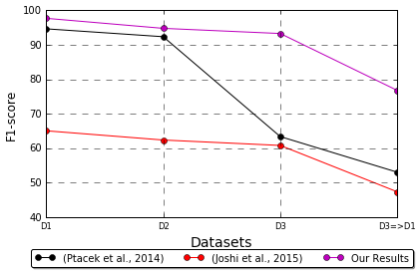
As discussed in the introduction, sarcasm is very much topic-dependent and highly contextual. For example, let us consider the tweet "I am so glad to see Tanzania played very well, I can now sleep well :P". Unless one knows that Tanzania actually did not play well in that game, it is not possible to spot the sarcastic nature of this sentence. Thus, an n-gram based sarcasm detector trained at time t_i may perform poorly to detect sarcasm in the tweets crawled at time t_j (given that there is a considerable gap between these time stamps) because of the diversity of the topics (new events occur, new topics are discussed) of the tweets. Sentiment and other contextual clues can help to spot the sarcastic nature in this kind of tweets. A highly positive statement which ends with a emoticon expressing joke can be sarcastic.

[3]We use *RBF* kernel, C=8 and gamma=0.01 to evaluate the method of Joshi et al. on Dataset 3 with 5-fold cross-validation.

[4]We report the result using all the features in this case.



(a) F1-score using different feature combinations.



(b) Comparison with the state of the art on benchmark datasets.

Figure 4: Plot of the performance of different feature combinations and methods.

State-of-the-art methods lack these contextual information which, in our case, we extract using pre-trained sentiment, emotion and personality models. Not only these pre-trained models, the baseline method (baseline CNN architecture) performs better than the state-of-the-art models in this generalizability test setting. In our generalizability test, when the pre-trained features are used with baseline features, we get 4.19% F1-score improvement over the baseline features. On the other hand, when they are not used with the baseline features, together they produce 64.25% F1-score.

Another important fact is that an n-grams model cannot perform well on unseen data unless it is trained on a very large corpus. If most of the n-grams extracted from the unseen data are not in the vocabulary of the already trained n-grams model, in fact, the model will produce a very sparse feature vector representation of the dataset. Instead, we use the word2vec embeddings as the source of the features, as word2vec allows for the computation of similarities between unseen data and training data.

5.7 Baseline Features vs Pre-trained Features

Our experimental results show that the baseline features outperform the pre-trained features for sarcasm detection. However, the combination of pre-trained features and baseline features beats both of themselves alone. It is counterintuitive, since experimental results prove that both of those features learn almost the same global and contextual features. In particular, baseline network dominates over pre-trained network as the former learns most of the features learned by the latter. Nonetheless, the combination of baseline and pre-trained classifiers improves the overall performance and generalizability, hence proving their effectiveness in sarcasm detection. Experimental results show that sentiment and emotion features are the most useful features, besides baseline features (Figure 4). Therefore, in order to reach a better understanding of the relation between personality features among themselves and with other pre-trained features, we carried out Spearman correlation testing. Results, displayed in Table 4, show that those features are highly correlated with each other.

	Sentiment	Happy	Fear	Openness	Conscientiousness
Sentiment	1.0	0.04*	0.03*	0.59*	0.83*
Happy		1.0	-0.48*	0.14*	0.12*
Fear			1.0	-0.10*	-0.09*
Openness				1.0	0.23*
Conscientiousness					1.0

Table 4: Spearman's correlations between different features. * Correlation is significant at the 0.05 level.

6 Conclusion

In this work, we developed pre-trained sentiment, emotion and personality models for identifying sarcastic text using CNN, which are found to be very effective for sarcasm detection. In the future, we plan to evaluate the performance of the proposed method on a large corpus and other domain-dependent corpora. Future work will also focus on analyzing past tweets and activities of users in order to better understand their personality and profile and, hence, further improve the disambiguation between sarcastic and non-sarcastic text.

Exploring Distributional Representations and Machine Translation for Aspect-based Cross-lingual Sentiment Classification

Jeremy Barnes Patrik Lambert* Toni Badia

*Webinterpret, Barcelona, Spain
{jeremy.barnes,toni.badia}@upf.edu, patrik.l@webinterpret.com

Abstract

Cross-lingual sentiment classification (CLSC) seeks to use resources from a source language in order to detect sentiment and classify text in a target language. Almost all research into CLSC has been carried out at sentence and document level, although this level of granularity is often less useful. This paper explores methods for performing aspect-based cross-lingual sentiment classification (aspect-based CLSC) for under-resourced languages. Given the limited nature of parallel data for under-resourced languages, we would like to make the most of this resource for our task. We compare zero-shot learning, bilingual word embeddings, stacked denoising autoencoder representations and machine translation techniques for aspect-based CLSC. We show that models based on distributed semantics can achieve comparable results to machine translation on aspect-based CLSC. Finally, we give an analysis of the errors found for each method.

1 Introduction

Sentiment analysis (SA) seeks to define the underlying sentiment of a text. The best results in SA require the use of a large number of resources; from tokenizers and parsers to large sentiment lexicons or hand-annotated corpora. The creation of these resources requires time, effort and a considerable monetary investment in order to ensure the quality and subsequent usefulness. Therefore, finding a way to perform sentiment analysis for under-resourced languages without having to repeat these efforts is an interesting endeavor. *Cross-lingual Sentiment Analysis* (CLSA) attempts to find methods to do just this. Most research on CLSA has been at document or sentence level. However, this does not capture the true granularity of opinionated text. Thus, in this paper we focus on CLSA at aspect-level[1]

Document- and sentence-level CLSA assume that an entire section of text expresses one sentiment towards one entity. This, however, is not always true. Aspect-based CLSA allows for multiple opinions towards multiple entities or aspects. Aspect-based CLSA can be decomposed into three subtasks: entity/aspect extraction, opinion holder extraction and sentiment classification. This last task, known as *Cross-lingual Sentiment Classification* (CLSC), has received little attention at aspect-level. Yet it would greatly benefit companies and government organizations that wish to gather information on the public opinions of their products or policies. In this paper we will only deal with improving or enabling aspect-based CLSC and leave the final goal of creating full aspect-based CLSA systems for under-resourced languages as future work.

Most research in CLSC has used Statistical Machine Translation (SMT) as a way of bridging the gap between languages, but there are drawbacks to this. First, an SMT system must be available for the language combination at hand. This requires a great deal of development and the quality of the sentiment analysis system used afterwards depends heavily on the quality of the SMT system. Secondly, study shows that even high quality SMT introduces noise into the data (Balahur and Turchi, 2014; Mohammad

[1]Here the term "aspect" refers to a feature of an entity. As an example taken from a hotel review, the sentence *"The rooms were great, but the service needs to improve"* contains two aspects (*rooms* and *service*) which pertain to the entity *hotel*. It is more useful to know that *rooms* is positive and *service* is negative than to know the overall sentiment towards *hotel*

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1613–1623, Osaka, Japan, December 11-17 2016.

et al., 2015). Finally, there are tasks in which systems which use distributed semantic representations to map between languages outperform SMT systems, e.g. cross-lingual document classification (Klementiev et al., 2012).

For this reason, a different representation of words and phrases, e.g. distributional vector representations, could prove to be a more effective approach and enable us to leverage information from resource-rich languages (English) to perform CLSA in a target language that lacks these resources (e.g. Spanish, Catalan, Basque).

This paper makes the following contributions:

- According to our knowledge, this is the most complete comparison of several types of distributed representations and machine translation for cross-lingual sentiment analysis.
- We give an analysis of the errors and possible ways to improve each system.
- We demonstrate that distributed representations can be competitive with machine translation for CLSC tasks.

2 Related Work

2.1 Monolingual Aspect-based Sentiment Analysis

Aspect-based sentiment analysis (ABSA) is a fine-grained approach to sentiment analysis. Many of the state-of-the-art ABSA systems in English require sophisticated NLP tools or hand-crafted sentiment lexicons. Hu and Liu (2004) propose WordNet-based methods for classifying aspect sentiment. Zhu et al. (2009) use sentiment lexicons. Moghaddam (2010) extracts an aspect and its nearest adjective and use a *k nearest neighbor* algorithm in order to estimate the rating of each aspect. Kiritchenko et al. (2014) use extracted features (part-of-speech tags, parsing features, sentiment lexicons, character-based information, n-grams) to train a *support vector machine* (SVM) for sentiment classification. These language-specific approaches do not lend themselves easily to CLSA because the target language often lacks the necessary resources.

2.2 Cross-lingual Sentiment Analysis

Aspect-based CLSA

In under-resourced languages, we lack resources and NLP tools which would allow us to create state-of-the-art systems similar to those mentioned. Therefore, the ability to leverage resources that already exist in English to perform sentiment analysis in other languages would be a great advantage. This would increase the performance of ABSA systems which are built using limited amounts of data in low-resourced languages and enable the creation of sentiment analysis systems in languages which have none at the moment.

Similarly, within CLSA, most researchers have worked at document- and sentence-level. In fact, there are only a handful of articles that deal with aspect-based CLSA. Zhou et al. (2012), Lin et al. (2014) and Klinger and Cimiano (2015) concentrate on extracting bilingual aspects but offer few ways to improve classification accuracy. Hass and Versley (2015) used machine translation and word alignment to map annotated syntactic nodes from English to German.

One of the difficulties at aspect-level is that the opinions attach to specific groupings of words, rather than a sentence or document. If we use SMT to create a new target language dataset, the opinionated units (e.g. opinion holder, opinion target, and opinion phrase) may be scattered or reordered. This would effectively reduce the usefulness of our new data because it would be difficult to project the opinion labels onto their corresponding word or phrase in the new dataset.

Lambert (2015) deals with this by using constrained SMT to translate the opinionated units within the context of the sentence. The classifiers trained on this SMT data achieve comparable results to their monolingual version. However, this is a state-of-the-art SMT system[2] which is not available in most language combinations. For these other languages, it would be useful to find alternative methods which do not require machine translation.

[2]The system achieves a *BLEU* score 45.3 in Spanish-English translation with true-case.

CLSA via Machine Translation

Advances in machine translation have made it possible to translate data from English to a target language or vice versa and use this data to train a classifying algorithm. There are reasons to believe that for well-resourced languages machine translation has reached a level that is useful for sentiment analysis (Banea et al., 2008; Duh et al., 2011; Balahur and Turchi, 2014; Mohammad et al., 2015). Much of the work has concentrated on the best combination of translation direction, classifiers and features (Banea et al., 2008; Banea et al., 2013; Balahur and Turchi, 2014). The advantage of this approach is that it is straight-forward to use a quality SMT system to create new resources by translating annotated corpora or sentiment lexicons (Mihalcea et al., 2007).

Nonetheless, there are disadvantages to using directly translated resources. Poor translation introduces a large amount of noise which hurts the performance of the classifier (Balahur and Turchi, 2014; Mohammad et al., 2015). It is clear that under-resourced languages are particularly susceptible to poor translation. Even with high quality machine translation, there is still a cross-lingual adaptation problem; the distribution of words and their polarity do not necessarily hold in cross-lingual contexts (Guo and Xiao, 2012; Mohammad et al., 2015). Therefore, we must find ways to minimize the undesirable effects of translation in cross-lingual sentiment analysis.

CLSA via Bilingual View

Another approach is to create a bilingual view of the data. The essence of this approach is to reduce the noise that translation introduces by presenting classifiers with complementary views. Wan (2009) creates a bilingual representation of the data through SMT and then uses co-training to take advantage of classifiers that commit complementary errors. This research seems promising, but there are some reasons to believe that the benefits of these techniques may have more to do with semi-supervised learning than cross-lingual transfer (Demirtas and Pechenizkiy, 2013).

Pan et al. (2011) use a bi-view non-negative matrix tri-factorization approach which allows for the incorporation of sentiment lexicon information. Lu et al. (2011) incorporate a joint bilingual model which makes use of unlabeled parallel or pseudo-parallel data in order to improve sentiment classification for both languages simultaneously.

CLSA via Latent View

Zhou et al. (2016) employ stacked denoising autoencoders to create a language independent representation of their data. This representation was then used as input for a linear SVM classifier.

For cross-lingual document classification, Prettenhofer and Stein (2011) use structural correspondence learning in order to find 'pivot' features. They use these features to create a representation of each document. These latent representations that encode the relationships betweens pivots and non-pivots are then used to train a linear classifier. Klementiev et al. (2012) create bilingual distributed representations as proposed by Bengio et al. (2003). They used these word vectors to classify cross-lingual documents.

The last two techniques are not entirely comparable to the first, since they perform cross-lingual document classification and not sentiment analysis. However, approaches which use latent representations are interesting because they have the potential to avoid some of the errors which are introduced by translation. To our knowledge, many techniques for creating latent bilingual representations (Chandar et al., 2014; Gouws et al., 2015; Vulić and Moens, 2016) have not been applied to CLSA. However, these techniques could provide a straightforward way to bridge the language gap.

3 Methodology

3.1 Datasets

The data used to train the sentiment analysis models are the English and Spanish OpeNER sentiment corpora (Agerri et al., 2013). We take a subset of these corpora which deal only with hotel reviews. Each review has annotations for opinion holders, opinion targets and opinion sentiment. We refer to this triplet (opinion holder, opinion target, opinion sentiment) as an opinion unit. The sentiment can be strong positive, positive, negative, or strong negative. A neutral category is not included. As such, when

training a classifier, rather than training on the complete sentence, we use the opinion unit. Table 1 shows the statistics for these corpora.

OpeNER Corpora	English	Spanish
Training Examples	2780	2991
Strong Pos	23.38%	29%
Pos	46.08%	50.34%
Neg	25.61%	17.41%
Strong Neg	4.93%	3.01%
Test examples	929	999
Strong Pos	23.36%	29.23%
Pos	46.07%	50.34%
Neg	25.62%	17.42%
Strong Neg	4.95%	3.00%

Table 1: Statistics of OpeNER Corpora

The corpora used to create the word embeddings are an English and Spanish Wikipedia corpus. These were taken from Wikipedia dumps in January 2016 and preprocessed to remove html markup and lowercase all words. We then performed sentence and word tokenization. We did not remove punctuation because this is often useful information for sentiment analysis. Table 2 gives the statistics for these corpora.

Wikipedia Corpora	English	Spanish
Number of sentences	118,900,197	26,777,415
Number of tokens	2,055,786,401	506,612,108

Table 2: Statistics of Wikipedia Corpora

The English-Spanish part of the Europarl v7 corpus[3] (Koehn, 2005) is used as parallel data. It contains around 2 million aligned sentences from the European Parliament. Table 3 shows the statistics for this corpus.

Europarl v7 Corpus	English	Spanish
Number of sentences	1,965,734	1,965,734
Number of tokens	49,093,806	51,575,784

Table 3: Statistics of Europarl v7 Corpus

3.2 Experiments

We performed a set of experiments in order to test different approaches for aspect-based CLSA. Each experiment requires a different amount of parallel data.

Representation of Training and Test Data for Sentiment Classification

For all experiments we use the same train and test split shown in Table 1. For each experiment, we trained a classifier on the English training data, performed the cross-lingual transfer on the Spanish test data and used this new data to test our classifier, as in Figure 1. One difficulty encountered when using vector representations is that the opinion units are variable length. This means that to train a classifier either we find a fixed-length representation for all opinion units or we use a classifier that accepts variable-length input. We decided to take an averaging approach, which has shown promise in other works (Iyyer et al., 2015). For each opinion unit we took the arithmetic mean of the words that compose the opinion unit,

[3]http://www.statmt.org/europarl

as shown in Figure 2, in order to create a fixed-length vector representation for each sentence. We then use these vectors to train a classifier. For the SMT transfer methods, we trained the classifier on unigram features. In all experiments, we used the *sequential minimal optimization* (SMO) classifier from the WEKA toolkit (Hall et al., 2009).

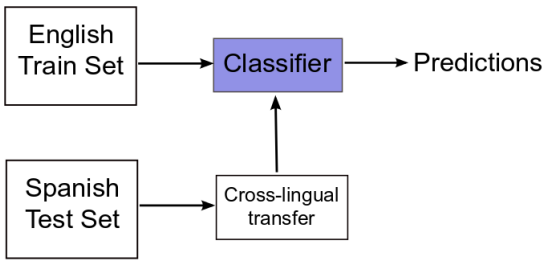

Figure 1: The process of cross-lingual sentiment classification. We assume that the opinion units have already been determined. The English train set is used to train a classifier. The Spanish test set is mapped accordingly and the classifier is tested on this cross-lingual test set.

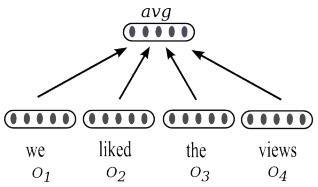

Figure 2: The representation of an opinion unit. For each word o_n in the opinion unit, we take its vector representation and average these vectors in order to create a fixed-length vector $avg = \sum_{i=1}^{n} \frac{o_i}{n}$, which we can use to train our classifier.

Zero-shot learning

Since we were interested in using the least amount of parallel data possible, we started with zero-shot learning. This is an approach which attempts to map between two monolingual vector representations using a "translation matrix" *W*. The desired effect is that the dot product of a Spanish word vector and *W* would be similar to the word vector of its English translation, as in Equation 1.

$$\mathbb{R}^{interesante} \circ W \approx \mathbb{R}^{interesting} \tag{1}$$

One could then perform a search for the most similar English vector and use this as a feature for classification. The only parallel data necessary is a bilingual dictionary. Given a pair of translated words and their associated vector representations $\{x_{eng}, x_{spa}\}$, we minimize the cost function in Equation 2 for our training vocabulary of length *n*:

$$\min_{W} \sum_{i=1}^{n} \parallel x_{eng} - x_{spa} \circ W \parallel^2 \tag{2}$$

Following Mikolov et al. (2013b) we created two sets of monolingual word embeddings using the Europarl v7 corpus (Koehn, 2005). We used the Skip-gram model (Mikolov et al., 2013a) and created 300 dimensional vectors using a window of 5 words, and 10 negative samples. We compiled a bilingual dictionary by taking the 8000 most common words in the English Wikipedia and translating them using Bing Translator[4]. Although Bing gives several options, we take only the first translation for use in our

[4]http://www.microsofttranslator.com/

bilingual dictionary. We then removed errors and ambiguous words and arrived at a final number of 4518 word pairs to train the matrix. Finally, we used stochastic gradient descent to optimize the translation matrix *W*. After creating the transition matrix *W*, we tested the effectiveness of this matrix translation to enable CLSC.

For each opinion unit in the corpora, we created a fixed-length vector representation, as shown in Figure 2. We now had a dataset with training instances such as $\{x_i : y_i\}$, where x_i was a 300 dimension vector and y_i was its corresponding label (Strong Positive, Positive, Negative, Strong Negative).

As a baseline, we trained and tested an SVM on the Spanish data from the OpeNER corpus as the Spanish test set has the same opinion units as the cross-lingual test set. We did the same with the English data, although this is not truly comparable[5]. Results are shown in Table 4.

We then created the cross-lingual test set by applying our translation matrix *W* to the Spanish test set. In order to find the most similar vector from the English word embeddings, we used a *k nearest neighbor* algorithm with cosine as the distance metric. Finally, we used the mean of the word embeddings as mentioned above to create the final fixed-length representation. We tested on the cross-lingual test set. The results are shown in Table 4.
