As expected, the benchmark model based on item sequence (experts' judgements) performed worse for *C* and *M* items than for *PD* and *DC* items. As discussed earlier, the former are grouped into sets and are not sequenced according to difficulty of individual items. However, even for simpler items the item sequence was not a strong predictor of item difficulty. One reason for this is that factors other than item difficulty may affect the item sequence in the form and therefore item position may not always accurately reflect the expert judgment about its difficulty. At the same time, this result is also consistent with Beinborn et al. (2014)'s results where English language teachers classified items into four groups (very easy, easy, medium, and difficult). The inter-rater agreement for three raters was not high (Fleiss κ = 0.36). This shows that the item difficulty rating is a challenging task even for experts.

Item text complexity was a stronger predictor of item difficulty for less complex item types (*PD* and *DC*) than for more complex item types. Interestingly, the best performance was observed for *PD* items even though the system had no access to the information about the graphic part of the item. For more complex items, *C* and *M*, the text complexity of the item text appeared to have a smaller contribution to overall item difficulty. Furthermore, we found that for *M* items the textual complexity of the longer listening passage shared between several items was less predictive of item difficulty than the textual complexity of the actual question and responses.

To investigate this further, we conducted the following experiment. First, for each item type, we calculated a range of deltas per each set of items (testlet-condition). Next, we paired three randomly selected items and calculated a range of deltas (random-condition). We conducted a descriptive analysis of delta ranges for these two conditions. Table 6 summarizes the results of this experiment.

The range of difficulty among items within the same testlet (or set) was quite wide. The average difficulty ranges were slightly lower than random-condition, but not largely different. If the overall difficulty of listening passage had substantial impact on the item difficulty, the difficulties of the items that shared the same listening passage might have been within a small range and therefore the difficulty ranges in the testlet condition would be smaller than for the random sets. However, we did not find such a tendency: the difficulty ranges of the testlets were comparable to random sets.

Furthermore, the maximum difficulty ranges within testlet condition were substantially large. For instance, it was 8.00 for *M* items of Group B, and this was only slightly lower than the difficulty range of entire *M* items (9.4 in Table 2). This analysis suggested that both easy and difficult items could be generated from the same listening passage, and only the passage difficulty itself may not be a strong predictor for the item difficulty. Accurate prediction of item difficulty requires a new set of features that capture the interaction between passages and questions.

Country	N	Item Type	Condition	Minimum	Maximum	Mean	standard deviation
Group A	250	*M*	testlet	0.10	6.80	2.26	1.17
			random	0.16	6.44	2.32	1.22
		C	testlet	0.10	6.60	2.00	1.09
			random	0.13	5.94	2.21	1.16
Group B	313	*M*	testlet	0.20	8.00	2.39	1.31
			random	0.12	7.51	2.46	1.29
		C	testlet	0.10	6.40	2.32	1.15
			random	0.13	6.72	2.47	1.27

Table 6: Comparison of difficulty ranges between testlets and random sets

5 Conclusion

Our analyses demonstrated that the generic features measuring item text complexity can be used to predict item difficulty. For simpler item types, the text complexity of the item text accounts for a larger share of variance than for more complex items. Our results also show that the accuracy of the generic system based on the text complexity features is equal to or better than the accuracy of human estimates. This result was consistent for a several types of items with different structure and across two different populations of test takers.

We also found that the most highly ranked features were related to item vocabulary, such as lexical frequency of the words as well as the level of concreteness. However, the system based on vocabulary features performed worse than the system based on all features. Finally, for sets of items which shared a common listening passage, the best performance was achieved by combining the text complexity of the printed questions and the recorded passage.

Abstract

The appropriate use of collocations is a challenge for second language acquisition. However, high quality and easily accessible Chinese collocation resources are not available for both teachers and students. This paper presents the design and construction of a large scale resource of Chinese collocational knowledge, and a web-based application (OCCA, Online Chinese Collocation Assistant) which offers free and convenient collocation search service to end users. We define and classify collocations based on practical language acquisition needs and utilize a syntax based method to extract nine types of collocations. Totally 37 extraction rules are compiled with word, POS and dependency relation features, 1,750,000 collocations are extracted from a corpus for L2 learning and complementary Wikipedia data, and OCCA is implemented based on these extracted collocations. By comparing OCCA with two traditional collocation dictionaries, we find OCCA has higher entry coverage and collocation quantity, and our method achieves quite low error rate at less than 5%. We also discuss how to apply collocational knowledge to grammatical error detection and demonstrate comparable performance to the best results in 2015 NLP-TEA CGED shared task. The preliminary experiment shows that the collocation knowledge is helpful in detecting all the four types of grammatical errors.

1 Introduction

Second language (L2) learners often have problems in appropriate use of word collocations (Bahns and Eldaw,1993; Farghal and Obiedat, 1995; Nesselhauf, 2003). For example, English speakers who are learning Chinese are likely to produce incorrect expressions e.g. 漂亮 的 歌 (piaoliang/beautiful de/* ge/song) because "beautiful song" is a reasonable collocation in English. However, 漂亮 (piaoliang/beautiful) is not an acceptable modifier for 歌 (ge/song) in Chinese (Lu, 1987). Bahns and Eldaw (1993) went deeply into this issue and suggested that leaner's collocational competence does not develop in parallel with general vocabulary knowledge, because words are usually acquired individually without taking note of their immediate environment (Siyanova and Schmitt, 2008).

This problem could be more serious for learning analytic languages such as Chinese, because apart from the negative transfer from the first language (L1), this typical analytic language does not have inflectional morphemes, and uses function words with little lexical meaning to express grammatical relationships. These function words are also highly involved in collocations. The following shows collocation examples with function words:

(a) 在 (zai/*) X 上 (shang/on) → on X
(b) 诚实 (chengshi/honest) 的(de/*) 人 (ren/person) → honest person
(c1) 买 (mai/buy) 东西 (dongxi/something) → buy something
(c2) 买 (mai/buy) 了(le/*) 东西 (dongxi/something) → have bought something
(c3) 买 (mai/buy) 着 (zhe/*) 东西 (dongxi/something) → be buying something

Example (a) is a two-word collocation in which the preposition 在 (zai) collocates with the postposition 上 (shang). The auxiliary word 的 (de) in Example (b) connects an attributive and a head noun. By comparing (c1), (c2) and (c3), the auxiliary words 了 (le) and 着 (zhe) are used to indicate perfective and progressive aspects. These examples illustrate at least three features of Chinese function words: (1) directly constituting specific collocations, e.g. a preposition and a postposition; (2) acting

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3254–3263, Osaka, Japan, December 11-17 2016.

as an auxiliary structural particle in a collocation, e.g. 的 (de); (3) indicating the aspect, e.g. 了 (le) and 着 (zhe). Therefore, teaching and learning Chinese collocations become a considerable challenge.

In order to offer informative reference of collocational knowledge to L2 teachers and learners, this paper discusses the construction of a Chinese collocational knowledge resource and its application for second language acquisition. We define nine types of collocations reflecting Chinese specific grammatical features, and automatically extract collocations from two source corpora: CTC[1], a Chinese text corpus for L2 learners (Yang and Xiao, 2015) and Simplified Chinese Wikipedia Corpus[2]. Sentences in the corpora are firstly processed by LTP-Cloud (Che et al., 2010), a Chinese NLP toolkit to do word segmentation, POS tagging and dependency parsing. Then we compile 37 rules based on word, POS and dependency relation features to extract the target word combinations. After building a collocation database containing over 1,750,000 collocations and the corresponding attributes, we design and construct the OCCA (Online Chinese Collocation Assistant) to offer free and convenient collocation search service to users. To examine the coverage, accuracy and efficiency of our collocation data, we compare it with two traditional collocation dictionaries and apply it to the grammatical error detection task. The experiment shows desirable results from both the comparison and the application.

The rest of the paper is structured as follows. In section 2 we review existing Chinese collocation resources and the automatic extraction methods. Section 3 discusses our definition and operational types for Chinese collocations. Section 4 describes the approach of extracting collocations from text corpora and building the Online Chinese Collocation Assistant. The comparisons and applications of our approach are discussed in Section 5 and 6. We draw brief conclusions in the last section based on the experimental results.

2 Related Work

The definition of collocation varies in previous studies, but most of them emphasize the importance of statistical frequency of word combinations (Firth, 1957; Church, 1990). Benson et al. (1986) defined collocation as "an arbitrary and recurrent word combination", and classified collocations into a lexical group and a grammatical group. Xu et al. (2009) gave a more specific definition: "a collocation is a recurrent and conventional expression containing two or more content word combinations that hold syntactic and/or semantic relations." This definition emphasizes the syntactic and semantic relations between words but excludes the function words.

Existing resources of collocational knowledge mainly fall into two types, i.e. collocation dictionary and collocation bank. Manually compiled dictionaries may have problems in coverage and consistency, and it is quite difficult to add new entries or collocations (Smadja, 1993). Besides, a list of typical collocations without contexts is not sufficient to support language learning. Xu et al. (2009) built Chinese Collocation Bank (CCB) with true collocations annotated in a large-scale news corpus. It is a valuable resource for collocation related research and NLP tasks, but might not be appropriate for language acquisition for two reasons. Firstly, collocations are domain dependent (Smadja, 1993). CCB annotated collocations from the People's Daily corpus (Yu et al., 2000), which consists of news articles of People's Daily, an official newspaper of the Chinese Communist Party. Frequent collocations in this corpus are mostly used in formal texts, and highly related to politics and economy. They might not be suitable to second language learning. Secondly, CCB defined collocations as content word combinations and did not deal with function words that are one of the most difficult parts for L2 learners.

Most previous studies used window-based methods to extract word combinations in a fixed window based on word co-occurrences or distribution scores (Church, 1990; Smadja, 1993; Sun et al., 1997; Xu and Lu, 2006). Obviously, these methods do not target at collocations with syntactic and/or semantic relations. Kilgarriff et al. (2004) used regular expressions over POS-tags to formalize rules of collocation patterns when building Word Sketch Engine. Huang et al. (2005) extended Sketch Engine to Chinese and found POS based rules were efficient in extracting grammatical information. However, they also addressed that the regular expression patterns faced challenges in long-distance collocation extraction and considerable risk of mis-classification, which is more serious in Chinese than in English.

[1] CTC (Corpus of Teaching Chinese as Second Language) contains text data from over 100 classic Chinese textbooks for L2 learning and New HSK (Chinese language proficiency Test) papers since 2009: http://www.aihanyu.org/basic.aspx.
[2] Chinese Wikipedia download: https://dumps.wikimedia.org/zhwiki/

Thus a better strategy should incorporate richer annotation of corpus and take more consideration of Chinese grammatical features.

3 The Proposed Approach

In contrast to definitions of collocation in the previous studies, We introduce function words into our collocation study, and identify four characteristics of collocations: (1) can be word combinations with more than two words; (2) can contain both content words and function words; (3) collocated words can be either adjacent or non-adjacent; (4) collocated words must hold syntactic or semantic relations.

We propose a syntax-based method based on dependency parsing and extract collocations from CTC, a text corpus for L2 learners to meet the domain needs. After preliminary studies, we find Chinese Wikipedia as a good supplement source because it has much bigger corpus size than CTC and the Wikipedia (WIKI hereafter) texts are from various domains. The collocations extracted from WIKI could serve as an important complement to CTC from both the coverage and the domain perspectives. In addition, complicated sentences in WIKI could be good resources for advanced-level learners.

In order to extract collocations based on the dependency trees efficiently and effectively, we define nine types of grammatical collocations as the extraction targets. As shown in Table 1, four of them have universal syntactic relations, while the other five types are Chinese unique collocations with specific syntactic or semantic relations that should be emphasized in second language acquisition. Function words are highly involved in all the types, and in addition to the most common two-word collocations, six types include three-word or four-word collocations.

Types	Language Independent	Function Words	No. of Words
Verb-Object (VO)	Y	direction verb, particle	2, 3, 4
Subject-Predicate (SP)	Y	direction verb, particle	2, 3, 4
Adjective-Noun (AN)	Y	particle	2, 3
Adverb-Predicate (AP)	Y	particle	2, 3
Classifier-Noun (CN)	N	classifier	2
Preposition-Postposition (PP)	N	preposition, direction noun	2
Preposition-Verb (PV)	N	prepostion, direction verb, particle	2, 3, 4
Predicate-Complement (PC)	N	direction verb, particle	2, 3, 4
Connective-Connective (CC)	N	conjunction, conjunctive adverb	2

Table 1. Collocation types

We will briefly introduce the five Chinese-dependent types in the following and the detailed descriptions for 26 forms of word combination based on the nine types are given in OCCA online user guide[3].

- **Classifier-Noun (CN):** Chinese classifier, also called measure word, is used to modify a noun after a number or quantifier. The translation of “a person" is 一个人 (yi/a ge/* ren/person), 个 (ge) is a measure word for 人 (ren/person). Most Chinese nouns require measure words based on their innate semantic and cognitive relations (Zhang, 2007; Her and Hsieh, 2010).
- **Preposition-Postposition (PP):** A preposition usually collocates with specific postpositions (also called direction nouns) to express spatial or temporal relations. They can constitute a prepositional phrase with a noun phrase in between, e.g. 在 桌子 上 (zai/* zhuozi/table shang/on) which means “on the table”.
- **Preposition-Verb (PV):** Both modern Chinese and English are S-V-O languages, however, word order in Chinese is often changed to S-P-O-V by some special prepositions to emphasize a part of the sentence, or to convey a nuance of the meaning (Hu et al., 2014). These prepositions directly introduce the objects of their collocated verbs, e.g. 把水喝了 (ba/* shui/water he/drink le/*) means “drink the water”. They only collocate with verbs that have certain semantic fea-

[3] OCCA user guide: http://occa.xingtanlu.cn/index.php?action=page&pid=11

tures, and most verbs must have one or two adjacent particles to indicate the aspect or direction (Wang, 1985; Lv, 1999; Zhang, 2001).

- **Predicate-Complement (PC):** Complement is a word, phrase or clause following the predicate (a verb or an adjective) to provide additional information, including result, direction, possibility, state, degree, quantity, duration, and location (Liu et al., 2001). To express these rich semantic features, complement has complicated internal structures. We summarize nine forms of Predicate-Complement collocation based on Liu et al. (2001)'s research.
- **Connective-Connective (CC):** Chinese conjunctions and adverbs can both serve as connectives between clauses to indicate various discourse relations, and these connectives are often used in a pair e.g. 因为 (yinwei/because) - 所以 (suoyi/so) for casual relation and 虽然 (suiran/although) – 但是 (danshi/but) for contrastive relation. We identify 45 connective pairs as word collocations based on Liu et al. (2001)'s research of conjunction and adverb usages.

After extracting collocations, we will construct a web-based collocation assistant (OCCA). In order to meet the practical requirements of learning and teaching which we have uncovered based on reviewing previous studies, the OCCA will provide users collocations with the following features: (1) given with context sentences; (2) defined and classified with full consideration of Chinese grammatical features, including syntactic structures and function words; (3) extracted from appropriate texts that are suitable for L2 learners in both domain and degree of difficulty; (4) updated easily with a change of corpus.

4 Extracting Collocations and Constructing OCCA

Figure 1 shows the steps in the process of extracting collocations and building OCCA. The details of each step will be explained as following.

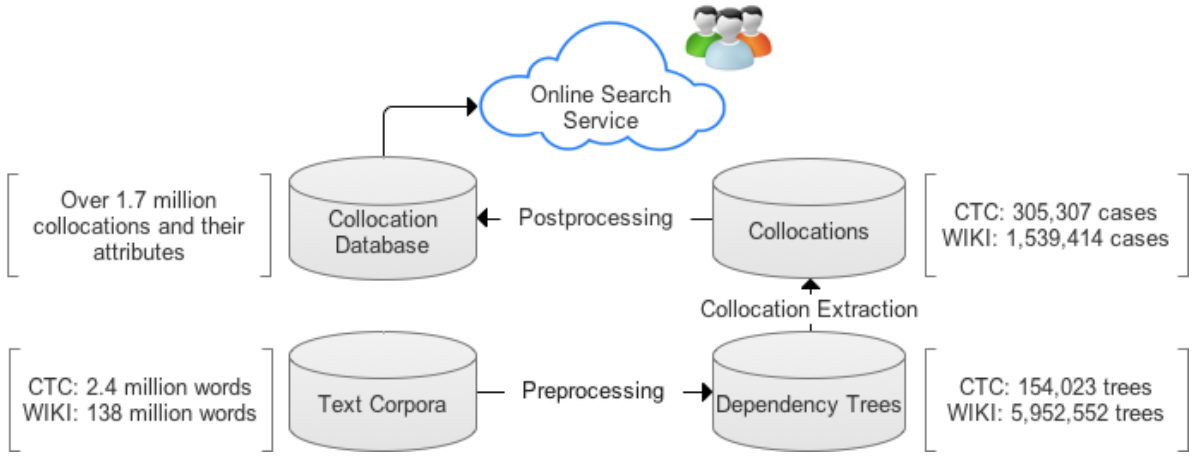

Figure 1. Procedure of our approach

```
<sent id="15213" cont="我们都笑了起来。">
  <word id="0" cont="我们" pos="r" ne="O" parent="2" relate="SBV"/>
  <word id="1" cont="都" pos="d" ne="O" parent="2" relate="ADV"/>
  <word id="2" cont="笑" pos="v" ne="O" parent="-1" relate="HED"/>
  <word id="3" cont="了" pos="u" ne="O" parent="2" relate="RAD"/>
  <word id="4" cont="起来" pos="v" ne="O" parent="2" relate="CMP"/>
  <word id="5" cont="。" pos="wp" ne="O" parent="2" relate="WP"/>
```

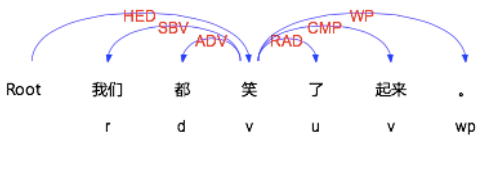

Figure 2. The pre-processing result of a Chinese sentence 我们都笑了起来 (wo'men/we dou/all xiao/laugh le/* qilai/*), which means "we all laugh"

4.1 Pre-processing

LTP-Cloud (Che et al., 2010), a Chinese NLP toolkit, is utilized to carry out word segmentation, POS tagging and dependency parsing for sentences in CTC and WIKI. We choose the latest released version (v3.3.1) of the toolkit to ensure the performance of each NLP module. We obtain over 6.1 million

dependency trees from the two corpora and the results are presented in XML files. Figure 2 shows an XML tree and its dependency graph of a Chinese sentence.

4.2 Collocation Extraction

Dependency tree is an ideal carrier of various grammatical features including dependency relations as well as POS tags that can be used in automatic collocation extraction. As shown in Table 2, we firstly build mappings between dependency relations and collocation types. These relations exist between headwords and their direct modifiers. As they are not in one-to-one mappings with collocation types, POS and word location features are utilized as constraints. In addition to the dependency relations in Table 2, we use the RAD (right adjunct) relation to identify structural and aspect particles that are necessary units in three-word and four-word collocations. Since collocated words in Connective-Connective (CC) collocations do not have direct dependency relations between each other, we only adopt word and POS features for extraction of this type. After analysing all the collocation forms, we manually compile 37 rules to extract the nine types of collocations from the dependency trees. Most rules deal with two-word collocations by extracting dependency triples {headword; modifier; dependency relation}, and also collocations that have more than two words and multiple relations.

Collocation Type	Dependency Relation	Collocation Type	Dependency Relation
VO	VOB (object of verb)	AP	ADV (adverbial)
	IOB (indirect object)	CN	ATT (attribute)
	FOB (fronting object)	PP	POB (preposition-object)
SP	SBV (subject of verb)	PV	ADV (adverbial)
AN	ATT (attribute)	PC	CMP (complement)

Table 2. Mappings between dependency relations and collocation types

Taking the sentence in Figure 2 as an example, three colocations 我们 笑 (wo'men/we xiao/laugh), 都 笑 (dou/all xiao/laugh) and 笑 了 起来 (xiao/laugh le/* qilai/*) will be extracted in this step. The following rule illustrates how the three-word Predicate-Complement collocation 笑了起来 is extracted based on the words' location, POS and dependency features:

if word[relate] == 'CMP' & word[parent] == word[id]-2 & sent[word[id]-2][pos] == v & sent[word[id]-1][relate] == 'RAD' & sent[word[id]-1][parent] == word[id]-2:

extract sent[word[id]-2][cont], sent[word[id]-1][cont], word[cont] as a three-word Predicate-Complement collocation.

4.3 Post-processing

In step 2, we extract 305,307 CTC collocations and 1,539,414 WIKI collocations. To refine the extraction results, we filter out 4,262 CTC and 84,893 WIKI collocations by seven filtering rules, e.g. exclude a collocation if there is a colon between the headword and its direct modifier in the sentence.

After that, we calculate the frequency of each collocation, and identify the relevance between two collocations if they have the same headword, direct modifier and dependency relation, e.g. examples (c1, c2, and c3) mentioned in Section 1. As the only difference is the structural particles, collocations like c2 and c3 are defined as variants of c1. The collocation relevance information could help users gain better understanding of grammatical and semantic roles of Chinese structural particles.

After post-processing, we obtain 1,755,566 collocations in the database. Unlike CCB (Chinese Collocation Bank) that only deals with content word combinations, our data covers a large number of collocations containing function words. Nearly 30% collocations are constituted by one or more function words including prepositions, conjunctions, direction verbs, direction nouns, structural and aspect particles. In addition to the most common two-word collocations, we also extract three-word and four-word collocations, which approximately account for 25% of the total number.

4.4 Building the Online Acquisition Services

We build OCCA based on Apache, PHP and MySQL. The website is http://occa.xingtanlu.cn/. Users can input a single keyword or multiple keywords to search for collocations from CTC (default) or WIKI database. The system outputs collocations with consideration of their relevance and ranks them based on frequency. Users can click a collocation for all the context sentences. The detailed user guide is available on OCCA website. Liu (2010) suggested that word collocations from a corpus can effec-

tively assist language teachers to summarize typical usage patterns and important lexical properties of words. As OCCA offers collocations with statistics and context sentences, it can serve as a good assistant in vocabulary teaching. Students might also use it to retrieve word usages they are uncertain about.

5 Comparison with two Collocation Dictionaries

We evaluate the coverage (collocation type and quantity) and accuracy of OCCA by comparing its searching results with two classic Chinese collocation dictionaries: Modern Chinese Collocation Dictionary (Mei, 1999) and Modern Chinese Content Word Collocation Dictionary (Lin and Zhang, 1992) hereafter referred as D1 and D2.

D1 and D2 collect collocations for over 6,000 and 8,000 entries. In OCCA the CTC and WIKI databases contain 7,632 and 47,475 keywords with occurrences greater than 10 respectively. Considering CTC is a more comparable resource with the dictionaries in vocabulary size, we only use WIKI collocation data as reference in the comparison. As we are building a collocation assistant for second language acquisition, 100 words with the highest error occurrences in the HSK Dynamic Composition Corpus[4] are used as our test words.

After searching for these 100 words in OCCA (the default CTC database), and looking up them in D1 and D2, we find that OCCA contains 98 of them, with higher coverage than D1 (78 words) and D2 (24 words)[5]. The reason for this is that students make mistakes involving function words more often than content words. However, the main lexical items in the dictionaries are content words only, e.g. nouns, verbs, and adjectives.

We also analyse the collocation data of 19 words in the intersection of the three resources. The comparison is conducted from three perspectives: collocation type coverage, collocation quantity and collocation accuracy. As shown in Table 3, for these 19 entries, D1 and D2 both show six types of collocations in our definition, omitting Preposition-Verb (PV) and Preposition-Postposition (PP) collocations that deal with the syntactic and semantic relations of prepositions. As D1 and D2 do not include conjunction entries, the Connective-Connective collocations are not involved in this comparison either. We count the collocations of the 19 entries in these resources and find OCCA is much higher than D1 and D2 in collocation quantities. However, by analysing the collocation data, we also find that OCCA does not contain some collocations in D1 and D2, e.g. "外交 (waijiao/diplomatic) 问题 (wenti/problems)", and "农村 (nongcun/village) 发展 (fazhan/develop)", mainly because of the domain and size limit of the CTC corpus. However, the WIKI database could serve as a good supplement because it covers nearly 63% of the 278 collocations that cannot be retrieved in CTC.

Resources	Types	Quantities	Accuracy
D1	6	622	~100.00%
D2	6	3,234	~100.00%
OCCA	8	9,705	95.19%

Table 3. Collocation data of 19 entries

Assuming D1 and D2 both have 100.00% precision in collocation data, we manually label the correctness of the 9,705 collocations retrieved from the CTC collocation data. 467 of them are annotated as inappropriate collocations, thus the accuracy is 95.19%. Among the 467 collocations, about 6% of them are due to tokenization errors in pre-processing, 87% of them result from parsing errors e.g. 把 X 产生 (ba/* X chansheng/ produce), and 7% of them are extracted from correct parsing results but cannot be taken as appropriate word collocations, e.g. "三 表示" (san/three biaoshi/means). We also find that over 86% of these mistakes occur only one time, and over 8% of them occur two times. Thus OCCA now only outputs collocations with occurrences no less than three times to reduce the negative effect. We will collect collocation errors reported by OCCA users and develop better filtering module based on these data in future work.

[4] HSK dynamic composition corpus is a Chinese leaner corpus released by Beijing Language and Culture University: http://202.112.195.192:8060/hsk/index.asp

6 Experiment on Grammatical Error Detection

Collocation data has been proved helpful in a list of Computer Aided Language Learning (CALL) tasks for English learners (Shei and Pain, 2000; Futagi et al., 2008; Wu et al., 2010). To examine the effectiveness of our Chinese collocation resource, we conduct a preliminary experiment on grammatical error detection task using the OCCA collocation data.

NLP technologies for Chinese grammatical error diagnosis (CGED) have received a considerable amount of attention in recent years (Yu et al., 2014; Lee et al., 2015). Various linguistic and computational resources including L1 corpora, L2 corpora and web N-gram data have been employed to identify the grammatical errors (Chang et al., 2012; Cheng et al., 2014; Lee et al., 2014). However, Chinese collocation resource is rarely used in previous studies.

We use the test set of 2015 NLP-TEA CGED shared task in the experiment. This data set consists of 1,000 Chinese sentences collected from the essay section of the computer-based Test of Chinese as a Foreign Language (TOCFL), administered in Taiwan (Lee et al., 2015). Half of these sentences are correct, while the other half include a single defined grammatical error: redundant (132), missing (126), selection (110), and disorder (132).

As the test sentences are in traditional Chinese, while our collocation data is simplified, we carry out the language conversion with the Open Chinese Convert tool[6]. After that, we extract 7,262 word combinations from the 1,000 sentences by taking the same pre-processing and collocation extraction methods described in Section 4.

By looking up each collocation in OCCA including both CTC and WIKI databases, 496 instances in 401 sentences are identified with zero occurrence. We assume these sentences contain improper word combinations and manually label these collocations to check if they are valid to indicate grammatical errors. Table 4 shows examples we consider the zero occurrence tokens are related with the errors.

Type	Examples	Correction
Redundant	可是现在我把什么事都不记得。 (Preposition-Verb: 把 记得)	可是现在我什么事都不记得。 But I can't remember anything now.
Missing	我们到现在都是以写信为连络。 (Verb-Object: 为 联络)	我们到现在都是以写信为连络方式。 We are still writing letters to each other.
Selection	排队了很多时间才轮到我。 (Predicate-Complement: 排队 很多 时间)	排队了很久才轮到我。 I queued for quite a while before my turn.
Disorder	他教书在那个很有名的大学。 (Predicate-Complement: 教书 在)	他在那个很有名的大学教书。 He is teaching at that famous university.

Table 4. Grammatical error examples with zero occurrence collocation

After manual analysis, we find the collocation data could successfully detect word errors in 212 sentences. Among them 41% of the errors are detected by non adjacent word combinations, e.g. 把- 记得 (ba/* jide/remember) in which 把 (ba/*) is a redundant word, and 29% of the errors are detected by 3-word or 4-word combinations, e.g. 排队 很多 时间 (paidui/queue henduo/much shijian/time) in which 很多 时间 is a word selection error.

We also calculate the sentence-level precision, recall and F1 score for four error types. Table 5 shows the test result and the performance of three teams that achieved the best precision (CYUT team run2), recall (NTOU team run1) and F1 score (NTOU team run2) in the error detection part of CGED shared task.

From the data in Table 5, we could see that the collocation data is a helpful resource in the detection of inadequate word combinations. Even though we adopt a very simple data retrieval method, it achieves higher Precision and F1 score than the average of the CGED teams. The precision of our method is very close to the best precision 0.7453 achieved by CYUT team, and we have higher recall and F1 score than they have. NTOU team (Lin and Chen, 2015) proposed to measure sentence likelihood scores with Chinese Web 5-gram data for error detection. Compared with the n-gram dataset that is widely used in grammatical error diagnosis, the most notable advantage of the collocation data is it

[6] Open Chinese Convert Project: https://github.com/BYVoid/OpenCC

captures not only adjacent words but also non-adjacent words with syntactic or semantic relations, thus it could be able to indicate errors that exist in a long distance, e.g. the preposition-verb example 把-记得(ba/* jide/remember) in Table 3.

Type	Precision	Recall	F1 score
Redundant (42)	0.8571	0.3182	0.4641
Missing (48)	0.8136	0.3810	0.5189
Selection (67)	0.7128	0.6091	0.6569
Disorder (55)	0.5392	0.4167	0.4701
Average	**0.7307**	**0.4312**	**0.5424**
CGED bestP Team (CYUT-run2)	**0.7453**	0.2400	0.3631
CGED bestR Team (NTOU-run1)	0.5000	**1.0000**	0.6667
CGED bestF1 Team (NTOU-run2)	0.5164	0.9760	**0.6754**
CGED average	**0.5600**	**0.6066**	**0.5327**

Table 5. Performance of grammatical error detection

It should also be noted that the recall of our method is lower than precision which means that not all the grammatical errors are related with word collocations, especially the word redundant and missing types. To understand the pros and cons of this collocation based method, we analyse the false positive (FP) and false negative (FN) cases and reach the following findings.

False positive cases are correct sentences that are identified with an error because they contain collocations that cannot be retrieved in our database. The most important reason is the word usage difference between traditional and simplified Chinese. Some common words in traditional Chinese e.g. 捷运(jieyun/subway) and 障碍者(zhang'aizhe/disabled person) have different representations e.g. 地铁(ditie/subway) and 残疾人(canjiren/disabled person) in Mandarin. There are also some word combinations incorrectly extracted because of the word segmentation and parsing errors.

False negative cases refer to the incorrect sentences whose errors are not detected by our method. By analysing these sentences, we find most of the errors are relevant with adverb and auxiliary usages. With an adverb or auxiliary missing or using incorrectly, word combinations in the sentence could still be grammatically correct but the whole sentence might not meet the strict requirement of word order or semantic pattern. The following sentence is an example with a word missing error that the collocation based method could not identify. In this sentence an adverb 都 (all) should be used to modify the adjective 差不多 (similar):

Sentence: 我们发现了每个国家人民*差不多。We find people in different countries are similar.

Correction: 我们发现了每个国家人民都差不多。We find people in different countries are all similar.

From the above analysis, we could see that the collocation based method could be effective in detecting a fairy proportion of grammatical errors, especially for those involved non adjacent words. However, the collocation data alone is far from enough, thus we need to combine the dataset with other language resources e.g. the Web 5-gram data and statistical models to explore better strategies.

7 Conclusions

This paper discusses the design and construction of Online Chinese Collocation Assistant (OCCA) for second language teaching and learning. We identify the important roles of function words in collocational knowledge and develop automatic extraction method to extract nine types of Chinese collocations from two text corpora. By searching for keywords in OCCA, users can easily obtain collocations with their statistics and context sentences that are helpful in the vocabulary teaching and learning. We compare the collocation data of OCCA with two traditional dictionaries, and find OCCA has much higher entry coverage and collocation quantity. It also has quite low collocation error rate at less than 5%. In order to investigate the helpfulness of OCCA, we conduct a preliminary experiment to apply the collocation resource to Chinese grammatical error detection. By implementing the simple data retrieval method, OCCA collocations are effective in detecting four types of grammatical errors and demonstrate comparable performance with comparison to the best results in 2015 NLP-TEA CGED shared task.

To minimize the negative impacts of mistakes and to offer much more reliable collocation resources, we will develop more efficient and effective methods for filtering and correcting collocations in the

future. We also hope to conduct further study to verify the effectiveness of OCCA by combining the collocation data with other language resources and methods in CALL tasks.

Joint Inference for Event Coreference Resolution

Abstract

Event coreference resolution is a challenging problem since it relies on several components of the information extraction pipeline that typically yield noisy outputs. We hypothesize that exploiting the inter-dependencies between these components can significantly improve the performance of an event coreference resolver, and subsequently propose a novel joint inference based event coreference resolver using Markov Logic Networks (MLNs). However, the rich features that are important for this task are typically very hard to explicitly encode as MLN formulas since they significantly increase the size of the MLN, thereby making joint inference and learning infeasible. To address this problem, we propose a novel solution where we implicitly encode rich features into our model by augmenting the MLN distribution with low dimensional unit clauses. Our approach achieves state-of-the-art results on two standard evaluation corpora.

1 Introduction

Within-document event coreference resolution is the task of determining which event mentions in a text refer to the same real-world event. Event coreference is arguably more challenging and less studied than entity coreference. The challenge stems in part from the fact that an event coreference resolver typically lies towards the end of the standard information extraction (IE) pipeline, assuming as input the noisy outputs of its upstream components. Specifically, a standard event coreference resolver takes as input the extracted event triggers, their arguments, and the entity coreference information, and aggregates this information through rules to resolve coreferent event mentions. Each component of this pipeline can introduce errors that naturally propagate to the event coreference resolver, thereby significantly affecting its performance. Further, the aforementioned pipeline architecture also fails to exploit inter-dependencies between the various components that can provide valuable insights to the resolver.

In light of these weaknesses, we propose a novel approach to within-document event coreference resolution based on Markov Logic Networks (MLNs) (Domingos and Lowd, 2009). In our approach, we jointly perform four key tasks in the IE pipeline: trigger identification and subtyping, argument identification and role determination, entity coreference resolution, and event coreference resolution. To our knowledge, this is the first attempt to design an MLN for event coreference resolution. MLNs are particularly well-suited for modeling *joint inference* tasks in natural language processing (NLP) due to the inherent relational structure and uncertainty typically associated with challenging NLP problems.

A major obstacle to the successful application of MLNs to NLP tasks is the high computational complexity of probabilistic inference and learning algorithms. The MLNs used in NLP are so large that even linear time inference algorithms are computationally infeasible. For instance, the rich sets of features that are typically used to solve the four tasks in the IE pipeline for event coreference, are ill-suited for modeling as explicit MLN formulas, since they will yield a large MLN having millions of features. Therefore, a major contribution of our work lies in the proposal of a novel hybrid approach where we embed such features as weighted unit clauses in a low-dimensional space, and then integrate these clauses with the rest of the MLN formulas during inference. Since this idea is generally applicable to modeling NLP tasks using MLNs, we believe that our work will be of interest to other NLP researchers as well.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3264–3275, Osaka, Japan, December 11-17 2016.

Georges Cipriani$_{[Person]}$, a former militant of the French far-left group Action Directe, {left}$_{ev1}$ the prison$_{[Origin]}$ in Ensisheim in northern France on parole on Wednesday$_{[Time]}$. He$_{[Person]}$ {left}$_{ev2}$ Ensisheim$_{[Origin]}$ in a police vehicle$_{[Instrument]}$ bound for an open prison near Strasbourg.

Table 1: Event coreference resolution example.

We evaluate our approach on corpora involving two languages, the new KBP 2015 English corpus and the Chinese portion of the ACE 2005 corpus. On both corpora, our approach performs significantly better than the baseline pipeline-based resolver. In particular, on the KBP corpus, we achieve the best result reported to date surpassing the previous best result by around 0.43 percentage points in average F1-score.

2 Definitions and Corpora

2.1 Definitions

We employ the following definitions in our discussion of event extraction and coreference:

- An **event mention** is an explicit occurrence of an event consisting of a textual trigger, arguments or participants (if any), and the event type/subtype.
- An **event trigger** is a string of text that most clearly expresses the occurrence of event, usually a word or a multi-word phrase
- An **event argument** is an argument filler that plays a certain role in an event.
- An **event coreference chain** (a.k.a. an **event hopper**) is a group of event mentions that refer to the same real-world event. They must have the same event (sub)type.

To understand these definitions, consider first the example shown in Table 1, which contains two event mentions, $ev1$ and $ev2$. Here, *left* is the trigger for both $ev1$ and $ev2$ with subtype Movement.Transport-Person. $ev1$ has three arguments, *Georges Cipriani*, *prison*, and *Wednesday* with roles *Person*, *Origin*, and *Time* respectively. $ev2$ also has three arguments, *He* and *Ensisheim*, and *police vehicle* with roles *Person*, *Origin*, and *Instrument* respectively.

2.2 Corpora

We employ two text corpora in two languages for evaluation. The *English* corpus was used in the Event Nugget Detection and Coreference task in the TAC KBP 2015 Event Track (henceforth the KBP 2015 corpus). This corpus is composed of two types of documents, newswire documents and discussion forum documents. The training set consists of 158 documents with 6538 event mentions distributed over 3335 event coreference chains, and the test set consists of 202 documents with 6438 event mentions distributed over 4125 event coreference chains. The *Chinese* corpus is the Chinese portion of the ACE 2005 training corpus. This corpus is composed of documents taken from six sources, and consists of 633 documents with 3333 event mentions distributed over 2521 event coreference chains. Note that ACE and KBP employ slightly different event ontologies: ACE defines 33 event subtypes and KBP defines 38 event subtypes, among which 31 subtypes are shared by both ontologies.

2.3 Key Differences between ACE and KBP

While both ACE and KBP rely on the aforementioned definitions, the guidelines they employ when annotating triggers and event coreference chains are slightly different. Below we highlight the differences that are relevant to our discussion.[1]

First, there are slight differences w.r.t. the annotation of triggers. ACE only allows single-word triggers, whereas KBP additionally allows multi-word triggers (e.g., *laid off*). Also, each word in ACE may trigger at most one event mention, whereas each (multi-)word in KBP may trigger multiple event mentions (e.g., *murder* can trigger two event mentions with subtypes Life.Die and Conflict.Attack).

[1]For detailed definitions, see http://cairo.lti.cs.cmu.edu/kbp/2015/event/annotation and http://www.itl.nist.gov/iad/mig/tests/ace/2005/ for the definitions of event coreference adopted by KBP 2015 and ACE 2005 respectively.

Second, KBP adopts a more relaxed definition of event coreference than ACE. Specifically, KBP requires that two event mentions be coreferent as long as they *intuitively* refer to the same real-world event. In our running example, $ev1$ and $ev2$ are coreferent according to KBP because they both refer to the same event of Cipriani leaving the prison. ACE, on the other hand, *additionally* requires that the corresponding *arguments* in the two event mentions be coreferent. In the example, $ev1$ and $ev2$ are *not* coreferent according to ACE because their *Origin* arguments are not coreferent (one Origin argument involves a prison and the other involves the city Ensisheim). Note that determining whether two entity mentions are coreferent is the task of entity coreference. Like event mentions, entity mentions have corpus-specific *entity types*.

3 Background

In this section, we give a brief overview of MLNs and discuss related work in event coreference resolution.

3.1 Markov Logic Networks

Formally, an MLN $\mathcal{M}$ is a set of pairs (f_i, θ_i) where f_i is a formula in first-order logic and θ_i is a real number. Given a set of constants, an MLN represents a ground Markov network, in which we have one binary random variable for each possible ground atom and one propositional feature for each possible grounding of each first-order formula. The weight associated with the feature is the weight attached to the corresponding formula. The ground Markov network represents the following probability distribution:

$$P_{\mathcal{M}}(\omega) = \frac{1}{Z} \exp\left(\sum_{f_i} \theta_i N_{f_i}(\omega)\right) \quad (1)$$

where $N_{f_i}(\omega)$ is the number of groundings of f_i that evaluate to True given a world ω (an assignment of $\{0, 1\}$ to all ground atoms). The use of first-order logic enables the user to succinctly represent prior, relational knowledge about the application domain, while the weights help model uncertainty in the truth of the first-order logic sentences.

3.2 Related Work

Existing within-document English event coreference resolvers have been evaluated on different corpora, such as MUC (e.g., Humphreys et al. (1997)), ACE (e.g., Ahn (2006), McConky et al. (2012), Chen and Ji (2009), S. and Arock (2012)), OntoNotes (e.g., Chen et al. (2011)) the (not publicly-available) Intelligence Community (IC) corpus (e.g., Cybulska and Vossen (2012), Araki et al. (2014)); the ECB corpus (e.g., Bejan and Harabagiu (2010; 2014), Lee et al. (2012)) and its extension, ECB+ (e.g.,Yang et al. (2015)); and ProcessBank (e.g., Araki and Mitamura (2015)). The newest event coreference corpus is the one used in the KBP 2015 Event Nugget Detection and Coreference shared task, in which the best performers are RPI's system (Hong et al., 2015), LCC's system (Monahan et al., 2015), and UI-CCG's system (Sammons et al., 2015). Among these corpora, ACE is the only one that is additionally composed of event coreference-annotated Chinese documents. It has been used to train SinoCoreferencer (Chen and Ng, 2014), a publicly-available Chinese event coreference resolver. Not all such corpora were carefully annotated: as Liu et al. (2014) pointed out, OntoNotes and ECB have only been partially annotated with event coreference links, for instance.

4 Baseline System

Our pipeline-based baseline system has five steps:

Step 1: Entity extraction. Our entity extraction model jointly identifies the entity mentions and their entity types. We train this model using CRF++[2], treating each sentence as a word sequence. Specifically, we create one instance for each word w and assign it a class label that indicates whether it begins an entity mention with type t_j (B-t_j), is inside an entity mention with type t_j (I-t_j), or is outside an entity mention

[2] https://taku910.github.io/crfpp/

(O). The features used to represent each instance for training the English CRF and the Chinese CRF are shown in Tables 2(a) and 3(a), respectively.

Step 2: Entity coreference resolution. Our entity coreference classifier is a pairwise classifier that determines whether two entity mentions are coreferent or not. To train this classifier, we employ SVM^{light} (Joachims, 1999), creating training instances using Soon et al.'s (2001) training instance creation method. Each training instance represents two entity mentions in each training document. The class value of a training instance is either positive or negative, depending on whether the two entity mentions are coreferent in the associated text. The features used to represent each instance for training the entity coreference classifiers for English and Chinese are shown in Tables 2(b) and 3(b), respectively.

After training, the resulting classifier can be used to classify each pair of entity mentions extracted in Step 1 as coreferent or not. We select as the antecedent of an entity mention em the closest preceding mention that is classified as coreferent with em.

Step 3: Trigger identification and subtyping. Since ACE allows only single-word triggers, our SVM-based Chinese trigger classifier takes as input a candidate trigger *word* (i.e., a word that survives Li et al.'s (2012) filtering rules) and outputs its event subtype (if it is a true trigger) or *None* (if it is not a trigger). In essence, it jointly (1) identifies event trigger words and (2) assigns a subtype to each identified trigger. To train this classifier, we create one training instance for each word w_i in each training document. If the word does not correspond to a trigger, the class label of the corresponding instance is *None*. Otherwise, the class label is the subtype of the trigger. The features used to represent each instance for training this classifier are shown in Table 3(c).

Because KBP additionally allows multi-word triggers, we recast the task of identifying English triggers as a sequence labeling task, where we train models using CRF++. Recall that since each (multi-)word may trigger multiple event mentions having different (sub)types, we train one CRF for each type. Specifically, to train the CRF for type t_j, we create one instance for each word w_i, assigning it a class label that indicates whether it begins a trigger with subtype s_{jk} (B-s_{jk}), is inside a trigger with subtype s_{jk} (I-s_{jk}), begins a trigger with other types (B-$\mathrm{t}_{m\neq j}$), is inside a trigger with other types (I-$\mathrm{t}_{m\neq j}$) or is outside a trigger (O). The features used to represent each instance for training this CRF are shown in Table 2(c). To improve the recall of event trigger detection, we augment the CRF output with heuristically extracted triggers. Specifically, we first construct a wordlist containing triggers that appear infrequently (less than 10 times) in the training data and do not belong more than one subtype according to the training data. Then, we extract any word as a trigger with the corresponding subtype as long as it appears in the wordlist.

Step 4: Argument identification and role labeling. Our argument identifier and role labeler is a classifier trained using SVM^{light} that jointly learns the tasks of (1) identifying the true arguments of an event mention and (2) assigning a role to each of its true arguments. To train this classifier, we create the training instances by pairing each true event mention em (i.e., event mention consisting of a true trigger) with each of em's candidate event arguments, considering an entity mention extracted in Step 1 a candidate argument of em if it appears in the same sentence as em. If the candidate argument is indeed a true argument of em, the class label of the training instance is the argument's role. Otherwise, its class label is *None*. The features used to represent each instance for training the English classifier and the Chinese classifier are shown in Tables 2(d) and 3(d), respectively.

After training, we can apply this classifier to classify test instances. To create test instances, we pair each *candidate* trigger (extracted in Step 3) with each of its candidate event arguments.

Step 5: Event coreference resolution. The event coreference classifier is a pairwise classifier that determines whether two event mentions are coreferent. To train this classifier, we use SVM^{light}, creating training instances using Soon et al.'s (2001) training instance creation method. The features used to represent each instance for training the event coreference classifier for English and Chinese are shown in Tables 2(e) and 3(e), respectively.

After training, we apply the resulting classifier to classify test instances. We select as the antecedent of an extracted event mention e the closest preceding mention that is classified as coreferent with e.

(a) Features for entity extraction. w is the word under consideration.

Lexical	word unigrams, bigrams, and trigrams formed from w with a window size of five.
Grammatical	w's part-of-speech (POS) tag; whether w is part of a NP; whether w is part of a pronoun, whether w is capitalized.
Semantic	the WordNet synset id of w; the WordNet synset ids of w's hypernym, its parent, and its grandparent.

(b) Features for entity coreference resolution. en_2 is the entity mention to be resolved and en_1 is a candidate antecedent of en_2.

Lexical	whether en_1 is a pronoun; whether en_1 is the subject of the sentence; whether en_1 is a noun; whether en_2 is a pronoun; whether en_1 is a noun; whether en_1 and en_2 have the exactly the same string; whether the modifiers of en_1 and en_2 match; the sentence distance between the strings of $en1$ and en_2.
Grammatical	the number, gender and animacy of en_1 and en_2; whether en_1 and en_2 agree w.r.t. number; whether en_1 and en_2 agree w.r.t. gender; whether en_1 and en_2 agree w.r.t. animacy.

(c) Features for event trigger identification and subtyping. t is the candidate trigger.

Lexical	t's POS tag, lemmatized and unlemmatized word unigrams, word bigrams, and word trigrams formed from t with a window size of five.
Syntactic	depth of t in its syntactic parse tree; path from the leaf node of t to the root in its syntactic parse tree; phrase structure expanded by the parent of t's node; phrase type of t's node.
Semantic	WordNet synset id of t; WordNet synset ids of t's hypernym, its parent, and its grandparent.

(d) Features for event argument identification and role labeling. en is a candidate argument of trigger t.

Basic	t's event subtype; en's entity type; en's head word; event subtype + head word; event subtype + entity type; t's POS tag.
Neighboring words	left/right neighbor word of en; left/right neighbor word of en + the word's POS; left/right neighbor word of en + the word's POS.
Syntactic	the phrase structure obtained by expanding the parent of t in the constituent parse tree; the phrase type of t; the path from en to t in the constituent parse tree; the dependency path from en to t.

(e) Features for event coreference resolution. ev_2 is the event mention to be resolved and ev_1 is a candidate antecedent of ev_2.

Event type features	whether ev_1 and ev_2 agree w.r.t. event type; whether they agree w.r.t. event subtype; the concatenation of their event types; and the concatenation of their event subtypes.
Trigger features	whether ev_1 and ev_2 have the same trigger; whether they have the same lemmatized trigger; whether the triggers of ev_1 and ev_2 or the hypernyms of these triggers are in the same WordNet synset; the concatenation of their triggers; the concatenation of POS tags of their triggers; whether their triggers agree in number if they are nouns; whether their triggers have the same modifiers and they are in the same entity coreference chain if they are nouns; the sentence distance between the triggers of ev_1 and ev_2; whether the triggers of ev_1 and ev_2 appear in a training document as a coreferent event mention pair; whether the triggers of ev_1 and ev_2 appear in the first sentence and headline if this is a newswire document; whether the sentence containing the the triggers of ev_1 and ev_2 are identical if this is a discussion forum document.
Argument features	whether ev_1 and ev_2 have arguments with the same role; whether the arguments have the same head word; whether they are in the same coreference chains; whether they have the same modifiers; the roles and number of the arguments that only appear in ev_1; and the roles and number of the arguments that only appear in ev_2.

Table 2: Features used in the English baseline system. POS tags, constituent parses and dependency parses are provided by CoreNLP (Manning et al., 2014). For all uses of WordNet (Fellbaum, 1998), only the first synset is used.

5 Joint Model

In this section, we describe our MLN-based joint model for event coreference resolution.

5.1 MLN Structure

Figure 1 shows our proposed MLN for event coreference resolution. It has five predicates subdivided into three categories: query, hidden and evidence.

The *query* predicate `EventCoref`(d,t_1,t_2) is true when two event mentions t_1 and t_2 in document d are coreferent. The *hidden* predicates are those that cannot be directly observed in the data. Our model contains three hidden predicates: (1) `Trigger`(d,t,p) is true when mention t in document d has event/trigger subtype p. A special type called "None" indicates that t does not contain a trigger. (2) `Argument`(d,t,a,r) asserts that entity mention a is an argument of event mention t in document d and its role is r. Again, we include a special role called "None", which indicates that the entity mention is not an argument of the event mention. The ! symbol in the predicate definition indicates that every entity mention must take one and only one argument role. (3) `EntityCoref`(d,a_1,a_2) is true when entity mentions a_1 and a_2 in document d are coreferent. The *evidence* predicates represent (ground) random variables

(a) Features for entity extraction. w is the word under consideration.

Lexical	word unigrams, bigrams, and trigrams formed from w with a window size of five.
Grammatical	w's POS tag; whether w is in a NP; whether w is part of a pronoun.
Wordlist-based	whether w can be found in each of the following 10 wordlists: Chinese surnames; famous GPE and location names (three wordlists); Chinese location suffixes; Chinese GPE suffixes; famous international organization names; famous company names; famous person names; and a list of pronouns.

(b) Features for entity coreference resolution. en_2 is an entity mention to be resolved and en_1 is a candidate antecedent of en_2.

Lexical	whether en_1 is a pronoun; whether en_1 is the subject of the sentence; whether en_1 is a noun; whether en_2 is a pronoun; whether en_1 is a noun; whether en_1 and en_2 are the same string; whether the modifiers of en_1 and en_2 match; the sentence distance between $en1$ and en_2.
Grammatical	the number, gender and animacy of en_1 and en_2; whether en_1 and en_2 agree w.r.t. number; whether en_1 and en_2 agree w.r.t. gender; whether en_1 and en_2 agree w.r.t. animacy.

(c) Features for event trigger identification and subtyping. t is a candidate trigger.

Lexical	word and POS n-grams formed from t with a window size of three
Syntactic	depth of t in its syntactic parse tree; path from the leaf node of t to the root in its syntactic parse tree; phrase structure expanded by the parent of t's node; the path from the leaf node of t to the governing clause; phrase type of t's node.
Semantic	whether t exists in a predicate list from the Chinese PropBank (Xue and Palmer, 2009); the entry number of t in a Chinese synonym dictionary.
Closest entity information	entity type of the syntactically/textually nearest entity to t in its syntactic parse tree; entity type of the syntactically/textually left/right nearest entity to t in its syntactic parse tree + entity.

(d) Features for event argument identification and role labeling. en is a candidate argument of trigger t.

Basic	t's event subtype; en's entity type; en's head word; t's subtype + en's head word; t's event subtype + en's entity type; t's POS tag.
Neighboring words	left/right neighbor word of en; left/right neighbor word of en + the word's POS tag; left/right neighbor word of t + the word's POS tag.
Syntactic	the phrase structure obtained by expanding the parent of t in the constituent parse tree; the phrase type of t; the path from en to t in the constituent parse tree; the dependency path from en to t.

(e) Features for event coreference resolution. ev_2 is the event mention to be resolved and ev_1 is a candidate antecedent of ev_2.

Event type features	whether ev_1 and ev_2 agree w.r.t. event type; whether they agree w.r.t. event subtype; the concatenation of their event types; and the concatenation of their event subtypes.
Trigger features	whether ev_1 and ev_2 have the same trigger; whether the trigger of ev_1 and ev_2 partially matched; whether they have the same lemmatized trigger; the concatenation of their triggers; the concatenation of part-of-speech tags of their triggers; whether their triggers agree in number if they are nouns; whether their triggers have the same modifiers if they are nouns; the sentence distance between the triggers of ev_1 and ev_2; the number of words between ev_1 and ev_2; whether the triggers of ev_1 and ev_2 appear in a training document as a coreferent event mention pair.
Argument features	whether ev_1 and ev_2 have arguments of the same role; whether the arguments have the same head word; whether they are in the same coreference chains; whether they have the same modifiers; the roles and number of the arguments that only appear in ev_1; and the roles and number of the arguments that only appear in ev_2.

Table 3: Features used in the Chinese baseline system. POS tags, constituent parses, and dependency parses are provided by CoreNLP (Manning et al., 2014). A detailed description of the wordlists used in the wordlist-based features can be found in Chen and Ng (2016). The Chinese synonym dictionary is HIT-SCIR's Tongyici cilin (extended).[3]

that can be directly observed in the data. In our MLN, we assume that we only observe the words; the predicate `Word`(d,t,w) is true when mention t in document d equals word w.

The MLN formulas are of two types. The first six formulas have infinite weight, which means that they are hard formulas and must always be satisfied. The last two formulas are soft, and their weights will be learned from the data. All logical variables in our formulas are universally quantified and therefore for brevity, we do not use them in the formulas. Formula 1 encodes the hard constraint that if two event mentions are coreferent, then they should share the same trigger subtype. Formula 2 specifies the hard constraint that if event mentions are coreferent, then their triggers subtypes cannot be "None." Formulas 3−6, all of which are hard formulas, specify the commutative and transitive properties of coreferent event and entity mentions. Formula 7, which is a soft formula, specifies the following dependency between coreferent entity mentions and coreferent event mentions: for two event mentions t_1 and t_2 having the same trigger subtype, if there exists an argument role r that is filled by argument a_1 in t_1

[3] `http://ir.hit.edu.cn/`

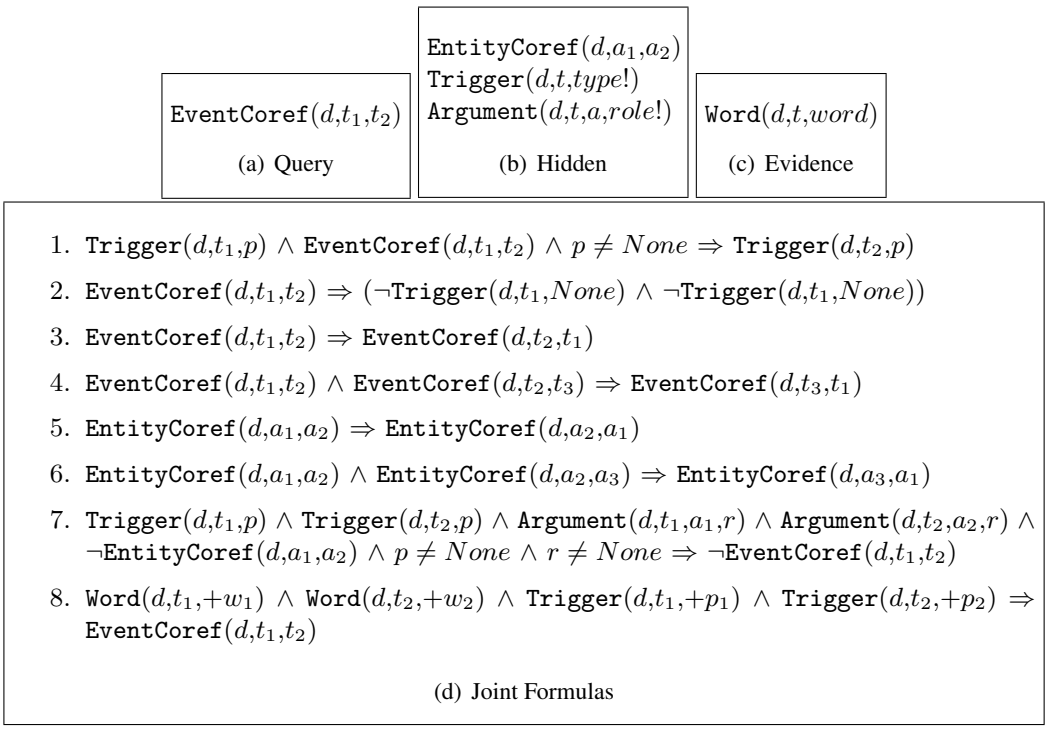

Figure 1: MLN structure.

and by a_2 in t_2, then t_1 and t_2 are not event coreferent if a_1 and a_2 are not entity coreferent.[4] Formula 8, which is also a soft formula, encodes the dependency between words in the text, trigger subtypes and event coreference. The $+$ sign in this formula indicates that for every grounding of the variables marked by the $+$ sign, we use a different weight for the soft formula.

5.2 Augmenting the MLN Distribution

Notice that the MLN shown in Figure 1 does not model the features used in the baseline systems. These features typically have high dimensionality and encoding them directly in the MLN is quite inefficient. For example, describing a trigram as an MLN formula results in d^3 ground formulas, where d is the number of words in our vocabulary. Therefore, the ground Markov network of an MLN that explicitly models all such high dimensional features would be extremely large and infeasible for inference. To address this issue, we implicitly encode the high-dimensional features by embedding them as weighted unit clauses, one for each grounding of the hidden and query predicates. Specifically, for each hidden/query ground atom X_i, we derive a weight $\phi(X_i)$ using the baseline system. This weight is computed as the distance from the hyperplane for the SVM-based classifiers and as a probability value for the CRF-based classifiers in the baseline system. We normalize each weight between the interval $[-1,1]$. The modified MLN distribution incorporating the new unit clauses is given by

$$P_{\mathcal{M}'}(\omega) \propto \exp\left(\sum_{f_i} \theta_i N_{f_i}(\omega)\right) \Phi(\omega) \tag{2}$$

where ω is a world (assignment on every ground atom) and $\Phi(\omega)$ acts as a prior on the set of hidden (**H**) and query (**Y**) ground atoms in the original MLN and is given by,

$$\Phi(\omega) = \exp\left(\sum_{X \in \mathbf{H} \cup \mathbf{Y}} \mathbb{I}_X(\omega)\phi(X)\right)$$

[4] According to the event coreference task definitions, arguments with certain roles cannot satisfy Formula 7. Hence, to reduce memory requirements, we restrict the application of Formula 7 to arguments having the following roles: Position, Person, Entity, Organization, Attack, Defendant, Adjudicator, Giver, Agent, Target, and Thing. In addition, we make it a soft (rather than hard) formula in view of the noisy outputs of our entity coreference resolver.

where $\mathbb{I}_X(\omega)$ is an indicator function that is equal to 1 if X is true in ω and 0 otherwise.

5.3 Setting the Soft Formula Weights

During inference time, we dynamically set the weights for the soft formulas (Formulas 7 and 8 in Figure 1) as follows. For each ground soft formula where its evidence atoms do not make it false, we set its weight to be the sum of the (normalized) SVM weights or CRF probabilities corresponding to its hidden and query atoms. We then multiply the soft weights with hyper-parameters η_1 and η_2 for Formulas 7 and 8 respectively and tune η_1 and η_2 using a grid search over the values $\{0.1, 0.25, 0.5, 0.75, 1.0\}$ to optimize the F1-score of event coreference resolution on the development set.

5.4 Inference

Given the prior-augmented MLN, $\mathcal{M}'$, the key task we are interested in is finding a truth assignment to all ground atoms of `EventCoref` that has the maximum probability given evidence on all ground atoms of `Word`. The following standard MAP inference task, which computes a joint assignment to all hidden and query variables given evidence, can be used to find the desired truth assignment.

$$\arg\max_{\omega} \left\{ \exp\left(\sum_{f_i} \theta_i N_{f_i}(\omega) \right) \Phi(\omega) \right\} \tag{3}$$

Unfortunately, the optimization problem given above is NP-hard in general. Moreover, the number of possible worlds in $\mathcal{M}'$ is extremely large and as a result naively searching over this large space (in order to solve the optimization problem) is computationally infeasible. As a concrete example, for the KBP 15 training dataset, we have 50 million ground atoms.

Fortunately, we can exploit the structure of the MLN given in Figure 1 in order to scale up MAP inference. In particular, the subset of ground atoms corresponding to two distinct documents are independent of each other. More formally, let $\mathbf{X}_i$ and $\mathbf{X}_j$ be the subset of ground atoms corresponding to two documents, say D_i and D_j respectively, then $\mathbf{X}_i$ is conditionally independent of $\mathbf{X}_j$ given evidence. Thus, given D documents in our corpus, the joint distribution represented by our MLN can be expressed as a product of D distributions. We can then perform inference independently over each such distribution, which greatly reduces the complexity of inference. Our inference procedure therefore follows an efficient, lazy, semi-lifted grounding strategy (Gogate and Domingos, 2011) that grounds the MLN for each document independently and solves Eq. (3) for each document separately using Gurobi (2013), a state-of-the-art integer linear programming solver.

6 Evaluation

6.1 Experimental Setup

We perform our evaluation on two corpora, the KBP 2015 English corpus and the Chinese portion of the ACE 2005 training corpus. For English, we train models on 128 of the training documents, tune parameters (the regularization parameters in SVM classifiers and the weights of the soft MLN formulas) on the remaining 30 training documents, and report results on the official test set.[5] For Chinese, since the ACE 2005 test set is not publicly available, we report five-fold cross validation results on the ACE 2005 training corpus. For each fold experiment, we employ three folds for classifier training, one fold for development (parameter tuning), and one fold for testing.

To evaluate event coreference performance on KBP, we follow the official KBP evaluation and employ four commonly-used scoring measures as implemented in version 1.7 of the official scorer provided by the KBP 2015 organizers, namely MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), CEAF_e (Luo, 2005) and BLANC (Recasens and Hovy, 2011), as well as the unweighted average of their F-scores.[6]

[5] Since the KBP 2015 corpus was not annotated with event arguments and entity coreference links, we train our entity mention extractor, our entity coreference resolver, and our event argument identification and role classification model on two LDC corpora provided by the TAC KBP 2015 task organizers (LDC2015E29 and LDC2015E68), as permitted by the rules of the shared task.

[6] The official KBP scorer is available at `http://cairo.lti.cs.cmu.edu/kbp/2015/event/scoring`.

Metric	English/KBP 2015						Chinese/ACE 2005					
	Baseline			**MLNs**			**Baseline**			**MLNs**		
	Prec	Rec	F1	Prec	Rec	F1	Prec	Rec	F1	Prec	Rec	F1
B^3	53.48	39.21	45.20	50.27	41.63	**45.54**	38.21	37.93	37.66	36.87	42.54	**39.50**
CEAF_e	42.33	38.54	**40.35**	47.53	33.48	39.29	40.28	37.76	38.98	41.02	41.19	**41.10**
MUC	50.52	29.13	36.96	47.07	38.21	**42.18**	40.02	40.27	40.14	39.37	44.70	**41.86**

English/KBP 2015						Chinese/ACE 2005					
Baseline			**MLNs**			**Baseline**			**MLNs**		
Prec	Rec	F1	Prec	Rec	F1	Prec	Rec	F1	Prec	Rec	F1
65.05	51.43	57.45	67.97	50.51	**57.95**	67.08	56.44	61.30	66.39	57.37	**61.55**

Table 5: Results for event trigger identification and subtyping on KBP 2015 and ACE 2005.

To evaluate event coreference performance on ACE, we follow previous work on event coreference (e.g., Yang et al. (2015)) and employ the aforementioned four scoring measures as implemented in the latest version (v8) of the CoNLL scorer (Pradhan et al., 2014), as well as the CoNLL score, which is the unweighted average of the MUC, B^3, and CEAF_e F-scores.[7] To our knowledge, there is only one difference between the implementations of the four scoring measures in the two scorers: while the CoNLL scorer considers an event mention correctly detected as long as it has an exact match with a gold event mention in terms of its left and right boundaries, the KBP 2015 scorer is stricter in that it considers an event mention correctly detected by additionally requiring that its event subtype be correctly determined.

6.2 Results and Discussion

The left half of Table 4 shows the results for English event coreference resolution on the KBP 2015 dataset. As can be seen, MLNs outperform the baseline system when evaluated on all but the CEAF_e metrics. W.r.t. the Average metric, MLNs achieve an F-score of 40.08, outperforming the baseline significantly by 1.44 points (paired t-tests, $p < 0.05$). To our knowledge, this is the best result reported to date on this corpus, with the top system in the KBP 2015 shared task achieving an Average F-score of 39.65. In general, the MLN could detect more event coreference chains than the baseline system, as seen from its higher recall in all but the CEAF_e metrics.[8]

The right half of Table 4 shows the results for event coreference resolution on the ACE 2005 Chinese corpus. As can be seen, MLNs outperform the baseline significantly by 1.8 points w.r.t. the CoNLL metric. In fact, MLNs achieve a higher score than the baseline w.r.t. each of the four scoring measures. Similar to what we observed on the KBP corpus, the consistently superior performance achieved by the MLN-based resolver can be attributed to its substantially higher recall accompanied by a slightly lower precision. In particular, since MUC is a link-based metric, the fact that the MLNs achieve a higher MUC recall on both datasets suggest that the MLNs are better at discovering event coreference links than the baseline.

One may argue that the MLNs may *not* be better than the baseline at discovering event coreference links: it may simply be the case that the joint inference process has allowed additional triggers to be extracted, which in turn allowed additional event coreference links to be established. To understand whether this is indeed the case, we compute the results for trigger identification and subtyping in Table 5. As can be seen, fewer English triggers are extracted after joint inference, whereas the reverse is true for Chinese. These results suggest that at least for English, the higher event coreference recall achieved by the MLNs is not attributable to better trigger identification and subtyping.

A closer examination of the outputs reveals that our resolver is comparatively better at extracting two types of coreference links that are traditionally considered difficult to extract. The first type involves triggers that are lexically different. For example, in the text segment "The former mayor of Detroit,

[7] The CoNLL scorer is available at `https://github.com/conll/reference-coreference-scorers`.

[8] As is commonly known, CEAF_e sometimes produces unintuitive scores. Specifically, the CEAF_e F-score may drop as more coreference links are correctly identified. See Moosavi and Strube (2016) for a detailed discussion.

Michigan was sentenced to 28 years in prison . . . Prosecutors asked for a minimum of 28 years for Kilpatrick, who resigned from the mayor's office in 2008 . . .", the link between event mentions triggered by *former* and *resigned*, both of which have type Personnel.End-position, is discovered by our resolver but not the baseline. The second type involves links between event mentions that are far from each other.

6.3 Error Analysis

To better understand how to improve our MLN-based resolver and to provide directions for future work, we conduct a qualitative analysis of its major sources of error in this subsection.

6.3.1 Two Major Types of Precision Error

Erroneous triggers. For both languages, our trigger classifier had difficulties with correctly classifying certain frequently-occurring words that are sometimes used as triggers and sometimes not. Specifically, the classifier misclassified many non-trigger instances of these words as triggers, which were subsequently used to establish coreference links by our resolver. A particularly interesting and challenging example involves the word "violent". Consider two sentences that appear in the same document: "The violent arrest of Ahmed al-Alwani is likely to inflame tensions in Sunni-dominated Anbar" and "Iraq troops arrest leading Sunni MP in violent raid". The first sentence contains two event mentions, one triggered by *violent* with type Conflict.Attack and the other triggered by *arrest* with type Justice.Arrestjail. The second sentence, contains only one event mention: it is triggered by *raid* with type Conflict.Attack and is coreferent with *violent*. While our system successfully detects all three triggers, it also erroneously detects *violent* in the second sentence as a trigger. This error gets propagated to our event coreference resolver, which posits the two occurrences of *violent* as coreferent.

Failure to extract arguments. Recall that our argument classifier does not extract any argument of an event mention that does not appear in the same sentence as its trigger. This severely limits its ability to extract arguments and has caused many spurious event coreference links to be established. For instance, our resolver erroneously posits two *violence* events as coreferent: it does not know that the two events took place in different countries, as the argument classifier failed to extract their location arguments (one is *Honduras* and the other is *Venezuela*).

6.3.2 Two Major Types of Recall Error

Missing triggers. For both languages, the trigger classifier failed to identify trigger words/phrases that are unseen or rarely-occurring in the training data. As a result, many links cannot be established.

Insufficient knowledge. Recall that our MLN-based resolver has achieved a higher recall than the baseline by doing a better job at establishing links between event mentions containing lexically different triggers. However, there are still many links between event mentions with lexically different triggers that our resolver fails to discover owing to the insufficient knowledge made available to it. This type of error is especially prominent on the Chinese corpus.

7 Conclusion

We proposed a novel joint inference based event coreference resolver using MLNs. Since encoding rich NLP features in MLNs is a challenging task, we encoded these features implicitly by adding weighted unit clauses to the MLN distribution. Results on an English corpus (KBP 2015) and a Chinese corpus (ACE 2005) show that our MLN based system achieved statistically significantly better performance than a pipeline-based resolver. Future work includes transferring our approach to other NLP tasks and exploring the possibility of incorporating active learning into our approach.

Abstract

Retrospective event detection is an important task for discovering previously unidentified events in a text stream. In this paper, we propose two fast centroid-aware event detection models based on a novel text stream representation – Burst Information Networks (BINets) for addressing the challenge, following the *D2N2K (Data-to-Network-to-Knowledge)* paradigm. The BINets are time-aware, efficient and can be easily analyzed for identifying key information (centroids). These advantages allow the BINet-based approaches to achieve the state-of-the-art performance on multiple datasets, demonstrating the efficacy of BINets for the task of event detection.

1 Introduction

Retrospective Event Detection (RED) (sometimes called topic detection) is a core task for text stream analysis, which aims to detect events that are previously unknown to the system (Wayne, 1998; Rajaraman and Tan, 2001) and is useful for many applications such as text stream summarization and evolutionary analysis of events in both news and social streams.

docid	time	text
d_1	Jan 12, 2010	A 7.0 magnitude quake hits the impoverished Caribbean nation of Haiti, killing more than 200,000 people, injuring an estimated 300,000.
d_2	Feb 27, 2010	A huge magnitude 8.8 earthquake strikes near the coast of south-central Chile, shaking buildings, causing blackouts and killing at least 147 people.
d_3	Apr 14, 2010	A 7.1-magnitude earthquake struck Tibetan Autonomous Prefecture of Yushu in southern Qinghai Province on April 14, 2010, killing at least 400 people and injuring more than 10,000.

Table 1: Documents discussing different earthquake events.

Most previous event detection approaches tend to use document- or keyword-based clustering models. Another solution proposed in recent years is to build a keyword graph to model the co-occurrence of keywords for detecting keyword communities as events (Sayyadi and Raschid, 2013). Even though these methods can achieve fair performance in small datasets, they have either of the following limitations:

- No time-awareness: many event detection models do not take into account time information. As a result, it is very likely that the documents that talk about different events (as Table 1 shows) are grouped into one cluster just because their lexical similarity is high.
- Inefficient: clustering-based methods tend to be time-consuming. For example, the time complexity of GAC (group average clustering) – the most commonly used clustering method in event detection – is $O(n^2 \log n)$. The computational challenge makes them difficult to work on a large dataset.

*This work was done when the first author was visiting Microsoft Research Asia

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3276–3286, Osaka, Japan, December 11-17 2016.

- Deviation of cluster centroids: it is likely that the clusters obtained by the methods are not event-centric, which has an adverse effect on the result, as illustrated in Figure 1.

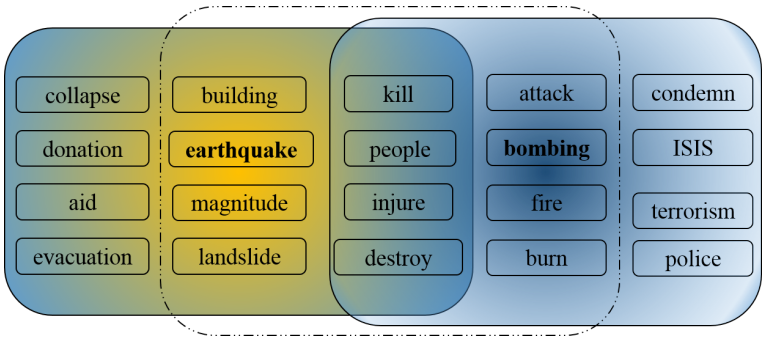

Figure 1: Deviation of cluster centroids: If clusters are not constructed around the centroid of the events (e.g., the dashline cluster is constructed around non-centroids such as *people*, *kill* and *injure* instead of *earthquake* or *bombing*), the performance will be adversely affected.

To offer a better solution to event detection without the above limitations, we propose to use a novel text stream representation: Burst Information Networks (BINets) (Ge et al., 2016a; Ge et al., 2016b). In contrast to the keyword graph which is based on word co-occurrence, a BINet is constructed based on burst co-occurrence. In a BINet (Fig. 2), a node is a burst of one word, which can be represented by the word with one of its burst periods, and an edge between two nodes indicates how strongly they are related (i.e., how frequently they co-occur). Since the nodes in a BINet contains temporal information (e.g., burst period), a BINet is time-aware in which nodes in a community are both topically and temporally coherent. Hence, we can say each community in a BINet corresponds to an event. Based on the BINet representation, we propose two fast centroid-aware event detection models. We show that the BINet-based models are efficient, allowing it to work on a large dataset, and the clusters obtained by the models center around the key information of events. Experiments on multiple datasets show that the BINet-based approaches achieve the state-of-the-art performance in terms of both accuracy and efficiency.

The contributions of this paper are:

- We propose to use BINets – a novel text stream representation for event detection, which is time-aware, can be efficiently built and support event-centric clustering, addressing the typical limitations of previous models.
- We propose two fast centroid-aware algorithms for event detection based on the BINet representation, which not only solve the centroid deviation problem but also are more efficient than traditional approaches.
- We construct and release a dataset for evaluating event detection models on a large text stream during a long time span.

2 Burst Information Networks

2.1 Burst Detection

A word's burst refers to a sharp increase of word frequency during a period. It usually indicates key information, important events or trending topics in a text stream as Figure 3 shows and is useful for many applications. In this paper, we detect a word's burst using the method of Zhao et al. (2012) which is a variant of (Kleinberg, 2003) and models burst detection as a burst state sequence decoding problem where a word w's burst state $s_t(w)$ at time t could be 1 or 0 to indicate if the word bursts or not at t. Specially, if a word w bursts at every time epoch during a period, we call this period a burst period of w and w has a burst during this period. In Figure 3, *earthquake* has 2 burst periods (i.e., Jan 12 - Jan 31, and Feb 27 - Mar 7), which correspond to two famous earthquake events (i.e., 2010 Haiti earthquake and 2010 Chile earthquake).

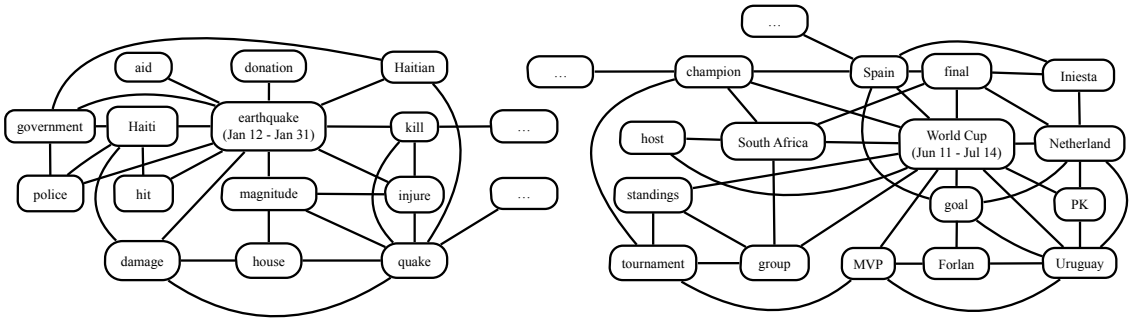

Figure 2: An example of Burst Information Network.

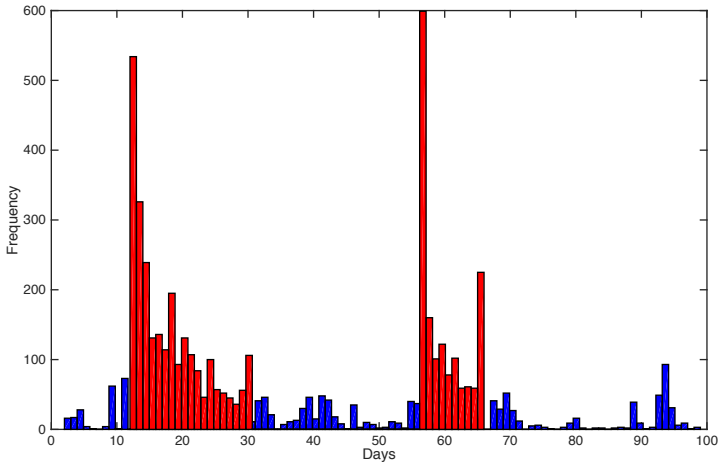

Figure 3: The frequency of *earthquake* during the first 100 days in 2010. There are two burst periods (red) for *earthquake* during the period, corresponding to two strong earthquake events happening in Haiti and Chile respectively.

Formally, we define $\mathcal{P}_i(w)$ as the ith burst period of the word w. It is a time interval, during which the word w bursts at every time epoch:

$$\mathcal{P}_i(w) = [t_i^s(w), t_i^e(w)]$$
$$\forall t \in \mathcal{P}_i(w) \;\; s_t(w) = 1$$

where $t_i^s(w)$ and $t_i^e(w)$ denotes the starting and ending time of the ith burst period of w, and $s_t(w)$ denotes the burst state of w at time t.

2.2 Burst Information Network Construction

A BINet represents associations between key facts in a text stream, which has been proven to be effective in multiple knowledge mining tasks (Ge et al., 2016a; Ge et al., 2016b). The basic component of a BINet is burst elements which are nodes of the information network:

A Burst Element is a burst of a word. It can be represented by a tuple: $\langle w, \mathcal{P}_i(w) \rangle$ where w denotes the word and $\mathcal{P}_i(w)$ denotes one burst period of w. Though a word may have multiple burst periods, a burst element has only one burst period. A word during its different burst periods will be regarded as different burst elements.

There are two main advantages using burst elements as nodes to build the information network:

- A burst element not only includes semantic information but also incorporates the temporal dimension. Nodes in a community are topically and temporally coherent while nodes that are topically or temporally distant cannot be adjacent, which makes it reasonable to consider a community in a BINet corresponds to an event.
- Since a burst element denotes a burst word during one of its burst period, its sense is likely to be consistent. Multiple bursts of a word will be considered as different burst elements. Therefore,

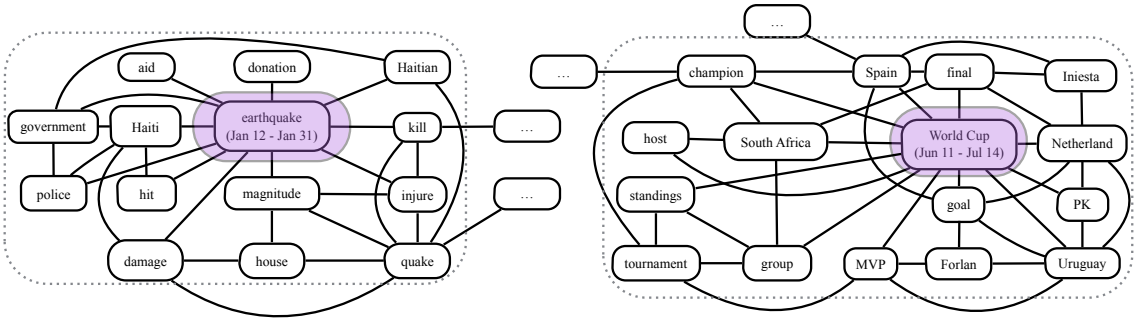

Figure 4: Node based detection model. Shaded nodes denote key nodes.

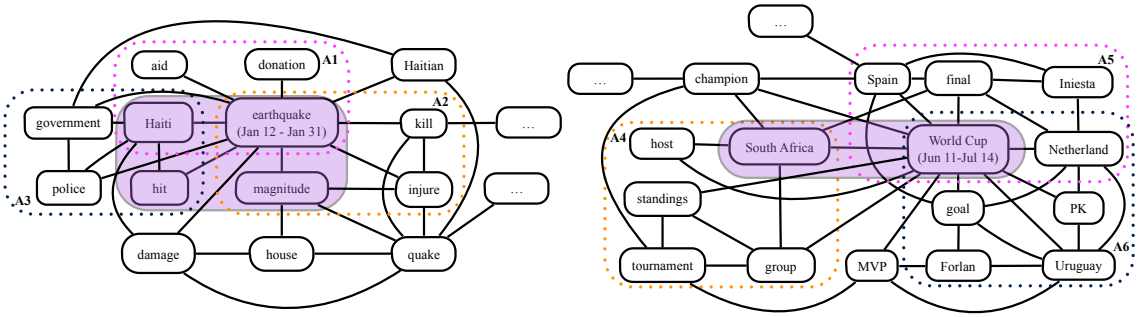

Figure 5: Area based detection model. Shaded areas denote key areas.

nodes in a BINet tends to be less ambiguous.

Formally, a BINet is defined as $G = \langle V, E \rangle$. Each node $v \in V$ is a burst element and each edge $e \in E$ denotes the association between burst elements. Intuitively, if two burst elements frequently co-occur, then they should be highly weighted. We define $\omega_{i,j}$ as the weight of an edge between v_i and v_j, which is equal to the number of documents where v_i and v_j co-occur.

3 Event detection based on the BINet

3.1 Motivation

The goal of event detection is to organize a text stream into multiple document sets, in each of which the documents coherently discuss the same event. The traditional clustering methods are usually inefficient and not time-aware. Moreover, they tend to suffer from the problem of deviation of cluster centroids, as illustrated in Figure 1. In Figure 1, *earthquake* and *bombing* are centroids (i.e., key information) of an earthquake event and a bombing event respectively. If clusters are constructed around the centroids (e.g., solid line clusters), the performance will be good; while if clusters center around non-centroid nodes (e.g., the dashline cluster centers around *kill* and *people*), the results will be poor.

To address the limitations above, we propose to model event detection problem as community detection on the BINet in which each community is both topically and temporally coherent, corresponding to one event. Instead of using popular community detection algorithms in social network analysis whose time complexity is high, we propose two fast centroid-aware event detection model: node-based detection model (NDM) and area-based detection model (ADM). Both of the approaches first identify the key nodes (or key areas) on the BINet, which indicate the centroid (i.e., key information) of events in the text stream, and then construct clusters that center around the key nodes (or key areas). The difference of the models is that NDM attempts to detect a bunch of node communities as clusters while ADM detects the overlapping document areas to form document clusters, as Figure 4 and Figure 5 depict. In some sense, NDM and ADM correspond to the keyword- and document-based clustering model respectively. In the following sections, we will present the details of NDM and ADM.

Community	The word of nodes with top PageRank value	Event
1	Iraq, war, Iraqi, US-led, Baghdad	Iraq war in 2003
2	flu, a/h1n1, health, virus, influenza	2009 A/H1N1 flu pandemic
3	earthquake, quake, Sichuan Province, Sichuan, quake-hit	Sichuan earthquake in 2008
4	Beijing, Olympic_Games, gold, medal, team	2008 Beijing Olympics
5	financial, crisis, global, economy, economic	financial crisis in 2008

Table 2: Example of the communities detected by our approach. Each community corresponds to one event and nodes with the top PageRank values tend to be keywords that are the most situable to describe the events.

3.2 Centroid-aware event detection models

3.2.1 Node-based detection model

The goal of node-based detection model (NDM) is to detect node communities on the BINet each of which corresponds to one event. To guarantee that detected communities center around the key nodes that correspond to key information (i.e,. centroid) of events in the text stream, we first identify the key nodes on the BINet.

Owing to the BINet representation, it is easy to identify the key nodes through the analysis of the network. Among a variety of ways to identify the influential nodes in a network, we simply adopt the Pagerank algorithm (Page et al., 1997). For a node v, its PageRank value $pr(v)$ is computed as follows:

$$pr(v) = d \sum_{v' \in N(v)} \hat{\omega}_{v,v'} \times pr(v') + \frac{1-d}{|V|}$$

where $|V|$ is the number of nodes in the BINet, $N(v)$ denotes the set of nodes adjacent to v, d is the damping factor and is set to 0.85, $\hat{\omega}_{v,v'} = \frac{\omega_{v,v'}}{\omega_{v',*}}$, which is the normalized weight of the edge between v and v'.

Intuitively, a node with a high PageRank value is usually important and likely to be the key node that indicates the key information of an event. Therefore, we rank nodes in the BINet by their PageRank value and choose the node which has the highest PageRank value and does not belong to any community as a key node to construct a community $\mathcal{E}$ around it with its closely related nodes:

$$\mathcal{E} = \{v\} \cup \{u | \hat{\omega}_{v,u} > \sigma_N\}$$

where v is the node with the highest PageRank value and does not belong to any community, $\hat{\omega}_{v,u}$ is the normalized weight of the edge between v and u, and σ_N is the threshold for selecting closely related nodes.

By repeating the process, we can detect multiple communities on the BINet efficiently, each of which centers around a key node. Table 2 shows some communities detected by this approach from 1995-2010 Xinhua news in English Gigaword. One can observe that each community corresponds to one event and nodes with the top PageRank values in a community tend to be key information of the events. We summarize the algorithm in Algorithm 1.

For NDM, we need to infer a document's event after community detection. For a document d, we infer the probability that d discusses the event e_k as follows:

$$P(e_k|d) = \frac{\sum_{v_k \in V_k(d)} pr(v_k)}{\sum_{v \in V(d)} pr(v)} \quad (1)$$

where $V(d)$ denotes the set of nodes that the words of d corresponds to in the BINet, $V_k(d) \subset V(d)$ denotes a subset of $V(d)$ that are in the community of the event e_k, and $pr(v)$ is the PageRank value of a node v. In Eq (1), the PageRank values of nodes in $V(d)$ can be considered as weights. The nodes with high PageRank values are highly weighted because they tend to indicate important topical and event information.

Algorithm 1 Node-based detection model

Input: Ranked list of nodes by PageRank value: $\mathcal{L}$, BINet: $G = \langle V, E \rangle$;
Output: A list of event communities: $\mathcal{C} = [\mathcal{E}_1, \mathcal{E}_2, ..., \mathcal{E}_k]$
while $\|\mathcal{L}\| > 0$ **do**
    $v \leftarrow \mathcal{L}[0]$ (the first element in $\mathcal{L}$)
    $\mathcal{E} \leftarrow \{v\} \cup \{u | \hat{\omega}_{v,u} > \sigma_N\}$
    $\mathcal{L} \leftarrow \mathcal{L} - \mathcal{E}$
    $\mathcal{C}.append(\mathcal{E})$
end while

3.2.2 Area-based Detection Model

A document area is the area (i.e., a set of nodes) on the BINet a document corresponds to. For example, $A3$ in Figure 5 is the area that the document written during the Haiti earthquake about *Haiti*, *government* and *police* corresponds to on the BINet. The idea of area-based detection model (ADM) is discovering the document areas that massively overlap on the BINet to construct clusters so that the documents whose areas are in the same cluster are about the same event. In contrast to NDM in which each item in a cluster is a node, the items in a cluster obtained by ADM is document areas on the BINet.

To guarantee that the clusters center around the centroids of events, we first identify key nodes on the BINet, as NDM does. In ADM, however, we treat a key area as the centroid of an event, which is different from NDM that treats a key node as an event centroid. To identify the key areas on the BINet, we first define the PageRank score of an area A as the normalized sum of the PageRank value of the nodes in it:

$$pr(A) = \frac{\sum_{v \in A} pr(v)}{\sqrt{|A|}}$$

Then, we repeatedly choose the area which has the highest PageRank score and does not belong to any cluster as a key area to construct a cluster with the areas that massively overlap it:

$$\mathcal{E} = \{A\} \cup \{A' | f(A, A') > \sigma_A\} \tag{2}$$

where σ_A is the threshold to construct cluster, $f(A, A')$ is a score to indicate how much A overlaps A' and it is computed as follows:

$$f(A, A') = \frac{|A \cap A'|}{|A \cup A'|} \tag{3}$$

We summarize the algorithm of ADM in Algorithm 2. As NDM, ADM detects events in a greedy manner; hence, the detection process is fast. However, in contrast to NDM, ADM allows one area to belong to multiple communities, which means that one document could belong to multiple events.

Algorithm 2 Area-based detection model

Input: Ranked list of documents areas: $\mathcal{L}$, BINet: $G = \langle V, E \rangle$;
Output: A list of event communities: $\mathcal{C} = [\mathcal{E}_1, \mathcal{E}_2, ..., \mathcal{E}_k]$
while $\|\mathcal{L}\| > 0$ **do**
    $A \leftarrow \mathcal{L}[0]$ (the first element in $\mathcal{L}$)
    $\mathcal{E} \leftarrow \{A\} \cup \{A' | f(A, A') > \sigma_A\}$
    $\mathcal{L} \leftarrow \mathcal{L} - \mathcal{E}$
    $\mathcal{C}.append(\mathcal{E})$
end while

4 Experiments and Evaluation

We conduct experiments to evaluate the performance of our approach. We first evaluate our approach on the TDT4 dataset to compare other event detection approaches. Then, we apply our approach on a larger corpus (2009 – 2010 news corpus) to test its scalability and performance.

For preprocessing, we remove stopwords and conduct lemmatization and name tagging using Stanford CoreNLP toolkit (Manning et al., 2014) before the construction of a BINet.

4.1 Evaluation on TDT4

The TDT4 collection is a well known dataset for comparing methods for event detection. The English part of the dataset includes approximately 29,000 news documents from news agencies such as CNN and BBC from October 2000 to Janurary 2001 (spanning 4 months), while only 1,884 documents[1] are annotated to be related to 71 human identified events (topics). As the setting adopted by previous work (Li et al., 2005; Sayyadi and Raschid, 2013), we use the annotated subset as gold standard for evaluating the performance of our models.

As most of the previous work (Yang et al., 1998; Li et al., 2005) addressing the event detection challenge, we use Micro-Precision, Micro-Recall, Micro-F1 as well as Macro-F1 to evaluate the performance. We compare our approach to the following models whose effectiveness on the TDT4 corpus has been verified by previous work:

- Allan[2] (Allan et al., 1998): A popular online event detection model, which is often used as a baseline to compare event detection models.
- GAC (Yang et al., 1998): A classical but effective approach for event detection using group average clustering.
- KeyGraph (Sayyadi and Raschid, 2013): Betweenness score based community detection approach on KeyGraph. It is notable that the evaluation measures used in Sayyadi and Raschid (2013) are somewhat different from those in this paper and other work – they used Macro-precision, Macro-recall[3] and Macro-F1. We only report its Macro-F1 in Table 3.
- Probabilistic model (Li et al., 2005): A time-aware probabilistic graphical model for event detection. It is the state-of-the-art approach on TDT4 dataset.

Models	Micro-P	Micro-R	Micro-F1	Macro-F1
Allan	0.64	0.57	0.60	0.62
GAC	0.83	0.63	0.72	0.75
KeyGraph	-	-	-	0.69
Probabilistic Model	0.85	0.67	0.75	0.78
BINet-NDM	0.79	0.69	0.74	0.75
BINet-ADM	0.81	0.70	0.75	0.77

Table 3: Performance of various event detection approaches on TDT4.

Table 3 shows the results[4] on the TDT4 dataset. The BINet approaches perform well on the dataset: Both NDM and ADM outperform the classical baselines (i.e., Allan, GAC and Keygraph). The ADM performs better than NDM and even achieves the comparable performance to the state-of-the-art approach by (Li et al., 2005) because the centroid in ADM is a key area that contains more information than a key node in NDM. The reasons for the good performance are two-fold: First, the BINet-based approach is time-aware, which avoid many unnecessary mistakes made by the baseline models that only take into account text content; Second, the BINet-based models are centroid-aware, which guarantee that

[1] Among these 1,884 documents, there are 38 documents belonging to more than one event.

[2] This baseline is often referred as kNN in literature (Li et al., 2005; Sayyadi and Raschid, 2013). However, to avoid the ambiguity with the popular kNN classification model, we simply refer it as Allan.

[3] For reference, the Macro Precision and Recall reported in Sayyadi and Raschid (2013) are 0.82 and 0.59 respectively.

[4] The results of *Allan*, *GAC* and *Probabilistic Model* are from Li et al. (2005) while the results of *KeyGraph* come from Sayyadi and Raschid (2013).

Model	Micro-P	Micro-R	Micro-F1	Macro-F1	Running time
GAC	-	-	-	-	>2 hours
KeyGraph	-	-	-	-	>2 hours
Probabilistic model	-	-	-	-	>2 hours
B-GAC	0.81	0.65	0.72	0.67	7189s (896s)
BINet-NDM	0.85	0.68	0.76	0.69	3591.98 (1350.08s)
BINet-ADM	0.84	0.71	0.77	0.71	3610.03s (1368.13s)

Table 4: Performance and running time of various event detection models on the 2-year news stream. We do not report the precision, recall and f-score for the models that cannot get results within 2 hours. The number in the round bracket is the running time of the model when it is run in 8-way parallel. The running time is measured on a workstation with Intel Xeon 3.5 GHz CPU and 64GB RAM.

the generated clusters center around centroids of events and avoid the problem of deviation of cluster centroids.

4.2 Evaluation on a 2-year news stream

Even though TDT4 is a widely used dataset for event detection, it has several limitations: First, the period of TDT4 dataset is short (only 4 months) as Li et al. (2005) claimed. In TDT4 dataset, hardly can we see multiple events of the same type in the TDT4 dataset (e.g., there is only one flood event in TDT4 dataset). Therefore, even if we just use content-based clustering methods regardless of time information, the performance is not bad. Second, the data size of the TDT4 corpus is so small compared with a real text stream that many stream-based features such as burst cannot function as well as in a real stream. To test the performance of our detection models on a real text stream, we construct a dataset using 2009 – 2010 news from English Gigaword (APW and XIN sections) as a text stream where there are 584,414 news articles in total. We construct a BINet on this dataset, which contains 46,254 nodes and 514,682 edges. For evaluation, we select 83 events that happened during 2009 – 2010 and annotate their relevant documents in the text stream. The selected events are all important events and have their corresponding Wikipedia pages. The annotation process is similar to (Li et al., 2005): we use the Wikipedia title of the events to search the candidate documents using Lucene and then manually identify if the returned documents are actually relevant to the events. Since this annotation process does not guarantee finding all the relevant documents to an event, we call the annotations silver standard[5]. In total, there are 2,584 documents that are annotated as relevant to those 83 events.

Table 4 shows the results of various approaches on the 2-year news stream. Due to the size of the dataset, most traditional event models cannot finish the detection task within two hours since their time complexity is too high. The B-GAC model proposed by (Zhao et al., 2012) is the only one that can finish the task within 2 hours because it adopts the split-merge-clustering strategy that splits[6] the data into multiple small pieces by time for clustering and then merges the clusters. Though such a strategy can alleviate the issue of the scalability, the split of data will affect the global overview of the text stream and have an adverse effect on finding the centroids of events. In contrast, our BINet-based approaches can finish detecting events within 1 hour without splitting the stream and achieve the best result owing to their awareness of both time[7] and event centroids.

We compare the time complexity of our centroid-aware event detection models to other commonly used event detection approaches, as shown in Table 5 where n is the number of documents, K is the event number (K in our BINet-based approaches depends on the selection of σ_N and σ_A), $|W|$ is the size of vocabulary, and $|V|$ and $|E|$ are the number of nodes and edges on the BINet respectively. The running time of NDM and ADM consist of four parts: burst detection, BINet construction, PageRank analysis,

[5]The annotation data can found at http://getao.github.io

[6]We split the 2-year news stream into 8 small pieces, each of which is a 3-month news stream so that it can get the result within 2 hours.

[7]For our BINet-based approaches, only burst detection part is run in parallel in 8-way parallel setting, which is different from B-HAC that splits the stream and clusters documents in parallel.

Models	Time complexity
GAC	$O(n^2 \log n)$
B-GAC	$O(n^2 \log n)$
Keygraph	$O(nK + \|W\|^3)$
NDM	$O(nK + \|V\| \log \|V\| + \|E\| + \|W\|T)$
ADM	$O(n(\log n + L) + \|V\| + \|E\| + \|W\|T)$

Table 5: Time complexity of various event detection models.

and event detection. The first three parts are the same for NDM and ADM, which are preliminary steps for event detection. The time complexity of burst detection algorithm is $O(T)$ for one word where T is the time span of the stream and it can be conducted in parallel for different words because the burst detection processes for different words are independent. The time complexity of the BINet construction and PageRank analysis is $O(n)$ and $O(|V| + |E|)$ respectively. For the event detection part, the time complexity of community detection of NDM is $O(|V| \log |V| + |E| + nK)$. The former term is the time cost for sorting nodes by PageRank value, and the second and the third term are the cost for constructing node communities and assigning events to documents respectively. The time complexity of the detection part in ADM is somewhat different. Its time complexity is $O(n \log n + nL)$. As NDM, the first term is the time for sorting document areas by PageRank value. The second term is the time cost for computing Eq (3) in which L is the average number of times that a document (area) is taken for computing Eq (3) and is affected by the selection of threshold parameter σ_A. In the worst case, $L = K$; while in the best case, $L = 1$, meaning that a document is taken for computing Eq (3) only once. In most cases, L is a small number. The running time of those parts of NDM and ADM is shown in Table 6. Note that, for the part of the PageRank computation, the time is measured by running the PageRank algorithm for 1,000 iterations.

	BINet-NDM	**BINet-ADM**
Burst detection	2,562.17s (320.27s)	2,562.17s (320.27s)
BINet construction	304.56s	304.56s
PageRank computation	716s	716s
Event detection	9.25s	27.3s
Total	3591.98s (1350.08s)	3610.03s (1368.13s)

Table 6: The running time of 4 parts of our BINet-based event detection approaches. The number in the round bracket is the running time of the model when it is run in 8-way parallel.

5 Related Work

Event detection is one of the most popular research topics in recent years and has been extensively studied for the decades (Yang et al., 1998; Swan and Allan, 2000; Allan, 2002; Fung et al., 2005; He et al., 2007; Sayyadi et al., 2009; Zhao et al., 2012; Sayyadi and Raschid, 2013; Ge et al., 2015). They are based on either document- or keyword-based clustering, which usually suffer from either unawareness of time, high expensive computation cost or deviation of cluster centroids. In contrast, our approach is time-aware, centroid-aware and so efficient that it can be run on a large text stream.

In addition, there is much work (Sakaki et al., 2010; Lee et al., 2011; Diao et al., 2012; Aggarwal and Subbian, 2012; Wang et al., 2013; Dong et al., 2015) studying event detection problem in social media. They usually use more or less social media features such as spatio-temporal information, which are not in the same setting with our task.

6 Conclusion and Future Work

This paper proposes to use a novel text stream representation – Burst Information Networks to address the retrospective event detection challenge. Based on the BINet, we propose two fast centroid-aware event

detection models that can effectively overcome the limitations of the previous event detection models and achieve the state-of-the-art performance on both TDT4 and a long-span text stream.

In the future, we plan to study events in a text stream more deeply based on the BINet representation. Since a BINet can offer a global overview of events in the stream level, we plan to use the BINets to derive an event's type, extract its schema and even fill its slots after we detect its corresponding regions on the BINet. Hopefully, this framework could work for endless event knowledge mining if it could be used for monitoring the massive text streams.

Abstract

Machine learning-based methods have obtained great progress on emotion classification. However, in most previous studies, the models are learned based on a single corpus which often suffers from insufficient labeled data. In this paper, we propose a corpus fusion approach to address emotion classification across two corpora which use different emotion taxonomies. The objective of this approach is to utilize the annotated data from one corpus to help the emotion classification on another corpus. An Integer Linear Programming (ILP) optimization is proposed to refine the classification results. Empirical studies show the effectiveness of the proposed approach to corpus fusion for emotion classification.

1 Introduction

Emotion classification aims to recognize human emotions, such as joy, $anger$ or $surprise$ in a given text. Emotion classification has a variety of applications including online chatting (Galik and Rank, 2012), news classification (Liu et al., 2013) and stock marketing (Bollen et al., 2011). In recent years, emotion classification in social media has been greatly popular in the Natural Language Processing (NLP) community (Chen et al., 2010; Purver and Battersby, 2012; Li et al., 2015). Because of the popularity of social media today, the analysis of short text on social media becomes more important (Kiritchenko et al., 2014; Wen and Wan, 2014; Wang et al., 2015). Users express their feelings and emotions on various social media platforms.

Existing emotion classification approaches are based on corpus classification methods where human-annotated emotion corpora are leveraged to train a machine learning-based emotion classification models. Recently, several different emotion corpora have been proposed by different researchers, such as Yao et al. (2014) and Huang et al. (2015). However, the size of each existing labeled corpus might be rather limited due to the high cost of data annotation, which results low performance in traditional supervised emotion classification.

In this paper, we propose a novel task, namely corpus fusion for emotion classification, which aims to leverage the data from different emotion corpora so as to alleviate the data deficiency problem. This task is motivated by the fact that although the emotion corpora are from different resources, they have the same objective of emotion classification. So it is easy to enlarge the size of the corpora by mixing the data of the same emotion category from two corpora. However, corpus fusion for emotion classification is challenging due to the following two factors:

First, the emotion taxonomies are often different between two emotion corpora because of the lack of an accepted standard. As a result, similar instances which express similar or same emotion can be categorized into different types of emotions under different taxonomies. An example from two emotion corpora (Yao et al., 2014; Huang et al., 2015) in Figure 1 expresses this problem. These two instances which express close emotion are labeled with different emotion classes under different emotion taxonomies.

Second, the annotation guidelines are often different between two emotion corpora because of different annotators. For example, the instance from Yao et al. (2014) in Figure 1 which contains a positive

*corresponding author

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3287–3297, Osaka, Japan, December 11-17 2016.

emotion $like$ may not be labeled as $positive$ under the taxonomy of Huang et al. (2015) because it doesn't contain a strong emotional word to express such a positive emotion. The numbers of emotion labels of each instance in two corpora are also different: some instances in Yao et al. (2014) have both primary emotion and secondary emotion, while most of the instances in Huang et al. (2015) are labeled with only one emotion. Because of the difference between emotion taxonomies, it is difficult to directly use the data from different emotion corpora together.

Yao et al. (2014): "我先是震惊，继而敬重，如同听到冯军哥的裸捐一样。" *(English Translation: "I was first shocked, and then respected. Just like when I heard the giving pledge made by Feng Jun.")* *Emotion Categories:* ***Like, Surprise***
Huang et al. (2015): "创意无处不在！令人感到震惊的街头3D艺术！" *(English Translation: "Creativity is everywhere! The shocking 3D street arts!")* *Emotion Categories:* ***Neutral Complex***

Figure 1: An example for two similar instances being categorized into different emotion categories under two emotion taxonomies

In this paper, we propose a corpus fusion approach to leverage the two emotion corpora, i.e., Yao et al. (2014) and Huang et al. (2015) in order to utilize the annotated data from each other. First, we perform supervised emotion classification on two corpora. Second, we refine the predicted emotion labels via a joint inference method, called Integer Linear Programming (ILP). A global objective function is minimized with the obtained posterior probabilities of the test instances. Two types of constraints, namely intra-corpus constraint and extra-corpus constraint are proposed in the ILP approach to address two challenges mentioned above. We use extra-corpus constraint to overcome the first challenge, and intra-corpus constraint is used for overcoming the second challenge. Results of experiments prove that our model makes a promotion on both classification accuracy and F_1-measure, and both intra-corpus constraints and extra-corpus constraints are effective for the corpus fusion task.

The reminder of this paper is organized as follows. Section 2 overviews the related studies. Section 3 introduces two corpora used in this paper. Section 4 proposes the approach to corpus fusion for emotion classification. Section 5 illustrates the experiments to evaluate the proposed approach. Section 6 gives the conclusion and future work.

2 Related Work

In last decade, mainstream approaches for emotion analysis are corpus-based machine learning methods. Several studies construct emotion corpus from social media platform such as blog, microblog and news portal. Gilad (2005) collects blog texts from LiveJournal to construct an emotion corpus with 815,494 blog articles. Quan and Ren (2009) build an emotion corpus from blogs with eight types of emotions on three granularity levels. Pak and Paroubek (2010) establish an emotion corpus by capturing tweets on Twitter. Yao et al. (2014) build an emotion corpus with seven emotion types from SINA microblog. Huang et al. (2015) construct an emotion from TENCENT microblog including both simple and complex emotion annotation.

According to the text granularity, emotion analysis works can be generally divided into three levels: document-level, sentence-level, and word-level. Gilad (2005) uses SVM to model a document-level

emotion classifier with blog articles. Yang et al. (2007) identify the emotion types of blog articles based on SVM and CRF with sentiment lexicon. Lin et al. (2007) use the articles on Yahoo! News to analysis the news readers' emotion.

Sentence-level emotion analysis is mainly based on emotion lexicon. Mohammad and Turney (2010) study the effect of word level emotion lexicons for sentence level emotion analysis. They use word level emotion lexicons based on Word Net and NRC-10 to predict the emotion in sentences with Logistic Regression and SVM. Das and Bandyopadhyay (2010) categorize the emotions on Bengali blog. They first identify the emotion of words in a sentence, then judge the emotion of this sentence according to the words' emotion. Aman and Szpakowicz (2007) implement a knowledge-based sentence level emotion recognition method.

Word-level emotion analysis aims to construct emotion lexicon, which plays an important auxiliary role in emotion analysis. Yang et al. (2014) propose Emotion-aware LDA model to build a domain-specific lexicon. Xu et al. (2010) use language resource, such as synonym dictionary, semantic dictionary, and labeled and unlabeled corpus to construct the similarity matrix between words and seed words. They build an emotion lexicon with five emotion classes using graph-based rules. As a special expression of words, emoticons play an important role in emotion analysis due to the explosion in social media. Tang et al. (2013) annotate data from microblog posts with the help of emoticons.

There are several studies to address corpus adaptation problem in NLP field. Gao et al. (2004) do a pioneer work by describing a transformation-based converter to transfer a certain word segmentation result to another annotation guideline. Jiang et al. (2009) investigate the automatic integration of word segmentation knowledge in different annotated corpora. Similar approaches are applied to constituency parsing (Zhu et al., 2011) and word segmentation (Sun and Wan, 2012)

Unlike all above studies, we propose a corpus fusion approach to emotion classification in order to address the corpus fusion problem to combine two corpora with different emotion taxonomies and annotation guidelines. To the best of our knowledge, this is the first attempt to address this task in emotion analysis.

3 Corpus

Two emotion corpora we used are respectively constructed by Yao et al. (2014) and Huang et al. (2015). We simply denote the two corpora as YAO (2014) and HUANG (2015) in the rest of this paper for convenience.

YAO (2014) is constructed from SINA microblog[1]. It categorizes emotions into seven classes: $happiness$, $anger$, $sadness$, $fear$, $like$, $surprise$ and $disgust$. The corpus consists of 14,000 instances, of which 7,407 instances express emotions. Each instance may include both primary emotion and secondary emotion, or just has one primary emotion. Table 1a illustrates the distribution of primary emotions and secondary emotions in this corpus.

Notation	Emotion Class	Primary Emotion	Secondary Emotion
e_{Y_1}	$happiness$	1460	359
e_{Y_2}	$anger$	669	203
e_{Y_3}	$sadness$	1173	269
e_{Y_4}	$fear$	148	61
e_{Y_5}	$like$	2203	546
e_{Y_6}	$surprise$	362	170
e_{Y_7}	$disgust$	1392	385
-	**Total**	**7407**	**1993**

(a) YAO (2014)

Notation	Emotion Class	Amount
e_{H_1}	joy	1038
e_{H_2}	$anger$	472
e_{H_3}	$sadness$	581
e_{H_4}	$fear$	94
e_{H_5}	$positive$	1178
e_{H_6}	$neutral$	1131
e_{H_7}	$negative$	2175
-	**Total**	**6669**

(b) HUANG (2015)

Table 1: Emotion categories and distribution on two corpora

[1] http://weibo.com

Huang et al. (2015) propose another emotion taxonomy with both basic emotions and complex emotions. Basic emotions include four emotion classes: joy, $anger$, $sadness$ and $fear$. Complex emotions contain three emotion classes: $positive$, $neutral$ and $negative$. This corpus is constructed from TENCENT microblog[2], and it consists of 15,540 instances. 6,669 instances express certain emotion. Although there is a very few multi-label annotation on it, we consider this corpus as single-label annotated. Table 1b shows the distribution of emotions in the two corpora.

4 Approach to Corpus Fusion for Emotion Classification

The corpus fusion approach to emotion classification aims to exploit the relationship between two corpora which have similar emotion taxonomies. Figure 2 illustrates the framework of our model. The testing results generated by the supervised emotion classifier are refined by ILP with label constraints.

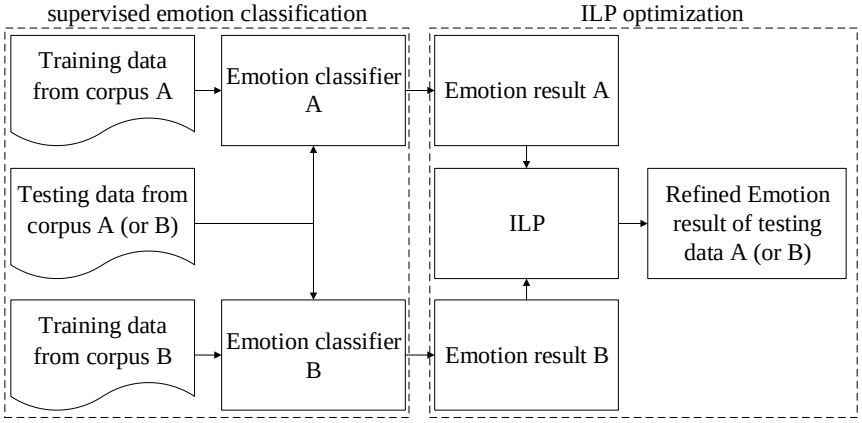

Figure 2: The framework of corpus fusion for emotion classification with ILP

4.1 Supervised Emotion Classification

Supervised classification problem trains a predictor f which maps an input vector x to the corresponding class label y on a set of training data. In emotion classification, a feature vector x is extracted from the instance. Formally, the objective of classification is defined as follows:

$$f(x) \rightarrow y, \quad y \in \{emotion1, emotion2, ...\} \tag{1}$$

In this task, we train plural binary predictors for each emotion class for the testing set from YAO (2014), and a 7-way predictor for the testing set from HUANG (2015). For one sample instance t_i from the testing set, predicting results r_{Y_i} and r_{H_i} indicating the predicted emotion labels, and we get two sets of probabilities P_{Y_i} and P_{H_i} which contain the probabilities of this sample belonging to each category in two emotion taxonomies:

$$\begin{aligned} P_{Y_i} &= \{p(r_{Y_i} = e_{Y_1}),\ p(r_{Y_i} = e_{Y_2})\ ...p(r_{Y_i} = e_{Y_7})\}, \\ P_{H_i} &= \{p(r_{H_i} = e_{H_1}),\ p(r_{H_i} = e_{H_2})\ ...p(r_{H_i} = e_{H_7})\} \end{aligned} \tag{2}$$

where $p(r_{Y_i} = e_{Y_1})$ denotes the probability of t_i belonging to $happiness$ under the emotion taxonomy of YAO (2014), and $p(r_{H_i} = e_{H_1})$ denotes the probability of t_i belonging to joy under the emotion taxonomy of HUANG (2015). The rest can be done in the same manner.

[2]http://t.qq.com/

4.2 Global Optimization with ILP

ILP optimization aims to refine the label result given the probability result. We design objective function and constraints to exploit the similarity between two emotion taxonomies. Like Roth and Yih (2004), we firstly define following assignment costs:

$$\begin{aligned} c_{Y_i} &= -log(p(r_{Y_i} = e_{Y_i})) + log(1 - p(r_{Y_i} = e_{Y_i})), \\ c_{H_i} &= -log(p(r_{H_i} = e_{H_i})) + log(1 - p(r_{H_i} = e_{H_i})), \\ & 1 \leq i \leq 7 \end{aligned} \tag{3}$$

where c_{Y_i} is the cost of t_i belonging to the ith emotion class under the taxonomy of YAO (2014), and c_{H_i} is the cost of t_i belonging to the ith emotion class under the taxonomy of HUANG (2015). For each sample t_i in testing set there can be two cost vectors C_Y and C_H, and two label vectors L_Y and L_H used on storing the refined labels of t_i:

$$C_Y = [c\_Y_1\ c\_Y_2\ ...\ c\_Y_7]^{\mathrm{T}}, \quad C_H = [c\_H_1\ c\_H_2\ ...\ c\_H_7]^{\mathrm{T}} \tag{4}$$

$$L_Y = [y_1\ y_2\ ...\ y_7], \quad L_H = [z_1\ z_2\ ...\ z_7] \tag{5}$$

where y_1 to y_7 indicate the emotion class of t_i under the taxonomy of YAO (2014), and z_1 to z_7 indicate that under the taxonomy of HUANG (2015). For instance, if the label vector L_Y=[0,1,0,0,0,0,1], it indicates that t_i is refined as $anger$ and $disgust$ under the emotion taxonomy of YAO (2014). The ILP optimization aims to acquire the refined emotion labels which are given by two label vectors.

ILP with Intra-corpus Constraints

We employ ILP with intra-corpus constraints to address the issue on annotation guideline. Note that we don't solely apply this type of constraints on the testing set of HUANG (2015) because it is considered to be single-labeled. On YAO (2014), the objective function can be defined as follows:

$$\begin{aligned} \min t &= |L_Y \times C_Y| \\ &= \sum_{i=1}^{7} (c\_Y_i y_i) \end{aligned} \tag{6}$$

Subject to:

$$y_i \in \{0,\ 1\}, \tag{7}$$

$$1 \leq \sum_{i=1}^{7} y_i \leq 2 \tag{8}$$

where formula (8) implies that one or two labels are chosen from the emotion taxonomy of YAO (2014) after optimization. The objective function above aims to minimize the product of cost vector and label vector. Furthermore, an additional constraint aiming to align the emotion classes between two taxonomies is defined as follows:

(C1) Co-occurrence constraint: We filter the emotion pairs with low co-occurrence frequency in YAO (2014). The filtered pairs all occur below 30 times in the corpus according to statistics. For instance, $happiness$ and $disgust$ rarely co-occur in the same instance.

$$\begin{aligned} & y_1 + y_2 \leq 1,\ y_1 + y_4 \leq 1,\ y_2 + y_4 \leq 1,\ y_2 + y_5 \leq 1, \\ & y_2 + y_6 \leq 1,\ y_4 + y_5 \leq 1,\ y_4 + y_6 \leq 1,\ y_4 + y_7 \leq 1 \end{aligned} \tag{9}$$

ILP with Extra-corpus Constraints

We leverage the similarity between two emotion taxonomies with extra-corpus constraints. Firstly, we add specific costs as follows:

$$\begin{aligned} & c\_align\_H_1 = c\_H_1 + c\_H_5,\ c\_align\_H_2 = c\_H_2 + c\_H_7, \\ & c\_align\_H_3 = c\_H_3 + c\_H_7,\ c\_align\_H_4 = c\_H_4 + c\_H_7, \\ & c\_align\_H_i = c\_H_i, 5 \leq i \leq 7 \end{aligned} \tag{10}$$

In formula (10), some costs in the original cost vector defined in formula (4) are added together. For example, c_H_1 and c_H_5 are added into $c\_align\_H_1$. It means that we align $happiness$ under the taxonomy of YAO (2014) to both joy and $positive$ under the taxonomy of HUANG (2015) together with the alignment constraint defined below. The cost vector C_H changes to:

$$C_H^{'} = [c\_align\_H_1\ c\_align\_H_2\ ...\ c\_align\_H_7]^{\mathrm{T}} \tag{11}$$

As a result, the objective function becomes to:

$$\begin{aligned} \min t &= |L_Y \times C_Y| + |L_H \times C_H^{'}| \\ &= \sum_{i=1}^{7}(c\_Y_i y_i + c\_align\_H_i z_i) \end{aligned} \tag{12}$$

Subject to:

$$y_i,\ z_i \in \{0,\ 1\}, \tag{13}$$

$$\sum_{i=1}^{7} y_i = 1, \tag{14}$$

$$\sum_{i=1}^{7} z_i = 1 \tag{15}$$

where formula (14) and (15) unify the number of possible labels on both taxonomies to one because we don't consider any intra-corpus constraints which are derived from the annotation guideline of YAO (2014) when extra-corpus is solely applied. The alignment constraint is defined as follows:

(C2) Alignment constraint: When a sample instance is categorized into a certain emotion e under one taxonomy, it can be categorized into an emotion $e^{'}$ which is same or similar to e under the other taxonomy. For instance, if an instance t is labeled as $disgust$ under the taxonomy of YAO (2014), it can be labeled as $negative$ under the taxonomy of HUANG (2015).

$$y_i = z_i,\ 1 \leq i \leq 7 \tag{16}$$

ILP with Two Types of Constraints

In this subsection, both intra-corpus and extra-corpus constrains are employed. The objective function is defined as follows:

$$\begin{aligned} \min t &= |L_Y \times C_Y| + |L_H \times C_H^{'}| \\ &= \sum_{i=1}^{7}(c\_Y_i y_i + c\_align\_H_i z_i) \end{aligned} \tag{17}$$

Subject to:

$$y_i,\ z_i \in \{0,\ 1\}, \tag{18}$$

$$1 \leq \sum_{i=1}^{7} y_i \leq 2, \tag{19}$$

$$\sum_{i=1}^{7} z_i = 1 \tag{20}$$

Moreover, constraint C1 and C2 are also employed to restrict the labels in both views of intra-corpus and extra-corpus. Additionally, we make a relaxation on the alignment constraint C2.

(C3) Relaxed Alignment constraint: We make a relaxation on C2 to allow more than one chosen label on YAO (2014). C2 makes the numbers of labels on two corpora be the same so that formula (19) becomes meaningless. We employ the following version to replace C2.

$$y_i \geq z_i,\ 1 \leq i \leq 7 \tag{21}$$

5 Experimentation

5.1 Experimental Setting

Features

Bag-of-words feature is adopted in training supervised emotion classifiers. Each instance is represented as a binary vector indicating the presence or absence of word unigrams.

Evaluation Metrics

We employ the widely used accuracy and F_1-measure on the multi-class-single-label emotion classification on HUANG (2015). On multi-class-multi-label emotion classification on YAO (2014), we employ two evaluation metrics to measure the performance. These metrics have been popularly used in multi-label classification problems (Godbole and Sarawagi, 2004).

- ***Accuracy:*** It gives an average degree of the similarity between the predicted and the ground truth label sets of all test examples:

$$Accuracy = \frac{1}{q}\sum_{i=1}^{q}\frac{|y_i \cap y_i^{'}|}{|y_i \cup y_i^{'}|} \tag{22}$$

  where q is the number of all test instances, $y_i^{'}$ is the estimated label and y_i is the true label.

- ***F_1-measure:*** It is the harmonic mean between precision and recall. It can be calculated from true positives, true negatives, false positives and false negatives based on the predictions and the corresponding actual values:

$$F_1 = \frac{1}{q}\sum_{i=1}^{q}\frac{|y_i \cap y_i^{'}|}{|y_i| + |y_i^{'}|} \tag{23}$$

5.2 Experimental Results with ILP Optimization

ILP with Intra-corpus constraints

In this experiment, intra-corpus constraints are applied for refining the predicting results. Note this experiment is only taken place on YAO (2014) in which an instance might have one or two labels. We experimentalize following methods for comparison:

- **Baseline:** We apply Maximum Entropy classifier with BOW feature as one baseline. Seven binary classifiers are trained for each emotion class. We balance the proportion of positive data and negative data for each classifier in order to achieve the best overall performance.

- **ILP with Intra-corpus Constraints:** ILP global optimization approach with defined intra-corpus constraints and objective function.

Table 2 shows the performance of ILP with intra-corpus constraints on the testing set of YAO (2014). According to the results, ILP approach with intra-corpus constraints overcomes the baseline with a 0.050 promotion in accuracy and a 0.013 promotion on F_1-measure, which demonstrates the effectiveness of proposed intra-corpus constraints.

	Accuracy	F_1
Baseline	0.375	0.243
ILP (Intra-corpus)	0.425	0.256

Table 2: Performance of ILP with intra-corpus constraints on YAO (2014)

ILP with Extra-corpus constraints

In this experiment, we apply extra-corpus constraints on ILP optimization to leverage the annotated data from two corpora. We experimentalize following methods for comparison:

- **Baseline:** Max Entropy classifier with BOW feature serves as baseline. In the experiment on YAO (2014), the baseline is same as the one used in the experiment with intra-corpus constraints. In the experiment on HUANG (2015), a 7-way classifier is trained for baseline. The proportion of training data for each emotion class follows its original proportion.
- **ILP with Intra-corpus Constraints:** ILP global optimization approach with defined extra-corpus constraints and objective function.

Table 3 shows the performance of ILP when extra-corpus constraints are utilized on both testing sets. Extra-corpus constraints improve the accuracy on YAO (2014), but the F_1-measure reduces. While on HUANG (2015), both accuracy and F_1-measure improve distinctly, proving the capability of extra-corpus constraints on corpus fusion to leverage the annotated data from other corpus.

	Accuracy	F_1
Baseline	0.375	0.243
ILP (Extra-corpus)	0.430	0.231

(a) On YAO (2014)

	Accuracy	F_1
Baseline	0.405	0.359
ILP (Extra-corpus)	0.431	0.386

(b) On HUANG (2015)

Table 3: Performance of ILP with extra-corpus constraints

ILP with Both Types of constraints

In this experiment, we apply both intra-corpus and extra-corpus constraints on ILP optimization to implement corpus fusion from both views. Following methods are experimentalized:

- **Baseline:** Same as those used in the experiment with extra-corpus constraints.
- **ILP with Intra-corpus Constraints:** ILP approach with only intra-corpus constraints. This method is only employed on YAO (2014).
- **ILP with Extra-corpus Constraints:** ILP approach with only extra-corpus constraints.
- **ILP with Both Types of Constraints:** ILP approach with both intra-corpus and extra-corpus constraints and defined objective function.

Table 4 shows the performance of ILP approach with both intra-corpus and extra-corpus constraints compared to baselines. From these tables, we can see that employing both constraints further improves accuracy and F_1-measure on YAO (2014). The joint use of both constraints avoids the decrease on F_1-measure when only extra-corpus constraints are applied. On HUANG (2015), ILP with both constraints slightly improves the accuracy compared to ILP with only extra-corpus, but the F_1-measure also decreases slightly. Intra-corpus constraints impact a little on HUANG (2015).

	Accuracy	F_1
Baseline	0.375	0.243
ILP (Intra-corpus)	0.425	0.256
ILP (Extra-corpus)	0.430	0.231
ILP (both)	0.440	0.261

(a) On YAO (2014)

	Accuracy	F_1
Baseline	0.405	0.359
ILP (Extra-corpus)	0.431	0.386
ILP (both)	0.435	0.382

(b) On HUANG (2015)

Table 4: Performance of ILP with both types of constraints

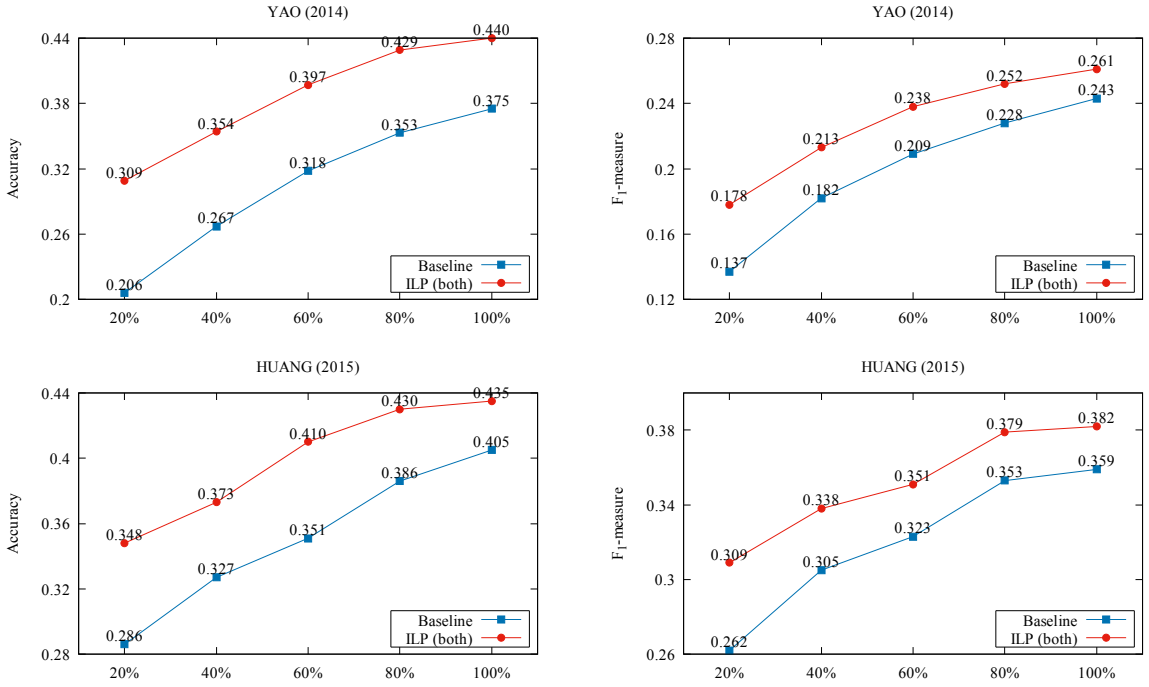

Figure 3: Performance of ILP with both types of constraints with different scales of training set

Figure 3 gives the performance of ILP with both constraints when different scales of training set are used. The improvement of ILP approach decreases with the increase of the scale of training set. It means that a highly performed baseline may reduce the space of promotion achieved by ILP optimization because the amount of error classified instances which can be refined decreases. Even so, ILP approach still improves the performance distinctly when the scale of training set is 100%.

6 Conclusion and Future Work

In this paper, we propose a corpus fusion approach to corpus fusion for emotion classification with ILP optimization. Specifically, we employ intra-task and extra-task constraints to better capture the similarity between two different emotion taxonomies and address the different annotation guidelines. Experiments demonstrate that ILP optimization improves the performance by using annotated data from other corpus, which has a different emotion taxonomy.

In our future work, we would like to seek better modification on ILP for further improvement. Moreover, we will try to adapt this approach to other NLP tasks where two or more corpora are available.

Effective LSTMs for Target-Dependent Sentiment Classification

Duyu Tang, Bing Qin, Xiaocheng Feng, Ting Liu
Harbin Institute of Technology, Harbin, China
{dytang, qinb, xcfeng, tliu}@ir.hit.edu.cn

Abstract

Target-dependent sentiment classification remains a challenge: modeling the semantic relatedness of a target with its context words in a sentence. Different context words have different influences on determining the sentiment polarity of a sentence towards the target. Therefore, it is desirable to integrate the connections between target word and context words when building a learning system. In this paper, we develop two target dependent long short-term memory (LSTM) models, where target information is automatically taken into account. We evaluate our methods on a benchmark dataset from Twitter. Empirical results show that modeling sentence representation with standard LSTM does not perform well. Incorporating target information into LSTM can significantly boost the classification accuracy. The target-dependent LSTM models achieve state-of-the-art performances without using syntactic parser or external sentiment lexicons.[1]

1 Introduction

Sentiment analysis, also known as opinion mining (Pang and Lee, 2008; Liu, 2012), is a fundamental task in natural language processing and computational linguistics. Sentiment analysis is crucial to understanding user generated text in social networks or product reviews, and has drawn a lot of attentions from both industry and academic communities. In this paper, we focus on target-dependent sentiment classification (Jiang et al., 2011; Dong et al., 2014; Vo and Zhang, 2015), which is a fundamental and extensively studied task in the field of sentiment analysis. Given a sentence and a target mention, the task calls for inferring the sentiment polarity (e.g. positive, negative, neutral) of the sentence towards the target. For example, let us consider the sentence: "*I bought a new camera. The picture quality is amazing but the battery life is too short*". If the target string is *picture quality*, the expected sentiment polarity is "positive" as the sentence expresses a positive opinion towards *picture quality*. If we consider the target as *battery life*, the correct sentiment polarity should be "negative".

Target-dependent sentiment classification is typically regarded as a kind of text classification problem in literature. Majority of existing studies build sentiment classifiers with supervised machine learning approach, such as feature based Supported Vector Machine (Jiang et al., 2011) or neural network approaches (Dong et al., 2014; Vo and Zhang, 2015). Despite the effectiveness of these approaches, we argue that target-dependent sentiment classification remains a challenge: how to effectively model the semantic relatedness of a target word with its context words in a sentence. One straight forward way to address this problem is to manually design a set of target-dependent features, and integrate them into existing feature-based SVM. However, feature engineering is labor intensive and the "sparse" and "discrete" features are clumsy in encoding side information like target-context relatedness. In addition, a person asked to do this task will naturally "look at" parts of relevant context words which are helpful to determine the sentiment polarity of a sentence towards the target. These motivate us to develop a powerful neural network approach, which is capable of learning continuous features (representations) without feature engineering and meanwhile capturing the intricate relatedness between target and context words.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3298–3307, Osaka, Japan, December 11-17 2016.

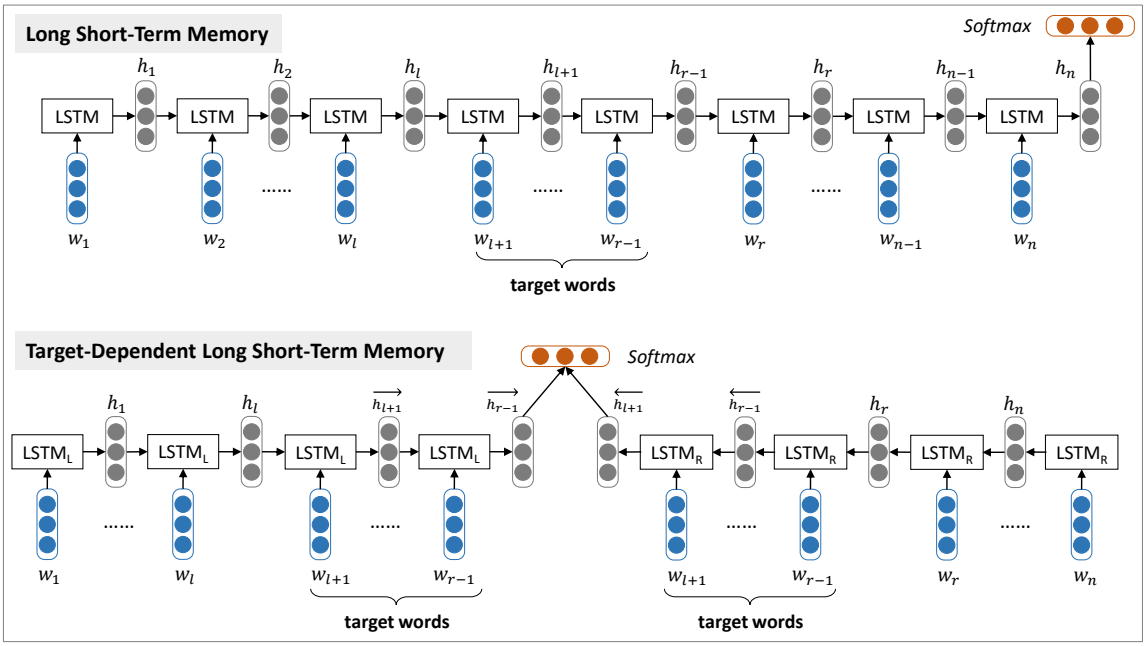

Figure 1: The basic long short-term memory (LSTM) approach and its target-dependent extension TD-LSTM for target-dependent sentiment classification. w stands for word in a sentence whose length is n, $\{w_{l+1}, w_{l+2}, ..., w_{r-1}\}$ are target words, $\{w_1, w_2, ..., w_l\}$ are preceding context words, $\{w_r, ..., w_{n-1}, w_n\}$ are following context words.

In this paper, we present neural network models to deal with target-dependent sentiment classification. The approach is an extension on long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) by incorporating target information. Such target-dependent LSTM approach models the relatedness of a target word with its context words, and selects the relevant parts of contexts to infer the sentiment polarity towards the target. The model could be trained in an end-to-end way with standard backpropagation, where the loss function is cross-entropy error of supervised sentiment classification.

We apply the neural model to target-dependent sentiment classification on a benchmark dataset (Dong et al., 2014). We compare with feature-based SVM (Jiang et al., 2011), adaptive recursive neural network (Dong et al., 2014) and lexicon-enhanced neural network (Vo and Zhang, 2015). Empirical results show that the proposed approach without using syntactic parser or external sentiment lexicon obtains state-of-the-art classification accuracy. In addition, we find that modeling sentence with standard LSTM does not perform well on this target-dependent task. Integrating target information into LSTM could significantly improve the classification accuracy.

2 The Approach

We describe the proposed approach for target-dependent sentiment classification in this section. We first present a basic long short-term memory (LSTM) approach, which models the semantic representation of a sentence without considering the target word being evaluated. Afterwards, we extend LSTM by considering the target word, obtaining the Target-Dependent Long Short-Term Memory (TD-LSTM) model. Finally, we extend TD-LSTM with target connection, where the semantic relatedness of target with its context words are incorporated.

2.1 Long Short-Term Memory (LSTM)

In this part, we describe a long short-term memory (**LSTM**) model for target-dependent sentiment classification. It is a basic version of our approach. In this setting, the target to be evaluated is ignored so that the task is considered in a target independent way.

We use LSTM as it is a state-of-the-art performer for semantic composition in the area of sentiment

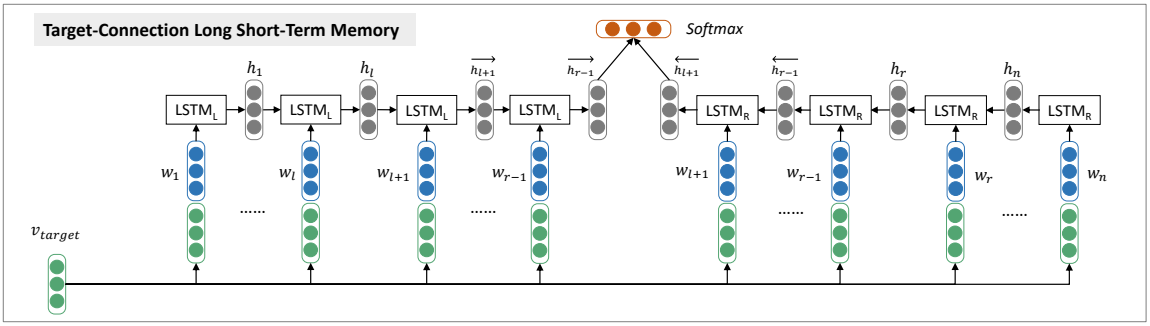

Figure 2: The target-connection long short-term memory (TC-LSTM) model for target-dependent sentiment classification, where w stands for word in a sentence whose length is n, $\{w_{l+1}, w_{l+2}, ..., w_{r-1}\}$ are target words, v_{target} is target representation, $\{w_1, w_2, ..., w_l\}$ are preceding context words, $\{w_r, ..., w_{n-1}, w_n\}$ are following context words.

analysis (Li et al., 2015a; Tang et al., 2015). It is capable of computing the representation of a longer expression (e.g. a sentence) from the representation of its children with multi levels of abstraction. The sentence representation can be naturally considered as the feature to predict the sentiment polarity of sentence.

Specifically, each word is represented as a low dimensional, continuous and real-valued vector, also known as word embedding (Bengio et al., 2003; Mikolov et al., 2013; Pennington et al., 2014; Tang et al., 2014). All the word vectors are stacked in a word embedding matrix $L_w \in \mathbb{R}^{d \times |V|}$, where d is the dimension of word vector and $|V|$ is vocabulary size. In this work, we pre-train the values of word vectors from text corpus with embedding learning algorithms (Pennington et al., 2014; Tang et al., 2014) to make better use of semantic and grammatical associations of words.

We use LSTM to compute the vector of a sentence from the vectors of words it contains, an illustration of the model is shown in Figure 1. LSTM is a kind of recurrent neural network (RNN), which is capable of mapping vectors of words with variable length to a fixed-length vector by recursively transforming current word vector w_t with the output vector of the previous step h_{t-1}. The transition function of standard RNN is a linear layer followed by a pointwise non-linear layer such as hyperbolic tangent function ($tanh$).

$$h_t = tanh(W \cdot [h_{t-1}; w_t] + b) \tag{1}$$

where $W \in \mathbb{R}^{d \times 2d}$, $b \in \mathbb{R}^d$, d is dimension of word vector. However, standard RNN suffers the problem of gradient vanishing or exploding (Bengio et al., 1994; Hochreiter and Schmidhuber, 1997), where gradients may grow or decay exponentially over long sequences. Many researchers use a more sophisticated and powerful LSTM cell as the transition function, so that long-distance semantic correlations in a sequence could be better modeled. Compared with standard RNN, LSTM cell contains three additional neural gates: an input gate, a forget gate and an output gate. These gates adaptively remember input vector, forget previous history and generate output vector (Hochreiter and Schmidhuber, 1997). LSTM cell is calculated as follows.

$$i_t = \sigma(W_i \cdot [h_{t-1}; w_t] + b_i) \tag{2}$$
$$f_t = \sigma(W_f \cdot [h_{t-1}; w_t] + b_f) \tag{3}$$
$$o_t = \sigma(W_o \cdot [h_{t-1}; w_t] + b_o) \tag{4}$$
$$g_t = tanh(W_r \cdot [h_{t-1}; w_t] + b_r) \tag{5}$$
$$c_t = i_t \odot g_t + f_t \odot c_{t-1} \tag{6}$$
$$h_t = o_t \odot tanh(c_t) \tag{7}$$

where $\odot$ stands for element-wise multiplication, σ is sigmoid function, W_i, b_i, W_f, b_f, W_o, b_o are the parameters of input, forget and output gates.

After calculating the hidden vector of each position, we regard the last hidden vector as the sentence representation (Li et al., 2015a; Tang et al., 2015). We feed it to a linear layer whose output length is class number, and add a $softmax$ layer to output the probability of classifying the sentence as positive, negative or neutral. Softmax function is calculated as follows, where C is the number of sentiment categories.

$$softmax_i = \frac{exp(x_i)}{\sum_{i'=1}^{C} exp(x_{i'})} \tag{8}$$

2.2 Target-Dependent LSTM (TD-LSTM)

The aforementioned LSTM model solves target-dependent sentiment classification in a target-independent way. That is to say, the feature representation used for sentiment classification remains the same without considering the target words. Let us again take "*I bought a new camera. The picture quality is amazing but the battery life is too short*" as an example. The representations of this sentence with regard to *picture quality* and *battery life* are identical. This is evidently problematic as the sentiment polarity labels towards these two targets are different.

To take into account of the target information, we make a slight modification on the aforementioned LSTM model and introduce a target-dependent LSTM (**TD-LSTM**) in this subsection. The basic idea is to model the preceding and following contexts surrounding the target string, so that contexts in both directions could be used as feature representations for sentiment classification. We believe that capturing such target-dependent context information could improve the accuracy of target-dependent sentiment classification.

Specifically, we use two LSTM neural networks, a left one LSTM_L and a right one LSTM_R, to model the preceding and following contexts respectively. An illustration of the model is shown in Figure 1. The input of LSTM_L is the preceding contexts plus target string, and the input of LSTM_R is the following contexts plus target string. We run LSTM_L from left to right, and run LSTM_R from right to left. We favor this strategy as we believe that regarding target string as the last unit could better utilize the semantics of target string when using the composed representation for sentiment classification. Afterwards, we concatenate the last hidden vectors of LSTM_L and LSTM_R, and feed them to a $softmax$ layer to classify the sentiment polarity label. One could also try averaging or summing the last hidden vectors of LSTM_L and LSTM_R as alternatives.

2.3 Target-Connection LSTM (TC-LSTM)

Compared with LSTM model, target-dependent LSTM (TD-LSTM) could make better use of the target information. However, we think TD-LSTM is still not good enough because it does not capture the interactions between target word and its contexts. Furthermore, a person asked to do target-dependent sentiment classification will select the relevant context words which are helpful to determine the sentiment polarity of a sentence towards the target.

Based on the consideration mentioned above, we go one step further and develop a target-connection long short-term memory (**TC-LSTM**). This model extends TD-LSTM by incorporating an target connection component, which explicitly utilizes the connections between target word and each context word when composing the representation of a sentence.

An overview of TC-LSTM is illustrated in Figure 2. The input of TC-LSTM is a sentence consisting of n words $\{w_1, w_2, ...w_n\}$ and a target string t occurs in the sentence. We represent target t as $\{w_{l+1}, w_{l+2}...w_{r-1}\}$ because a target could be a word sequence of variable length, such as "*google*" or "*harry potter*". When processing a sentence, we split it into three components: target words, preceding context words and following context words. We obtain target vector v_{target} by averaging the vectors of words it contains, which has been proven to be simple and effective in representing named entities (Socher et al., 2013a; Sun et al., 2015). When compute the hidden vectors of preceding and following context words, we use two separate long short-term memory models, which are similar with the strategy used in TD-LSTM. The difference is that in TC-LSTM the input at each position is the concatenation of word embedding and target vector v_{target}, while in TD-LSTM the input at each position only includes

the embedding of current word. We believe that TC-LSTM could make better use of the connection between target and each context word when building the representation of a sentence.

2.4 Model Training

We train LSTM, TD-LSTM and TC-LSTM in an end-to-end way in a supervised learning framework. The loss function is the cross-entropy error of sentiment classification.

$$loss = -\sum_{s \in S} \sum_{c=1}^{C} P_c^g(s) \cdot log(P_c(s)) \tag{9}$$

where S is the training data, C is the number of sentiment categories, s means a sentence, $P_c(s)$ is the probability of predicting s as class c given by the $softmax$ layer, $P_c^g(s)$ indicates whether class c is the correct sentiment category, whose value is 1 or 0. We take the derivative of loss function through back-propagation with respect to all parameters, and update parameters with stochastic gradient descent.

3 Experiment

We apply the proposed method to target-dependent sentiment classification to evaluate its effectiveness. We describe experimental setting and empirical results in this section.

3.1 Experimental Settings

We conduct experiment in a supervised setting on a benchmark dataset (Dong et al., 2014). Each instance in the training/test set has a manually labeled sentiment polarity. Training set contains 6,248 sentences and test set has 692 sentences. The percentages of positive, negative and neutral in training and test sets are both 25%, 25%, 50%. We train the model on training set, and evaluate the performance on test set. Evaluation metrics are accuracy and macro-F1 score over positive, negative and neutral categories (Manning and Schütze, 1999; Jurafsky and Martin, 2000).

3.2 Comparison to Other Methods

We compare with several baseline methods, including:

In **SVM-indep**, SVM classifier is built with target-independent features, such as unigram, bigram, punctuations, emoticons, hashtags, the numbers of positive or negative words in General Inquirer sentiment lexicon. In **SVM-dep**, target-dependent features (Jiang et al., 2011) are also concatenated as the feature representation.

In **Recursive NN**, standard Recursive neural network is used for feature learning over a transfered target-dependent dependency tree (Dong et al., 2014). **AdaRNN-w/oE**, **AdaRNN-w/E** and **AdaRNN-comb** are different variations of adaptive recursive neural network (Dong et al., 2014), whose composition functions are adaptively selected according to the inputs.

In **Target-dep**, SVM classifier is built based on rich target-independent and target-dependent features (Vo and Zhang, 2015). In **Target-dep**$^+$, sentiment lexicon features are further incorporated.

The neural models developed in this paper are abbreviated as LSTM, TD-LSTM and TC-LSTM, which are described in the previous section. We use 100-dimensional Glove vectors learned from Twitter, randomize the parameters with uniform distribution $U(-0.003, 0.003)$, set the clipping threshold of softmax layer as 200 and set learning rate as 0.01.

Experimental results of baseline models and our methods are given in Table 1. Comparing between SVM-indep and SVM-dep, we can find that incorporating target information can improve the classification accuracy of a basic SVM classifier. AdaRNN performs better than feature based SVM by making use of dependency parsing information and tree-structured semantic composition. We can find that target-dep is a strong performer even without using lexicon features. It benefits from rich automatic features generated from word embeddings.

Among LSTM based models described in this paper, the basic LSTM approach performs worst. This is not surprising because this task requires understanding target-dependent text semantics, while the basic LSTM model does not capture any target information so that it predicts the same result for different

Method	Accuracy	Macro-F1
SVM-indep	0.627	0.602
SVM-dep	0.634	0.633
Recursive NN	0.630	0.628
AdaRNN-w/oE	0.649	0.644
AdaRNN-w/E	0.658	0.655
AdaRNN-comb	0.663	0.659
Target-dep	0.697	0.680
Target-dep$^+$	0.711	**0.699**
LSTM	0.665	0.647
TD-LSTM	0.708	0.690
TC-LSTM	**0.715**	0.695

Table 1: Comparison of different methods on target-dependent sentiment classification. Evaluation metrics are accuracy and macro-F1. Best scores are in bold.

targets in a sentence. TD-LSTM obtains a big improvement over LSTM when target signals are taken into consideration. This result demonstrates the importance of target information for target-dependent sentiment classification. By incorporating target-connection mechanism, TC-LSTM obtains the best performances and outperforms all baseline methods in term of classification accuracy.

Comparing between Target-dep$^+$ and Target-dep, we find that sentiment lexicon feature could further improve the classification accuracy. Our final model TC-LSTM without using sentiment lexicon information performs comparably with Target-dep$^+$. We believe that incorporation lexicon information in TC-LSTM could get further improvement. We leave this as a potential future work.

3.3 Effects of Word Embeddings

It is well accepted that a good word embedding is crucial to composing a powerful text representation at higher level. We therefore study the effects of different word embeddings on LSTM, TD-LSTM and TC-LSTM in this part. Since the benchmark dataset from (Dong et al., 2014) comes from Twitter, we compare between sentiment-specific word embedding (SSWE)[2] (Tang et al., 2014) and Glove vectors[3] (Pennington et al., 2014). All these word vectors are 50-dimensional and learned from Twitter. SSWE$_h$, SSWE$_r$ and SSWE$_u$ are different embedding learning algorithms introduced in (Tang et al., 2014). SSWE$_h$ and SSWE$_r$ learn word embeddings by only using sentiment of sentences. SSWE$_u$ takes into account of sentiment of sentences and contexts of words simultaneously.

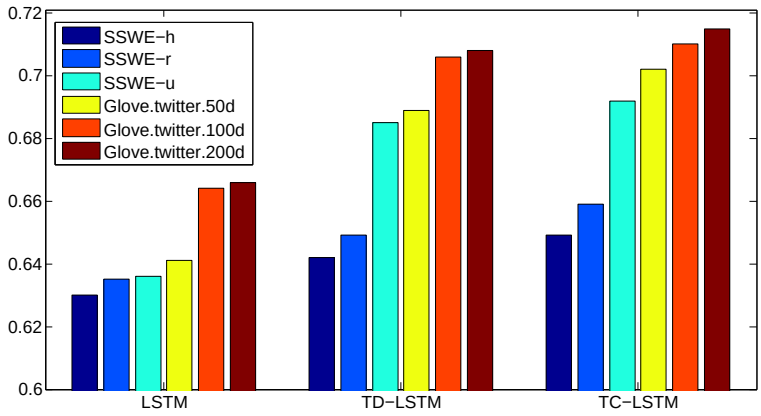

Figure 3: Classification accuracy of LSTM, TD-LSTM and TC-LSTM with different word embeddings. We compare between SSWE$_h$, SSWE$_r$, SSWE$_u$ and Glove vectors.

[2]SSWE vectors are publicly available at `http://ir.hit.edu.cn/~dytang`

[3]Glove vectors are publicly available at `http://nlp.stanford.edu/projects/glove/`

From Figure 3, we can find that $SSWE_h$ and $SSWE_r$ perform worse than $SSWE_u$, which is consistent with the results reported on target-independent sentiment classification of tweets (Tang et al., 2014). This shows the importance of context information for word embedding learning as both $SSWE_h$ and $SSWE_r$ do not encode any word contexts. Glove and $SSWE_u$ perform comparably, which indicates the importance of global context for estimating a good word representation. In addition, the target connection model TC-LSTM performs best when considering a specific word embedding.

	50dms	100dms	200dms
LSTM	27	95	329
LSTM-TD	20	93	274
LSTM-TC	65	280	1,165

Table 2: Time cost of each model with 50dms, 100dms and 200dms Glove vectors. Each value means how many seconds cost in each training iteration.

We compare between Glove vectors with different dimensions (50/100/200). Classification accuracy and time cost are given in Figure 3 and Table 2, respectively. We can find that 100-dimensional word vectors perform better than 50-dimensional word vectors, while 200-dimensional word vectors do not show significant improvements. Furthermore, TD-LSTM and LSTM have similar time cost, while TD-LSTM gets higher classification accuracy as target information is incorporated. TC-LSTM performs slightly better than TD-LSTM while at the cost of longer training time because the parameter number of TC-LSTM is larger.

3.4 Case Study

In this section, we explore to what extent the target-dependent LSTM models including TD-LSTM and TC-LSTM improve the performance of a basic LSTM model.

Example	gold	LSTM
*i hate my **ipod** look at my last tweet before the argh one that 's for you*	-1	0
*okay soooo ... ummmmm .... what is going on with **lindsay lohan**' s face? boring day at the office = perez and tomorrow overload. not good*	0	-1
*i heard ShannonBrown did his thing in the **lakers** game!! got ta love him*	0	1
*Hey **google**, thanks for all these great Labs features on Chromium, but how about " Create Application Shortcut"?!*	1	0

Table 3: Examples drawn from the test set whose polarity labels are incorrectly inferred by LSTM but correctly predicted by both TD-LSTM and TC-LSTM. For each example, target words are in **bold**, "gold" is the ground truth and "LSTM" means the predicted sentiment label from LSTM model.

In Table 3, we list some examples whose polarity labels are incorrectly inferred by LSTM but correctly predicted by both TD-LSTM and TC-LSTM. We observe that LSTM model prefers to assigning the polarity of the entire sentence while ignoring the target to be evaluated. TD-LSTM and TC-LSTM could take into account of target information to some extend. For example, in the 2nd example the opinion holder expresses a negative opinion about his work, but holds a neutral sentiment towards the target "*lindsay lohan*". In the last example, the whole sentence expresses a neutral sentiment while it holds a positive opinion towards "*google*".

We analyse the error cases that both TD-LSTM and TC-LSTM cannot well handle, and find that 85.4% of the misclassified examples relate to neutral category. The positive instances are rarely misclassified as negative, and vice versa. A example of errors is: "*freaky friday on television reminding me to think wtf happened to **lindsay lohan**, she was such a terrific actress , + my huge crush on haley hudson.*", which is incorrectly predicted as positive towards target "*indsay lohan*" in both TD-LSTM and TC-LSTM.

3.5 Discussion

In order to capture the semantic relatedness between target and context words, we extend TD-LSTM by adding a target connection component. One could also try other extensions to capture the connection between target and context words. For example, we also tried an attention-based LSTM model, which is inspired by the recent success of attention-based neural network in machine translation (Bahdanau et al., 2015) and document encoding (Li et al., 2015b). We implement the soft-attention mechanism (Bahdanau et al., 2015) to enhance TD-LSTM. We incorporate two attention layers for preceding LSTM and following LSTM, respectively. The output vector for each attention layer is the weighted average among hidden vectors of LSTM, where the weight of each hidden vector is calculated with a feedforward neural network. The outputs of preceding and following attention models are concatenated and fed to $softmax$ for sentiment classification. However, we cannot obtain better result with such an attention model. The accuracy of this attention model is slightly lower than the standard LSTM model (around 65%), which means that the attention component has a negative impact on the model. A potential reason might be that the attention based LSTM has larger number of parameters, which cannot be easily optimized with the small number of corpus.

4 Related Work

We briefly review existing studies on target-dependent sentiment classification and neural network approaches for sentiment classification in this section.

4.1 Target-Dependent Sentiment Classification

Target-dependent sentiment classification is typically regarded as a kind of text classification problem in literature. Therefore, standard text classification approach such as feature-based Supported Vector Machine (Pang et al., 2002; Jiang et al., 2011) can be naturally employed to build a sentiment classifier. Despite the effectiveness of feature engineering, it is labor intensive and unable to discover the discriminative or explanatory factors of data. To handle this problem, some recent studies (Dong et al., 2014; Vo and Zhang, 2015) use neural network methods and encode each sentence in continuous and low-dimensional vector space without feature engineering. Dong et al. (2014) transfer a dependency tree of a sentence into a target-specific recursive structure, and get higher level representation based on that structure. Vo and Zhang (2015) use rich features including sentiment-specific word embedding and sentiment lexicons. Different from previous studies, the LSTM models developed in this work are purely data-driven, and do not rely on dependency parsing results or external sentiment lexicons.

4.2 Neural Network for Sentiment Classification

Neural network approaches have shown promising results on many sentence/document-level sentiment classification (Socher et al., 2013b; Tang et al., 2015). The power of neural model lies in its ability in learning continuous text representation from data without any feature engineering. For sentence/document level sentiment classification, previous studies mostly have two steps. They first learn continuous word vector embeddings from data (Bengio et al., 2003; Mikolov et al., 2013; Pennington et al., 2014). Afterwards, semantic compositional approaches are used to compute the vector of a sentence/document from the vectors of its constituents based on the principle of compositionality (Frege, 1892). Representative compositional approaches to learn sentence representation include recursive neural networks (Socher et al., 2013b; Irsoy and Cardie, 2014), convolutional neural network (Kalchbrenner et al., 2014; Kim, 2014), long short-term memory (Li et al., 2015a) and tree-structured LSTM (Tai et al., 2015; Zhu et al., 2015). There also exists some studies focusing on learning continuous representation of documents (Le and Mikolov, 2014; Tang et al., 2015; Bhatia et al., 2015; Yang et al., 2016).

5 Conclusion

We develop target-specific long short term memory models for target-dependent sentiment classification. The approach captures the connection between target word and its contexts when generating the representation of a sentence. We train the model in an end-to-end way on a benchmark dataset, and show that

incorporating target information could boost the performance of a long short-term memory model. The target-dependent LSTM model obtains state-of-the-art classification accuracy.

Towards assessing depth of argumentation

Manfred Stede
Applied Computational Linguistics
UFS Cognitive Sciences
University of Potsdam / Germany
stede@uni-potsdam.de

Abstract

For analyzing argumentative text, we propose to study the 'depth' of argumentation as one important component, which we distinguish from argument quality. In a pilot study with German newspaper commentary texts, we asked students to rate the degree of argumentativeness, and then looked for correlations with features of the annotated argumentation structure and the rhetorical structure (in terms of RST). The results indicate that the human judgements correlate with our operationalization of depth and with certain structural features of RST trees.

1 Introduction

In recent years, *argumentation mining* has emerged as a discipline that aims to identify portions of argumentation in text and moreover – in some of the work – to relate them to one another, so that the full structure of arguments is being represented. A natural application for this new field is the mining of arguments in customer reviews (e.g., (Villalba and Saint-Dizier, 2012)), where the goal is to move beyond finding positive and negative statements by also finding the reasons that customers provide for their judgements. But the general task can be applied in many other domains as well. For example, the early research of Mochales Palau and Moens (2009) sought to identify premises and conclusions in legal text; another early work on finding theses in student essays (Burstein et al., 2003) has recently been extended to detecting more argumentative structure in such essays (Stab and Gurevych, 2014), (Nguyen and Litman, 2015); other genres that are being tackled include online dialogue (Oraby et al., 2015), multi-party dialogue (Budzynska et al., 2013) and scientific papers (Kirschner et al., 2015).

Despite the manifold recent activities, the field is still young, and a number of basic issues still require attention. This concerns the design of annotation schemes and possibly finding a consensus on them, but also the more fundamental problem of defining the notion of, and identifying instances of, *argumentative text*. While it is tempting to assume that earlier work on text-level subjectivity classification can be used to determine whether some (portion of) text is argumentative, we argue below that this is generally not the case. Going further, we posit that 'argumentativeness' is a matter of degree, and that determining this degree should also be considered a subtask of argumentation mining. We use the genre of newspaper editorials to conduct a small study where human raters are asked to assess how 'argumentative' different texts are, or in other words, what their 'argumentative depth' is. We will defend the introduction of this term by demonstrating that depth is to be distinguished from argument *quality*, which is already an object of study in the community.

Our next task then is to explain how such judgements arise, i.e., to find features that differentiate texts of different argumentative depths. We show that some simple surface features are not sufficient, and then turn to the underlying pragmatics, as it is – to some extent – captured in analyses according to Rhetorical Structure Theory (RST; (Mann and Thompson, 1988)). It was designed as a tool to make the reasons for a text's coherence explicit, and the specific notion of coherence relation used in RST (as opposed to other approaches such as the Penn Discourse Treebank (Prasad et al., 2008) or Segmented Discourse Representation Theory (Asher and Lascarides, 2003)) is decidedly *intentional*. This makes RST a good

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3308–3317, Osaka, Japan, December 11-17 2016.

candidate for checking whether its text representations are able to predict argumentative depth. The corpus we are using in our study has already been annotated with RST trees in earlier work, so we can use this data when looking for correlations with argumentation structure.

The paper is structured as follows. Section 2 introduces the notion of 'argumentativeness' and compares it to that of 'subjectivity', and introduces our approach to characterising the depth of argumentation. Section 3 describes the newspaper corpus we are using, and Section 4 presents the pilot study on annotating and measuring depth. Finally, Section 5 provides a summary and an outlook on future work.

2 Subjectivity versus Argumentation

To define our terminology, we start from the notion of 'text type' (Werlich, 1975) or 'discourse mode' (Smith, 2003), which posits that a passage of text can be of one of the following types: narrative, descriptive, instructive, expository, or argumentative. These classes refer to the central purpose of the passage, and – as especially Smith has shown – they correlate with certain linguistic features (aspect, Aktionsart, tense progression, etc.). The function of argumentative text, in general, is to influence the beliefs or attitudes of the readers by assembling a constellation of propositions that serve to defend a particular standpoint on a controversial issue (cf. (van Eemeren et al., 1996)).

'Subjectivity' in linguistics encompasses several different phenomena, which all serve to distinguish it from the 'objective' statement, but can do so in quite different ways, such as making speculations on future events, reporting on one's feelings, attributing content to third parties or to hearsay, or evaluating some entity in terms of valence (positive/negative). The latter is the notion that is mostly used in Computational Linguistics, and it is the central target of most work on subjectivity classification. This task can be applied on sentence or text level, and it has been done with bag-of-words models, PoS tags, or linguistic features that tend to be more roubst against domain changes (Petrenz and Webber, 2011), (Krüger et al., to appear). Importantly, subjectivity is orthogonal to the text types mentioned above: Texts of all types may be predominantly subjective, and most may not (a likely exception being the argumentative type).

What has – to the best of our knowledge – not been addressed in depth so far is the distinction between the tasks of classifying subjectivity (versus objectivity) on the one hand and argumentativeness (versus non-argumentativeness) on the other. To see why this is necessary, consider the following examples from the Brexit reader-discussion website of the *Irish Times*:[1]

(1) Sir, Born in London of an Irish mother and English father during the second World War and living in Dublin since 1968, I endeavoured to encourage my English relatives not to exit.
It looks like a case for returning my British passport, if Ireland will look favourably on my application for a replacement. Yours, etc.

(2) Sir, A black day for Europe. The age of populism and demagoguery is well and truly upon us, from Donald Trump to Ukip. The centre is under threat and is buckling. We must passionately embrace the centre ground and with it the EU. The EU is undoubtedly flawed but it has guaranteed peace in Europe for 70 years and made the idea of war laughable. It has united countries that for millennia were enemies and all it asks, as per Article 2 of the European Union Treaty, is respect for human dignity, freedom, democracy, equality, among other lofty goals. (...) Yours, etc.

Both are clearly subjective and both express an opinion (incidentally the same) on the issue, but only (2) states a thesis/claim and provides reasons in support (and even grants a possible objection), thus clearly qualifies as presenting an argument. (1), in contrast, gives a very short personal narrative followed by a description of the speaker's attitude.

We find the same difference in product reviews. Consider these camera reviews from an Amazon website:[2]

[1] http://www.irishtimes.com/opinion/letters/brexit-the-readers-have-their-say-1.2698710

[2] https://www.amazon.co.uk/product-reviews/B00IK01PJC/ref=cm_cr_arp_d_paging_btm_51?ie=UTF8

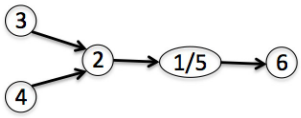

Figure 1: Argumentation structure of example (4)

(3) Camera completely broke whilst on a once in a lifetime holiday and I was nowhere where I could buy a new one. Absolutely gutted as it was first time using camera!

(4) [You'll be lucky if you manage to focus this camera.]$_1$ [Bought to take pictures of jewellery for online sale, the macro function which boasts as having a 5cm macro ability is awful.]$_2$ [For one it is an automatic macro which means that the camera should automatically detect whether the picture requires macro or not - it does not.]$_3$ [For two it should focus on the item in question at even 10cm distance - it does not.]$_4$ [You end up with blurry edges and unfocused pictures.]$_5$ [I was expecting SO much more from an Amazon best seller.]$_6$

Like in the Brexit examples, we sense basically the same opinions (which here resulted in the same low star rating), but the first user gives merely a narration while the second argues (in a fairly complex way with recursive support structure). We added brackets and indices to the sentences so that we can refer to them in our analysis of the argument structure, which was built using the scheme of Peldszus and Stede (2013) and is shown in Figure 1.[3] A brief description of this scheme will be provided in the next section; for now, notice that text segments can be related by SUPPORT and ATTACK relations, and collectively form a tree whose root is the central claim of the text. In our example, all relations are SUPPORT, and we omit the labels here. The node '1/5' indicates that these units in the text convey essentially the same message. Intuitively, to check the representation, a pair of segments in a support relation can be paraphrased with a *why*-link: "I was expecting much more." - "Why?" - "Pictures are unfocused." - "Why?" - "The macro function is awful" - "Why'?" - "Camera doesn't detect macro mode, and camera doesn't focus at close distance."

Using the example, we can begin to make the notion of argumentative depth explicit. For one thing, the measure should contain the proportion of the number of tokens that are taking part in the argumentation analysis: This reflects the amount of non-argumentative information in the text. Furthermore, the measure should reflect the complexity of the tree structure – a flat tree where a claim is supported by a few independent backings is intuitively (and technically) less 'deep' than a structure involving recursion. To measure this, we here simply calculate the average length of the paths from each leaf node to the root. (More elaborate measures could distinguish between the branching factor at the root node and elsewhere, etc.) These two values then constitute our description of argumentative depth – for the time being, we refrain from proposing a way of combining them into a single value. For example (4) and its structure, the pair is: 1.0 / 3.0.

Depth of argumentation, we wish to emphasize, is not the same as quality of argumentation. A writer can build up a fairly complex structure, yet the individual claim/support relations may be weak or even flaky. Here is a (constructed) short camera review to illustrate the point:

(5) I bought this camera yesterday, and I really like it. So even if some people say it's a bad product, you can go ahead and buy it, too. Because it is simply wonderful!

Quality, in this view, is a feature of the reasoning schemes underlying the argumentation, whereas depth is a purely structural measure of the argument as it is presented by the author in the text.

[3]For reasons of space, we cannot discuss all aspects of the analysis here and omit, *inter alia*, a justification of defining the boundaries of segments (argumentative discourse units). See (Peldszus and Stede, 2013).

3 Argumentation in Newspapers: Our Corpus

Our overall goal is to determine whether argumentative depth can be (i) reliably annotated by humans, and (ii) measured automatically. To this end, we wish to correlate it with different layers of linguistic analysis. In order to start this, we favour a corpus of argumentative text that is annotated with argument structure and also with additional layers. The German 'Potsdam Commentary Corpus' (Stede and Neumann, 2014) fulfills this criterion, as it comes with sentence syntax, connectives and their arguments, coreference, and rhetorical structure. We will concentrate here on rhetorical structure; note that our findings do not depend on any specifics of German; a corpus in any other language could be used in the same way.

3.1 The genre of commentary

Most newspapers offer 'opinion' pages with editorials that comment upon current affairs. The specifics of this genre depend to some extent on the different national traditions, but we expect that classifications like that of Schneider and Raue (1996) for German commentary do largely apply to the press in some other countries as well. The authors propose six categories, which include the 'opinion article' (a long piece that slowly builds up a position and encourages readers to reflect), the 'pro and contra' (a crisp and traceable argumentation in favour of a position), the 'on the one/the other hand' (a piece that looks at both sides and remains undecided), and the 'pamphlet' (a strong opinion with little real argumentation). This is, of course, an analytical framework only – actual articles in papers are usually not labelled in this way.

3.2 Data

The Potsdam Commentary Corpus is drawn from two different newspapers: One part is 'pro and contra' (which is in fact their headline) pieces from *Tagesspiegel*; the other is a mix of articles from the opinion page of the local newspaper *Märkische Allgemeine Zeitung* (henceforth: MAZ). All texts are about 10-12 sentences long. The pro/contra articles always come as a pair: One is in favour, one is against the issue under discussion, which may be of local (e.g., Should Berlin build more refugee centers), national (e.g., Should there be mandatory fees for public radio and TV in Germany), or global (e.g., Should we push for a stronger proposal on fighting climate change) relevance. The reader may then decide with whom to side. Given this setting, plus the brevity, we can safely assume a high degree of argumentative depth.

The opinion articles from MAZ, on the other hand, are quite diverse in their argumentative nature: Some merely re-state a piece of news and add some subjective evaluation to it; some try to explain why some event happened; some indulge in a piece of trivia; some take a clear position on a political question and defend it, like a pro/contra text does. Therefore, we can expect to find texts of rather different argumentative depths here, similar to the differences between example texts (1) and (2), and between (3) and (4) above.

For the experiments described below, we selected 15 texts for feature development, and 14 texts for testing; 80% come from MAZ, the rest are 'pro and contra' texts. Both sets were not drawn randomly: They should reflect the spectrum from low to high degree of argumentative depth in roughly equal proportion; these decisions were made by the author (and subject to confirmation by our annotators).

3.3 Annotation layers

For the purposes of this paper, two of the layers provided in the corpus are relevant. The (German) annotation guidelines for these and other layers are freely available.[4]

Rhetorical structure: We are using the RST annotations that were produced for version 2 of the Potsdam Commentary Corpus in 2014. They are largely conforming to the proposals by Mann and Thompson (1988), but the annotation guidelines make some minor modifications. As a preperatory step, the text is first segmented into a sequence of Elementary Discourse Units (EDUs); our guidelines explain which types of clauses constitute such an EDU and which do not. A central concept for our analysis below is

[4] https://publishup.uni-potsdam.de/opus4-ubp/frontdoor/index/index/docId/8276

nuclearity: Most coherence relations in RST distinguish between a central text span (nucleus) and a less important one (satellite); a few treat both (or more) spans as equally important, these are called 'multinuclear'. The result of an RST analysis is a tree structure that joins adjacent EDUs, and then recursively the larger spans.

Using the nuclearity information at each level of that tree, one can read off the central units of the text: those that can be reached from the root of the tree by following only 'nucleus' edges towards the leafs (EDUs). In the second tree of Figure 2 below, EDU 8 is the single central unit; in the the first tree, it is the set of EDUs reached by following all four Joint segments downward.[5] (For an introduction to RST, see also (Taboada and Mann, 2006)).

Argumentation structure: The 'pro/contra' texts in the corpus are already annotated for argumentation, following the scheme proposed by Peldszus and Stede (2013), which is codified in our guidelines. For the MAZ texts, we produced these annotations now, following the same guidelines.

Like with RST, an argumentation structure is also based on a segmentation into elementary units, but these may be larger ('argumentative discourse units' or ADUs). The analysis is a tree whose root represents the 'central claim' unit of the text. The other nodes correspond to ADUs, and the edges to SUPPORT or ATTACK relations, where the latter distinguish between REBUT (challenging the validity of the assertion in the ADU) and UNDERCUT (challenging not the validity of individual ADUs, but the supposition of a SUPPORT relation between two). In contrast to an RST analysis, there is no constraint that only adjacent segments may be conjoined by a relation. Furthermore, the argumentation structure need *not* span the text completely: Parts of it can be deemed irrelevant for the argument made, which is important for our notion of argumentative depth as introduced above.

4 Experimental study

4.1 Features

Simple features. Depth of argumentation is unlikely to be detectable with straightforward surface (or 'near-surface') features. Nonetheless, we tested two simple features that have been used in subjectivity classification (see above) and that might be relevant here: The presence of modal verbs and of 'argumentative' connectives: those that signal a contrastive or causal (in the wide sense) relation.

Argumentation structure: depth measure. The Peldszus/Stede annotation scheme had so far been applied by its authors to pro/contra commentaries and to very short 'microtexts' (Peldszus and Stede, 2016a). Our present annotation is thus its first application to texts which are not as easy to handle: Portions of text might be irrelevant for the argument, and both the central claim and the attachment points of relations can be hard to identify. We will test if our depth measure reflects differences in 'argumentativeness' as perceived by readers.

Rhetorical structure. In the literature there is an ongoing and so far not quite conclusive discussion on the relationship between RST analysis and argumentation analysis (e.g., (Azar, 1999), (Peldszus and Stede, 2013), (Green, 2015), (Peldszus and Stede, 2016b)). Clearly, as mentioned in the beginning, the design of the relations by Mann and Thompson (1988) suggests that the theory be especially amenable to argumentative text. Thus it can be expected that a structural analysis in terms of semantic and pragmatic relations, equipped with nuclearity, might capture what we are characterizing as depth of argumentation here. The first feature that comes to mind is the distribution of semantic versus pragmatic relations (as they have been categorized by the RST and the guideline authors); in particular, we treat Antithesis, Concession, Evaluation, Evidence, Justify, and Reason as 'pragmatic' relations. In the category 'semantic', we include all others except the 'textual' relations Joint, List, Preparation, Conjunction. Here, the hypothesis is "The more pragmatic relations, the more depth" (and conversely for the semantic relations). Then, we use a more elaborate feature to examine some structural properties of the RST tree. The data

[5] The notation in the figure uses straight lines for nucleus links and curved arrows for satellite links. Notice that in the upper tree, EDUs 4-8 have been collapsed in order to fit the tree onto the page. In both trees, segment 1 is missing, because the headline of the text is left out of the analysis.

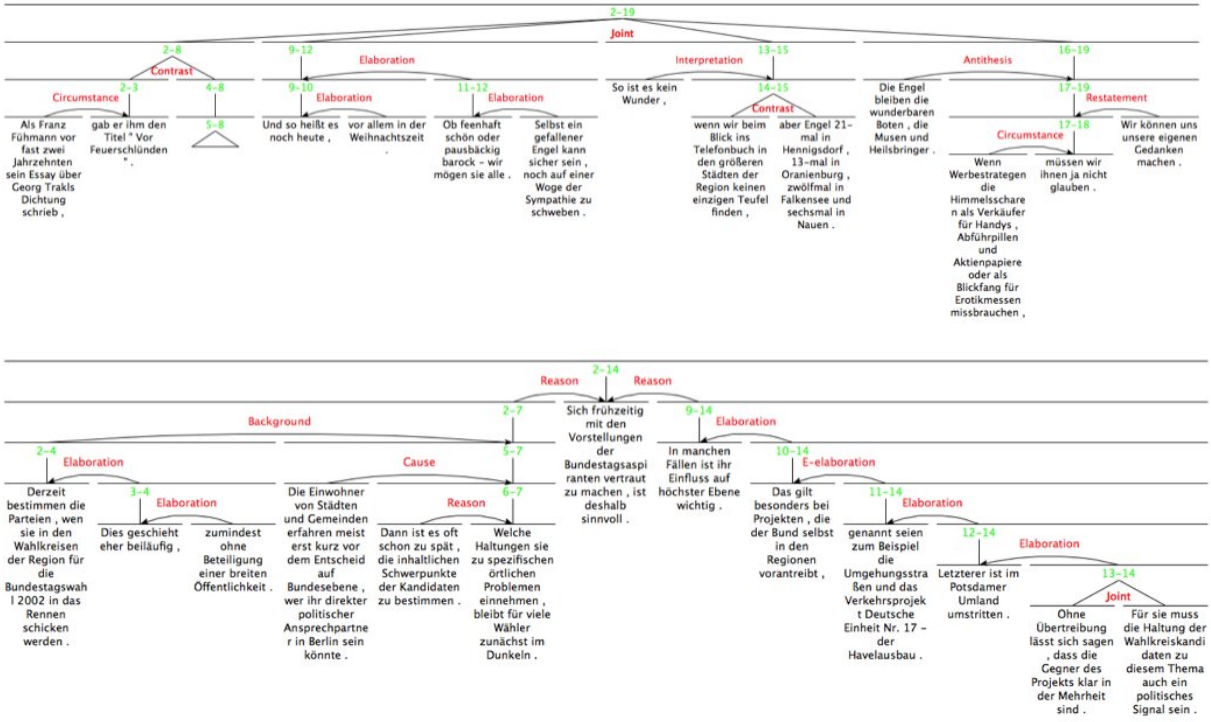

Figure 2: RST trees with very different nuclearity mass distribution

in the development set suggests a tendency for 'deeply argumentative' texts to have a clearly-identifiable central nucleus, whereas other texts can have multinuclear relations toward the top of the tree, which signifies that several points are perceived as being equally important to the author of the text. For illustration, consider Figure 2, which shows the structure of two texts from our development set. We thus seek to measure the distribution of the 'nuclearity mass' (NM) across the tree. We are not aware of such a measure having been described in the literature, and here suggest two variants. Call the number of satellite links on a path from leaf node to root the 'sat value' of that leaf node.

- NM1: The proportion of leaf nodes with a sat value of 0 or 1 (i.e., 'central' units).
- NM2: Let l_i be the length of the path (irrespective of the nuc/sat distinction) from leaf i to the root. Then, NM2 is the sum of those l_i where i has a sat value of 0 or 1, divided by the sum of l_i for all i of the tree.

While NM1 considers just the number of central nodes, NM2 also takes their distance from the root into consideration. For the upper tree in Figure 2, the two values are 0.93 and 0.88; for the lower tree they are 0.23 and 0.11.

4.2 Collecting judgements on argumentative depth

Having obtained hypotheses from the development set, we proceeded to test them on our second set (14 texts). We had students rate these texts for argumentativeness and then split them into two groups of 'low' and 'high' argumentative depth.

It is not trivial to elicit a judgement on 'argumentative depth', since this is obviously not an established concept. We were interested in intuitive judgements of readers that were not influenced by attempts on (mentally) building an explicit representation of the argumentation. For this reason, we worked with first-year students that had not received any training in argumentation analysis. Our procedure was to

Rank	Value	Source	Expect.	Rank	Value	Source	Expect.
1	4.8	ProCon	high	9	2.8	MAZ	high
2	4.2	MAZ	high	10	2.8	MAZ	medium
3	3.8	MAZ	high	11	2.4	MAZ	low
4	3.8	MAZ	high	12	2.2	MAZ	low
5	3.4	ProCon	high	13	2.0	MAZ	low
6	3.4	MAZ	medium	14	1.8	MAZ	low
7	3.4	MAZ	low	15	1.0	News	low
8	3.2	ProCon	high	16	1.0	News	low

Table 1: Text ranking obtained via students' answers to questionnaire

present them with a questionnaire posing the following questions, where the answer was to be given as a position on a 1..5 Likert scale:[6]

- Is the text a news report or an opinion text?
- If the text is a news report, is the reporting clear or unclear?
- If the text is an opinion text, is the position of the author clearly represented?
- If the text is an opinion text, does the author provide clearly recognizable arguments for his or her position?

The first question was meant as a first proxy for the amount of 'opinion' in the texts and in particular to identify non-commentaries. To make it work properly, we added filler items to the texts: two news reports taken also from the *Tagesspiegel*, which were of roughly the same length as the commentaries. The second question then merely served to balance the question set – the answers were not used in determining the ranking, which was based only on the answers to the last two questions. Notice that the last one does not refer to structural depth but merely to the presence of arguments and their clarity; this means that the students did not rate 'depth' directly. (In a future version of the study we plan to add a question to that effect.)

Every student judged three texts, which were mixed according to our expectations on argumentative depth. Most, but not all, students saw one of the news texts (filler) in their set. 30 students participated, so we obtained 90 judgements in total, which amounts to 5 per text (14 commentaries plus 2 news), over which we calculated averages.

4.3 Results

We translated the ratings into a ranking of the texts, ranging from low to high opinion/argument. Table 1 shows for each text its rank and its accumulated value on the Likert scale, its source, and the depth category we had originally expected for it. The first good news is that the news reports (fillers) were easily identified – they are thus discarded from the subsequent evaluation. Then, using the arithmetic mean, we determined the cutoff to form the two groups of eight 'high' and six 'low' argumentative texts (shown in the two halves of the table). Below we call the groups H and L.

As the table shows, our expectations on ranking are mostly confirmed, with two exceptions at rank 8 and 9, which we had estimated higher up.

Simple features. No difference between the two groups can be found for the frequency of modal verbs and of contrastive/causal connectives (neither on the development nor on the test set).[7]

[6] In addition, we asked whether the text was considered generally 'understandable' so that we could discard judgements where the student apparently had not understood the text well enough. This happened only in two instances.

[7] As pointed out by a reviewer, simple features might be indicative of just the first component of our depth measure (the proportion of argumentative tokens); testing this is left for a follow-up study with a larger corpus.

	pragmatic relations	semantic relations	NM1	NM2
group H	d: 43.17% / t: 38.3%	d: 35.0% / t: 45.8%	d: 37.29% / t: 40.79%	d: 28.1% / t: 33.82%
group L	d: 45.13% / t: 28.03%	d: 32.5% / t: 55.88%	d: 49.75% / t: 55.99%	d: 41.22% / t: 46.63%

Table 2: Results for RST features. d = dev set / t = test set

Argumentation structure. On the test set, the average proportion of tokens participating in the argumentation is 0.81 in group H and 0.31 in group L – a very clear difference. The average path lengths in the argumentation tree also confirm the expectation: In group H it is 1.59, and in group L only 1.09. It seems that our depth measure can capture the difference between the groups.

Rhetorical structure. Table 2 summarizes the results for the various RST features. For one thing, it shows that the results on our (more or less equally small) development and test sets can differ considerably, which suggests that more data is needed to obtain more reliable results. However, other tentative conclusions can be drawn: The figures indicate that the distribution of semantic/pragmatic relations is not a good feature for depth of argumentation, whereas both ways of measuring the distribution of nuclearity mass yield clear differences.

5 Summary

Constraining ourselves to monologue text, we suggested assessing the 'depth' of argumentation as a subtask of argumentation mining, when it aims at reconstructing the full structure of the argument. Our measure combines (i) the proportion of the text that contributes to the argument and (ii) a simple account of the complexity of the tree representing the argument: the average length of the paths in that tree. We hinted at the possibility of using more sophisticated variants of (ii). Importantly, we pointed out that depth is a purely structural measure, which is to be distinguished from argument 'quality' as it is being addressed in related work.

To test our measure, we conducted a pilot study with a small corpus of annotated newspaper commentary texts, supplemented by filler items (news reports). Using a set of questions, we obtained judgements on opinionatedness and argumentativity from human raters, which led to ranking the texts and then splitting them into two groups of high and low argumentative depth, respectively. We found that the depth measure can serve to differentiate the groups.

In addition, we were interested to see whether the human judgements correlate with simple surface features and with aspects of the rhetorical structure of the texts. As for the former, we tested modal verbs and connectives (standardly used in subjectivity classification) but could not find an effect. Regarding rhetorical structure, interestingly, the distribution of 'semantic' versus 'pragmatic' relations (as defined in RST) turns out not to differentiate between the groups. However, two measures of distributing the 'nuclearity mass', which we proposed here, do reflect the distinction. We conjecture that these measures can account for the clarity and focus of the argumentation. One next step is to experiment with variants of the RST measures, trying to combine relational and structural features.

To obtain more evidence for the validity of the results, both on the depth measure and the correlations with rhetorical structure, we plan to supplement the study with another experiment on a larger number of texts from the commentary corpus. Given a broader set of data, proper statistical measures can be computed for annotator agreement and the correlations. Furthermore, as noted earlier, the questionnaire will be extended in such a way that raters make judgements on depth more explicitly; in the pilot, we only asked for an intuitive judgement of the presence of clearly recognizable arguments (irrespective of their potential recursive structure).

Afterwards, it will be interesting to apply the approach to other genres, such as student essays, where we expect to find similar differences of argumentative depth. For the genre we studied here, newspaper commentary, we see our work as a contribution to identifying sub-genres (different types of commentary) and explaing the differences between them.

Abstract

Video event detection is a challenging problem in information and multimedia retrieval. Different from single action detection, event detection requires a richer level of semantic information from video. In order to overcome this challenge, existing solutions often represent videos using high level features such as concepts. However, concept-based representation can be confusing because it does not encode the relationship between concepts. This issue can be addressed by exploiting the co-occurrences of the concepts, however, it often leads to a very huge number of possible combinations. In this paper, we propose a new approach to obtain the relationship between concepts by exploiting the syntactic dependencies between words in the image captions. The main advantage of this approach is that it significantly reduces the number of informative combinations between concepts. We conduct extensive experiments to analyze the effectiveness of using the new dependency representation for event detection on two large-scale TRECVID Multimedia Event Detection 2013 and 2014 datasets. Experimental results show that i) Dependency features are more discriminative than concept-based features. ii) Dependency features can be combined with our current event detection system to further improve the performance. For instance, the relative improvement can be as far as 8.6% on the MEDTEST14 10Ex setting.

1 Introduction

Detecting event from videos has been an important research topic due to the explosion of internet videos. In order to build a reliable event detection system, one must rely on the video content rather than simply using textual metadata (Davidson et al., 2010). However, internet videos are often captured under arbitrary conditions, which makes the large content variation among videos of the same event. To handle this problem, we can represent videos using multimodal features such as Dense trajectories (Wang and Schmid, 2013), SIFT (Lowe, 2004), and audio MFCC (Lee et al., 1988). Another approach to tackle this problem is to represent videos using the concept-based representation, i.e., video is represented by the concept detection scores indicating the presence of the concepts. This approach is particularly helpful when the number of training videos are scarce (Chen et al., 2014; Habibian et al., 2014b; Habibian et al., 2013; Ma et al., 2013; Ye et al., 2015). Some other works further select a subset of informative concepts for event detection (Jiang et al., 2015; Mazloom et al., 2013).

Nevertheless, the concept-based representation has two drawbacks i) It is non-trivial to obtain a large concept vocabulary. That is why people often combine concepts from multiple vocabularies to construct a larger one, in the hope to cover a wide range of concepts in real world videos (Yu et al., 2014). ii) The relationship between concepts, e.g., co-occurrence, are not captured. However, these relationships can convey a richer level of semantic information which can not be found from encoding individual concepts. Figure 1 illustrates the benefit of exploiting these relationships for event detection.

One can obtain the relationships between concepts by harvesting the social-tagged images (Li et al., 2012), however, tag information is often far from the actual content of the image. Visual phrases (Sadeghi and Farhadi, 2011) models a person and an interacting object through the use of a composite template.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3318–3327, Osaka, Japan, December 11-17 2016.

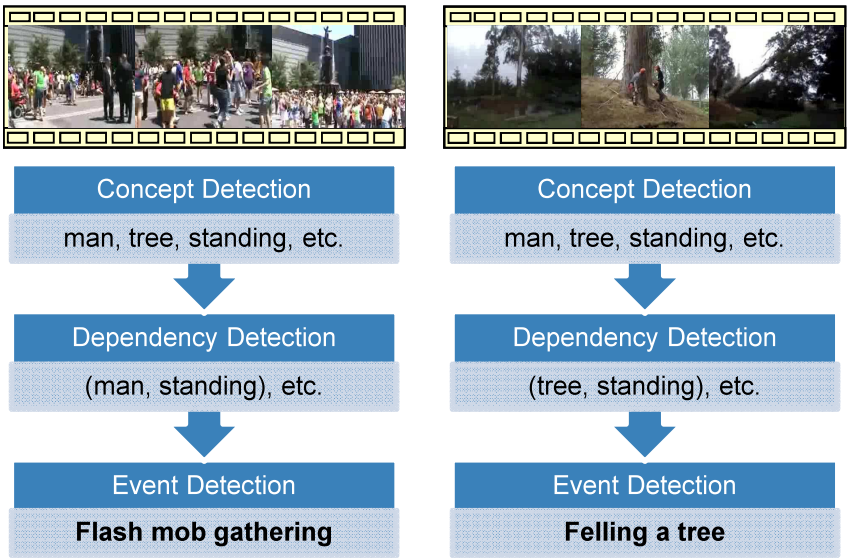

Figure 1: An illustrative example of limitation when using concept-based representation for video. In both videos, "man", "tree", and "standing" can be detected. However, if the dependency *(man, standing)* is also detected, it is more likely a "flash mob gathering". On the other hand, if *(tree, standing)* is detected, it is probably a "Felling a tree" event.

This approach might not be applicable to real world application because there are only 17 visual phrases being used and they are manually selected. Singh et al. (Singh et al., 2015) select relevant concept pairs for event detection by discovering from the event text query. Habibian et al. (Habibian et al., 2014a) also utilize the event query to discover the co-existence or exclusive existence relationships for zero-shot event detection. Assari et al. (Assari et al., 2014) and Can et al. (Can and Manmatha, 2014) model the concept co-occurrences or dependencies based on the joint distributions of two concepts, which relies on the concept detection scores. Borth et al. (Borth et al., 2013) have exploited some syntactic dependencies, such as the combination of adjectives and nouns, for training a sentiment analysis model.

The main drawback of the existing works is that the concept relationships are either manually defined or learned from the concept-based representation, which may face the effect of cumulative error. We address the former issue by exploiting more relationships between concepts such as syntactic dependency relations like subject and object. Such kind of syntactic relationships can also automatically eliminate irrelevant combinations between words or concepts. Typically, we propose a new approach to obtain the relationship between concepts by extracting the word dependencies from the image captions using standard natural language processing technologies. We then train a dependency model directly from the captioned images and use these dependencies as features for event detection.

What differentiates our approach from the previous works is that we explore a comprehensive set of relationship between concepts that is based on the syntactic dependencies. The immediate benefit of our approach is that we can easily obtain a large and informative dependency vocabulary from a much smaller concept vocabulary. In short, the contributions of this paper are twofold: i) A pilot study to exploit word dependencies as features for video event detection. These dependencies encode not only the co-occurrences but also various types of co-occurrences between concepts. ii) We report comprehensive experiments to demonstrate the benefit of the new dependency-based representation.

2 Word Dependency

The central idea in the present paper is to exploit word dependencies as features for event detection. Therefore, the development of the model to predict dependencies for a given video is a key issue. In the following section, we describe a method for obtaining training data for dependency prediction, and our model for dependency prediction.

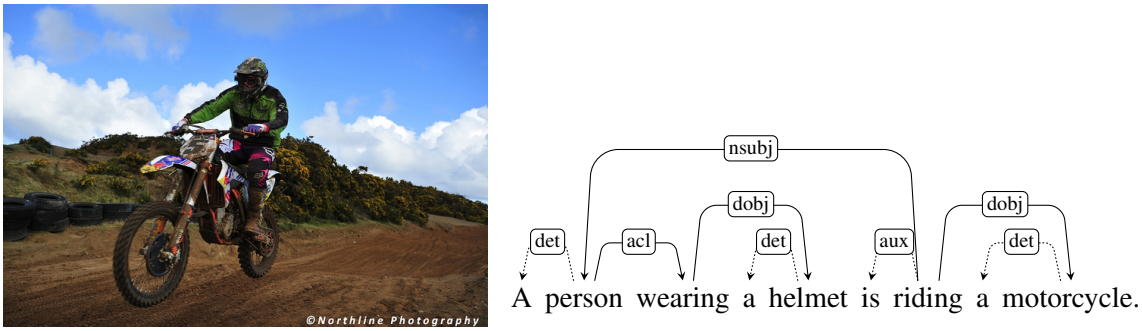

Figure 2: Example of word dependencies. Solid arrows show dependencies included in our vocabulary, while dotted arrows indicate dependencies excluded.

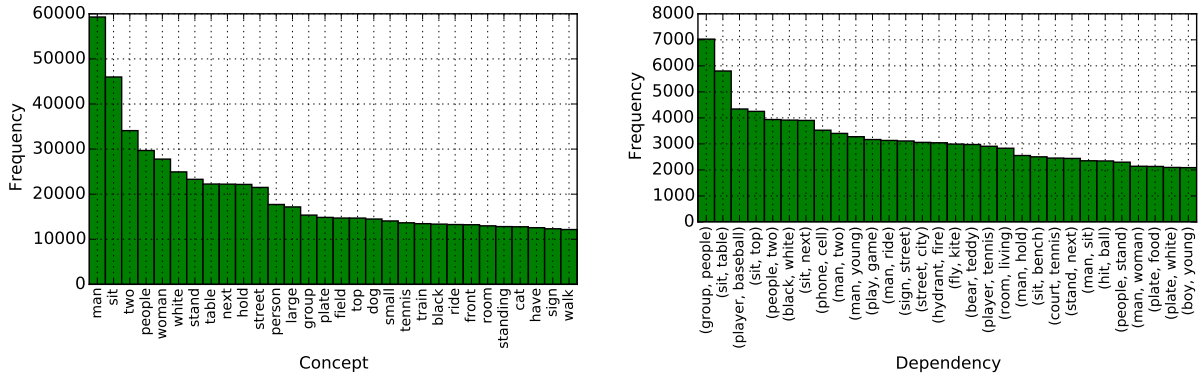

Figure 3: Top 30 frequent concepts and dependencies extracted from the MSCOCO captions.

2.1 Dependency Extraction

Dependency tree represents relationships among words in a sentence, such as subject-verb and verb-object relations. Figure 2 shows an image, its caption, and the dependency tree of the caption obtained by applying Stanford Parser (Manning et al., 2014). For example, an arrow from "riding" to "person" is labeled with "nsubj", which means "person" is a *nominal subject* of "riding".[1] Dependency trees can represent more precise semantic information than a bag of concepts. In this example, the dependecy tree indicates that "person" is the subject of "riding", not the object. This distinction is crucial in event detection as exemplified in Figure 1.

Dependency tree is defined as a set of dependencies, each of which is a triple (*label*, *head*, *dependent*), where *label* is a dependency label (e.g. "nsubj"), *head* is a source word of the dependency (e.g. "riding"), and *dependent* is the other side of the dependency (e.g. "person").

As dependencies consist of pair of words, the simplest way to construct a vocabulary of dependecies is to enumerate all pairs of words. However, this is obviously infeasible. When we have n words and k dependency labels, the total number of dependencies is kn^2. As in the typical situation where $n = 20,000$ and $k = 40$, we need to consider 16 billion dependencies.

In fact, most of the dependencies are not useful for event detection. One reason is that dependencies that appear in real text are very sparse; i.e., most of the triples do not appear. For example, the dependency ("dobj", "wear", "motorcycle"), which means *something is wearing a motorcycle*, is unlikely to appear in real text, because it does not make sense. The distribution of dependencies is highly skewed, and it is not clever to consider all combinations of words and dependency labels. Another reason is that several types of dependencies represent only grammatical relations, and do not convey semantic information.

[1]Dependency labels are defined in the guideline of Universal Dependencies. For details, see: `http://universaldependencies.org/`.

Table 1: Comparison of our model prediction with human evaluation on the COCO validation dataset.

Mean AP	Model prediction	Human evaluation
Concept	0.4347	**0.4410**
Dependency	0.1282	**0.2033**

For example, the dependency ("aux", "riding", "is") describes that "is" is an auxiliary verb of "riding", but this dependency is purely grammatical and does not include any semantic information.

These observations lead us to the idea that we extract a vocabulary of semantically informative dependencies from real texts by excluding unnecessary dependencies. Our solution here is to process dependencies obtained by dependency parsing in the following manner.

1. Apply a dependency parser to caption texts and obtain dependency trees.
2. Remove function words, such as determiners and punctuations, and select top n frequent words as a concept vocabulary.
3. Select dependencies in which both words are included in the concept vocabulary.
4. Cluster dependency labels that have similar relations.

Because our dependencies are extracted from real texts, our vocabulary of dependencies does not include semantically meaningless dependencies. Step 2 and 3 further exclude purely grammatical dependencies and less frequent dependencies. Step 4 is intended to further reduce semantically subtle distinctions. For example, two labels, "nsubj" and "csubj", are defined to represent subject relations, but their distinction (nominal vs. clausal) is not particularly important for our purpose. Therefore, we collapse such semantically similar dependency labels to get a reduced number of dependency types.

In Figure 2, solid arrows show dependencies included in our vocabulary, while dotted arrows indicate dependencies excluded. This example demonstrates that our method selects dependencies that capture semantic information of original texts while excluding less informative dependencies.

2.2 Dependency Modeling

Images and caption texts for the development of the dependency prediction model are obtained from the training set of Microsoft COCO (Lin et al., 2014), which contains 82,783 images and 414,113 captions constructed by crowdsourcing. Stanford CoreNLP 2015-04-20 is used for dependency parsing. We selected $n = 1,000$ concepts, which covers 89.4% of words (excluding function words) in the caption texts of the training data. Using this concept vocabulary, the method described in Section 2 extracted 20,931 dependencies that have more than 10 occurrences in the training data, which cover 63.3% of all the dependencies in the original caption texts. Top 30 frequent concepts and dependencies extracted from the training captions are shown in Fig. 3.

We consider the problem of predicting dependencies as a multi-label classification task because multiple dependencies can present in one image. To train the dependency model, we finetune a deep neural network on the COCO images from the VGG (16 layers) network (Simonyan and Zisserman, 2014). We add a cross-entropy loss layer on top of a sigmoid layer to account for the loss function. The entire network is trained using the Stochastic Gradient Descent (SGD) optimizer.

We compare the model predictions with the human performance to evaluate the effectiveness of our concept and dependency models. In order to measure the human accuracy, we use concepts/dependencies of one gold caption as the predicted labels, and use concepts/dependencies from the remaining captions of the same image as gold labels. If an image has multiple captions, we repeat this procedure so that every caption is used as the prediction, and report the average performance.

The detailed comparison of our model prediction with human performance is shown in Table 1. We found that our concept prediction model has comparable performance with agreement among human-annotated captions, while our dependency prediction is inferior to the human performance. The low agreement between annotators on the dependency evaluation also demonstrates the inherent challenge of dependency modeling.

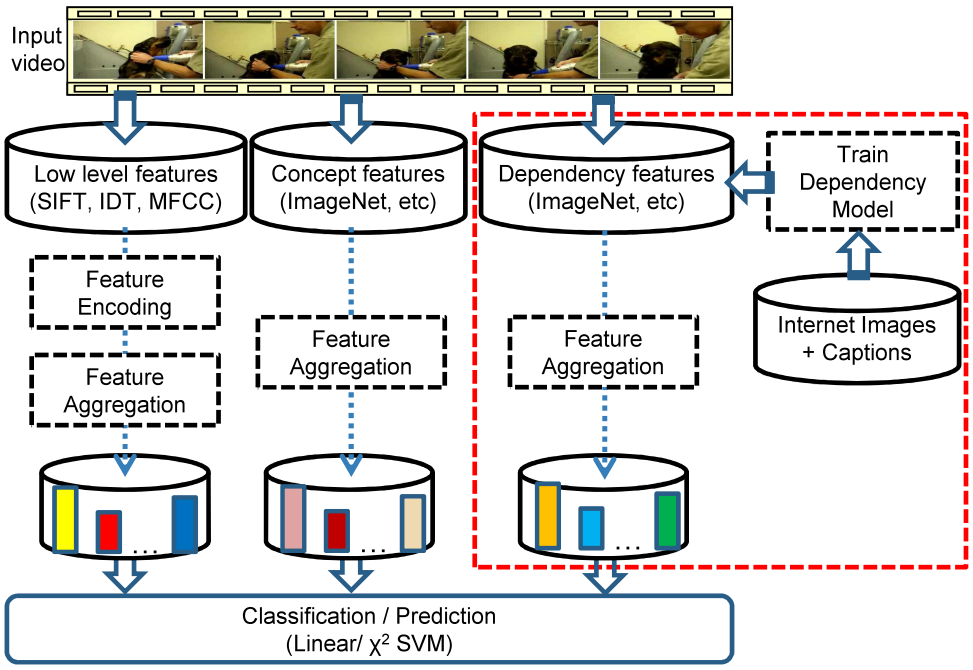

Figure 4: Overview of our event detection framework.

3 Event Detection Framework

In this section, we present a common event detection system, which consists of four main components: feature extraction, feature encoding, feature classification, and feature fusion (Fig. 4).

3.1 Feature extraction

Our framework supports a large variety of features including low-level and high-level features. Low-level features such as audio MFCC and Dense trajectories (Wang and Schmid, 2013) can be extracted from temporal windows spanning of several frames, while still image features such as SIFT (Lowe, 2004) is extracted from sampled frames of video. These raw low-level features require a special encoding technique to generate video-level representation, which will be described in Section 3.2.

We also extract high-level features such as visual concept features extracted from deep visual models. For example, our framework supports state-of-the-art deep learning features which are extracted from pre-trained deep models (Simonyan and Zisserman, 2014). These models are trained on large image collection such as ImageNet (Deng et al., 2009). Using these models, we can extract concept scores for each sampled frame and aggregate them into the final representation for each video. One can also utilize features from the previous fully-connected layers, such as `fc6` and `fc7`, to train the event detectors because they often retain richer information than the last full-connected layer.

Our concept and dependency features can be also considered as high-level features. However, different from the aforementioned high-level features that are extracted from pre-trained visual models, our concept and dependency features are extracted from our concept and dependency models respectively.

3.2 Feature encoding

We use Fisher Vector encoding to map local descriptors extracted from low-level features into the video-level representation. The Fisher vector (FV) has been successfully employed for various image and action classification problems (Perronnin and Dance, 2007; Wang and Schmid, 2013). It can be considered as an extension of Bag-of-Words (BoW) encoding where both first- and second-order statistics between the local descriptors and their assigned codewords are also encoded. Therefore, Fisher vector can achieve comparable performance to that of BoW while using a much smaller codebook.

In our experiment, we first randomly selected one million local descriptors for training a Gaussian mixture model (GMM), which is later used as the codebook for encoding. As suggested in (Perronnin et

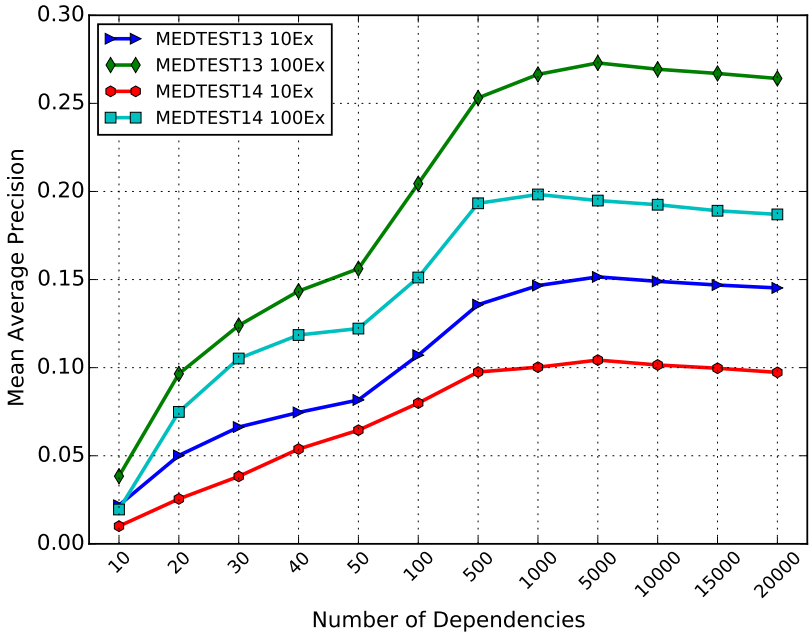

Figure 5: Results of event detection performance with respect to various vocabulary sizes.

al., 2010), it is better to reduce the local feature dimension by using principal component analysis (PCA) and apply power normalization, e.g., with $\alpha = 0.5$, followed by L2-normalization to the Fisher vector.

3.3 Feature classification

We use LibSVM (Chang and Lin, 2011) for training event detectors. The pre-computed kernel technique is utilized to reduce the training time. This technique is especially useful when the number of events are large. For low-level features, which are encoded using Fisher vector encoding, we use linear SVM for training and testing. For high-level features, since its feature dimension is rather small, we employ the χ^2 kernel SVM to obtain a better recognizing performance.

3.4 Feature fusion

Different features cover various characteristics of multimedia data. Hence it is natural to combine these features to get the benefit from multi-modal features. For the sake of simplicity, we use the average late fusion strategy for feature combination.

4 Experiments

We conduct experiments on the TRECVID Multimedia Event Detection (MED) 2013 and 2014 benchmarks under the 10Ex and 100Ex settings, in which only 10 and 100 training videos are given for each event respectively (Over et al., 2014). Dependency features are extracted from the final layer (fc8) of the dependency network presented in Section 2.2 for each sampled frame in video (1 frame every 4 seconds) and then aggregated to form the video representation. We employ LibSVM (Chang and Lin, 2011) with the exponential-χ^2 kernel for event training and testing. All the results are reported in terms of mean average precision (mean AP).

4.1 How many dependencies?

We first study how different number of dependencies affect to the event detection performance. We found that selecting the most frequent dependencies contributes more than randomly selecting the same number of dependencies. Following this observation, we only consider the top frequent dependencies, and report the results in Fig. 5. Small vocabulary sizes often result in a poor outcome. When increasing the vocabulary size, the performance also increases rapidly. The highest performance can be obtained

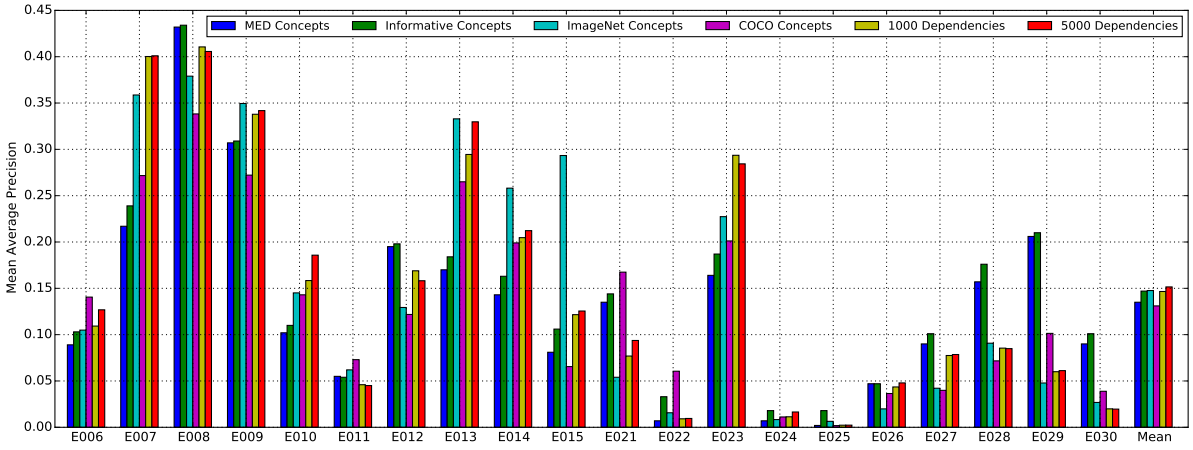

Figure 6: Performance comparison of dependency features with other methods on the MEDTEST13 10Ex setting. Performance of each event is reported in each group, the last group shows the average performance over all events. *MED Concepts* refers to concepts obtained from video annotations (Habibian et al., 2013), and *Informative Concepts* refers to selected concepts in (Mazloom et al., 2013). The mean average precisions from left to right are 0.1350 (MED Concepts), 0.1470 (Informative Concepts), 0.1476 (ImageNet Concepts), 0.1310 (COCO Concepts), 0.1466 (1000 Dependencies) and **0.1515** (5000 Dependencies).

by using around thousands of dependencies. However, if more than ten thousands of dependencies are added to the vocabulary, the performance tends to slightly drop. The reason is that at this point, the dependencies become much less frequent, so their detectors might become less reliable as well.

4.2 Comparison with other methods

Figure 6 shows the performance of our dependency features on the MEDTEST13 10Ex. We include the reported results on the same setting in (Habibian et al., 2013) and (Mazloom et al., 2013) for comparison. The performance of ImageNet concepts (Deng et al., 2009) are produced using the same network that was used to fine-tune our dependency model (Simonyan and Zisserman, 2014). We also select 1,000 COCO concepts as described in Section 2 and report its performance. The best dependency run can outperform the COCO concept run with a relative improvement of **15.6%**. Our dependency features only achieve a marginal improvement over the ImageNet baseline. However, this result is already encouraging because our dependency model was trained with around 80K labeled images, compared to about one million labeled images of the ImageNet model.

4.3 Contribution to our MED system

Finally, we conduct experiments to demonstrate the contributions of our dependency feature to our event detection system. State-of-the-art event detection systems (Yu et al., 2014; Yu et al., 2015) often employ features from multiple modalities such as audio and visual features. Following this strategy, we implemented a number of features in our system including audio MFCC (Lee et al., 1988), SIFT (Lowe, 2004), and Dense trajectories (Wang and Schmid, 2013). In light of the success of deep learning, we also use features extracted from (Simonyan and Zisserman, 2014), which is a pre-trained network on ImageNet (Deng et al., 2009). We also include the reported performance of recent state-of-the art systems in (Yu et al., 2014) and (Yu et al., 2015) for comparison.

Table 2 compares performance of all aforementioned features. Our (5,000-dimensional) dependency feature outperforms ImageNet concepts in all settings, while still inferior to the performance of the Dense trajectories features (Wang and Schmid, 2013). When combining our existing system with the new dependency feature, we achieve a relative improvement of **6.8%** and **8.6%** on the MEDTEST13 10Ex and MEDTEST14 10Ex settings respectively. We report lower results than the ones reported in (Yu et al., 2014; Yu et al., 2015). The reason can be due to the fact that they included more concept features

Table 2: Contribution of the new dependency features to our event detection system.

in their system such as Google Sports (Karpathy et al., 2014) and YFCC concepts (Thomee et al., 2015). Example of some detected concepts for each event can be found in Table 3.

5 Conclusions and Future Work

We exploited word dependencies as a new semantic video representation for recognizing complex events. Different from the existing works, this representation encodes the relationship between concepts based on the syntactic dependencies between words. Therefore it captures semantically richer information, which is crucial for video event detection. We demonstrated that the dependency-based representation is more discriminative than the concept-based representation. Moreover, it also helps improve the detection performance of our existing event detection system.

One limitation of the current work is that we exploited image captions rather than video captions. The main reason is that we have not found any large-scale video captioning corpus for this project. Also the accuracy of dependency prediction from video would be less accurate since video is more challenging to model. In the future work, we plan to extend this work to further modeling word dependencies from video captions.

Predicting Restaurant Consumption Level through Social Media Footprints

Yang Xiao, Yuan Wang, Hangyu Mao, and Zhen Xiao
School of Electronics Engineering and Computer Science, Peking University, China

Abstract

Accurate prediction of user attributes from social media is valuable for both social science analysis and consumer targeting. In this paper, we propose a systematic method to leverage user online social media content for predicting offline restaurant consumption level. We utilize the social login as a bridge and construct a dataset of 8,844 users who have been linked across Dianping (similar to Yelp) and Sina Weibo. More specifically, we construct consumption level ground truth based on user self-report spending. We build predictive models using both raw features and, especially, latent features, such as topic distributions and celebrities clusters. The employed methods demonstrate that online social media content has strong predictive power for offline spending. Finally, combined with qualitative feature analysis, we present the differences in words usage, topic interests and following behavior between different consumption level groups.

1 Introduction

Over the past decade, microblogging services like Twitter and Sina Weibo have built up a huge user base. For example, by the end of 2014, Sina Weibo has accumulated more than 500 million users, out of which 167 million are monthly active users. With the growing popularity of microblogging service, businesses are also looking for new opportunities on social media, e.g., identifying target consumers and marketing their products. Compared with traditional consumer targeting scenarios, social media has several factors in its favour. Firstly, traditional consumer targeting techniques are mainly based on users' query logs or web access histories, and it is generally limited by session length (Dasgupta et al., 2012). While on social media, users have accumulated much more abundant traces, such as tweets, relationships and profiles. Secondly, according to a recent study (Nielson, 2012), 92% of consumers believe recommendations from friends over all other forms of advertising and 64% of salesperson believe word of mouth is the most effective way of marketing. Since social network links both friends and families, it becomes a natural platform for business to take advantage of word of mouth utility (Trusov et al., 2009).

Demographic profile is the starting point of defining target consumers for marketing. Demographic includes multiple aspects such as simple attributes like gender and age, and more complicated attributes like income, personality and consumption level. Since a large number of users provide their profiles on social media, inferring user attributes such as gender (Ciot et al., 2013; Liu and Ruths, 2013; Rao et al., 2011), age (Al Zamal et al., 2012; Nguyen et al., 2013), political polarity (Volkova et al., 2014), or occupation(Preoţiuc-Pietro et al., 2015a) from social media has already been widely studied. In this paper, we focus on the consumption level attribute prediction.

Consumption behavior reflects one's economic capacity and living standards (Brewer et al., 2012). An accurate consumption level prediction model can help business dealers identify their target consumers and recommend suitable products. Moreover, since consumption level is an important factor of economic status (Stutzer, 2004), effective prediction of consumption level will facilitate social economic researches on social media. However, unlike the gender attribute that is displayed on one's page, or political orientation that is unequivocally stated in one's tweets, consumption behavior related attributes are hard to acquire automatically from microblogging service.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3328–3338, Osaka, Japan, December 11-17 2016.

In this paper, we take advantage of the "socialization" of third party websites to build the ground truth collection. Specifically, we map one's Weibo (the largest microblogging service in China) account to his or her corresponding Dianping (the largest consumer review site in China) account. We carefully construct a dataset of 8,844 users who have been linked across Dianping and Weibo, and use one's self-report spending history to build the consumption level ground truth.

We propose a systematic method that takes social media features for consumption level prediction. We hypothesize that consumption level is correlated with various features, mainly including three aspects. The first aspect is user profiles including gender, age and education. Secondly, we hypothesize that language use in social media is a predictive factor for consumption level. We take textual features as the second aspect for prediction. Finally, we hypothesize that people of different economic statuses have their own unique tastes and interests. We take the following links which reflect one's interests and tastes as the third aspect for prediction. Owing to the noisy tweet content and sparse following relationships, this problem is technically challenging. We make use of topic modeling and LIWC categories to generate dense representations of text features. For graph features, due to the large quantities of users on Weibo, using raw following relationships directly has sparsity problem. To address it, we propose a matrix factorization algorithm on following matrix and naturally generate dense representations of user following preferences.

We take the raw features, and especially latent features as input features. We adopt the gradient boosted decision tree that can generate nonlinear combinations of input features, to predict user's consumption level. Empirical experiments demonstrate that rich features on social media have strong predictive power for consumption level, and latent features have best prediction performance. We conduct Spearman correlation test between topic preference and restaurant spending. We have found that the topic preference of a user is significantly correlated with the consumption level. We also report several new findings about consumption level and behavior on social media, e.g., users who follow topics such as luxury brands and politics, or talk more about money (e.g., audit, cash, owe) tend to be of higher consumption level, while users who follow topics about popular stars, use more character expressions and more assent words (e.g., agree, OK, yes) tend to be of lower consumption level. These findings will facilitate future attempts to consumer targeting, and may suggest extension application to spending prediction in other domains. The flexibility of our approach lies in that we identify important and general types of correlations that are easy to leverage from external social media sites.

2 Dataset Description

We focus on Sina Weibo, the largest Chinese microblogging service, as the studied microblogging service. We select a popular crowd-sourced review site, Dianping as the external website to help construct user consumption level ground truth. We do not adopt the automatic user linking methods but use "self-disclosure" to identify the same user across these two medias: some Weibo users provide their Dianping links in their tweets. This approach generates an accurate linking of across-website users.

Weibo Dataset: Sina Weibo is the largest Chinese microblogging service. We crawl the Weibo search page[1] to find those who declare their Dianping pages in their tweets. In this way, we get 62,015 users and then we crawl all the detailed information of these linked users, including profiles, tweets, followers and following links.

Dianping dataset: Dianping[2] is the largest social based crowd-sourced review site in China, which is similar to Yelp in terms of overall design and service. Dianping has two major components: users and local businesses. Users on Dianping can comment on and grade for local businesses, e.g., restaurants and hotels. Besides score and comment, user can also provide how much an average person spend for a meal in the restaurant. Each restaurant is usually assigned a small set of taste categories, price, score and starts a thread of reviews. We crawl all the reviews of 62,015 linked users mentioned above. The linked users have posted 286,069 reviews for 35,650 restaurants. We also crawl the 35,650 restaurants pages. The 35,650 restaurants are located in 45 cities in China, covering 98 different taste categories.

[1] http://s.weibo.com/

[2] http://www.dianping.com/

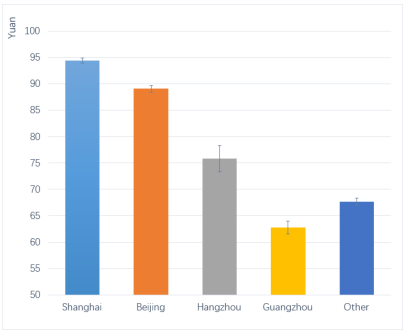

Figure 1: Average spending in different cities

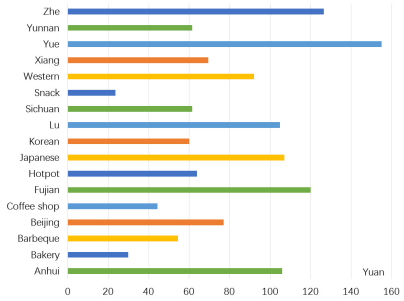

Figure 2: Average spending of different categories

We calculate the average restaurant spending in different cities and the result is shown in Figure 1. As shown in the figure, big cities such as Beijing and Shanghai are more expensive than other cities such as Guangzhou and Hangzhou. Moreover, users in Beijing and Shanghai take a share of 78.8% of our users. To make the population in our dataset more homogeneous, we only keep those who are located in Beijing or Shanghai. Dianping contains many categories of restaurants and different categories have different prices. The prices of different categories are shown in Figure 2. Since categories like cafe shop mainly provide drinks and can not be taken as real restaurants, we filter out restaurants in such categories. In order to gain a reliable estimation of consumption level, we only keep those who have post more than ten reviews. Finally, we obtain a total of 8,844 users. We find that these users are active on Weibo. They have posted 13,026,078 tweets and have 3,078,497 following links in total. We summarize the data statistics in Table 2.

Users	Tweets	Followings	Restaurants	Reviews
8,844	13,026,078	3,078,497	35,650	286,069

Table 1: Data statistics of our dataset for linked across-media users.

3 Problem Definition

If we can estimate one's consumption level according to his or her microblogging account, we can help the businesses design suitable marketing strategies, e.g., sending coupons to those who are more sensitive to price. We formulate this task as a typical prediction task: it aims to estimate the user consumption level. We assume the following general definition of the task: given a user's accumulated spending history $h^{(i)}$ and corresponding social media data s, we would like to test with varying type of s how accurate introduction of s can predict the label of $h^{(i)}$.

To formulate the consumption level prediction task, we assume that there are a set of m users $U = \{u^{(1)}, u^{(2)}, u^{(3)}, ...u^{(m)}\}$. For each user, let $y^{(i)}$ denotes the consumption level of user $u^{(i)}$. Higher value of $y^{(i)}$ means higher consumption level. A feature vector $x^{(i)}$ can be constructed for each user $u^{(i)}$. The aim of the learning task is to derive a prediction function f such that, for each feature vector $x^{(i)}$, it outputs a consumption level $f(x^{(i)})$.

4 Features

In this section, we discuss features extracted from Weibo service. In particular, we study how to derive effective latent features for the task.

4.1 Raw Features

Raw features are features that can be directly extracted from one's Weibo homepage. In this category, we consider the following three aspects:

I. METADATA Demographic fields of users. Fields such as gender and education level are binary features. Education level with value one indicates the user has accessed to university education. Tags

are a list of self reported words that users describe themselves. A separate binary feature is included for each unique tag. A user has 4 tags on average. For example, a user use tags such as music and shopping to represent one's interest.

II. RAWWORDS Unigrams in one's tweets and retweets. We use binary features for each unique unigram.

III. RAWFOLLOW All users that one follows. We use binary features for each unique followee.

4.2 Latent Features

In addition to raw features, we consider leveraging the latent features to improve predictions. We attempt to find semantics from the sparse user word matrix and user following matrix.

LIWC of Tweets (LIWCT)

Linguistic Inquiry and Word Count is a dictionary that classifies English words into psychological meaningful categories (Tausczik and Pennebaker, 2010). LIWC demonstrates its ability to detect psychological meaning in a wide range of applications such as emotionality investigation (Alpers et al., 2005) and personality prediction (Pennebaker and King, 1999). Previous study on social media shows that LIWC provides effective psychological features to determine the relationship between users (Adali et al., 2012) and the credibility of comments (Ott et al., 2011). Chinese LIWC (Huang et al., 2012) is a Chinese version LIWC that classifies 7444 Chinese words into 71 dimensions. Chinese LIWC have some slight differences from English one due to the difference in language, e.g., stemming is not needed for Chinese and verbs in Chinese do not have tense form. In general, the function of Chinese LIWC is similar to the English one.

We hypothesize that people at different consumption levels have different scores on LIWC features. For each user, we calculate the count of words that fall into each LIWC category, and get a vector of 71 dimensions. The vector is then normalized by the sum of the all values in it. Each value in the vector represents the user's usage preference on the linguistic category.

Topic Modeling of Tweets (LDAT)

In addition to employing raw text features, i.e., RAWWORD, we also use a high level representation of words to discover latent semantics. In order to distill topics from tweets, we adopt Latent Dirichlet Allocation method (Blei et al., 2003), which is an unsupervised learning method to discover latent topic distribution using large amounts of documents.

The model has two parameters, i.e., the document topic distribution θ_i and the topic word distribution φ_i. By learning θ_i and φ_i, document's topic distribution can be obtained and hence we get user's preferences on each topic. Since we care about user's topic distribution instead of a single tweet's topic distribution, we aggregate the user's tweets and retweets into documents and take the documents as the input of LDA model.

We take the resulted vector θ_i to describe user u_i's topic distribution. In this study, we set topic number k to 200 and run LDA with 500 iterations using Gibbs[3] sampling.

SVD Following Matrix (SVDF)

Because economic status is the central concern of hierarchical society, people of different economic statuses have their own unique tastes and interests (Wong and Ahuvia, 1998). Intuitively, if one is interested in some areas, it is natural that he or she will follow some related celebrities on social media. Therefore, celebrities that one follows can reflect the interest of the user (Lim and Datta, 2012). Since celebrities have large quantities of followers, in this paper, we take the account that has more than 30,000 followers as a celebrity account. The most direct way of utilizing celebrity features is to take each individual celebrity as a distinct feature aspect, i.e., RAWFOLLOW. However, since the celebrity accounts are of a huge number, using the celebrity features directly can result in sparsity problem. To tackle this problem, we use matrix decomposition to capture the hidden interest of one user. The row of the matrix denotes users in our dataset, the column of the matrix denotes the celebrity accounts and the element

[3]http://gibbslda.sourceforge.net/

f_{ij} is set to 1 if user u_i follows celebrity c_j. Different from traditional matrix decomposition task that has elements ranging from 1 to 5, in our case, the element of matrix only have two values representing whether user follows the celebrity. Hence, we choose the following logistic loss as our optimization goal.

$$U(i) = \arg\min_{w} \sum_{j} \log(1 + \exp(-f_{ij} \cdot w^T C(j))) + \lambda \|w\|^2$$

where f_{ij} denotes whether user u_i follows celebrity c_j, $U(i)$ denotes the latent vector of u_i, $C(j)$ denotes the latent vector of c_j and λ is the regularization coefficient.

We take the resulted $U(i)$ with varying length to describe one's interest. In this study, we employ stochastic gradient descent for matrix factorization parameter inference (Rendle, 2012) .

5 Clustering and Labeling

In this section, we introduce how we derive user consumption level label $y^{(i)}$ from the consumption history $h^{(i)}$. We use Gaussian mixture model to cluster users over their price space. The motivation for clustering is to find the natural structure of consumption prices and avoid manual threshold settings. This makes the labels of users more reliable and applicable to other dataset. The following part introduces the Gaussian mixture model and how we apply it to our dataset.

Gaussian mixture model is a probabilistic model which assumes that data is generated from finite number of Gaussian distributions. Given n data points $\mathbf{x} = \{x_1, x_2, x_3, ..., x_n\}$, the probability of generating the data x_i is as follows:

$$p(x_i|\pi, \Theta) = \sum_{z=1}^{k} p(z|\pi) p(x_i|\theta_z)$$

where π denotes the distribution over components, $p(x_i|\theta_z)$ is normal distribution where $\theta_z = (\mu_z, \sigma_z)$. $p(x_i|\theta_z)$ can be formulated as $p(x_i|\theta_z) = \frac{1}{\sqrt{2\pi}\sigma_z} e^{-\frac{(x_i-\mu_z)^2}{2\sigma_z^2}}$

In our task, we calculate average of the user u_i's spending history $h^{(i)}$ for each user, and in this way we get a list containing average spending of all users, i.e., $L = \{avg(h^{(1)}), ...avg(h^{(m)})\}$. $L^{(i)}$ ranges from 33 Yuan to 436 Yuan. We calculate average spending irrespectively of restaurant category because we find that most users visit diverse categories of restaurants. Since we focus on the relative consumption level of users instead of the real spending of users, we formalize the task as classification task. We apply the Gaussian mixture model to the spending list L. We assume that users come from k (k=2) different consumption levels, and the user's label $y^{(i)}$ is the cluster number the user belongs to.

6 Experiment

In the above section, we have shown how to extract features from social media and how to derive labels from spending history. We are going a step further to figure out the feasibility of using these social media features to predict the user's consumption level. We conduct experiments on the collected Weibo and Dianping dataset as described in Section 2. We set the component number of Gaussian mixture model to 2, i.e., users are labeled either one or zero indicating whether they are of high consumption level. We take 60% of users as training portion, 20% as validation portion and the remaining 20% as the test portion. For the evaluation, we take the accuracy, precision, recall and F1 measure as the evaluation metrics.

6.1 Quantitative Evaluation

We employ GBDT[4] and logistic regression[5] as the prediction models. Since traditional survey-based consumption behavior analysis task mainly focus on demographic attributes (Jang et al., 2004; Fodness, 1994), in this paper, we refer to the results obtained with feature METADATA as *baseline*. Specifically,

	LDAT	0.7451	0.7303	0.7863	0.7573
	SVDF	0.7673	0.7760	0.7635	0.7697
	ALL	0.8012	0.7821	0.8413	0.8106

Table 2: Prediction results with different feature sets.

for *baseline* features, we use logistic regression to combine all features together, which is a one layer classifier; for the RAW features and LATENT features, we construct a two layer classifier to combine heterogeneous features, i.e., in the first layer, we construct base classifiers using single feature sources, then we build a second layer classifier on top of the first layer classifier which takes the output of base classifiers as input. In our study, for the second layer classifier, we employ logistic regression to combine heterogeneous features. Since features such as RAWWORD and RAWFOLLOW are of high dimensions, we use L1 regularized logistic regression to construct base classifier; for the LATENT features, we use GBDT as the prediction model to construct non-linear base classifier. For LATENT feature base classifier selection, we have compared logistic regression with GBDT and found that GBDT preforms better than logistic regression. Therefore, we choose GBDT as the base classifier. The prediction results with different set of features are listed in Table 2.

For *baseline* features, we conduct experiments on age, gender, education and tags. As shown in Table 2, tags are the most predictive features and perform better than education and age. This is reasonable because tags contain much richer information than age and education and are related to user's profession and interests. Furthermore, the gender feature performs the same as random guess, hence we do not incorporate the gender feature into baselines. This suggest that the man and the woman do not have significant difference in restaurant consumption.

For RAW feature source, the amount of feature candidates is very large, e.g., hundreds of thousands of words. By borrowing the idea of feature selection in previous text classification task (Forman, 2003), we use χ^2 test to select representative features for classification. We select 4715 features for RAWWORD and 7820 features for RAWFOLLOW, which achieves best performance for prediction. Results in Table 2 suggest that RAW features are competitive for consumption level prediction, e.g., while baseline features can achieve 58.89% accuracy and 62.10% F1, RAWWORD alone can achieve 65.74% accuracy and 66.28% F1, and RAWFOLLOW alone can achieve 69.45% accuracy and 71.37% F1.

For LDAT feature source, we set the vocabulary size to 31514 and the number of topics to 200. By distilling topic semantics from tweets of users, the prediction accuracy can achieve 74.51%, which has been improved by 13.34% in contrast to RAWWORD. For LIWCT feature source, we would have expected LIWCT performs better than RAWWORD, since it categorizes the words into psychological and linguistic meaningful categories. A closer analysis of LIWCT features reveal that the vocabulary of LIWCT has relatively small overlap with the most distinguishing words in RAWWORD. For SVDF feature source, we conduct experiments with varying length of SVDF features. We find that when the length is more than 25, the performance does not increase, hence we set the length to 25 in our experiments. As presented in Table 2, accuracy of SVDF method achieves 76.73% and is much better than the result of RAWFOLLOW feature. This is also because SVDF features can capture high level interest of users.

Table 3: Topics sorted by absolute of Spearman correlation coefficient ρ. Topic labels are manually created.

6.2 Qualitative Analysis

In the above, we demonstrated that latent features, such as LDAT and SVDF, are the most effective features for predicting user consumption level. In this section, we conduct further hypothesis test to analyze the language divergence and the interest divergence between users at different consumption levels.

To select topics that are most correlated with consumption level, we present the formal Spearman correlation coefficient[6] test. The Spearman's coefficient ρ lies in the interval $[-1, 1]$, and a value of "+1" or "-1" indicates a perfect, positive or negative Spearman correlation. Intuitively, it is straightforward to generate two rankings of users, either by average spending or by topic preference. However, it is noted that ρ is sensitive to small value differences of both measures, and it will be difficult to obtain robust correlation values in this case. To capture the general trend, therefore, we group users according to their average spending. We sort users according to their average spending in descending order, split users equally into 100 buckets and examine the correlation at the group level.

Table 3 demonstrates the most correlated topics sorted by absolute of ρ. It is worth noting that topics with positive correlation coefficients reflect interests of high consumption level users, while topics with negative correlation coefficients reflect interests of low consumption level users. As shown in the table, users of higher consumption level prefer topics such as "Luxury Brands", while in contrast users of lower consumption level care more about "Mass Brands". This is consist with previous study on consumer behavior (Wong and Ahuvia, 1998), which shows that people buy luxury brands to take it as publicly visible markers of their economic status. Interestingly, we also find that users who speak Shanghai dialect are more likely to be of higher consumption level. We also conduct the correlation test within only Shanghai users, and we find that Shanghai dialect is also significantly correlated with high spending.

[6]http://en.wikipedia.org/wiki/Spearman's_rank_correlation_coefficient

Topic ID	Label	t (Age)	t (Gender)
13	Seafood	0.8837	$2.2599^{\ddagger}$
32	Politics	$10.1372^{\S}$	$-30.1144^{\S}$
71	Luxury brands	$-1.8778^{\dagger}$	$9.5550^{\S}$
198	Driving	$7.8684^{\S}$	$-7.2142^{\S}$
120	Tennis	$-2.5192^{\ddagger}$	-0.8891
45	Shanghai dialect	$4.7150^{\S}$	$5.9072^{\S}$
192	Auto	$2.8303^{\S}$	$-13.6531^{\S}$
135	Mass brands	-0.7032	$7.0779^{\S}$
19	Cooking	$-2.8099^{\S}$	$7.3084^{\S}$
112	Stars	$-2.7430^{\S}$	$2.7556^{\S}$
142	Character expression	$-7.4935^{\S}$	1.0283

Table 4: Topic preference t-test between different age and gender groups. "†","‡", "§" indicate the t test is significant at the level of 0.1, 0.05 and 0.01 respectively.

While on the other hand, users who use more web trending "Character expressions" tend to be of lower consumption level. Since our ground truth dataset is based on spending in restaurants, the top topics also cover food related topics, i.e., "Seafood" and "Cooking". "Seafood" is generally more expensive and hence it is an indicator of higher consumption level, while users who love "Cooking" may prefer dine in and consume less in restaurants. Moreover, high consumption level users talk more about "Politics", "Driving" and "Auto".

We conduct t test to analyze the interaction between topic preference and profile factors. Table 4 demonstrates the t test results. According to user self report age, we divide users into two groups, i.e., older than 30 years old or younger than 30 years old. A positive t indicates that elder group has higher preference on the topic. As shown in the table, elder users prefer topics such as "Politics", "Driving", "Shanghai dialect" and "Auto", and younger users prefer topics such as "Character expression", "Stars", "Luxury brands", "Cooking" and "Tennis". Generally speaking, elder people have higher spending power. Therefore, topics that elder users prefer are positively correlated with spending, while most topics that younger users prefer are negatively correlated with spending. Similarly, we conduct t test of topic preference between female users and male users. Topics such as "Character expression" and "Tennis" have no significant difference between females and males. Female users have significantly higher preference on topics such as "Luxury brands", "Cooking" and "Seafood", and male users have higher preference on topics such as "Driving" and "Auto".

Celebrity		Celebrity		Celebrity	
Dianping Coupon Shanghai	-	Beijing subway	-	Tourism related company	+
Beijing TV cusine programme	-	Reciting words app	-	International radio anchor	+
Comic dialogue player	-	Beijing SKP	+	Waldorf astoria	+
UK shopping	+	Wine related magazine	+	Charity fund	+

Table 5: Top celebrity features selected by χ^2. '+' or '-' indicates the sign of correlation.

For the celebrity features, we select the celebrities with highest χ^2 scores and present them in Table 5. As listed in the table, users of low consumption level follow celebrity such as coupon, subway, TV cuisine programme and reciting words app. On the contrary, high consumption level users follow celebrity such as traveling, wine, high grade hotels and international radio host.

For the LIWCT features, we also select the categories that have strongest correlation coefficient ρ with consumption level. Interestingly, we found that high consumption level users talk more about money (e.g., audit, cash, owe). On the contrary, low consumption level users talk more about time (e.g, end, until, season) and assent words (e.g., agree, OK, yes).

7 Related Work

User profiling aims to infer attributes of users from massive online data. Demographic attributes are widely used for ad targeting (Cheng and Cantú-Paz, 2010) and product recommendation (Wang et al., 2015). Traditional user profiling is mainly based on users' search logs or web access histories (Weber and Castillo, 2010; Hu et al., 2007). Recently, more and more researchers focus on user profiling on social media (Fink et al., 2012; Goswami et al., 2009; Tu et al., 2015).

In addition to simple demographic attributes such as gender or age, recently, researchers focus on complicated attributes such as political orientation (Pennacchiotti and Popescu, 2011), tags (Feng and Wang, 2012), locations (Backstrom et al., 2010; Pavalanathan and Eisenstein, 2015), occupation (Preoţiuc-Pietro et al., 2015a) and personal interests (Yang et al., 2011). However, the economic status related attributes have not been fully explored, which is partially due the difficulty in ground truth collection. Preoţiuc-Pietro et al. (2015b)'s work on income prediction from social media is the most relevant work to ours. Though consumption and income are related, as previous work on social economics (Brewer et al., 2012) has pointed out, " the amount of consumption in any period is not constrained to be equal to income in that period". Recent work on social economic classification (Lampos et al., 2016) is also related to our work. Their work focus on behavior features while we focus on language features and latent features. Furthermore, besides prediction task, we conduct an exploratory data analysis of language use patterns between users of different consumption levels. This work is also related to the study of food consumption on twitter (Abbar et al., 2015), and the work showed that foods mentioned in tweets are correlated with national obesity and diabetes statistics. The authors (Abbar et al., 2015) conduct experiments mainly from nutrition and health aspects, while we conduct experiments from the social economic aspect.

Our work is also related to mining heterogeneous social networks (Deng et al., 2012; Wang et al., 2011; Deng et al., 2011). Recently, many researchers focus on mapping accounts on different sites to one person (Zafarani and Liu, 2009; Liu et al., 2013) in real world. By utilizing these studies, we can link more users from Dianping and Weibo, and hence scale our task to larger dataset. Moreover, there are also works that utilize user linking feature to leverage social media knowledge for solving the cold start problem on third party website (Xiao et al., 2014; Zhang and Pennacchiotti, 2013). Since we estimate user consumption level accurately, it can also be used to solve the cold start problem in recommendation scenario.

8 Conclusion

In this paper, we focus on understanding the relationship between user's online social media behavior and offline restaurant spending. We link user's social media account and corresponding review site account, and then build consumption level ground truth based on user self report spending in their reviews. We propose the topic modeling methods and the matrix factorization methods to tackle the feature sparsity problem. We demonstrate that raw features and latent features on social media can predict consumption level with strong accuracy. The empirical analysis measures the correlation between social media features and consumption levels, and sheds light on language use differences across users at different consumption levels.

Abstract

Recently, topic modeling has been widely applied in data mining due to its powerful ability. A common, major challenge in applying such topic models to other tasks is to accurately interpret the meaning of each topic. Topic labeling, as a major interpreting method, has attracted significant attention recently. However, most of previous works only focus on the effectiveness of topic labeling, and less attention has been paid to quickly creating good topic descriptors; Meanwhile, it's hard to assign labels for new emerging topics by using most of existing methods. To solve the problems above, in this paper, we propose a novel fast topic labeling framework that casts the labeling problem as a k-nearest neighbor (KNN) search problem in probability distributions. Our experimental results show that the proposed sequential interleaving method based on locality sensitive hashing (LSH) technology is efficient in boosting the comparison speed among probability distributions, and the proposed framework can generate meaningful labels to interpret topics, including new emerging topics.

1 Introduction

A wealth of topic models have been proposed to extract interesting topics in the form of multinomial distributions from the corpus automatically, which are useful data mining tools for the statistical analysis of document collections and other discrete data. A common, major challenge in applying all such topic models is to accurately interpret the meaning of each topic. In general, it is very difficult for users to understand a topic merely based on the multinomial word distribution, especially when they are not familiar with the background knowledge. Topic labeling, which generates meaningful labels for a topic so as to facilitate topic interpretation, has attracted increasing attention recently.

Early research on topic labeling generally either select top words in the distribution as primitive labels (Blei et al., 2003; Ramage et al., 2009), or generate labels manually in a subjective manner (Mei et al., 2006; Mei and Zhai, 2005). However, it is highly desirable to automatically generate meaningful labels. Several automatical labeling methods have been proposed recently (Mei et al., 2007; Lau et al., 2010; Lau et al., 2011; Magatti et al., 2009; Mao et al., 2012; Hulpus et al., 2013; Mehdad et al., 2013; Cano et al., 2014). These existing approaches generally take following steps to generate meaningful labels for a given topic: (1) extract candidate labels; (2) rank candidate labels. First, most of existing methods extract candidate labels from a document collection by natural language processing techniques for a given topic, which is time-consuming; for example, the candidate labels in the method proposed by Mei et al. (2007) are extracted from a reference collection using chunking and statistically important bigrams, which is time-consuming. Second, most of existing approaches depend on external knowledge sources such as Wikipedia and Google Directory etc, which cannot be used to label new emerging topics learned from a stream, such as Twitter, because there is no timely information about the new emerging topics in Wikipedia or Google Directory; for example, the method proposed by Lau et al. (2011) uses Wikipedia article titles as candidate labels, which is hard to assign correct labels for the new emerging topics in Twitter because there may not be the timely articles about the new emerging topics in Wikipedia. Thus, despite the success of these works, they are either time-consuming or hard to assign labels for new emerging topics.

*Corresponding author.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3339–3348, Osaka, Japan, December 11-17 2016.

Thus, it is highly desirable to rapidly generate meaningful labels for a topic word distribution while assign labels for new emerging topics as correctly as possible. However, to the best of our knowledge, no existing method has been proposed to satisfy the demand, except that the simplest method which uses top-n words in the distribution to interpret a topic. In this paper, we study this fundamental problem which most topic models suffer from, and propose a labeling framework to rapidly label a topic while assign labels for new emerging topics as correctly as possible.

Topics can be represented as vectors, i.e. j^{th} topic, T_j = (w_{1j}, w_{2j}, ..., w_{tj})^T. Each dimension corresponds to a separate word, and its value in the vector is the probability value. Due to the characters of distributions, we have two observations: (1) Similar topics all have higher probability values over the relevant words, thus a topic is near its similar topics in a probability vector set; For example, the topic "Military" and "Air Force" have both higher probability values over words like "soldier", "missile" and "death" than that over other words, except that the topic "Air Force" has higher probability values over words like "warcraft", "F22" and "pilot", than the topic "Military"; (2) Two different probability distributions might have the same label, because the inherent semantics of a distribution (i.e. topic) is not only reflected by the concrete probability values, but also by the focused words; for example, the following two topics don't have the same distributions, but they are the same topic, and the label is "Military".

	tank	bomb	...	death	take	cup	gun
$topic_1$	0.18	0.10	...	0.11	0.0002	0.007	0.08
$topic_2$	0.17	0.09	...	0.12	0.0003	0.009	0.07

Intuitively, when an event occurs, the information about the event exists in all kinds of sources (labeled data and unlabeled data), such as news, forums and social networks. Thus, these sources are parallel information channels. It is believed that the labels in labeled data will cover most topics in unlabeled data. Through the idea of parallel information channels, in a domain, if there is a database where each record consists of a topic word distribution and its corresponding label [1], and the database is updated uninterruptedly by learning from the latest labeled data as soon as possible; we can interpret a given topic by the labels of k-nearest distributions in the database (i.e. probability vector set) while assign labels for new emerging topics as correctly as possible. If the database is large, timely, and cover most kinds of topics in a domain, it's a reasonable labeling solution to label topics in the domain.

There are two challenges to achieve the intuition: (1) how to quickly find the k-nearest neighbours in a large probability vector set, given a high-dimensional topic word distribution; (2) how to update the database from the latest data as soon as possible.

We proposed a fast labeling framework to solve the two challenges: (1) to finding k-nearest distributions quickly, we use locality sensitive hashing (LSH) as a dimensionality reduction technique to accelerate distribution similarity comparison; (2) to accelerate the update speed of the database, we modify the batch learning algorithm for Labeled LDA to obtain an online learning algorithm.

2 Related work

In most existing research effects on statistical topic modeling, people generally either select top words in the distribution as primitive labels (Blei et al., 2003; Ramage et al., 2009; Ramage et al., 2011), or generate more meaningful labels manually in a subjective manner (Mei et al., 2006; Mei and Zhai, 2005). However, extracting top terms is not very useful to interpret the coherent meaning of a topic (Mei et al., 2007). Meanwhile manually generated labels require lots of human effort to generate such labels, and can easily be biased towards the user's subjective opinions.

Thus, several automatical labeling methods have been proposed recently. In 2007, Mei et al. first proposed probabilistic approaches to automatically label multinomial topics by extracting a set of candidate labels from a reference collection using chunking and statistically important bigrams, and the top ranked labels were chosen to represent the topic (Mei et al., 2007). Magatti et al. (2009) introduced an algorithm to label topics automatically according to a given category hierarchy. The hierarchy was obtained from the Google Directory and the OpenOffice English Thesaurus. The most similar label is assigned to the topic. Lau et al. (2010) proposed to label a topic via selecting one of the top-10 topic terms to label the

[1] Different distributions can have same label

overall topic by a reranking model. Different with their previous method (Lau et al., 2010), Lau et al. (2011) enlarged the candidate labels by making use of Wikipedia article titles.

Mao et al. (2012) proposed two effective algorithms that automatically assign concise labels to each topic in a hierarchy by exploiting sibling and parent-child relations among topics. The structured data in DBpedia is used to label topics (Hulpus et al., 2013). Mehdad et al. (2013) introduced a topic labeling approach that assigns the most representative phrases for a given set of sentences covering the same topic. Cano et al. (2014) proposed a summarisation framework to label the topics learned from Twitter, which is independent of external sources and only relies on the identification of dominant terms in documents related to the latent topic. Word embedding is also used to help label topics (Jin et al., 2016). Interestingly, Aletras and Stevenson (2013) proposed to label topics with images rather than text. Candidate images for each topic are retrieved from the web by querying a search engine using the top-n terms. The most suitable image is selected by using a graph-based algorithm.

Overall, these methods first extract the candidate labels, then rank these labels according to corresponding scoring function. The labeling framework is showed in Figure 1 (a). Despite the success of these works, they are either time-consuming or hard to assign labels for new emerging topics. Thus, in this paper, we will focus on the problems above, and proposed our fast topic labeling framework.

Figure 1: (a) Traditional topic labeling framework and (b) Fast topic labeling framework.

3 Fast Topic Labeling Framework

In this paper, we will study topic labeling problem from a different perspective, i.e. cast it as k-nearest neighbor (KNN) search problem in a probability vector set. As shown in Figure 1 (b), our framework consists of two main components described in the following sections.

3.1 Online Labeled LDA

One important component of our proposed framework is to construct a "topic-label" database which consists of probability distributions over words and corresponding labels, denoted as $DB_{m,n}$, m is the number of topics, and n is the size of vocabulary. We can use Labeled LDA (LLDA) proposed by Ramage et al. (2009) to construct the "topic-label" database. LLDA models the documents with labels, and obtains a probability distribution for each label. The training algorithm for LLDA runs in batch mode, and cannot update the database timely. However, in order that the framework can assign labels for new emerging topics as correctly as possible, the proposed framework needs to process latest labeled data timely, and add gradually new learned records into the "topic-label" database. Thus, we propose a online algorithm for Labeled LDA, called OLLDA, to accelerate the update speed of "topic-label" database.

We define the vector of corresponding labels of document d to be $\boldsymbol{\psi}^{(d)}$, and the number of labels to be M_d, i.e. $M_d = |\boldsymbol{\psi}^{(d)}|$. Similar to the batch variational inference for LDA (Blei et al., 2003), the batch variational inference for Labeled LDA approximates the true posterior by a simpler distribution $q(z, \theta, \beta)$, which is indexed by a set of free parameters. These parameters are optimized by maximizing the lower bound:

$$\log p(\boldsymbol{w}|\alpha, \eta, \Psi) \geq L(\boldsymbol{w}, \phi, \gamma, \boldsymbol{\lambda}, \Psi) \triangleq \mathbb{E}_q[\log p(\boldsymbol{w}, \boldsymbol{z}, \boldsymbol{\theta}, \boldsymbol{\beta}, \Psi|\alpha, \eta)] - \mathbb{E}_q[\log q(\boldsymbol{z}, \boldsymbol{\theta}, \boldsymbol{\beta})]. \quad (1)$$

To maximize the lower bound, we have to minimize the KL divergence between $q(\boldsymbol{z}, \boldsymbol{\theta}, \boldsymbol{\beta})$ and the

posterior $p(\boldsymbol{z}, \boldsymbol{\theta}, \boldsymbol{\beta}, \Psi|\boldsymbol{w}, \alpha, \eta)$. The distribution $q(\boldsymbol{z}, \boldsymbol{\theta}, \boldsymbol{\beta})$ can be fully factorized into the form:

$$q(z_{di} = l) = \phi_{dw_{di}l}; \qquad q(\theta_d) = \text{Dir}(\theta_d; \gamma_d); \qquad q(\beta_l) = \text{Dir}(\beta_l; \gamma_l), \tag{2}$$

where l is the index of a label, and also the index of corresponding topic. The posterior over the per-word topic assignments z is parameterized by ϕ, the posterior over the per-document topic weights θ is parameterized by $\boldsymbol{\gamma}$, and the posterior over the topics β is parameterized by $\boldsymbol{\lambda}$. Equation (1) factorizes to

$$\begin{aligned}
L(\boldsymbol{w}, \boldsymbol{\phi}, \boldsymbol{\gamma}, \boldsymbol{\lambda}, \Psi) = & \sum_{d, z_d \in \Psi} \{\mathbb{E}_q[\log p(w_d|\theta_d, z_d, \beta)] + \mathbb{E}_q[\log p(z_d|\theta_d)] - \mathbb{E}_q[\log q(z_d)] + \mathbb{E}_q[\log p(\theta_d|\alpha)] \\
& - \mathbb{E}_q[\log q(\theta_d)] + (\mathbb{E}_q[\log p(\beta|\eta)] - \mathbb{E}_q[\log q(\beta)])/D\} \\
= & \sum_d \sum_w n_{dw} \sum_{l \in \boldsymbol{\psi}^{(d)}} \phi_{dwl}(\mathbb{E}_q[\log \theta_{dl}] + \mathbb{E}_q[\log \beta_{lw}] - \log \phi_{dwl}) - \log \Gamma(\sum_{l \in \boldsymbol{\psi}^{(d)}} \gamma_{dl}) + \sum_{l \in \boldsymbol{\psi}^{(d)}} \\
& (\alpha - \gamma_{dl})\mathbb{E}_q[\log \theta_{dl}] + \log \Gamma(\gamma_{dl}) + (\sum_{l \in \boldsymbol{\psi}^{(d)}} - \log \Gamma \sum_w \lambda_{lw}) + \sum_w (\eta - \lambda_{lw})\mathbb{E}_q[\log \beta_{lw}] \\
& + \log \Gamma(\lambda_{lw}))/D + \log \Gamma(M_d \alpha) - M_d \log \Gamma(\alpha) + (\log \Gamma(W\eta) - W \log \Gamma(\eta))/D \\
\triangleq & \sum_d l(n_d, \phi_d, \gamma_d, \boldsymbol{\lambda}, \psi^{(d)}),
\end{aligned} \tag{3}$$

where W is the size of the vocabulary and D is the number of documents. $l(n_d, \phi_d, \gamma_d, \boldsymbol{\lambda}, \psi^{(d)})$ denotes the contribution of document d to the lower bound of Formula (1). This reveals that the variational objective relies only on n_{dw}, the number of times word w appears in document d. Thus, an online inference algorithm for Labeled LDA can be derived.

We can use coordinate ascent to optimize L over the variational parameters $\boldsymbol{\phi}$, $\boldsymbol{\gamma}$, $\boldsymbol{\lambda}$:

$$\phi_{dwl} \propto exp\{\mathbb{E}_q[\log \theta_{dl}] + \mathbb{E}_q[\log \beta_{lw}]\}; \qquad \gamma_{dl} = \alpha + \sum_w n_{dw}\phi_{dwl}; \qquad \lambda_{lw} = \eta + \sum_d n_{dw}\phi_{dwl}. \tag{4}$$

As the d^{th} vector of word counts n_d is observed, we perform an EM algorithm to obtain optimal parameter values. Similar to the work (Hoffman et al., 2010), we use the weight $\rho_d \triangleq (\tau_0 + d)^{-\kappa}$ to control the rate at which old values of $\boldsymbol{\lambda}$ are forgotten and $\tau_0 \geq 0$ slows down the early iterations of the algorithm, where $\kappa \in (0.5, 1]$ is needed to guarantee convergence. The proposed online variational inference for Labeled LDA (OLLDA) is described in Algorithm 1.

Algorithm 1 Online Variational Inference for Labeled LDA

```
1: ρ_d = (τ_0 + d)^{-κ}
2: Initialize λ randomly.
3: for d = 0 to ∞ do
4:     E step:
5:     Initialize γ_dl = 1.
6:     repeat
7:         for each word w in document d do
8:             for each label l of document d do
9:                 Set φ_dwl ∝ exp{E_q[log θ_dl] + E_q[log β_lw]}
10:                Set γ_dl = α + Σ_w φ_dwl n_dw
11:            end for
12:        end for

16:    Set λ = (1 − ρ_d)λ + ρ_d λ̃.
17: end for
```

3.2 Distribution Similarity Ranking

After constructing the "topic-label" database, we have to rank distributions for a given topic. To compute similarity between two distributions, there are many metrics, such as Kullback-Leibler divergence

(KL divergence, KL) and Jensen-Shannon Divergence (JSD). Generally speaking, the vocabulary of a distribution is large (over 100K) while the number of records in database is also large, thus it's costly in computing and storage. For example, assume that the number of vocabulary is 100,000, the number of topics is 100,000, and the size of a float is 4 bytes, we need at least 40G space to store distributions.

Locality Sensitive Hashing (LSH), as a dimensionality reduction technique, has been widely applied in large-scale data mining, such as near-duplicate webpage detection (Manku et al., 2007) and image retrieval (Vogel and Schiele, 2007). The key idea of LSH is to assign a number to each point in a metric space by a function h uniformly selected from a family of hashing functions H so that the probability of collision (i.e., assigned by an identical number) is much higher for points close to each other than those far apart (Charikar, 2002). LSH functions involve the creation of short signatures (fingerprints) for each vector (point) in space such that those vectors that are closer to each other are more likely to have similar fingerprints. LSH functions are generally based on randomized algorithms and are probabilistic.

Based on LSH technology, the proposed distribution similarity ranking method will take the following three steps, described below.

3.2.1 Initial Ranking

To accelerate distribution similarity comparison and decrease the storage space, we will choose two representative types of LSH, cosine hash family (**Simhash** (Charikar, 2002)) and the Euclidean hash family (**P-stable LSH** (Datar et al., 2004)), as initial distribution similarity metrics.

Given a probability distribution (i.e. a topic), after obtained the ranked list of topics by a distribution similarity metric (such as Simhash, P-stable LSH), the corresponding labels of returned topics can be used to label the given topic. Because it's useless to assign too many labels to a topic, our systems will return top-20 topics for each given topic.

3.2.2 Re-ranking

A distribution similarity metric does not consider the inherent property of topics. For example, two different points in a probability vector set might have the same label. Thus, we have to consider the nature of topics. Because top-n words of similar topics should be similar, so we will re-rank the order of topics by making use of overlap similarity between top-n word set of the given topic and each in top-20 returned topics. Top-n, as a parameter, will be selected by experiments.

3.2.3 Sequential Interleaving of Two Lists

Given two ranking lists generated by different methods, to obtain benefit from the both results, we consider an interleaving process on these two ranking lists to obtain a better ranking list. Lots of works have been done to interleave two ranking lists of documents in information retrieval area (Hofmann et al., 2011; Hofmann et al., 2012; Chukllin et al., 2015). We borrow the interleaving idea in information retrieval area to handle this problem, and propose a a novel interleaving algorithm, called Sequential Interleaving, to obtain a better ranking list by merging two ranking lists.

In a retrieved list generated by an algorithm, the ranking position of a topic in the list can be treated as a reflection of "confidence level", which is how "good" the algorithm thinks the topic is similar to the given topic. Intuitively, the confidence level $\mathrm{CL}(p, L_r)$ for the probability distribution p of the position r in the ranking list L, should be an inverse function form of the ranking position r. To define the function form of $\mathrm{CL}(p, L_r)$, we inspect the metrics used to evaluating a retrieved list in information retrieval. DCG is a ranking-aware metric which can effectively evaluate how relevant a ranking list is for the query. Its widely-used binary value form (Chapelle et al., 2012) is defined as:

$$\mathrm{DCG}(L) = \sum_{r=1}^{len(L)} \frac{rel_{L_r}}{\log_2(r+1)} \tag{5}$$

where rel_{L_r} is the relevance of the document ranked at r in the ranking list L. In this formula, DCG reflects total confidence level of all documents in the ranking list, thus we can define $\mathrm{CL}(p, L_r)$ as:

$$\mathrm{CL}(p, L_r) = \begin{cases} \frac{1}{\log_2(r+1)} & p \in L, \\ 0 & p \notin L. \end{cases} \tag{6}$$

where p is a probability distribution, and r is the ranking postion of p in the ranking list L.

Given a topic, there are two ranking lists of top-k similar probability distributions (i.e. topics), and the goal is to combine the two ranking lists to obtain a better top-k ranking list. We first obtain the union of the two ranking lists L_1 and L_2, then for each probability distribution p in the union, to compute the total confidence level of p by the following simple formula:

$$\text{TotalCL}(p, L_1, L_2) = \alpha \sum_{L_{1_i}=p} \text{CL}(p, L_{1_i}) + (1-\alpha) \sum_{L_{2_j}=p} \text{CL}(p, L_{2_j}) \tag{7}$$

where $L_{1_i} = p$ denotes the probability distribution p is at the position i in the ranking list L_1, and α is a prior weighting factor. Finally, we sort all the probability distributions by using $\text{TotalCL}(p, L_1, L_2)$, and then give the top-k similar interleaved probability distributions as final ranking result; and thus the labels of these distributions are the top-k candidate labels for the given topic. The proposed algorithm is called Sequential Interleaving. Because the proposed framework requires the high speed of k-nearest neighbor search for a given topic, only locality sensitive hashing algorithms satisfy the condition, thus we combine the re-ranking lists of Simhash and P-stable by proposed Sequential Interleaving method to obtain a ranking list, and abbreviated as si. In this paper, we fairly treat the re-ranking results of Simhash and P-stable by setting α = 0.5.

4 Experiments and results

In this section, we present the results of the efficiency and effectiveness of the proposed method over three data sets.

4.1 Experiment Setup

Data Sets: We explore three different genres of data sets: the Simulated data (**SIMU**), the Conference proceedings (**CONF**), the Twitter dataset (**TW**). To construct the first dataset, we simulated 10,000 distributions over 10,000 words ($DB_{10000,10000}$), and 100,000 distributions over 10,000 words ($DB_{100000,10000}$). After collecting 2,924 fullpapers of four conference (SIGIR, SIGKDD, CIKM, and WWW) proceedings from the year 2010 to 2013, from Google Scholar, conference u-disks and authors' homepage, we obtained the second dataset. The last dataset contains 2.1G microblogs with 3503 hashtags, which removed microblogs without hashtag and hashtags whose idf is less than 50, downloaded from Twitter website in six days. We built "topic-label" database over the last two data sets by our OLLDA algorithm. Specifically, for **CONF**, we trained OLLDA over the data from CIKM2013 to obtain probability distributions with labels as test queries, and trained OLLDA over the remaining data as "topic-label" database; for **TW**, to increase the number of points with same labels in a probability vector set, we split the dataset into 12 pieces according to the time order, and trained separately OLLDA over the $1^{th} \sim 11^{th}$ pieces as "topic-label" database, and over the 12^{th} piece as test queries. All test queries in two datasets can be as the new emerging topics. After training, the statistics of data sets are shown in Table 1 [2].

Baselines: Because proposed framework is totally different with existing methods, e.g., the input of most of existing methods is a topic and a collection which generates the topic, and the input of the proposed framework is only a topic, thus, we cannot compare them directly. Meanwhile there is no related work that focus on efficiency of topic labeling. Essentially, the core of the proposed framework is the comparison among distributions, thus, we choose KL divergence (KL) and Jensen-Shannon Divergence (JSD) as distribution similarity metrics in our framework, as baselines. All methods in this paper are denoted as $FR_{metric,ranking\_stage}$, where *metric* means which distribution similarity metric to choose, and *ranking_stage* means *Initial Ranking* or *Re-ranking*. We use "1" to denote "Initial Ranking" and "2" denote "Re-ranking". For example, assume that the distribution similarity metric is JSD, and just use initial ranking, the method can be denoted as $FR_{jsd,1}$. The sequential interleaving result of the ranking lists of $FR_{sh,2}$ and $FR_{ps,2}$ is denoted as FR_{si}.

All experiments were conducted on a server with dual 6-core Intel i7 cpus with 3.4Ghz, 32G memory.

[2] All "topic-label" databases have been published at "https://github.com/TopicLabeling/tldb".

4.2 Efficiency of Distribution Similarity Metrics over Simulated Data

We sample respectively 20 probability distributions from $DB_{10000,10000}$ and $DB_{100000,10000}$ as test queries and rank the distributions in corresponding SIMU dataset, then compute avarage time per query and space cost. Because the main cost in our distribution similarity ranking is spent in "Initial Ranking" stage, and the cost of re-ranking is little, thus only report the results in "Initial Ranking" stage. Table 2 shows a detailed comparison of $FR_{kl,1}$, $FR_{jsd,1}$, $FR_{sh,1}$ and $FR_{ps,1}$ on two SIMU datasets. We can make two observations from the table: the computing time and storage space of $FR_{ps,1}$ and $FR_{sh,1}$, are significantly less than that of baseline methods. In a word, the efficiency of LSH significantly outperforms the baselines in terms of time and space.

Table 1: The statistics of CONF and TW data sets.

	CONF	TW
Num. of Vocabulary	25,160	189,841
Num. of Labels	586	3,503
Num. of Distributions	957	12,139

Table 2: The efficiency of four methods over the SIMU datasets.

	$\mathbf{DB_{10000,10000}}$		$\mathbf{DB_{100000,10000}}$	
Methods	**Time (s)**	**Space (M)**	**Time (s)**	**Space (M)**
$FR_{kl,1}$	5.761	1,230.830	546.514	12,0206.272
$FR_{jsd,1}$	5.051	1,206.972	656.120	12,211.392
$FR_{sh,1}$	0.078	**115.996**	**0.504**	**674.750**
$FR_{ps,1}$	**0.075**	411.028	0.689	4,020.030

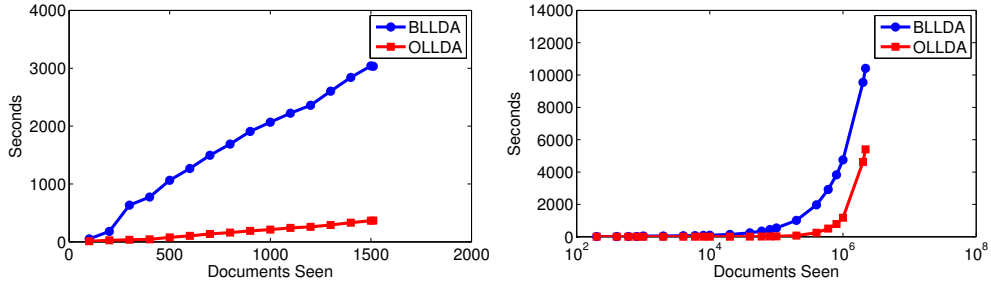
4.3 Performance of Proposed Framework over Real-world Data

As described above, the distributions in our "topic-label" database has their corresponding labels, which are used as standard labels (ground truth). We first show some sample results of our fast labeling methods in Table 4. For comparison, we also show the baselines' labels and standard labels for the same topics. It is clear that the rapidly generated labels can all capture the meaning of the topic to some extent; indeed, most of them are as good as standard labels (e.g., "social network" and "michael jackson"), though some are not (e.g., "text classification") but they are similar to standard labels.

4.3.1 Efficiency of OLLDA

OLLDA has several learning parameters: $\kappa \in (0.5, 1]$ and $\tau_0 \geq 0$. Similar to Hoffman's parameter choosing method (Hoffman et al., 2010), we also set $\kappa = 0.5$ and $\tau_0 = 64$ as the best learning parameter settings for both corpora.

In this experiment, we evaluated the efficiency of OLLDA, compared with batch LLDA (BLLDA). We simulated the situation that documents are coming in a stream. For our OLLDA, the model parameters are updated every time a new document arrives. We computed total training time cost at some points of the seen documents using OLLDA. As for BLLDA, we computed the training time cost at the same points, and note that each run has to use all of the documents previously seen.



(a) Conf (b) Twitter

Figure 2: Training Time On Two Real Datasets

When a new document arrives, BLLDA has to run over all observed documents for many iterations again. Since the time for each iteration grows with the number of documents, the total time for BLLDA grows fast. However, OLLDA only processes the new coming document and update parameters. Thus, as Figure 2 shows, BLLDA costs much more time to get the new parameters compared with OLLDA,

especially when the number of observed documents is large. When running over the entire Conf corpus, the training time of OLLDA is less than 400 seconds, while BLLDA takes more than 3,000 seconds, which is about 8 times longer. Over TW dataset, BLLDA takes more than 10,000 seconds, while OLLDA takes less than 6,000 seconds.

In Figure 2 (b), when the number of observed documents is large, the time cost increases quickly for OLLDA and BLLDA, because of the greater number of parameters and IO cost. However, OLLDA still performs better than BLLDA. If we use mini-batch trick and other optimize technologies in OLLDA, the efficiency of OLLDA will get greater improvement.

4.3.2 Effectiveness of Distribution Similarity Ranking

We compute the following performance metrics over CONF and TW dataset: (1) *Match at top N results (**Match@N**)*, which indicates whether the top N results contain any correct labels; (2) *Precision at top N results (**P@N**)*.

Table 3: The effectiveness of four methods over the CONF and TW datasets.

Datasets	Methods	Match@N				P@N			
		N=1	N=3	N=5	N=10	N=1	N=3	N=5	N=10
CONF	$FR_{kl,1}$	0.0000	0.0000	0.0069	0.0069	0.0000	0.0000	0.0014	0.0007
	$FR_{jsd,1}$	**0.1458**	**0.2569**	**0.2847**	**0.3819**	**0.1458**	**0.0949**	**0.0667**	**0.0458**

From Table 3, we can make several observations: (1) For both datasets, $FR_{x,2}$ performs better than $FR_{x,1}$, *x* denotes *sh* or *ps*, which shows that the step "Re-ranking" is effective. (2) For both datasets, FR_{si} performs better than $FR_{sh,2}$ and $FR_{ps,2}$, which shows that the step "Sequential Interleaving" is effective. (3) For both datasets, $FR_{jsd,1}$ performs better than $FR_{sh,1}$ and $FR_{ps,1}$ in most cases, which shows that JSD is good distribution similarity comparision method. However, the time cost of $FR_{jsd,1}$ is higher than LSH methods, showed in Table 5. (4) For both datasets, the performance of $FR_{ps,1}$ is alway poorer than that of $FR_{sh,1}$. Given a probability distribution $\vec{p}$, assume that $\mathbf{P}$ is the set of all probability

distributions, and the set $S_1 = \{p_i | \cos^{-1} \frac{\vec{p}_i \cdot \vec{p}}{\|\vec{p}_i\| \|\vec{p}\|} \leq \theta, p_i \in \mathbf{P}\}$, and assume that $\vec{p}_0$ is a probability distribution, which satisfies $p_0 = argmin_{p_i \in S_1} \|\vec{p}_i - \vec{p}\|$, and the set $S_2 = \{p_i | \ \|\vec{p}_i - \vec{p}\| \leq \ \|\vec{p}_0 - \vec{p}\|\}$. It's easy to prove that $S_2 \subseteq S_1$. That means: the point p_0 locates in the bound of S_1 and S_2, however, the set for Euclidean-based methods is subset of the one for angle-based methods, which means that the ability of finding KNN points for angle-based methods are better than the one for Euclidean-based methods in probability distributions. Thus, $FR_{sh,1}$ always performs better than $FR_{ps,1}$. (5) For CONF dataset, the metric values of all methods are not high. Because our metrics only count the labels which are same as standard labels, and ignore the similar labels. Furthermore, the ratio ($\frac{Num.of Distributions}{Num.of Labels}$) in CONF is small (showed in Table 1). Small ratio means that a lable has fewer points in a probability vector set, thus it's natural that the values of all metrics are very low. Thus, we evaluate all ranking results judged manually by three students, and take use of voting method to obtain the final results, showed in Table 6. The table shows that the metric values increase, and FR_{si} performs best. (6) For TW dataset, the performance of FR_{si} is the best among all methods. The improvements are significant by t-test at the 95% significance level. Thus, the overall results show that proposed distribution similarity ranking is effective. Meanwhile, because the test queries in two datasets can be as the new emerging topics, thus the results also show that the proposed method can handle the new emerging topics.

Table 5: The efficiency over the CONF and TW datasets.

$FR_{jsd,1}$	0.350	0.650	0.700	0.900	0.350	0.467	0.360	0.295
$FR_{sh,1}$	0.350	0.600	0.700	0.750	0.350	0.300	0.280	0.210
$FR_{ps,1}$	0.200	0.250	0.450	0.800	0.200	0.167	0.150	0.175
FR_{si}	**0.467**	**0.750**	**0.831**	**0.950**	**0.467**	**0.530**	**0.455**	**0.375**

4.3.3 Efficiency of Distribution Similarity Ranking

For each query in test set, we rank the distributions in corresponding dataset, then compute avarage time per query. Table 5 shows a detailed comparison of $FR_{sh,1}$, $FR_{ps,1}$, $FR_{kl,1}$ and $FR_{jsd,1}$ on **TW** and **CONF**. We can make following observations: the computing time of $FR_{ps,1}$ and $FR_{sh,1}$, are significantly less than other methods. In a word, the efficiency of the proposed distribution similarity ranking method based on LSH significantly outperforms the baselines in terms of time.

5 Conclusion

In this paper, we cast the rapid labeling problem as a k-nearest neighbor (KNN) search problem among existing "topic-label" database, which is updated uninterruptedly by online learning from the latest data. The experimental results show that the proposed framework can generate meaningful labels that are useful for interpreting topics in real time.

Abstract

Using neural networks to generate replies in human-computer dialogue systems is attracting increasing attention over the past few years. However, the performance is not satisfactory: the neural network tends to generate safe, universally relevant replies which carry little meaning. In this paper, we propose a content-introducing approach to neural network-based generative dialogue systems. We first use pointwise mutual information (PMI) to predict a noun as a keyword, reflecting the main gist of the reply. We then propose `seq2BF`, a "*sequence to backward and forward sequences*" model, which generates a reply containing the given keyword. Experimental results show that our approach significantly outperforms traditional sequence-to-sequence models in terms of human evaluation and the entropy measure, and that the predicted keyword can appear at an appropriate position in the reply.

1 Introduction

Automatic human-computer conversation is a hot research topic in natural language processing (NLP). In past decades, researchers have developed various rule- or template-based systems, which are typically in vertical domains, e.g., transportation (Ferguson et al., 1996) and education (Graesser et al., 2005). In the open domain, data-driven approaches play an important role, because the diversity and uncertainty make it virtually impossible for humans to design rules or templates. Isbell et al. (2000) and Wang et al. (2013) use information retrieval methods to search for a reply from a pre-constructed database; Ritter et al. (2011) formalize conversation as a statistical machine translation task.

Recently, the renewed prosperity of neural networks brings new opportunities to open-domain conversation (Vinyals and Le, 2015; Shang et al., 2015; Serban et al., 2016a; Li et al., 2016a). In these studies, researchers leverage sequence-to-sequence (`seq2seq`) models to encode a *query* (user-issued utterance) as a vector and to decode the vector into a *reply*. In both encoders and decoders, an RNN keeps one or a few hidden layers; at each time step, it reads a word and changes its state accordingly. RNNs are believed to be well capable of modeling word sequences, benefiting machine translation (Sutskever et al., 2014), abstractive summarization (Rush et al., 2015) and other tasks of natural language generation. Contrary to retrieval methods, neural network-based conversation systems are *generative* in that they can synthesize new utterances; results in the literature also show the superiority of `seq2seq` to phrase-based machine translation for dialogue systems (Shang et al., 2015). In our study, we focus on neural network-based generative *short-text conversation*, where we do not consider context information, following Wang et al. (2013) and Shang et al. (2015).

Despite these, neural networks' performance is far from satisfactory in human-computer conversation. A notorious problem is the *universal reply*: the RNN prefers to generate safe, universally relevant sentences with little meaning, e.g., "something" (Serban et al., 2016a) and "I don't know" (Li et al., 2016a). One problem may lie in the objective of decoding. If we choose a reply with the maximal estimated

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3349–3358, Osaka, Japan, December 11-17 2016.

probability (either greedily or with beam search), it is probable to obtain such universal replies, because they do appear frequently in the training set. Another potential problem is that, the query may not convey sufficient information for the reply, and thus the encoder in `seq2seq` is less likely to obtain an informative enough vector for decoding.

In this paper, we propose a content-introducing approach to generative short-text conversation systems, where a reply is generated in a two-step fashion: (1) First, we predict a keyword, that is, a noun reflecting the main gist of the reply. This step does not capture complicated semantic and syntactic aspects of natural language, but estimates a keyword with the highest pointwise mutual information against query words. The keyword candidates are further restricted to nouns, which are not as probable as universal words (e.g., *I* and *you*), but can introduce substantial content to reply generation. (2) We then use a modified encoder-decoder model to synthesize a sentence containing the keyword. In traditional `seq2seq`, the decoder generates the reply from the first word to the last in sequence, which prevents introducing certain content (i.e., a given word) to the reply. To tackle this problem, we propose `seq2BF`, a novel "*sequence to backward and forward sequences*" model, based on our previous work of backward and forward language modeling (Mou et al., 2015). The `seq2BF` model decodes a reply starting from a given word, and generates the remaining previous and future words subsequently. In this way, the predicted keyword can appear at an arbitrary position in the generated reply.

The rest of this paper is organized as follows. Section 2 describes the proposed approach; Section 3 presents experimental results. Section 4 briefly reviews related work in the literature. Finally we conclude our paper and discuss future work in Section 5.

2 Our Approach

In this section, we present our content-introducing generative dialogue system in detail. Subsection 2.1 provides an overview of our approach, Subsection 2.2 introduces the keyword predictor, and Subsection 2.3 elaborates the proposed `seq2BF` model. We describe training methods in Subsection 2.4.

2.1 Overview

Figure 1 depicts the overall architecture of our approach, which comprises two main steps:

Step I: We first use PMI to predict a keyword for the reply, as shown in Figure 1a.

Step II: After keyword prediction, we generate a reply conditioned on the keyword as well as the query. More specifically, we propose the `seq2BF` model, which generates the backward half of the sequence (Figure 1b) and then the forward half (Figure 1c).

Notice that, the RNNs in Step II do not share parameters (indicated by different colors in the figure) because they differ significantly from each other. Moreover, the encoder and decoder do not share parameters either, which is standard in `seq2seq`. For clarity, we do not assign different colors for encoders and decoders, but separate them with a long arrow in Figures 1b and 1c.

2.2 Keyword Prediction

In this step, we use pointwise mutual information (PMI) to predict a keyword for the reply. We leverage such surface statistics because this step outputs a single keyword, which does not capture complicated syntax and semantics of queries and replies. Our goal of content introducing is to suggest a word that is especially suited to the query, instead of predicting a most likely (common) word. Hence, the pointwise mutual information is an appropriate statistic for keyword prediction.

Formally, we compute PMI of a query word w_q and a reply word w_r using a large training corpus by

$$\mathrm{PMI}(w_q, w_r) = \log \frac{p(w_q, w_r)}{p(w_q)p(w_r)} = \log \frac{p(w_q|w_r)}{p(w_q)} \tag{1}$$

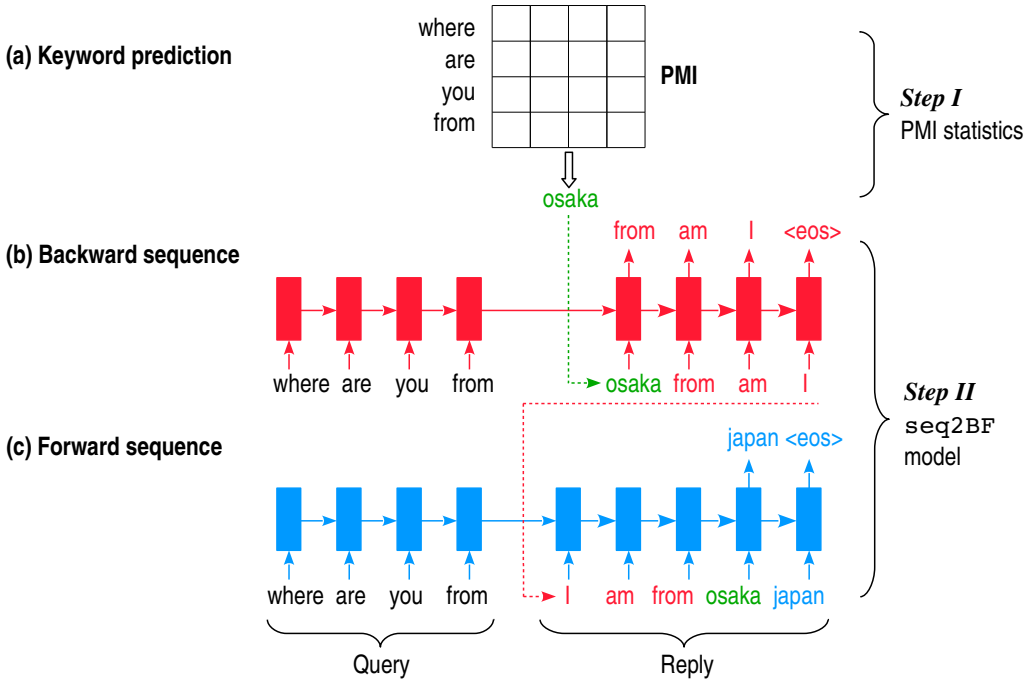

Figure 1: An overview of our content-introducing approach to generative dialogue systems.

When predicting, we choose the keyword w_r^* with the highest PMI score against query words $w_{q_1}, \cdots w_{q_n}$, i.e., $w_r^* = \text{argmax}_{w_r} \text{PMI}(w_{q_1} \cdots w_{q_n}, w_r)$, where

$$\text{PMI}(w_{q_1} \cdots w_{q_n}, w_r) = \log \frac{p(w_{q_1} \cdots w_{q_n}|w_r)}{p(w_{q_1} \cdots w_{q_n})} \tag{2}$$

$$\approx \log \frac{\prod_{i=1}^n p(w_{q_i}|w_r)}{\prod_{i=1}^n p(w_{q_i})} = \sum_{i=1}^n \log \frac{p(w_{q_i}|w_r)}{p(w_{q_i})} = \sum_{i=1}^n \text{PMI}(w_{q_i}, w_r) \tag{3}$$

The approximation is due to the independency assumptions of both the prior distribution $p(w_{q_i})$ and posterior distribution $p(w_{q_i}|w_r)$. While the two assumptions may not be true, we use them in a pragmatic way so that the word-level PMI is additive for a whole utterance. Experiments show that this treatment generally works well.

Different from choosing the most likely word, PMI penalizes a common word by dividing its prior probability; hence, PMI prefers a word that is most "mutually informative" with the query. Moreover, we manually restrict keyword candidates to nouns, so that this step can introduce substantial content to reply generation, which will be discussed in the next part.

2.3 The seq2BF Model

To insert the predicted keyword into sequence generation, we cannot use the traditional seq2seq model. In existing approaches, we usually decompose the probability of an output sentence $\boldsymbol{r} = r_1 r_2 \cdots r_m$ given an input sentence $\boldsymbol{q} = q_1 q_2 \cdots q_n$ by

$$p(r_1, \cdots, r_m|\boldsymbol{q}) = p(r_1|\boldsymbol{q}) p(r_2|r_1, \boldsymbol{q}) \cdots p(r_m|r_1 \cdots r_{m-1}, \boldsymbol{q}) = \prod_{i=1}^m p(r_i|r_1 \cdots r_{i-1}, \boldsymbol{q}) \tag{4}$$

The output sentence is thus predicted in sequence from r_1 up to r_m either greedily or with beam search. I personally believe such decomposition is mainly inspired by the observation that humans always say a sentence from the beginning to the end.

However, in our content-introducing approach to generative dialogue systems, the predicted keyword could appear at the beginning (r_1), the middle (r_2 to r_{m-1}), or the end (r_m) of the reply. It is then natural

to decompose the probability starting from the given word. In particular, the predicted keyword k splits a reply into two (sub-)sequences:

$$\begin{aligned} \text{Backward sequence:} \quad & r_{r-1}, \cdots, r_1 \\ \text{Forward sequence:} \quad & r_{k+1}, \cdots, r_m \end{aligned}$$

and the joint probability of remaining words can be written as

$$p\left(\begin{matrix} r_{k-1} \cdots r_1 \\ r_{k+1} \cdots r_m \end{matrix} \middle| r_k, \boldsymbol{q} \right) = \prod_{i=1}^{k-1} p^{(\text{bw})}(r_{k-i}|r_k, \boldsymbol{q}, \cdot) \prod_{i=1}^{m-k} p^{(\text{fw})}(r_{k+i}|r_k, \boldsymbol{q}, \cdot) \tag{5}$$

where $p(\text{- - -}|r_k, \boldsymbol{q})$ refers to the probability of the backward and forward subsequences given the split word r_k and an encoded query $\boldsymbol{q}$. Notice that both the backward and forward sequence generators include a wildcard allowing rich inner-subsequence and/or inter-subsequence dependencies. In our previous study of backward-and-forward (B/F) language modeling (Mou et al., 2015), we propose three variants: (1) **sep-B/F**: The backward and forward sequences are generated separately. (2) **syn-B/F**: The backward and forward sequences are generated synchronously using a single RNN, two output layers at each time step for the two sequences. (3) **asyn-B/F**: The two sequences are generated asynchronously, that is, we first generate the backward "half" sequence, conditioned on which we then generate the forward "half." Our previous experiments show the asyn-B/F is the most natural way of modeling backward and forward sequences, and thus we adopt this variant in `seq2BF`.

Specifically, our `seq2BF` model works as follows. A `seq2seq` neural network encodes a query and decodes a "half" reply, that is, the first set of factors in Equation 5 becomes $p^{(\text{bw})}(r_{k-i}|r_k, \boldsymbol{q}, \cdot) = p^{(\text{bw})}(r_{k-i}|r_k \cdots r_{k-i+1}, \boldsymbol{q})$, where $1 \leq i \leq k-1$. The decoder here outputs words in a reversed order from r_{k-1}, r_{k-2} to r_1, so that the reversed "half" sequence is fluent with respect to the given word, at least from a mathematical perspective. (Please see Figure 1b.)

Then another `seq2seq` model encodes the query again, but decodes the entire reply, provided that the first half of the reply is given (Figure 1c), i.e., $p^{(\text{fw})}(r_{k+i}|r_k, \boldsymbol{q}, \cdot) = p^{(\text{fw})}(r_{k+i}|r_1 \cdots r_k \cdots r_{k+i-1}, \boldsymbol{q})$, $(1 \leq i \leq m-k)$. Here, the forward generator is aware of the backward half sequence $r_1 \cdots r_{k-1}$, where the word order is reversed again, so that they are in a normal order for fluent forward generation.

In both backward and forward `seq2seq` models, we use RNNs with gated recurrent units (GRUs) for information processing (Cho et al., 2014), given by

$$\boldsymbol{r}_t = \sigma(W_r \boldsymbol{w}_t + U_r \boldsymbol{h}_{t-1} + \boldsymbol{b}_r) \tag{6}$$

$$\boldsymbol{z}_t = \sigma(W_z \boldsymbol{w}_t + U_r \boldsymbol{h}_{t-1} + \boldsymbol{b}_z) \tag{7}$$

$$\widetilde{\boldsymbol{h}}_t = \tanh\Big(W_h \boldsymbol{w}_t + U_h(\boldsymbol{r} \circ \boldsymbol{h}_{t-1}) + \boldsymbol{b}_h\Big) \tag{8}$$

$$\boldsymbol{h}_t = (1 - \boldsymbol{z}_t) \circ \boldsymbol{h}_{t-1} + \boldsymbol{z}_t \circ \widetilde{\boldsymbol{h}}_t \tag{9}$$

where W's and U's are weights and $\boldsymbol{b}$'s are bias terms. $\boldsymbol{w}_t$ is the word embedding; $\boldsymbol{h}_t$ is the hidden state at the time step t. "$\circ$" denotes element-wise product.

2.4 Model Training

Training (i.e., parameter estimation) is always a most important thing in the neural network regime, and oftentimes, problems arise when we prepare the dataset.

Fortunately, the `seq2BF` model can be trained without additional labels. We randomly sample a word in a reply as the split word, take the first half, and reverse its word order; in this way, we obtain the training data for the backward sequence generator. The forward sequence generator is essentially a `seq2seq` encoder and decoder from queries to replies. The difference between the pure `seq2seq` and the forward generator of `seq2BF` lies in the inference stage: in our scenario, we ignore the query-reply `seq2seq` generator's output at the beginning steps, but feed it with the "half" reply obtained by our backward sequence generator as well as the predicted keyword (red and green words in Figure 1c); then we let the `seq2seq` model generate remaining future words (blue words in Figure 1c).

It should be emphasized that the backward sequence generator requires "half" replies starting from the split word as training data, and that we cannot train the model with a full reversed sentence. Otherwise, the backward part will undesirably generate an entire reversed reply, and the forward part cannot add much to it.

3 Experiments

3.1 Dataset

We evaluated our approach on a Chinese dataset of human conversation crawled from the Baidu Tieba[1] forum. We used 500,000 query-reply pairs to train the `seq2BF` model. We had another unseen 2000 and 27,871 samples for validation and testing, respectively. To obtain PMI statistics in the first step (Figure 1a) of our method, we use a much larger dataset containing 100M query-reply pairs.

Chinese language is different from English in that a Chinese character carries more semantics than an alphabet. For example, the characters 黑 and 板 mean "black" and "board" in English, respectively; the term 黑板 means "blackboard." Because we have far more Chinese terms than English words, our `seq2BF` is trained in the character level out of efficiency concerns. But we train the keyword predictor with noun phrases (Chinese terms), by noticing that *blackboard* is different from *board*, despite some subtle relations. Fortunately, the two granularities can be integrated together straightforwardly: during backward sequence generation, we only need to condition the model on the character sequence in the key term instead of a single keyword, that is, we have several green inputs in Figure 1b. In our study, we kept 2.5k noun terms as candidate keywords and 4k characters for `seq2BF` generation.

3.2 Hyperparameters

In our experiments, word embeddings and recurrent layers were 500d. We used rmsprop to optimize all parameters except embeddings, with initial weights uniformly sampled from $[-.08, .08]$, initial learning rate 0.002, moving average decay 0.99, and a damping term $\epsilon = 10^{-8}$. Because word embeddings are sparse in use (Peng et al., 2015), we optimized embeddings asynchronously by stochastic gradient descent with the learning rate divided by $\sqrt{\epsilon}$. We set the mini-batch size to 50. These values were mostly chosen empirically by following Karpathy et al. (2015) and Mou et al. (2015); they generally work well in our scenarios. We did not tune the hyperparameters in this paper, but are willing to explore their roles in dialogue generation as future work.

The validation set (containing 2k query-reply samples) was used for early stop only. We chose the parameters yielding the highest character-level BLEU-2 score on our validation set.

3.3 Performance

We evaluated our results in terms of the following criteria:

- **Human Evaluation**. We had six volunteers[2] to annotate the results of our content-introducing `seq2BF` and baselines. To ensure the quality of human evaluation, we randomly sampled 200 queries and replies in the test set. The samples and volunteers were further split into two equal-sized groups of different annotation protocols:
  - *Pointwise annotation*. The volunteers were asked to annotate a score indicating the appropriateness of a reply to a given query: 0 = bad reply, 2 = good reply, and 1 = borderline.
  - *Pairwise annotation*. Given a certain query, the volunteers were asked to judge whether pure `seq2seq` is better than, equal to, or worse than `seq2BF` (with content introducing). If they could not understand both replies, they were asked to choose "equal."

  All our human evaluation were conducted in a random, blind fashion, i.e., we randomly shuffled the samples and volunteers did not know which system generated a particular reply. Notice that we did not define what a "good" or "bad" reply is; otherwise, the annotation may be biased towards certain systems. Rather, annotators had their own subjective discretion. While criteria may differ from

[2] All volunteers are well-educated native speakers of Chinese and have received a Bachelor's degree or above.

(a)

Method	PointHuman	Length	Entropy
seq2seq	0.58	**5.61**	6.960
seq2BF$_-$	0.46	5.60	6.971
seq2BF$_+$	**0.67**	5.31	**9.139**
Groundtruth	–	9.19	8.832

(b)

PairHuman			
Method	**Wins**	**Ties**	**Loses**
seq2seq	24.7	26.0	49.3
seq2BF$_+$	**49.3**	26.0	24.7

Table 1: The performance of our content-introducing seq2BF (denoted as seq2BF$_+$) dialogue system in comparison with pure seq2seq and seq2BF without predicted keywords (seq2BF$_-$). **PointHuman**: Pointwise human evaluation. (Annotator agreement: std=0.33, Fleiss' κ=0.27.) **PairHuman**: Pairwise human evaluation, which shows the percentage at which a system wins, loses, or ties in comparison with the other (κ=0.29).

person to person, the ranking of average scores reflects the comparison of different dialog systems. (In our study, the ranking is consistent among all six annotators.)

- **Length**. The length of an utterance is an objective, surface metric that reflects the substance of a generated reply.

- **Entropy**. Entropy is another objective metric, which shows the serendipity of a reply by measuring the amount of information contained in the utterance. We computed the average character-level entropy, given by

$$-\frac{1}{|R|}\sum_{w\in R}\log_2 p(w) \tag{10}$$

where R refers to all replies, $|R|$ is the number of words in all replies, and $p(\cdot)$ is the unigram probability of a character in the training set.

The latter two metrics are "intrinsic," by which we mean no reference (groundtruth reply) is needed to compute the metric. They are used in Serban et al. (2016b).[3] In our experiments, objective metrics were assessed with all test samples.

We do not include BLEU scores as our evaluation criteria, which are used in Li et al. (2016a). As a pilot study, we also asked two volunteers to write their own replies to 50+ queries. One obtained 1.69 BLEU-4 score. (The result is lower than 1.74 obtained by an automatic dialogue system in Li et al. (2016a); this may be caused by different datasets and languages.) What surprises us is that the other volunteer obtained 0 BLEU-2 score, indicating that no bi-gram overlaps between his replies and the references. This result provides evidence of the diversity among human replies, and thus we abandoned BLEU scores as evaluation criteria. We reported this case study in our paper so as to shed more light on the research of evaluation metrics in dialogue systems.

Table 1 compares our content-introducing seq2BF with the seq2seq baseline. Also included is the seq2BF model without content introducing, that is, we slacked the keyword constraint in the backward sequence generator (Figure 1b), and let it generate a reversed half reply freely.

As seen in Table 1a, the content-introducing seq2BF model yields the highest pointwise human annotation result. For seq2BF without content introducing, we obtain low scores, showing that artificially splitting a sequence into two parts itself is not a fancy way of modeling natural language sentences. However, given a keyword predicted by PMI statistics, the backward and forward sequence generation can significantly improve the dialogue system in comparison with pure seq2seq. In the pairwise annotation protocol, the content-introducing seq2BF model also outperforms traditional seq2seq to a large extent. We computed standard deviation (0.33) and discrete-class Fleiss' κ scores (0.27–0.29), showing fair annotator agreement (Fleiss, 1971). While the agreement is comparable to previous results, e.g., 0.2–0.4 reported in Shang et al. (2015), we find the disagreement mainly comes from the discretion of

[3]The entropy equation in Serban et al. (2016b, v3) has a minor error. We confirmed this with Serban via personal emails.

	Chinese	English (translated)
Query	李有男友公开过了	It's known that *Li*† has a boyfriend.

Table 3: Fine-grained analysis of character-level entropy. In the seq2BF$_+$ model, we analyze the average entropy of keywords and remaining words separately.

the "goodness" of a reply (so that the annotation complies with the subjective nature of human evaluation). All annotators yielded the same system-level ranking order, providing consistent evidence of the effectiveness of our approach.

Regarding intrinsic metrics, our seq2BF with a predicted keyword generates slightly shorter replies than seq2seq, but contains far richer information, as the entropy increases by 30%. The results verify that content introducing is particularly useful in generative human-computer dialogue systems.

3.4 Case Studies and Discussion

We provide case studies in Table 2.[4] As we see, the seq2seq responder prefers safe, universally relevant utterances like "me too." In these examples, the replies generally match the queries in meaning, but such universal replies are too boring and thus undesirable in real applications. In the seq2BF model with content introducing, we predict a keyword of the reply with PMI. This yields meaningful words/terms like *rumor* and *score*, serving as the gist of the reply. Then the seq2BF model generates previous and future words to obtain a more complete utterance (maybe not a whole sentence because of the casualness in human conversation). The proposed "backward and forward sequences" mechanism ensures that the predicted keyword can appear at an arbitrary position in the utterance.

We delve deep into the question: why seq2seq models (or variants) tend to generate universal

[4]Due to Chinese-English translation, some characteristics cannot be fully presented in the English text, e.g., the position of the given word, the length of the reply, and even the part-of-speech of a word. Nevertheless, we present the predicted keyword and its translated counterpart in bold and thus the aforementioned characteristics can be visually demonstrated to some extent.

replies? We may have two conjectures: (1) The seq2seq model cannot capture rich enough semantics other than "yes," "me too," etc. (2) The sequence generator is able to capture rich semantics, but starting from a high-level universal word at the beginning, it is unlikely to fall into concrete concepts.

We present in Table 3 the average character-level entropy of keywords and non-keywords. We find that, provided with a noun term, seq2BF can generate meaningful remaining words (keyword excluded) with an entropy of 7.422, higher than 6.971 given by seq2BF without keywords. Noticing that the seq2BF model is exactly the same in content-introducing and non-content-introducing settings, we believe the second conjecture holds. Choosing the most likely reply yields universal utterances; moreover, RNN sequence generators are reluctant to introduce concrete concepts, provided with one or a few universal words/terms (like *I* and *you*) that are greedily chosen at the beginning.

Fortunately, our content-introducing seq2BF works in an opposite fashion. We first predict a meaningful but not that probable noun term as the keyword; then we feed seq2BF with such concrete keyword that provides substantial content. In this way, our approach significantly outperforms pure seq2seq generation in short-text conversation systems.

4 Related Work

4.1 Dialogue Systems

Automatic human-computer conversation has long attracted the attention of researchers. In early decades, people design rule- or template-based systems, but they are mainly in vertical domains (Ferguson et al., 1996; Misu and Kawahara, 2007). Although such approaches can also be extended to the open domain (Han et al., 2015), their generated sentences are subject to 7 predefined forms and thus are highly restricted. For open dialogues, researchers have applied data-driven approaches, including retrieval methods (Isbell et al., 2000; Wang et al., 2013), phrase-based machine translation (Ritter et al., 2011), and recurrent neural networks (Sordoni et al., 2015; Shang et al., 2015).

A hot research topic in human-computer conversation is mixed-initiative systems, for example, the TRAINS-95 system for route planning (Ferguson et al., 1996) and AutoTutor for learner advising (Graesser et al., 2005). Li et al. (2016b) propose a proactive dialogue system that can introduce new content when a stalemate occurs. The system is chatbot-like and in the open domain; an external knowledge base is used for searching related entities as new content. They propose a random walk-like reranking algorithm based on retrieval results. Different from Li et al. (2016b)'s work, our paper addresses the problem of content introducing in open-domain generative dialogue systems.

4.2 Neural Networks for Sentence Generation

Sutskever et al. (2014) propose seq2seq for machine translation; the idea is to encode a source sentence as a vector by a recurrent neural network (RNN) and to decode the vector to a target sentence by another RNN. Bahdanau et al. (2015) enhance it with an attention mechanism. These approaches largely benefit natural language generation tasks such as abstractive summarization (Rush et al., 2015), question answering (Yin et al., 2016), and poetry generation (Wang et al., 2016).

For neural network-based dialogue systems, Sordoni et al. (2015) summarize a query and context as bag-of-words features, based on which an RNN decodes the reply. Shang et al. (2015) generate replies for short-text conversation by seq2seq-like neural networks with local and global attention. Yao et al. (2015) and Serban et al. (2016a) design hierarchical neural networks for multi-turn conversation.

To address the problem of universal replies, Li et al. (2016a) propose a mutual information training objective. Serban et al. (2016b) apply a variational Bayes approach that imposes a probabilistic distribution on the hidden variables and encodes the parameters of the posterior distribution. A very recent study similar to ours is Xing et al. (2016), where replies are augmented with topic information. In a dialogue-like question-answering system, Yin et al. (2016) query a knowledge base and insert a selected triple into an answer sentence by a soft logistic unit. In such approach, however, the answer may not actually appear in the generated sentence, especially when the test patterns are different from training ones. Unlike existing work, our seq2BF model guarantees the predicted keyword can appear in the reply at an appropriate position.

5 Conclusion and Future Work

In this paper, we proposed a content-introducing approach to generative short-text conversation systems. Instead of generating a reply sequentially from the beginning word to the end as in existing approaches, we used pointwise mutual information to predict a keyword, i.e., a noun term, for the reply. Then we proposed a "sequence to backward and forward sequences" (`seq2BF`) model to generate a reply containing the predicted keyword. The `seq2BF` mechanism ensures the keyword can appear at an arbitrary position in the reply, but the generated utterance is still fluent. Experimental results show that our approach consistently outperforms the pure `seq2seq` model in dialogue systems in terms of human evaluation and the entropy measure.

In future work, we would like to apply different keyword prediction techniques (e.g., neural sentence models) to improve the performance; the proposed `seq2BF` model can also be extended to other applications like generative question answering, where the answer may be given by searching an external database or knowledge base.

Disfluent but effective? A quantitative study of disfluencies and conversational moves in team discourse

Abstract

Situated dialogue systems that interact with humans as part of a team (e.g., robot teammates) need to be able to use information from communication channels to gauge the coordination level and effectiveness of the team. Currently, the feasibility of this end goal is limited by several gaps in both the empirical and computational literature. The purpose of this paper is to address those gaps in the following ways: (1) investigate which properties of task-oriented discourse correspond with effective performance in human teams, and (2) discuss how and to what extent these properties can be utilized in spoken dialogue systems. To this end, we analyzed natural language data from a unique corpus of spontaneous, task-oriented dialogue (CReST corpus), which was annotated for disfluencies and conversational moves. We found that effective teams made more self-repair disfluencies and used specific communication strategies to facilitate grounding and coordination. Our results indicate that truly robust and natural dialogue systems will need to interpret highly disfluent utterances and also utilize specific collaborative mechanisms to facilitate grounding. These data shed light on effective communication in performance scenarios and directly inform the development of robust dialogue systems for situated artificial agents.

1 Introduction

Effective coordination is fundamental to teamwork in many fields, particularly for teams working under stress. Though a variety of team structures exist, actions teams are among the most demanding, due to the need for the teammates to engage in goal-oriented, interdependent tasks, and to dynamically adapt their decision-making, communication, and planning strategies (Serfaty et al., 1993; Sundstrom et al., 2000). Recently, action teams have begun to incorporate artificial agents in mixed-initiative roles (see Sycara and Sukthankar (2006) for a thorough review). Such teams are largely employed in performance scenarios (e.g., search and rescue missions, military squads, surgical teams), and require strong team communication to achieve complex objectives in a time-sensitive context. Among the many elements needed for coordination in human-agent teams, perhaps the most important for team success is establishing *common ground*. Common ground is a mutual understanding between teammates, involving shared knowledge of the task environment, goals, perspectives, and other factors. For common ground to be established, it is important that teammates not only share information, but also ensure that the information was understood the way it was intended. This process, known as *grounding*, results in a mutual recognition by both parties of the shared information being a part of their common ground and forms the basis for coordination in both dialogue and action (Clark, 1996).

1.1 Task-oriented remote dialogue

Though there is no objective way to measure common ground, evidence for it may be found in the team communication channels. However, grounding in task-oriented remote communication is complicated by a number of factors, including time pressure/workload (Entin and Serfaty, 1999; Khawaja et

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3359–3369, Osaka, Japan, December 11-17 2016.

al., 2012; Urban et al., 1996), mode of interaction (Clark and Brennan, 1991; Doherty-Sneddon et al., 1997; Krauss and Weinheimer, 1966), and team structure (Bortfeld et al., 2001; Clark and Krych, 2004). Given the difficulty of grounding exchanges in task-oriented dialogue, it is not surprising that communication channels in remotely-communicating action teams are very noisy, often containing features such as disfluency, overlapping speech, and ambiguity.

Disfluencies are particularly interesting because they are very common in spontaneous speech, and have been implicated in various interpersonal and cognitive functions (Nicholson et al., 2003). One view holds that disfluencies are noise resulting from increased production difficulty due to cognitive workload. Several studies have found support for this view by showing that disfluency rates tend to increase with higher workload (Berthold and Jameson, 1999; Lindström et al., 2010). Another position is that disfluencies may not be solely due to workload, but may reflect underlying coordination processes such as monitoring one's addressee (Clark and Krych, 2004) or soliciting help in the dialogue (Bortfeld et al., 2001). In support of this view are studies showing that speakers detect and utilize disfluencies to help process surrounding speech (Brennan and Schober, 2001), resolve reference ambiguities (Arnold et al., 2007), hold the conversational floor (Smith and Clark, 1993), improve recall (Corley et al., 2007), and mark discourse structure (Swerts, 1998). Barr (2001) has likened disfluencies to a form of "vocal gestures" due to their ability to provide insight into a speaker's metacognitive state. Despite these findings, no prior studies have examined the role of speech disfluencies with regard to performance in an unscripted collaborative task. Thus, it remains unclear whether the interpersonal benefit of disfluency overrides the cognitive drawback also associated with disfluent speech. Moreover, most of the existing literature on the benefit of disfluency deals with filled pauses, whereas relatively little is known about other types, such as self-repairs. It is also unclear what types of coordination strategies (if any) successful teams use to overcome the various grounding constraints associated with task-oriented communication, and how these strategies interact with a team's ability to establish common ground. Our study was designed to address these gaps in the literature.

1.2 Present study

The present study consists of a quantitative investigation of factors that influence effective grounding and performance in remotely-communicating action teams. Given that grounding is often constrained by factors such as coordination strategy, speaker role, and time pressure/workload, our aim was to explore how these factors interact with team communication and, ultimately, performance. The data consisted of the linguistic- and dialogue-level annotations in the Cooperative Remote Search Task (CReST) corpus (Eberhard et al., 2010) obtained from unscripted communication between a (remotely-located) director and a searcher, who was located in an indoor environment and collaboratively performed a number of tasks involving objects in the environment (see Section 2 for more information). Since the task was specifically designed to simulate the structure of action teams in which a robot may play a vital role (e.g., urban search and rescue), the results can inform our understanding of the kinds of communication and coordination strategies that artificial agents will need to adopt to be effective partners in these hierarchical, mixed-initiative teams.

1.3 Predictions

One specific prediction is that effective teams would be those in which the director plays a greater role in managing the task, and searchers are the more receptive party. Additionally, effective teams will minimize *joint collaborative effort* (Clark and Wilkes-Gibbs, 1986) by establishing common ground with respect to objects and locations in the environment. Evidence for this would be the use of various communication strategies, including: establishing shared referents and shorthand conventions (Clark and Wilkes-Gibbs, 1986), completing one another's utterances (Clark and Schaefer, 1989), taking a partner's perspective (Brennan et al., 2010), and breaking up longer utterances into installments (Clark and Brennan, 1991).

Evidence of collaborative dialogue may also manifest in increased disfluency rate. Though some disfluent speech may be expected due to the difficult nature of the task, an increase in self-repairs may also indicate that a speaker is self-monitoring and adjusting their speech for clarity and accuracy (Clark and

Krych, 2004). In this way, self-repairs may serve to minimize collaborative effort by fixing a problematic utterance before one's partner needs to intervene (Levelt, 1983). This can minimize the number of dialogue turns and lead to more efficient exchanges. Thus, we predict that effective teams would make more disfluencies due to the need to plan and coordinate at higher speeds. Disfluencies would be mainly self-repairs caused by monitoring one's listener and dynamically adjusting one's speech to aid comprehension.

2 Method

The CReST corpus (Eberhard et al., 2010) was used to evaluate speech patterns in 10 teams (20 individuals) of people performing a collaborative, remote, search task. Approximately 8 minutes of language data were extracted for each team. Contained in the corpus is dialogue that occurred before and after a time-limit warning which allows us to examine the effects of time pressure. The corpus also provides an objective measure of the pairs' task performance, which we used to operationalize "effectiveness of communication". Additionally, the members of each team had asymmetrical roles, which we included as an additional factor. Lastly, the corpus was annotated for various linguistic and dialogue events in the speech, including conversational moves and disfluencies (see Eberhard et al. (2010) for additional details about the corpus).

2.1 Task description

The members of each pair were randomly assigned to the *Director* role and *Searcher* role. The director was seated in front of a computer that displayed a floor plan map of the search environment and wore a headset for remotely communicating with the searcher. The searcher also wore a headset and was situated in the search environment which consisted of a hallway and 6 connected office rooms. Neither was familiar with the environment. Distributed throughout the environment were 8 blue boxes, each with three colored blocks, 8 empty green boxes (numbered 1-8), 8 empty pink boxes, and a cardboard box that was at the furthest point from entrance at the end of a hallway. Some of the colored boxes were partially hidden behind a door, on a chair, under a table, etc.

The pairs were informed that the director's map showed the locations of all the boxes except the green ones and that the locations of some of the blue boxes were inaccurate. They were told that the searcher was to retrieve the cardboard box, put the blue blocks from the blue boxes into it, and report the locations of the green boxes to the director, who was to mark them on the map by dragging green icons numbered 1-8. They were told that instructions for the pink boxes would be given to them later. Five minutes into the task, the director's communication with the searcher was put on hold and the director was told that each blue box contained a yellow block which was to be put into each of the pink boxes. To examine effects of time pressure, the director also was told that they had 3 minutes to complete all of the objectives, and a timer that counted down the 3 minutes was displayed next to the map.

2.2 Disfluency annotation

Disfluencies were coded according to the HCRC Disfluency Coding Manual (Lickley, 1998), which includes categories for prolongations, pauses (filled and silent), and self-repairs: *repetitions* (e.g., "L-look in the box"), *substitutions* (e.g., "the pink- uh, blue box"), *insertions* (e.g., "go into the room- the nearby room") and *deletions* (e.g., "we don't have- let's hurry up"). Disfluency rates were calculated for each participant as a proportion per every 100 words. *Speech rate* (words per minute, or w.p.m.) and *mean length of utterance* (average number of words per turn at talk, or MLU) also were calculated.

All annotations were carried out using the open-source EXMARaLDA Partitur-Editor (Schmidt and Wörner, 2009). For extracting disfluency data from the annotated files, we used a custom-built search tool called DeepSearch9[1].

[1]Our custom search tool, DeepSearch9, will be made available for research purposes

2.3 Dialogue annotation

The transcribed utterances were hand-annotated for type of conversational move using Carletta et al. (1997)'s scheme. *Initiation* moves include Instruct, Explain, Wh- and Yes/No questions. Two other Initiation moves are subcategories of Yes/No questions, namely, Check and Align. Checks seek confirmation that one has correctly understood what the partner recently said, often by repeating or paraphrasing the partner's utterance. Aligns explicitly request confirmation that a partner has understood what was just said and is ready to move on. They typically are in the form of an "okay?" or "right?" appended to the end of an Instruct or Explain move. *Response* moves include Acknowledge, Wh-, Yes- and No- Replies. Utterance-initial "okays" and "alrights" were coded as *Ready* moves; they serve as a preparation for the following initiation move (e.g., "*Okay*, now go into the next room"). The rates of producing each type of move were calculated by dividing them by the total number of utterances.

2.4 Team effectiveness

Performance was scored with respect to the number of colored boxes whose task was completed, with a maximum score of 24. The average score was 9.9 (range 1 - 19) and the median was 8. The median score was used to divide the 10 teams into an *effective* and *ineffective* group with average scores of 14.8 (S.D. = 4.0) and 5.0 (S.D. = 2.5), respectively.

3 Results

To test our hypotheses of the factors that influence effective team communication, we examined differences in disfluency rate and dialogue moves between teams in the effective and ineffective performance groups. Time pressure and speaker role were used as factors in the analysis. Some relevant dialogues from the corpus are also discussed below to show the various communication and grounding strategies that teams used.

3.1 Grounding strategies

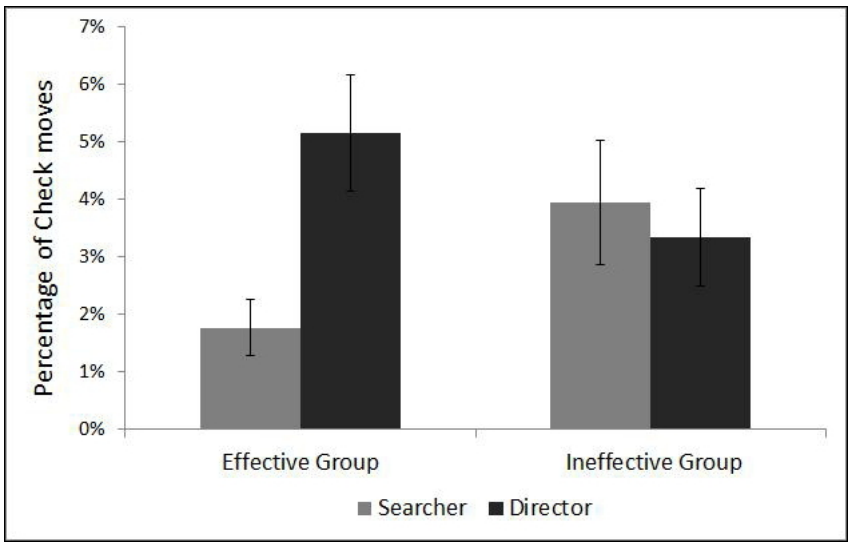

Figure 1: Group x Speaker interaction for Check moves. Error bars represent standard error of the mean.

First, we analyzed group differences in the dialogue moves to test our hypothesis that team effectiveness was related to successful grounding and collaboration. The rates of types of dialogue moves were analyzed with 2x2x2 mixed ANOVAs with Time Pressure and Speaker as within-subjects factors and Group as a between-subjects factors. There was a Group x Speaker interaction for *Check* moves ($F(1,32) = 7.053$, $p = .012$), with effective directors producing more than the ineffective directors, and ineffective searchers producing more than the effective searchers (see Fig. 1). The 3-way interaction was also significant in the analysis of the *Ready* moves ($F(1,32) = 4.657$, $p = .039$). Effective directors'

rate of *Ready* moves was higher than the effective searchers' with and without time pressure, whereas ineffective directors' rate of *Ready* moves decreased to the level of the ineffective searchers' under time pressure (see Fig. 2). Together, the results support our prediction that, compared to ineffective directors, effective directors sought confirmation of their searcher's understanding more often (*Check* moves) and maintained consistent control over the dialogue structure (*Ready* moves).

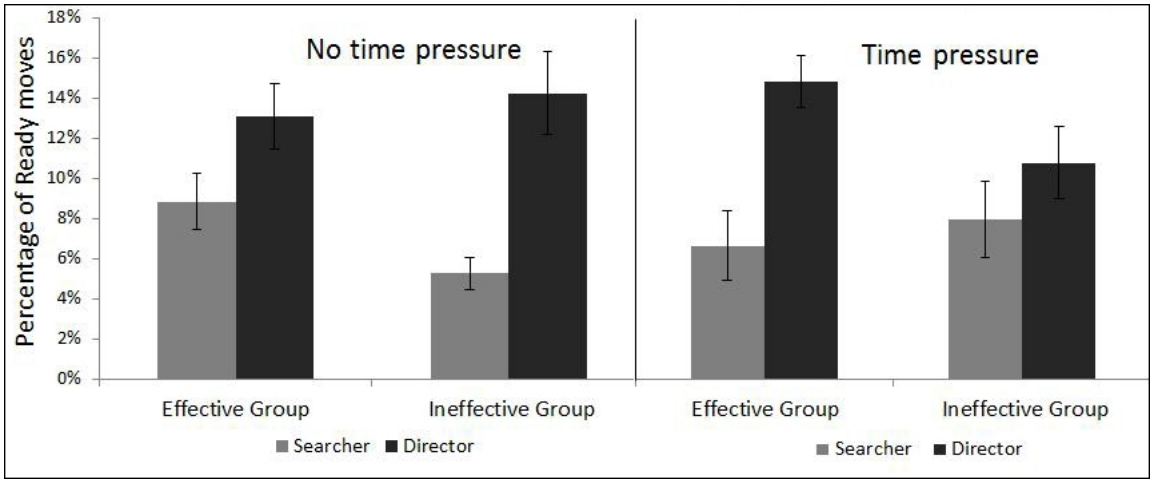

Figure 2: Group x Speaker x Time Pressure interaction for Ready moves. Error bars represent standard error of the mean.

One particular communication strategy used by effective teams was grounding of referents - particularly in room labeling. Since the rooms were not labeled on the map or in the environment, some of the teams developed and utilized a shorthand way to describe them to each other. Consider the following example from an effective team:[2]

D: Okay you're going into the next room
S: Room two
D: Room two, we'll say room two
S: Alright

This is an example of the searcher using a *replacement* (Clark and Wilkes-Gibbs, 1986) to ground a referent. The director initially said "next room", but the searcher proposed "room two" instead. Notice how the director agreed to this shorthand label, and then this was again confirmed by the searcher. This contribution served to establish "room two" as part of the team's common ground. They were able to use this later to minimize joint effort, as in:

S: I'm walking back into [pause] room two
D: Okay
—
S: I'm going back into room one
D: Okay room one, like the very first starting room?
S: Yeah
D: Okay

Here, the label "room one" was used by the searcher, although this was not previously established. The director initiated a *Check* utterance to confirm that they were talking about the same room. After

[2]In the dialogue examples, hyphens (-) indicate repaired segments, colons (:) indicate prolongations, and commas (,) indicate brief silent pauses, with longer pauses contained in brackets. For readability, the director will be referred to as male and the searcher as female in this and all subsequent dialogue examples.

confirmation by the searcher, the grounding was successful and the interaction continued along. Ineffective teams exhibited difficulty grounding referents as seen in the following example:

S: So green number 3 [pause] that was um
D: In the booth
S: Yeah that was in the- [pause] the little room
D: Where in the booth? Where?
S: It wasn't in the big room, it was in the little room, it was right next to the blue box on the chair

Here, the director referred to "the booth", while the searcher referred to a "little room". Since they did not establish common terminology for these referents, the team lost efficiency by taking additional turns.

Additional conversational turns were not always signs of inefficient coordination, however. For example, effective teams facilitated grounding by presenting a task subgoal in installments (Clark and Brennan, 1991) as illustrated here:

D: If you: turn around go out of that room
S: Okay
D: Straight in front of you should be a chair
S: Yes
D: At a table, there's a blue box there
S: Yes
D: Okay, get that

The searcher's acknowledgement following each installment allowed the director to continue on. This strategy also identifies the particular point of grounding difficulty, which is not possible when an entire subgoal is communicated in a single complex turn as illustrated by the following example from an ineffective team:

D: If you look completely straight- straight- straight [pause] like keep walking straight before you even hit the wall, there should be some shelving it looks like. Open the blue box there
S: Wait w- where- where? Sorry {laughs}

Overall, these results suggest that effective teams were better at coordinating their actions by using various dialogue moves and communication strategies to enhance grounding. Effective directors also played a central role in managing the task responsibilities, and sustained this initiative even under time pressure.

3.2 Disfluencies as collaborative tools

To test our hypothesis that disfluencies serve collaborative functions, we examined group differences in disfluency rate. A MANOVA was conducted on the rates of the four types of self-repairs, with Group and Time Pressure as factors. There was a significant effect of Group ($F(4,33) = 2.787$, $p = .042$) on rates of self-repair disfluencies (see Fig. 3): *Insertions* ($F(1,36) = 4.292$, $p = .046$), *Deletions* ($F(1,36) = 4.414$, $p = .043$), and a trending effect for *Substitutions* ($F(1,36) = 2.826$, $p = .101$). In all cases, the effective group had higher disfluency rates, which was not due to longer utterances because the groups' MLU did not differ ($F < 1$). For hesitation disfluencies, a MANOVA conducted on prolongations, filled- and silent-pauses found no effect of performance group on these disfluency measures ($F < 1$). This was expected because these disfluencies (especially filled pauses) were the most common in the corpus, and did not exhibit speaker differences in previous analyses (Nicholson et al., 2003). Overall, the finding that self-repairs increased for the effective teams supports our hypothesis that these types of disfluencies are not solely due to production difficulty, but rather may serve an interpersonal function.

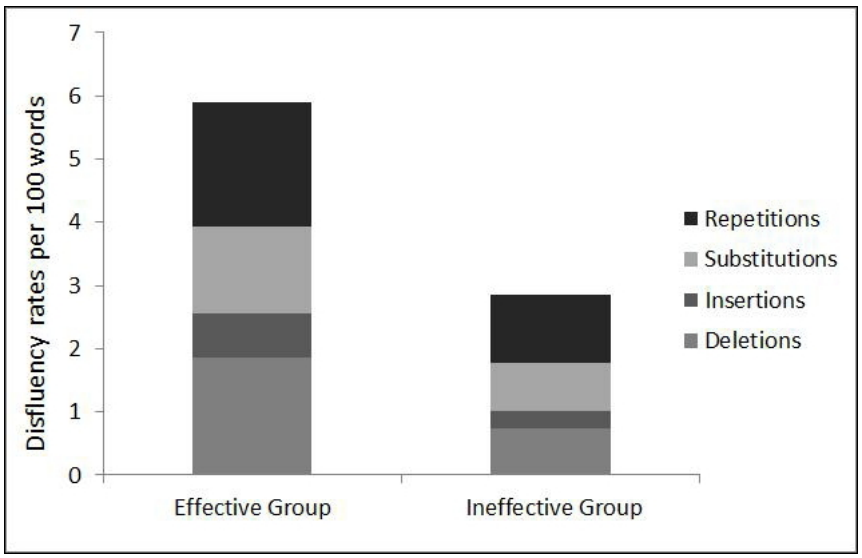

Figure 3: Group effect for disfluency rate

Examples from the corpus further show how disfluencies were used by effective teams as collaborative tools to enhance grounding. Consider the following dialogue exchange from one of the top performing teams under time pressure:

S: Yeah, there's one all the way to the right
D: Okay, you should see- you should [pause] be- go to that end hallway

The director's mixed substitution/deletion self-repair served to make the utterance more accurate and clear for the searcher. Since the director was unsure of exactly what the searcher was seeing, he repaired his utterance and changed it to an instruction that did not provide false information, and that was simpler to understand. This is in line with prior evidence (e.g., Clark and Wilkes-Gibbs (1986)) showing that self-repairs increase when people accommodate their partner's perspective.

Due to the fast-paced nature of the task, some searchers tended to "think out loud" and update their directors with new information as they obtained it. This naturally led to an increase in disfluency, as in the following example from an effective team:

S: But I'm out of- I'm out of- uh [pause] actually, there's a blue one to my left
D: Yes there should be- yes pick that up

In this exchange, the searcher started to say that she is out of blocks, but then changed this mid-sentence (via deletion disfluency) to share new information ("there's a blue one to my left"). Similarly, the director used a substitution to confirm the prior utterance ("yes there should be") and also as a new instruction ("yes pick that up"). The disfluencies here maximized the information that each speaker shared in a single turn, leading to increased efficiency under time pressure.

Effective teams were also able to resolve reference ambiguities through the use of disfluencies, as in the following example:

D: There's also one in the second- [pause] uh, we only have three minutes to do this, okay
S: Okay, second cubicle I got that

Here, the searcher was able to predict that the director was referring to the cubicle, even though this was part of the deleted reparandum, and the word "cubicle" was not even explicitly uttered. The silent pause combined with the non-lexical filler "uh" may have signaled that the director was referring to an object, namely, the cubicle. Despite the fact that this segment of the utterance was deleted, the

searcher was still able to resolve the intended referent by drawing on the mutual knowledge that both teammates share a similar floor plan of the room.

For effective teams in the study, the benefit of clarifying an utterance may have outweighed the cost of disfluent speech because it is cheaper for a person to repair their own speech rather than to have a partner do it for them (Levelt, 1983). In cases where an error was not self-repaired (such as the miscommunication of an important goal), this could have led to misinformation resulting in confusion or loss of efficiency. As a whole, these data suggest that self-repairs served as collaborative tools in the discourse, and were utilized by effective teams to enhance coordination and performance.

4 Discussion

4.1 Summary of results

Overall, the results of our investigation revealed a number of novel effects of disfluencies and dialogue moves in task-oriented remote communication. In our analysis of dialogue moves, we found that the best performing directors used more Check utterances than the ineffective directors (see Fig. 1). Check utterances are used as a means to gauge a partner's understanding, and are especially useful for reducing uncertainty when interlocuters are remotely separated and need to establish shared knowledge. Effective directors also produced more Ready utterances under time pressure than ineffective directors (see Fig. 2), indicating that they showed receptiveness to their partner and maintained control over guiding the team through the changing task conditions. We also observed that more effective teams produced twice as many self-repair disfluencues as the less effective teams. Although previous studies have demonstrated some effects of disfluency on dialogue (Arnold et al., 2007; Brennan and Schober, 2001), ours is the first to link these effects with improved performance in a joint task involving spontaneous speech. Our results indicate that effective teammates were monitoring their own speech and repairing it for clarity and accuracy in order to accommodate their partner's perspective and facilitate grounding. In this way, disfluencies suggest a greater team awareness, which may have contributed to improved performance (see Fig. 3). Overall, the ability to establish common ground through collaborative exchanges seemed to be the key factor in effective team performance. Effective teams were able to accomplish this through particular communication strategies that involved: self-monitoring one's speech for clarity (e.g., self-repairs), being responsive to one's teammate (e.g., Ready moves), as well as monitoring them for understanding (e.g., Check moves).

4.2 Application to spoken dialogue systems

Our results shed light on task-oriented communication and directly inform the development of robust dialogue systems that rely on interactive, collaborative mechanisms. It is important that such systems are able to utilize the information contained in team discourse to gain insight into speakers' cognitive and performance states, and to make better predictions about the course of the interaction. Specifically, the finding that self-repairs are strong indicators of collaborative processes and are increasingly utilized in effective teams, suggests that the detection and interpretation of speech disfluency can be of great benefit to dialogue systems. While there have been numerous approaches to automated disfluency detection (many of which used statistical models trained on the Switchboard corpus, e.g., Qian and Liu (2013)), our findings suggest that these approaches lack several specific components needed for use in robust dialogue systems, including: (1) incremental, on-line processing, (2) identifying the function of the repair, (3) use of the repair to make predictions about subsequent dialogue, (4) use of additional non-linguistic information in the model (e.g., speaker role, cognitive state, etc.), and (5) generalizing to domains other than two-party telephone conversations. While some existing systems attempt to solve these problems individually (e.g., domain generality: Georgila et al. (2010); repair function: Hough et al. (2013); incrementality: Zwarts et al. (2010)), no current approach combines these elements into a unified system. Such an integrated approach is important going forward because it will allow systems to handle the kinds of natural utterances that people make in task-oriented discourse.

Importantly, our findings also highlight the need for dialogue systems to handle incremental input. Given the abundance of time-sensitive information that can be extracted from discourse channels (dis-

fluency, turn-taking, back-channel feedback, etc.), this is an important next step to improve dialogue processing. Though some progress has recently been made on dialogue managers that can handle incremental semantic input (Buß et al., 2010; Schlangen et al., 2009), there has been little to no work on integrating these mechanisms with the planning and reasoning (not to mention vision and motor) capabilities of artificial agents that coordinate their actions with humans. This is a necessary step in order to test the benefit of the collaborative mechanisms our study revealed, and to advance the state of the art of spoken dialogue systems.

4.3 Future directions

Future work will be necessary on both the experimental and computational ends. Future studies will need to evaluate larger samples that are carefully controlled for variables that might influence performance (e.g., gender, age, familiarity, etc.). In addition, workload will need to be objectively measured in order to determine if the effects of time pressure were experienced differently by teams of varying performance. An objective workload measure will also allow for investigation into the *cause* of speech disfluency, specifically in terms of whether it is due to task demands or to intentional signaling (Nicholson et al., 2003).

On the computational end, our results support the development of spoken dialogue systems that can track various dimensions of "team cohesion" based on discourse measures. Such systems can be used in team training exercises in order to identify when a team is under-performing, to find areas of weakness, and to improve overall coordination. An artificial agent with such capacity can also take appropriate actions to repair a problematic interaction through a range of strategies (e.g., *Check* and *Ready* moves, frequent acknowledgments, establishing shared referents, etc.) that we and others found to minimize joint collaborative effort. As a whole, these abilities would improve on the capabilities of existing dialogue systems, and would enable artificial agents to function as more effective teammates.

5 Conclusions

This first study connecting spontaneous speech, dialogue, and task performance supports previous literature and introduces novel findings about the effects of self-repair disfluencies and dialogue moves on coordination and performance in remotely-communicating action teams. The best-performing teams in our study utilized a variety of communication strategies to enhance coordination, including monitoring for understanding, perspective-taking, self-repairs and others. Importantly, we showed that these strategies can be identified by discourse properties available in team communication channels. Applying these empirical results to spoken dialogue systems is an important future direction that can lead to more natural and improved human-agent interaction. By better understanding effective team communication we can design more robust systems that take advantage of the kinds of interactive, collaborative mechanisms inherent in dialogue, to improve coordination and performance in all kinds of human teams.

A Neural Network Approach for Knowledge-Driven Response Generation

Abstract

We present a novel response generation system. The system assumes the hypothesis that participants in a conversation base their response not only on previous dialog utterances but also on their background knowledge. Our model is based on a Recurrent Neural Network (RNN) that is trained over concatenated sequences of comments, a Convolution Neural Network that is trained over Wikipedia sentences and a formulation that couples the two trained embeddings in a multimodal space. We create a dataset of aligned Wikipedia sentences and sequences of Reddit utterances, which we we use to train our model. Given a sequence of past utterances and a set of sentences that represent the background knowledge, our end-to-end learnable model is able to generate context-sensitive and knowledge-driven responses by leveraging the alignment of two different data sources. Our approach achieves up to 55% improvement in perplexity compared to purely sequential models based on RNNs that are trained only on sequences of utterances.

1 Introduction

Over the recent years, the level of users' engagement and participation in public conversations on social media, such as Twitter, Facebook and Reddit has substantially increased. As a result, we now have large amounts of conversation data that can be used to train computer programs to be proficient conversation participants. Automatic response generation could be immediately deployable in social media as an auto-complete response suggestion feature or a conversation stimulant that adjusts the participation interest in a dialogue thread (Ritter et al., 2011). It should also be beneficial in the development of Question-Answering systems, by enhancing their ability to generate human-like responses (Grishman, 1979).

Recent work on neural networks approaches shows their great potential at tackling a wide variety of Natural Language Processing (NLP) tasks (Bengio et al., 2003; Mikolov et al., 2010). Since a conversation can be perceived as a sequence of utterances, recent systems that are employed in the automatic response generation domain are based on Recurrent Neural Networks (RNNs) (Sordoni et al., 2015; Shang et al., 2015; Vinyals and Le, 2015), which are powerful sequence models. These systems base their generated response explicitly on a sequence of the most recent utterances of a conversation thread. Consequently, the sequence of characters, words, or comments, in a conversation, depending on the level of the model, is the only means with which these models achieve contextual-awareness, and in open-domain, realistic, situations it often proves inadequate (Vinyals and Le, 2015).

In this paper we address the challenge of context-sensitive response generation. We build a dataset that aligns knowledge from Wikipedia in the form of sentences with sequences of Reddit utterances. The dataset consists of sequences of comments and a number of Wikipedia sentences that were allocated randomly from the Wikipedia pages to which each sequence is aligned. The resultant dataset consists of $\sim$ 15k sequences of comments that are aligned with $\sim$ 75k Wikipedia sentences. We make the aligned corpus available at `github.com/pvougiou/Aligning-Reddit-and-Wikipedia`.

We propose a novel model that leverages this alignment of two different data sources. Our architecture is based on coupling an RNN using either Long Short-Term Memory (LSTM) cells (Hochreiter and

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3370–3380, Osaka, Japan, December 11-17 2016.

Schmidhuber, 1996) or Gated Recurrent Units (GRUs) (Cho et al., 2014) that processes each sequence of utterances word-by-word, and a Convolutional Neural Network (CNN) that extracts features from each set of sentences that corresponds to this sequence of utterances. We pre-train the CNN component (Kim, 2014) on a subset of the retrieved Wikipedia sentences in order to learn filters that are able to classify a sentence based on its referred topic. Our model assumes the hypothesis that each participant in a conversation bases their response not only on previous dialog utterances but also on their individual background knowledge. We use Wikipedia[1] as the source of our model's knowledge background and align Wikipedia pages and sequences of comments from Reddit[2] based on a predefined topic of discussion.

Our work is inspired by recent developments in the generation of textual summaries from visual data (Socher et al., 2014; Karpathy and Li, 2014). Our core insight stems from the idea that a system that is able to learn how to couple information from aligned datasets in order to produce a meaningful response, would be able to capture the context of a given conversation more accurately.

Our model achieves up to 55% improved perplexity compared to purely sequential equivalents. It should also be noted that our approach is domain independent; thus, it could be transferred out-of-box to a wide variety of conversation topics.

The structure of the paper is as follows. Section 2 discusses premises of our work regarding both automatic response generation and neural networks approaches for Natural Language Processing (NLP). Section 3 presents the components of the network. Section 4 describes the structure of the dataset. Section 5 discusses the experiments and the evaluation of the models. Section 6 summarises the contributions of the current work and outlines future plans.

2 Related Work

Since Bengio's introduction of neural networks in statistical language modelling (Bengio et al., 2003) and Mikolov's demonstration of the extreme effectiveness of RNNs for sequence modelling (Mikolov et al., 2010), neural-network-based implementations have been employed for a wide variety of NLP tasks. In order to sidestep the *exploding* and *vanishing gradients* training problem of RNNs (Bengio et al., 1994; Pascanu et al., 2012), multi-gated RNN variants, such as the GRU (Cho et al., 2014) and the LSTM (Hochreiter and Schmidhuber, 1996), have been proposed. Both GRUs and LSTMs have demonstrated state-of-the-art performance for many generative tasks, such as SMT (Cho et al., 2014; Sutskever et al., 2014), text (Graves, 2013) and image generation (Gregor et al., 2015).

Despite the fact that CNNs had been originally employed in the computer vision domain (LeCun et al., 1998), models based on the combination of the convolution operation with the classical Time-Delay Neural Network (TDNN) (Waibel et al., 1989) have proved effective on many NLP tasks, such as semantic parsing (Yih et al., 2014), Part-Of-Speech Tagging (POS) and Chunking (Collobert and Weston, 2008). Furthermore, sentence-level CNNs have been used in sentiment analysis and question type identification (Kalchbrenner et al., 2014; Kim, 2014).

The concept of a system capable of participating in human-computer conversations was initially proposed by Weizenbaum (Weizenbaum, 1966). Weizenbaum implemented ELIZA, a keyword-based program that set the basis for all the descendant *chatterbots*. In the years that followed, many template-based approaches (Isbell et al., 2000; Walker et al., 2003; Shaikh et al., 2010) have been suggested in the scientific literature, as a way of transforming the computer into a proficient conversation participant. However, these approaches usually adopt variants of the nearest-neighbour method to facilitate their response generation process from a number of limited sentence paradigms and, as a result, they are limited to specific topics or scenarios of conversation. Recently, models for Statistical Machine Translation have been used to generate short-length responses to a conversational incentive from Twitter utterances (Ritter et al., 2011). In the recent literature, RNNs have been used as the fundamental component of conversational response systems (Sordoni et al., 2015; Shang et al., 2015; Vinyals and Le, 2015). Even though these systems exhibited significant improvements over SMT-based methods (Ritter et al., 2011), they either adopt the length-restricted-messages paradigm or are trained on idealised dataset that undermines the

[1] http://www.wikipedia.com
[2] https://www.reddit.com

generation of responses in open domain realistic scenarios.

We propose a novel architecture for context-sensitive response generation. Our model is trained on a dataset that consists of realistic sequences of Reddit comments that aligned with sets of Wikipedia sentences. We use an RNN and a CNN components to process the sequence of comments and their corresponding set of sentences respectively and we introduce a learnable coupling formulation. The coupling formulation is inspired by the Multimodal RNN that generates textual description from visual data (Karpathy and Li, 2014). However, unlike Karpathy's approach, we do not allow the feature that is generated by the CNN component to diminish between distant timesteps (i.e. Section 3.3).

3 Our Model

Our task is to generate a context-sensitive response to a sequence of comments by incorporating background knowledge. The proposed model is based on the assumption that each participant in a conversation phrases their responses by taking into consideration both the past dialog utterances and their individual knowledge background. We train the model on a set of M sequences of Reddit comments and N summaries of Wikipedia pages that are related to the main discussed topic of a conversation. During training our models takes as an input a sequence of one-hot[3] vector representations of words $x_1, x_2, ..., x_T$ from a sequence of comments and a group of sentences S that is aligned with this sequence of utterances. We use a sentence-level CNN, which processes the group of sentences, in parallel with a word-level RNN that processes the sequence of comments in batches and propose a formulation that learns to couple the two networks to produce a meaningful response to the preceding comments. We experiment with two different commonly used RNN variants that are based on: (i) the LSTM cell and (ii) the GRU. We pre-train our CNN sentence model on a subset of the Wikipedia-sentences dataset in order for it to learn to classify a sentence based on the topic-keyword that was matched for its corresponding page acquisition.

Please note that since *bias* terms can be included in each weight-matrix multiplication (Bishop, 1995), they are not explicitly displayed in the equations that describe the models of this section.

3.1 Sentence Modelling

Models based on CNNs achieve their basic functionality by convolving a sequence of inputs with a set of filters in order to extract local features. We adopt the Convolutional Sentence Model from (Kim, 2014) and we expand it in order to meet our specific needs for a multi-class, rather than binary classification. Let $t_{1:l}$ the concatenation of the vectors of all the words that exist in a sentence s. A *narrow* type convolution operation with a filter $m \in \mathbb{R}^{k \times m}$ is applied to each m-gram in the sentence s in order to produce a *feature map* $\mathbf{c_{mf}} \in \mathbb{R}^{l-m+1}$ of features:

$$c_{mf_j} = tanh(m^T t_{j-m+1:j}) \ , \tag{1}$$

$$\mathbf{c_{mf}} = \begin{bmatrix} c_{mf_1} \\ \vdots \\ c_{mf_3} \end{bmatrix} \ , \tag{2}$$

with $l \geq m$. Shorter sentences are *padded* with zero vectors when necessary. The most relevant feature from each feature map is captured by applying the max-over-time pooling operation (Collobert and Weston, 2008). The consequent matrix is the result of concatenating the max values from each feature map that has been produced by applying an f number of m length filters over the sentence s. The network results in a fully-connected layer and a $softmax$ that carries out the classification of the sentences. The architecture of the sentence model is illustrated on the left side of Figure 1.

3.2 Sequence Modelling

We describe two commonly used RNN variants that are based on: (i) the LSTM cell and (ii) the GRU. We experiment with both of them in order to explore which one serves better the sequential-modelling

[3]Each x_t refers to the one-hot representation vector of a vocabulary token. One-hot is a vector that contains a 1 at the index of this particular x_t token in the vocabulary with all the other values set to zero.

needs of our full architecture.

Let $h_t^l \in \mathbb{R}^n$ be the aggregated output of a hidden unit at timestep $t = 1...T$ and layer depth $l = 1...L$. The vectors at zero layer depth, $h_t^0 = \mathbf{W_{x \rightarrow h}} x_t$, represent vectors that are given to the network as an input. The parameter matrix $\mathbf{W_{x \rightarrow h}}$ has dimensions $[|X|, n]$, where $|X|$ is the cardinality of all the potential one-hot input vectors. All the matrices that follow have dimension $[n, n]$.

3.2.1 Long Short-Term Memory

Our LSTM cells' architecture is adopted from (Zaremba and Sutskever, 2014):

$$in_t^l = sigm(\mathbf{W_{in}^l} h_t^{l-1} + \mathbf{W_{h \rightarrow in}^l} h_{t-1}^l) \ , \tag{3}$$

$$f_t^l = sigm(\mathbf{W_f^l} h_t^{l-1} + \mathbf{W_{h \rightarrow f}^l} h_{t-1}^l) \ , \tag{4}$$

$$cell_t^l = f_t^l \odot cell_{t-1}^l + in_t^l \odot tanh(\mathbf{W_{cell}^l} h_t^{l-1} + \mathbf{W_{h \rightarrow cell}^l} h_{t-1}^l) \ , \tag{5}$$

$$out_t^l = sigm(\mathbf{W_{out}^l} h_t^{l-1} + \mathbf{W_{h \rightarrow out}^l} h_{t-1}^l) \ , \tag{6}$$

$$h_t^l = out_t^l \odot tanh(cell_t^l) \ , \tag{7}$$

where in_t^l, f_t^l, out_t^l and $cell_t^l$ are the vectors at timestep t and layer depth l that correspond to the *input gate*, the *forget gate*, the *output gate* and the *cell* respectively.

3.2.2 Gated Recurrent Unit

The Gated Recurrent Unit was proposed as a less-complex implementation of the LSTM (Cho et al., 2014).

$$reset_t^l = sigm(\mathbf{W_{reset}^l} h_t^{l-1} + \mathbf{W_{h \rightarrow reset}^l} h_{t-1}^l) \ , \tag{8}$$

$$update_t^l = sigm(\mathbf{W_{update}^l} h_t^{l-1} + \mathbf{W_{h \rightarrow update}^l} h_{t-1}^l) \ , \tag{9}$$

$$\widetilde{h_t^l} = tanh(\mathbf{W_{in}^l} h_t^{l-1} + \mathbf{W_{h \rightarrow h}^l} (reset_t^l \odot h_{t-1}^l)) \ , \tag{10}$$

$$h_t^l = (1 - update_t^l) \odot h_{t-1}^l + update_t^l \odot \widetilde{h_t^l} \ , \tag{11}$$

where $reset_t^l$, $update_t^l$ and $\widetilde{h_t^l}$ are the vectors at timestep t and layer depth l that represent the values of the *reset gate*, the *update gate* and the *hidden candidate* respectively.

3.3 Coupling

After the pre-training of the CNN is complete, and the fully-connected and $softmax$ layers are removed, the CNN is connected to the hidden units of the last layer L of the recurrent component. This is illustrated in Figure 1. The recurrent component is implemented with either LSTMs or GRUs. At each timestep, the RNN is processing a word from a sequence of comments and the CNN is extracting local features by convolving this sequence's corresponding sentences with groups of differently sized filters. The red-coloured edges in Figure 1 represent the learnable parameters during training.

The coupling formulation that follows is inspired by the Multimodal RNN that generates textual description from visual data (Karpathy et al., 2014). Since, we do not want to allow the effect of sentence features, which represent the background knowledge of our model, to diminish between distant timesteps we differentiate from Karpathy's approach; and instead of providing the feature that is generated by the CNN to the RNN only at the first timestep, we provide it at every timestep. Furthermore, Karpathy employs the *simple* RNN or Elman network (Elman, 1990) as the sequence modelling component of his architecture whereas we adopt multi-gated RNN variants.

It should be noted that in the equations that follow, the term $CNN_h \in \mathbb{R}^{\sum \mathbb{MF}}$ would refer to the output of the sentence-level CNN with its fully-connected and $softmax$ layers disconnected, where $\mathbb{MF}$ is the group of all the feature maps that are generated for each different filter size. During training the resultant embeddings, which are computed by the CNN_h processing a group of sentences S and the RNN variant

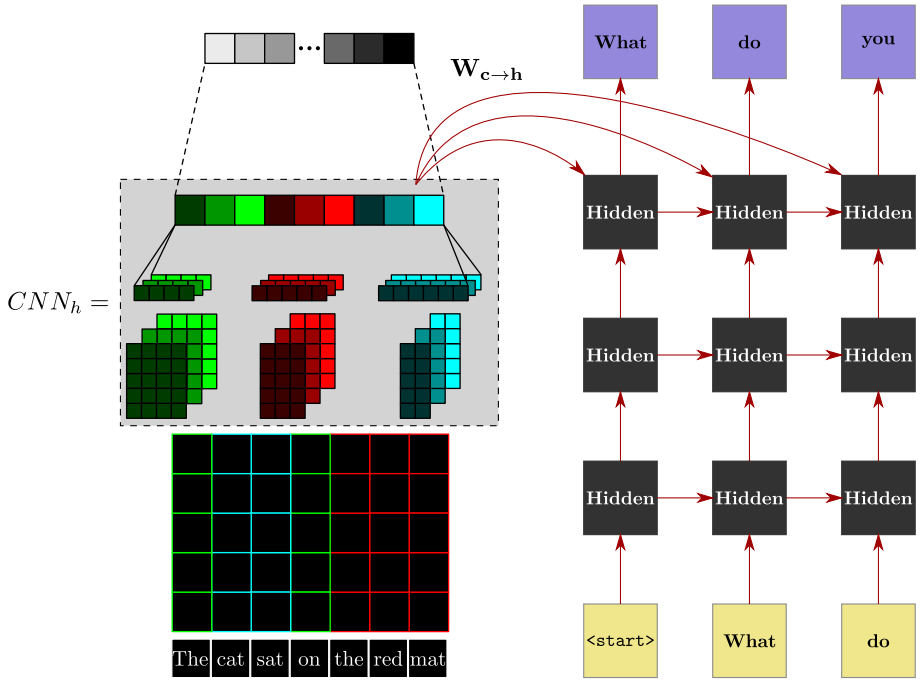

Figure 1: The architecture of our generative model. At each timestep, the RNN is processing a word from a sequence of comments and the CNN_h is extracting local features by convolving this sequence's corresponding sentences with a set of three differently sized filters. The red-coloured edges are the learnable parameters during training. Each comment in a sequence is augmented with start-of-comment `<start>` and end-of-comment `<end>` tokens.

processing the sequence of one-hot input word vectors $x_1, x_2, ..., x_T$ from the corresponding sequence of comments, are coupled in a hidden state $h_1, h_2, ..., h_T$. The prediction for the next word is computed by projecting this hidden state h_t to sequence of outputs $y_1, y_2, ..., y_T$:

$$c_S = \mathbf{W_{c \to h}} CNN_h(S) \ , \tag{12}$$

$$h_t = h_t^L \odot c_S \ , \tag{13}$$

$$y_t = softmax(\mathbf{W_y} h_t). \tag{14}$$

4 Dataset

We create a dataset[4] of aligned sentences from Wikipedia and sequences of utterances from Reddit. A shared, fixed, vocabulary was used for both data sources. We treat Wikipedia as a "cleaner" data source and we formed our vocabulary in the following manner. First, we included all the words that occur 2 or more times in the Wikipedia sentences. Subsequently, from the Reddit sequences of comments, we included any words that occur at least 3 times across both data sources. The resultant shared dictionary includes 56280 of the most frequent words. Every out-of-vocabulary word is represented by a special `NaN` token.

In constructing our dataset, our goal is to align Wikipedia sentences with sequences of comments from Reddit. We found that topics related to philosophy and literature are discussed on Reddit with the exchange of longer and more elaborative messages than the responses of the majority of conversational subjects on social media. A dataset that consists of long and detailed responses would provide more room for conversation incentives and would allow us to investigate the performance of our architectures against dialog exchanges with longer comments. We compiled a list of 35 predetermined topic-keywords from the philosophical and literary domain. By utilising the `search` feature of both the Reddit API[5]

[4] `github.com/pvougiou/Aligning-Reddit-and-Wikipedia`
[5] reddit.com/dev/api

and the MediaWiki API[6], we extracted: (i) sequences of comments from conversational threads most related to each keyword and (ii) the 300 Wikipedia pages most related to each keyword after carrying out Wikipedia's automatic disambiguation procedure. In order to increase the homogeneity of the dataset in terms of the length of both the sequences of comments and the sentences, we excluded sequences and sentences whose length exceeded: (i) $\overline{len} - \sigma = 1140$ and (ii) $\overline{len} - 2 \cdot \sigma = 54$ words respectively. The resultant dataset consists of 15460 sequences of Reddit comments and 75100 Wikipedia sentences.

4.1 Reddit

Reddit is absolved from the length-restricted-messages paradigm, facilitating the generation of longer and more meaningful responses. Furthermore, Reddit serves as an openly-available question-answering platform. Our research hypothesis is that a neural network trained on sequences of questions and their corresponding answers will be able to generate responses that escape the concept of daily-routine expressions, such as "good luck" or "have fun", and facilitate a playground for more detailed and descriptive dialogue utterances.

Each different conversation on Reddit starts with a user submitting a *parent-comment* on a subreddit. A sequence of utterances then succeeds this parent comment. Since we wanted to investigate how our model performs against long-term dependant dialog components, we set the depth of conversation to 5. Starting from the parent-comment, we follow the direction of the un-ordered tree of utterances until the fourth-level child-comment. If a comment (node) leads to n responses (children), we copy the observed sequence n times and for each sequence, we continue until the fourth response (leaf). Based on the above structural paradigm, we extracted sequences with at least four children-comments, of which we retained the only first four utterances along with the original parent-comment of the sequence. Note that each comment in a sequence is augmented with the respective start-of-comment `<start>` and end-of-comment `<end>` tokens.

Topic	Reddit Sequence of Comments	Wikipedia Sentences
Noam Chomsky	<start> Noam Chomsky: Bernie Sanders is Not a Radical. He has Mass Support for Positions on Healthcare & Taxes <end> <start> Funny, because Bernie Sanders's idol Eugene Debs ran against FDR <end> <start> Maybe Clinton will be FDR <end> <start> Watch out, Japanese. <end> <start> Japanese You misspelled Syrians <end>	For Chomsky, there are minimalist questions but the answers can be framed in any theory. ⋮ Minimalism in structured writing or topic-based authoring is based on the ideas of John Millar Carroll. Minimalism is about reducing the interference of the information with the users sense-making process. An error, in fact, is the teachable moment that the content can exploit.

Table 1: Example of the alignment of our dataset. One sequence of comments is coupled with a set of sentences. The sentences are randomly allocated from the Wikipedia pages which have been extracted based on the same search term (**Noam Chomsky**) as the corresponding sequence.

4.2 Wikipedia

Wikipedia sentences are used as the knowledge background of our model. We chose to include only sentences from the Wikipedia summaries, since in preliminary experiments, we found that including all the textual material of a page introduces a lot of noise to our data. The 13410 Wikipedia summaries that matched the search criteria were split into sentences. Each sentence was labelled with the initial topic-keyword that was matched for its corresponding page acquisition. A subset of 30000 labelled sentences was used for pre-training the CNN component of our architecture.

[6] mediawiki.org/wiki/API:Main_page

4.3 Dataset Alignment

We choose to align each sequence of Reddit utterances with 20 Wikipedia sentences. Both the Wikipedia pages to which the sentences correspond and the sequence of comments have been extracted using the same search-term. An example of the structure of the dataset is displayed in Table 1.

5 Experiments

The full network was regularised by introducing a dropout (Zaremba et al., 2014) value of 0.4 to the non-recurrent connections between the last hidden state, h_t, and the softmax layer of the network. In order to avoid any potential exploding gradients training problems, we enforce an l_2 constraint on the gradients of the weights in order for them to be no greater than 5 (Sutskever et al., 2014).

- The CNN component is trained with narrow convolutional filters of widths 3, 4, 5 and 6, with 300 feature maps each. We use the rectifier as activation function. All of the parameters were initialised with a random uniform distribution between -0.1 and 0.1. The network was trained for 10 epochs using stochastic gradient descent with a learning rate of 0.2. We regularised the network by introducing a dropout (Hinton et al., 2012) value of 0.7 to the connections between the pooling and the softmax layer of the network.

- For the recurrent component of our networks, we use 2 layers of (i) 1000 LSTM cells and (ii) 1000 GRUs, resulting in approximately 16M and 12M recurrent connections respectively. All of the parameters are initialised with a random uniform distribution between -0.08 and 0.08. The networks were trained for 10 epochs, using stochastic gradient descent with a learning rate of 0.5. After the 7th epoch in the LSTM case and 3rd epoch in the GRU case, the learning rate was decayed by 0.2 every half epoch.

The dataset is split into training, validation and test with respective portions of 80, 10 and 10. A sample of responses that is generated by our proposed systems is shown in Table 2.

5.1 Experimental Results

Examples of responses that are generated by our proposed systems and their respective purely sequential equivalents are shown in Table 2. The sequences of comments and their corresponding sentences are sampled randomly from the test set. Our architectures learn to couple information that exists in the sequence of comments with knowledge that is contained in the Wikipedia sentences and is, potentially, related to context of those comments.

When a piece of information in the sequence of comments is successfully aligned with the content of its corresponding Wikipedia sentences a knowledgeable, context-sensitive response is generated. A representative example of this functionality is provided in the last sequence of comments in Table 2, where the context of the sequence is coupled with the fact that *Chomsky supported Bernie Sanders in the United States presidential election* (i.e. from the allocated to that sequence of Reddit utterances Wikipedia sentence: "In late 2015, Chomsky announced his support for Vermont U.S. senator Bernie Sanders in the upcoming 2016 United States presidential election."[7]). In case no information alignment is identified between the content of the sequence of comments and the Wikipedia sentences, the generation procedure is based almost explicitly on the sequence of utterances, and a response is generated in a similar to the purely sequential models' fashion.

5.2 Automatic Evaluation

We use perplexity on the test set to evaluate our proposed models against their purely sequential equivalents. Perplexity measures the cross-entropy between the predicted sequence of words and the actual, empirical, sequence of words. The results are illustrated in the top part of Table 3. Our proposed architectures achieve 55% and 45% improvement in perplexity compared to their respective purely LSTM- and GRU-based equivalents.

Sequence of Comments	<start> My grandfather had a miniature set of all of Shakespeare's plays. It's 111 years old. <end> <start> Had? What happened to them? <end> <start> Less what happened to them, more what happened to him. <end> <start> I may have gone to your grandfather's estate sale. <end> <start> Literally as far away as you could be and stay in the same country. Also, we aren't having an estate sale. <end>	<start> Stephen Colbert & Stephen King <end> <start> This post made me realise that King played Bachman in Sons of Anarchy. He was fantastic in the role as well. <end> <start> Fun Fact: Stephen King writes under the pseudonym "Richard Bachman". <end> <start> Fun Fact: Richard NaN cause of death, per his creator, was "cancer of the pseudonym, a rare form of NaN." <end> <start> [Oh, here's a fun fact:] <end>
LSTM	<start> I don't. <end>	NaN.
GRU	<start> You are not so bad. <end>	<start> I meant that I was the one that was the first time to point. <end>
LSTM Coupled With ConvNet	<start> I was thinking the same. I saw it as a kid and I found Shakespeare and I was working in the head for a long time. <end>	<start> I was just thinking the same thing. <end>
GRU Coupled With ConvNet	<start> I don't know what I heard. <end>	<start> I remember searching for other people [spoiler] ("Apparently nothing is not "in" the books"). My personal favorite authors, not a whole story, but as a try to cause it to me. <end>
Sequence of Comments	<start> Can you write a six word story? According to legend, Ernest Hemingway once won a bet by writing a six word story comprised of these words: For sale. Baby shoes. Never worn. What's the best six word story you can write? Mine is, "She lied about having the procedure." <end> <start> I came; I saw; I conquered. <end> <start> "Veni, vidi, vici" said it better <end> <start> A better love story than twilight <end> <start> I'm fucking tired of this joke. <end>	<start> Noam Chomsky: The US would be recognized as a top terrorist state if international law was applied. <end> <start> You're not connecting the dots enough. The "regular" America gets cheap goods and oil through the bellicose actions of the "harsh" America. Now increasingly the actions of "harsh" America tend to benefit a tiny subset of the American people, but let's not pretend like our actions around the world don't have a multitude of practical effects on the American people as a whole. <end> <start> The thinking that if we didn't oppress people around the globe we wouldn't be able to maintain our lifestyle is misguided at best. <end> <start> So you're saying there's no economic benefit to our actions? I think you're mistaken. <end>
LSTM	<start> I think the "cause" is a good idea. <end>	<start> I don't think you are saying that it is a good idea. <end>
GRU	<start> No, it's not. <end>	<start> I would say that the "best" in the way we could have to do, and it is a big one. <end>
LSTM Coupled With ConvNet	<start> I don't think it's a mischaracterization to attribute this man's suicide to paranoia brought on by shady government surveillance. He was depressed, probably because of the holy few stories, the first step is to not like the world of his relationships, because he talks to the first one. <end>	<start> I don't think the majority of society has nothing to do with Sanders terrorism. <end>
GRU Coupled With ConvNet	<start> I think some of his memories was a family. <end>	<start> This is very radical I think Chomsky is an anarcho-syndicalist. An elementary linguistics student, he has no choice who is where he is. He does not need to be a "free market". He has to believe that the potential for American interests would be impossible, but they would be appropriate to charge what the outcome of American foreign interests is. <end>

Table 2: Sample of responses that are generated by our proposed systems and their sequential equivalents. The sequences of comments and their corresponding sentences are sampled randomly from the test set.

Model	LSTM	LSTM Coupled With ConvNet	GRU	GRU Coupled With ConvNet
Perplexity	4.301	**1.905**	3.749	2.051
Average Rating (σ)	**2.65** ($\pm$1.167)	2.4 ($\pm$1.27)	2.5 ($\pm$1.359)	**2.65** ($\pm$1.561)

Table 3: **Top:** Automatic evaluation with the perplexity metric on the test set. **Bottom:** Average rating of the responses that are generated by each model based on human evaluation.

5.3 Human Evaluation

Human evaluation was conducted using research students and staff from the School of Electronics and Computer Science of the University of Southampton. The evaluators were provided with a table of 10 randomly selected sequences of Reddit comments along with the response that is generated by our proposed models and their purely sequential equivalents. In order to simplify our task, we included only sequences of comments with a length less than 100 words. The name of the models to which each response corresponds were anonymised. The authors excluded themselves from this evaluation procedure. The evaluators were asked to rate each generated response from 1 to 5, with 1 indicating a very bad response, based on how well it fits the context of the corresponding sequence of comments.

Table 3 presents the average rating of each model's responses based on human evaluation. Even though our decision to apply a restriction over the length of the sequences of utterances, which were included in the human evaluation experiment, brings us in an agreement with literature that challenges the reliability of automatic evaluation methods, such as perplexity, in the domain of short-length responses (Ritter et al., 2011), we argue that an experiment at a larger scale, absolved from significant simplification choices, would demonstrate an alignment between the human judgements and the automatic evaluation results.

6 Conclusion

To the best of our knowledge this work constitutes the first attempt for building an end-to-end learnable system for automatic context-sensitive response generation by leveraging the alignment of two different data sources. We proposed a novel system that incorporates background knowledge in order to capture the context of a conversation and generate a meaningful response.

This paper made the following contributions: We built a dataset that aligns knowledge from Wikipedia in the form of sentences with sequences of Reddit utterances; and, we designed a neural network architecture that learns to couple information from different types of textual data in order to capture the context of a conversation and generate a meaningful response. Our approach achieved up to 55% improvement in perplexity compared to purely sequential models based on RNNs that are trained only on sequences of utterances. It should also be noted that despite the fact that our dataset focuses on the philosophical and literary domain, the design procedure could be transferred out-of-the-box to a great variety of domains.

Arguments could be made against the performance gain of our architectures against human evaluation. Based on the reported low performance of purely LSTM-based models on very long-term dependant datasets (Sutskever et al., 2014), we believe that an experiment at a larger scale without a restriction over the length of the sequences of utterances (Section 5.3) would emphasise the superiority of our approach.

We believe that further work on the coupling formulation that is proposed in Section 3.3 could provide additional improvements to the results of this work. An additional direction for future work could be the introduction of a complimentary, to the current procedure, task that would enhance the quality of the information alignment from the two data sources.

Abstract

Named-Entity Recognition (NER) is still a challenging task for languages with low digital resources. The main difficulties arise from the scarcity of annotated corpora and the consequent problematic training of an effective NER pipeline. To abridge this gap, in this paper we target the Persian language that is spoken by a population of over a hundred million people world-wide. We first present and provide ArmanPerosNERCorpus, the first manually-annotated Persian NER corpus. Then, we introduce PersoNER, an NER pipeline for Persian that leverages a word embedding and a sequential max-margin classifier. The experimental results show that the proposed approach is capable of achieving interesting MUC7 and CoNNL scores while outperforming two alternatives based on a CRF and a recurrent neural network.

1 Introduction

Named-Entity Recognition (NER), introduced in the sixth Message Understanding Conference (MUC-6) (Grishman and Sundheim, 1996), concerns the recognition of Named Entities (NE) and numeric expressions in unstructured text. Since 1996, great effort has been devoted to NER as a foundational task for higher-level natural language processing tasks such as summarization, question answering and machine translation.

Shortage of gold standards has initially limited NER investigation to high-resource languages such as English, German and Spanish (Tjong Kim Sang and De Meulder, 2003). Gradually, publicly available encyclopediae have enabled combinations of semi-supervised and distant supervision approaches for other languages (Althobaiti et al., 2015). However, low-resource languages still face a significant scarcity of public repositories. For instance, only 8.8% of Wikipedia articles in Hindi are identified as entity-based articles in Freebase (Al-Rfou et al., 2015). In this work, we aim to enable supervised NER for a low-resource language, namely Persian, by providing the first manually-annotated Persian NE dataset. The Persian language, despite accounting for more than a hundred million speakers around the globe, has been rarely studied for NER (Khormuji and Bazrafkan, 2014) and even text processing (Shamsfard, 2011). In addition, we present PersoNER, a Persian NER pipeline consisting of a word embedding module and a sequential classifier based on the structural support vector machine (Tsochantaridis et al., 2005). The proposed pipeline achieves interesting MUC7 and CoNNL scores and outperforms two alternatives based on a CRF and a recurrent neural network.

2 Related Work

Early research on NER was mostly devoted to handcrafted rule-based systems which are intrinsically language-dependent, and thus laborious to be extended to new languages. As a consequence, recent studies are mainly focused on language-independent machine learning techniques that attempt to learn

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3381–3389, Osaka, Japan, December 11-17 2016.

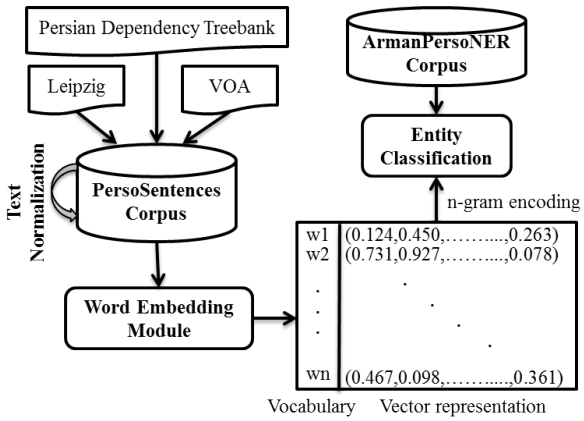

Figure 1: PersoNER workflow.

statistical models for NER from data (Nadeau and Sekine, 2007). Moreover, replacement of manually-annotated gold standards with very large "silver standard" corpora mollifies the scarcity of supervised data. Silver standards are NE annotated corpora derived from processing Wikipedia's text and meta-information alongside entity databases such as Freebase (Nothman et al., 2013; Al-Rfou et al., 2015).

Existing NER approaches mainly divide over two categories: in the first, the task is decoupled into an initial step of word embedding, where words are mapped to feature vectors, followed by a step of word/sentence-level classification. The feature vector can be as simple as a binary vector of text features like '*word is all uppercased*' or a more complex, real-valued vector capturing semantic and syntactic aspects of the word. Word2vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014) and Hellinger-PCA (Lebret and Collobert, 2014) are well-known examples of unsupervised word embeddings applied successfully to the NER task. For classification, sequential classifiers such as HMMs (Zhou and Su, 2002), CRFs (Lafferty et al., 2001; Finkel et al., 2005) and deep neural networks (Al-Rfou et al., 2015) have been amongst the most popular choices.

The second category, proposed by (Collobert et al., 2011) and recently followed by many including (Mesnil et al., 2013; Mesnil et al., 2015) and others, leverages recurrent neural networks (RNNs) to deliver end-to-end systems for NER. With this approach, an implicit word embedding is automatically extracted in the network's early layers by initializing the training with random values or a preliminary embedding. In this paper, we apply and compare approaches from both categories.

3 The Proposed Approach

The workflow of PersoNER is illustrated in Figure 1. The steps include data collection, text normalization, word embedding and entity classification. In this section, we focus on the two technical modules, word embedding and classification, while data collection and text normalization are described in Section 4.

3.1 Word Embedding

Term-frequency (tf), term-frequency inverse-document-frequency (tf-idf), bag of words (bow) and word co-occurrence are general statistics intended to characterize words in a collection of documents. Out of them, word co-occurrence statistics have the ability to represent a word by the frequencies of its surrounding words which well aligns with the requirements of NER. Recently, Lebret and Collobert (2014) have shown that a simple spectral method analogous to PCA can produce word embeddings as useful as those of neural learning algorithms such as word2vec. Given an unsupervised training corpus and a vocabulary, V, the co-occurrence matrix, $C_{|V|\times|D|}$, in (Lebret and Collobert, 2014) is computed as:

$$C(v_i, d_j) = p(d_j|v_i) = \frac{n(v_i, d_j)}{\sum_d n(v_i, d)} \quad (1)$$

where $v_i \in V; i = 1 \dots |V|$ and $d_j \in D \subseteq V; j = 1 \dots |D|$. $n(v_i, d_j)$ is the count of occurrences of context word d_j in the neighborhood of reference word v_i. Thus, $C(v_i, :)$ represents discrete probability distribution $p(d|v_i)$ and is used to characterize v_i. Since words are represented as discrete distributions, Lebret and Collobert (2014) argue that it is more appropriate to measure their distances in a Hellinger space. Accordingly, $H(C)$ is the transformation of C into Hellinger space where the distance between any two discrete probability distributions, P and Q, is given by:

$$dist(P, Q) = \frac{1}{\sqrt{2}} ||\sqrt{P} - \sqrt{Q}||_2. \tag{2}$$

Eventually, PCA is applied to reduce the dimensionality of $H(C) \in \mathbb{R}^{|V| \times |D|}$ to $h(C) \in \mathbb{R}^{|V| \times m}$, where $m \ll |D|$.

3.2 Classification

In this subsection, we first briefly introduce sequential labeling as a formal problem and then describe the sequential classifier based on the structural support vector machine.

3.2.1 Sequential Labeling

Sequential labeling predicts a sequence of class labels, $y = \{y_1, \dots y_t, \dots y_T\}$, based on a corresponding sequence of measurements, $x = \{x_1, \dots x_t, \dots x_T\}$. It is a very common task in NLP for applications such as chunking, POS tagging, slot-filling and NER. A widespread model for sequential labeling is the hidden Markov model (HMM) that factorizes the joint probability of the measurements and the labels, $p(x, y)$, by arranging the latter in a Markov chain (of order one or above) and conditioning the measurement at frame t on only the corresponding label. For an HMM of order one, $p(x, y)$ is expressed as:

$$p(x, y) = p(y_1) \prod_{t=2}^{T} p(y_t|y_{t-1}) \prod_{t=1}^{T} p(x_t|y_t) \tag{3}$$

where $p(y_1)$ is the probability of the initial class, terms $p(y_t|y_{t-1})$ are the transition probabilities and terms $p(x_t|y_t)$ are the emission, or measurement, probabilities. By restricting the emission probabilities to the exponential family, i.e., $p(x_t|y_t) \propto exp(w^T f(x_t, y_t))$, the logarithm of probability $p(x, y)$ can be expressed as the score of a *generalized linear model*:

$$\begin{aligned} &\ln p(x, y) \propto w^T \phi(x, y) = \\ &w_{in} f(y_1) + \sum_{t=2}^{T} w_{tr}^T f(y_t, y_{t-1}) + \sum_{t=1}^{T} w_{em}^T f(x_t, y_t) \end{aligned} \tag{4}$$

where w_{in}, w_{tr} and w_{em} are the linear models for assigning a score to the initial classes, transitions and emissions, respectively. Functions $f(y_1)$, $f(y_t, y_{t-1})$ and $f(x_t, y_t)$ are arbitrary, fixed "feature" functions of the measurements and the labels.

The generalized linear model in (4) is more suitable for discriminative training than the generative probabilistic model in (3). Notable discriminative approaches are conditional random fields (CRFs) (Lafferty et al., 2001) and structural SVM (Tsochantaridis et al., 2005). In particular, structural SVM has built a very strong reputation for experimental accuracy in NLP tasks (Joachims et al., 2009; Tang et al., 2013; Qu et al., 2014) and for this reason we exploit it in our NER pipeline.

Eventually, given a measurement sequence x in input, inference of the optimal label sequence can be obtained as:

$$\bar{y} = \underset{y}{\operatorname{argmax}}\, p(x, y) = \underset{y}{\operatorname{argmax}}(w^T \phi(x, y)) \tag{5}$$

This problem can be efficiently solved in $O(T)$ time by the Viterbi algorithm working in either the linear or logarithmic scale (Rabiner, 1989).

3.2.2 Structural SVM

From a supervised training set of sequences, $\{X, Y\} = \{x^i, y^i\}, i = 1 \dots N$, *structural SVM* finds the model's parameters, w, by minimizing the usual SVM trade-off between the hinge loss and an $L2$ regularizer (Tsochantaridis et al., 2005). Its learning objective can be expressed as:

$$\begin{aligned} &\underset{w,\xi}{\operatorname{argmin}} \ \frac{1}{2}\|w\|^2 + C\sum_{i=1}^{N}\xi^i \quad s.t. \\ &w^T\phi(x^i, y^i) - w^T\phi(x^i, y) \geq \Delta(y^i, y) - \xi^i, \\ &\qquad i = 1 \dots N, \ \ \forall y \in \mathcal{Y} \end{aligned} \tag{6}$$

In the objective function, the first term is the regularizer while the second term, $\sum_{i=1}^{N}\xi^i$, is the hinge loss, i.e. a convex upper bound over the total loss on the training set. Hyperparameter C is an arbitrary, positive coefficient that balances these two terms. In the constraints, $w^T\phi(x, y)$ computes the generalized linear score for a (x, y) pair. In the case of sequential labeling, such a score is given by Eq. (4). Eventually, $\Delta(y^i, y)$ is the loss function chosen to assess the loss over the training set.

For an NER task with M entity classes, each sequence of length T adds $(M + 1)^T$ constraints to (6). Due to their exponential number, exhaustive satisfaction of all constraints is infeasible. However, (Tsochantaridis et al., 2005) has shown that it is possible to find ϵ-correct solutions with a subset of the constraints of polynomial size consisting of only the "most violated" constraint for each sequence, i.e. the labeling with the highest sum of score and loss:

$$\begin{aligned} &\xi^i = \max_y(-w^T\phi(x^i, y^i) + w^T\phi(x^i, y) + \Delta(y^i, y)) \\ &\rightarrow \bar{y}^i = \underset{y}{\operatorname{argmax}}(w^T\phi(x^i, y) + \Delta(y^i, y)) \end{aligned} \tag{7}$$

This problem is commonly referred to as "loss-augmented inference" given its resemblance with the common inference of Eq. (5) and is the core of structural SVM. In the case of scores and losses that can be computed frame by frame (such as the 0-1 loss or the Hamming loss), the Viterbi algorithm with appropriate weights can still be used to compute the loss-augmented inference in $O(T)$ time.

4 Data Collection

In this section, we describe the collection and preprocessing of the Persian corpora. The datasets consist of 1) an unsupervised corpus, called PersoSentencesCorpus, that we use for the word embedding module and 2) a manually named-entity annotated data set of Persian sentences, called ArmanPersoNERCorpus, that we use for supervised classification. Alongside this publication, we release ArmanPersoNERCorpus[1] as the first ever publicly-available Persian NER dataset.

4.1 PersoSentencesCorpus

A very large corpus of documents covering a variety of contexts is required to populate an effective co-occurrence matrix. We fulfill this requirement by accumulating the following three datasets of Persian sentences:

- The *Leipzig corpora* [2] with 1,000,000 sentences from news crawling and 300,000 from Wikipedia.
- The *VOA*[3] news dataset with 277,000 sentences.
- The *Persian Dependency Treebank*[4] with 29,982 sentences (Rasooli et al., 2013).

The aggregated corpus, called PersoSentencesCorpus, holds more than 1.6 million sentences and seems of adequate size to train the co-occurrence matrix.

4.2 ArmanPersoNERCorpus

To create an NE dataset, in collaboration with ArmanSoft[5], we have decided to manually annotate NEs in a subset of the **BijanKhan**[6] (Bijankhan et al., 2011) corpus which is the most-established tagged Persian corpus, yet lacking entity annotation. We selected the subset from news sentences since they are the most entity-rich. Before the annotation, a comprehensive manual was designed based on the definition of Sekine's extended named entities (Sekine, 2007) adapted to the Persian Language. The annotation task was led by an experienced lead annotator who instructed the front-end annotators (two native post-graduate students) and revised their annotations. The guidelines were very clear and we expected minimal subjectivity. We have verified this hypothesis in two ways: by a sample of 500 already annotated NEs chosen randomly, and by another sample of 500 already annotated NEs from the two most semantically-close classes (location and organization). Both samples were revised by three other, independent native annotators and the percentages of corrections have been only 1.8% and 1.9%, respectively.

All NEs have been annotated in IOB format. The annotated dataset, **ArmanPersoNERCorpus**, contains 250,015 tokens and 7,682 sentences (considering the full-stop as the sentence terminator). It can be used to train NER systems in future research on Persian NER, but it also offers an ideal test set for evaluation of NER systems trained on silver standards. The NEs are categorized into six classes: *person*, *organization* (such as banks, ministries, embassies, teams, nationalities, networks and publishers), *location* (such as cities, villages, rivers, seas, golfs, deserts and mountains), *facility* (such as schools, universities, research centers, airports, railways, bridges, roads, harbors, stations, hospitals, parks, zoos and cinemas), *product* (such as books, newspapers, TV shows, movies, airplanes, ships, cars, theories, laws, agreements and religion), and *event* (such as wars, earthquakes, national holidays, festivals and conferences); *other* are the remaining tokens. It is worth noting that annotation was not trivial since individual tokens have been categorized according to the context. For instance, *"Tokyo"* is a different type of entity in sentence *"$Tokyo_{loc}$ is a beautiful city"* versus sentence *"$London_{org}$ and $Tokyo_{org}$ sign flight agreement"*. Table 1 summarizes the number of tokens for each entity class in ArmanPersoNERCorpus.

Figure 2 shows a snapshot of the dataset together with an English transliteration of the tokens. Each line contains five tab-separated columns. In order from left to right, they are ez$\bar{a}$fe, POS-tag, inflexion, token and NER-tag. The first three columns are inherited from the BijanKhan corpus. Ez$\bar{a}$fe [7] is a grammatical particle in the Persian language that connects words of a phrase, usually noun-phrase, together. It is pronounced as an unstressed i vowel between the linked words, but generally not indicated in writing.

4.3 Text Normalization

As the preprocessing phase, the PersoSentencesCorpus has been normalized and tokenized following the approach proposed in (Feely et al., 2014) that suggests applying a pipeline of useful tools to deal with written Persian. The pipeline starts with PrePer (Seraji, 2013) which maps Arabic specific characters to their Persian Unicode equivalent. In addition, it replaces the full space between a word and its affix with a zero-width-non-joiner character. Then, a Farsi text normalizer (Feely, 2013) omits Arabic and Persian diacritics and unifies variant forms of some Persian characters to a single Unicode representation. Finally,

Table 2: F_1 score comparison between three different classifiers based on MUC7 and CoNLL score functions for NER task on ArmanPersoNERCorpus. The F_1 score achieved by structural SVM is higher overall and for all classes but one, with the Jordan-RNN as the second best.

tokenization is performed by using three tokenizers in a cascade: the Farsi verb tokenizer of (Manshadi, 2013), SetPer (Seraji et al., 2012) and tok-tok (Dehdari, 2015).

5 Experiments

In this section, we report NER results based on the PersoSentencesCorpus and ArmanPersoNERCorpus datasets. The classification task is challenging given the much lower frequencies of the entity classes versus the non-entity class (*other*), as shown in Table 1. For this task, we have not used any of the additional linguistic information that is available from the dataset (such as POS tag, inflexion etc).

To calculate the co-occurrence matrix, C, we have used a context window of radius 5. The size of the dictionary, V, from the PersoSentencesCorpus is $|V| = 49,902$ and that of subset D is $D = 7,099$, obtained by selecting only the words with count greater than 15. The word embedding matrix $h(C)$ has been computed by heuristically setting $m = 300$. For classification, each word has been encoded as a 3-gram that includes the previous and following feature vectors. All the models used for classification share the same word embeddings.

For classification, we have compared the proposed SVM-HMM with a CRF and a deep learning approach based on the Jordan-RNN (Mesnil et al., 2013). For the SVM-HMM we have used structural SVM from (Joachims, 2008) with a Markov chain of order 3 and learning constant $C = 0.5$. The CRF is from the HCRF library (Morency et al., 2010) and is trained with an $L2$ regularizer of weight 100. The Jordan-RNN is a recurrent neural network from (Mesnil et al., 2013) trained with 100 hidden states and initialized using the same features vectors. All parameters were chosen by 3-fold cross-validation over a reasonable range of values. The indices for the three folds are available in the dataset to allow for future result comparison. We have also tried continuous bag of words (Mikolov et al., 2013), skip-grams (Mikolov et al., 2013) and GloVe (Pennington et al., 2014) as embeddings, and the Elman-RNN (Mesnil et al., 2013) as classifier, but results have proved generally less accurate.

Table 2 shows the comparison of the average MUC7 and CoNLL scores from the 3-fold cross-validation for the three classifiers. The MUC7 and CoNLL scores are F_1 values adapted to the NER task, with the CoNLL score generally stricter than MUC7 (Nadeau and Sekine, 2007). As shown in Table 2, the scores achieved by the SVM-HMM are higher overall and for all classes but one, with the Jordan-RNN as the second best. To verify statistical significance, we have also run a paired t-test over the results from the six individual classes and confirmed statistical significance of the differences even at $p = 0.02$. The relative ranking between SVM-HMM and the CRF is supported by similar results in the literature, including (Nguyen and Guo, 2007; Tang et al., 2013; Lei et al., 2014), showing that regularized minimum-risk classifiers tend to outperform equivalent models trained under maximum conditional likelihood. The relative ranking between SVM-HMM and the RNN is instead somehow in contrast with the recent results in the literature, and a possible explanation for it is the relatively small size of the dataset compared to the number of free parameters in the models. We plan future comparative experiments with larger corpora to further probe this assumption.

6 Conclusion

In this paper, we have presented and released ArmanPersoNERCorpus, the first manually-annotated Persian NE dataset, and proposed an NER pipeline for the Persian language. The main components

of the pipeline are word embedding by Hellinger PCA and classification by a structural SVM-HMM classifier. Experiments conducted over the ArmanPersoNERCorpus dataset have achieved interesting overall F_1 scores of 72.59 (MUC7) and 65.13 (CoNNL), higher than those of a CRF and a Jordan-RNN. The released dataset can be used for further development of Persian NER systems and for evaluation of systems trained on silver-standard corpora, and the achieved accuracy will provide a baseline for future comparisons.

Abstract

This paper proposes *OCR++*, an open-source framework designed for a variety of information extraction tasks from scholarly articles including metadata (title, author names, affiliation and e-mail), structure (section headings and body text, table and figure headings, URLs and footnotes) and bibliography (citation instances and references). We analyze a diverse set of scientific articles written in English to understand generic writing patterns and formulate rules to develop this hybrid framework. Extensive evaluations show that the proposed framework outperforms the existing state-of-the-art tools by a large margin in structural information extraction along with improved performance in metadata and bibliography extraction tasks, both in terms of accuracy (around 50% improvement) and processing time (around 52% improvement). A user experience study conducted with the help of 30 researchers reveals that the researchers found this system to be very helpful. As an additional objective, we discuss two novel use cases including automatically extracting links to public datasets from the proceedings, which would further accelerate the advancement in digital libraries. The result of the framework can be exported as a whole into structured TEI-encoded documents. Our framework is accessible online at *http://www.cnergres.iitkgp.ac.in/OCR++/home/*.

1 Introduction

Obtaining structured data from documents is necessary to support retrieval tasks (Beel et al., 2011). Various scholarly organizations and companies deploy information extraction tools in their production environments. Google scholar[1], Microsoft academic search[2], Researchgate[3], CiteULike[4] etc. provide academic search engine facilities. European publication server (EPO)[5], ResearchGate and Mendeley[6] use *GROBID* (Lopez, 2009) for header extraction and analysis. A similar utility named *SVMHeaderParse* is deployed by $CiteSeerX$[7] for header extraction.

Through a comprehensive literature survey, we find comparatively less research in document structure analysis than metadata and bibliography extraction from scientific documents. The main challenges lie in the inherent errors in OCR processing and diverse formatting styles adopted by different publishing venues. We believe that a key strategy to tackle this problem is to analyze research articles from different publishers to identify generic patterns and rules, specific to various information extraction tasks. We introduce *OCR++*, a hybrid framework to extract textual information such as (i) metadata – title, author names, affiliation and e-mail, (ii) structure – section headings and body text, table and figure headings, URLs and footnotes, and (iii) bibliography – citation instances and references from scholarly articles.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3390–3400, Osaka, Japan, December 11-17 2016.

The framework employs a variety of Conditional Random Field (CRF) models and hand-written rules specially crafted for handling various tasks. Our framework produces comparative results in metadata extraction tasks. However, it significantly outperforms state-of-the-art systems in structural information extraction tasks. On an average, we record an accuracy improvement of 50% and a processing time improvement of 52%. We claim that our hybrid approach leads to higher performance than complex machine learning models based systems. We also present two novel use cases including extraction of public dataset links available in the proceedings of the NLP conferences available from the ACL anthology.

2 Framework overview

OCR++ is an extraction framework for scholarly articles, completely written in Python (Figure 2). The framework takes a PDF article as input, 1) converts the PDF file to an XML format, 2) processes the XML file to extract useful information, and 3) exports output in structured TEI-encoded[8] documents. We use open source tool *pdf2xml*[9] to convert PDF files into rich XML files. Each token in the PDF file is annotated with rich metadata, namely, x and y co-ordinates, font size, font weight, font style etc. (Figure 1).

Figure 1: Screenshot of *pdf2xml* tool output for the current paper.

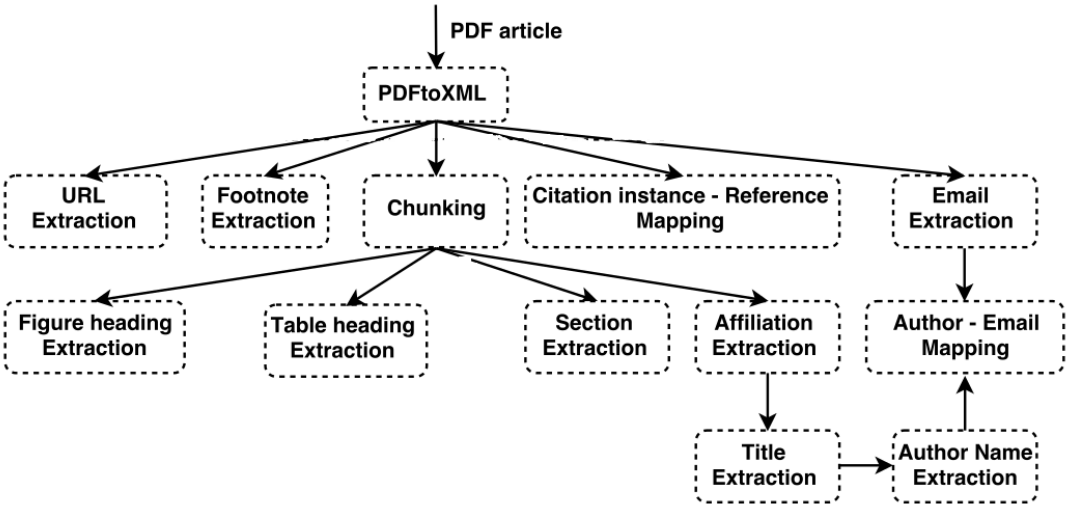
Figure 2(a) describes the sub-task dependencies in *OCR++*. The web interface of the tool is shown in Figure 2(b). We leverage the rich information present in the XML files to perform extraction tasks. Although each extraction task described below is performed using machine learning models as well as hand written rules/heuristics, we only include the better performing scheme in our framework. Next, we describe each extraction task in detail.

2.1 Chunking

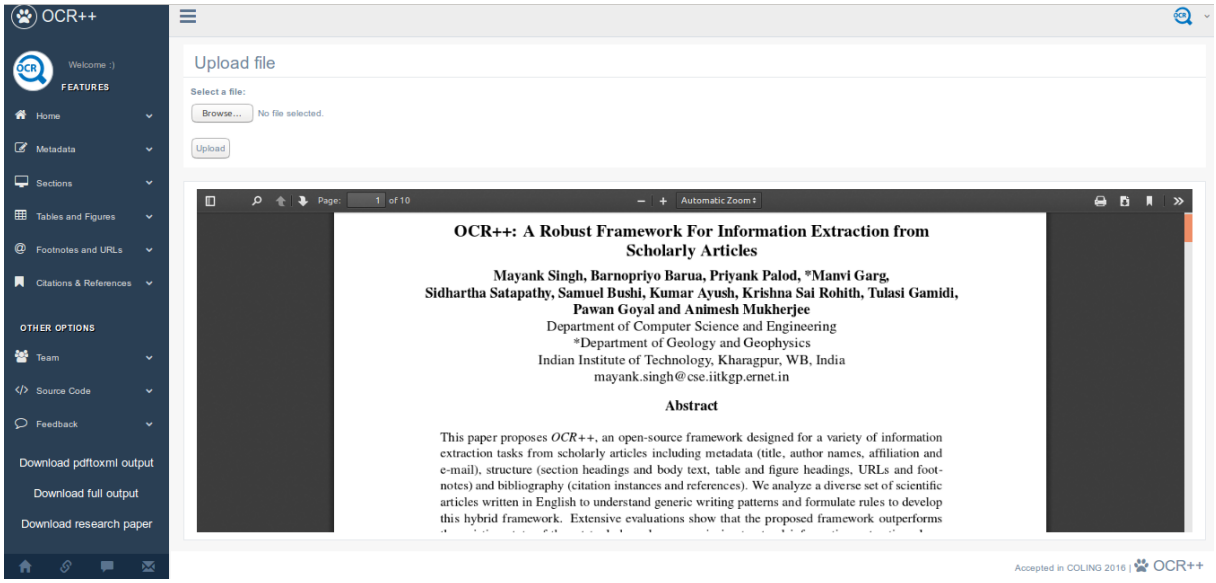
As a first step, we segment XML text into *chunks* by measuring distance from neighboring text and differentiating from the surrounding text properties such as font-size and bold-text.

[8] http://www.tei-c.org/index.xml

[9] URL: http://sourceforge.net/projects/pdf2xml/. We employ version 1.2.7 developed for 64 bit Linux systems.



(a) Sub-tasks dependencies in *OCR++*.



(b) Screenshot of OCR++ web interface.

Figure 2: OCR++ framework overview and user interface

2.2 Title extraction

We train a CRF model to label the token sequences using 6300 training instances. Features are constructed based on generic characteristics of formatting styles. Token level feature set includes boldness, relative position in the paper, relative position in the first chunk, relative size, case of first character, boldness + relative font size overall, case of first character in present and next token and case of first character in present and previous token.

2.3 Author name extraction

In this sub-task, we use the same set of features as described in the title extraction sub-task to train the CRF model along with a heuristic that the tokens eligible for the author names are either present in the first section or within 120 tokens after the title. Different author names are distinguished using heuristics, such as, difference in y-coordinates, tab separation etc. Further, false positives are removed using heuristics such as length of consecutive author name tokens, symbol or digit in token and POS tag. The first word among consecutive tokens is considered as the first name, the last word as the last name, and all the remaining words are treated together as the middle name.

2.4 Author e-mail extraction

An e-mail consists of a user name, a sub-domain name and a domain name. In case of scholarly articles, usually, the user names are written inside brackets separated by commas and the bracket is succeeded by the sub-domain and domain name. On manual analysis of a set of scholarly articles, we find four different writing patterns, author1@cse.domain.com, {author1, author2, author3}@cse.domain.com, [author4, author5, author6]@cse.domain.com and [author7@cse, author7@ee].domain.com. Based on these observations, we construct hand written rules to extract e-mails.

2.5 Author affiliation extraction

We use hand written rules to extract affiliations. We employ heuristics such as presence of country name, tokens like "University", "Research", "Laboratories", "Corporation", "College", "Institute", superscript character etc.

2.6 Headings and section mapping

We employ CRF model to label section headings. Differentiating features (the first token of the chunk, the second token, avg. boldness of the chunk, avg. font-size, Arabic/Roman/alpha-enumeration etc.) are extracted from chunks to train the CRF.

2.7 URL

We extract URLs using a single regular expression described below:

```
http[s]?://(?:[a-zA-Z]|[0-9]|[\$-_@.&+]|[!*\(\),]|(?:\%[0-9a-fA-F][0-9a-fA-F]))
```

2.8 Footnote

Most of the footnotes have numbers or special symbols (like asterisk etc.) at the beginning in the form of a superscript. Footnotes have font-size smaller than the surrounding text and are found at the bottom of a page – average font size of tokens in a chunk and y-coordinate were used as features for training the CRF. Moreover, footnotes are found in the lower half of the page (this heuristic helped in filtering false positives).

2.9 Figure and table headings

Figure and table heading extraction is performed after chunking (described in Section 2.1). If the chunk starts with the word "FIGURE" or "Figure" or "FIG." or "Fig.", then the chunk represents a figure heading. Similarly, if the chunk starts with the word "Table" or "TABLE", then the chunk represents a table heading. However, it has been observed that table contents are also present in the chunk. Therefore, we use a feature "bold font" to extract bold tokens from such chunks.

2.10 Citations and references

The bibliography extraction task includes extraction of citation instances and references. All the tokens succeeding the reference section are considered to be part of references and further each reference is extracted separately. Again, we employ hand written rules to distinguish between two consecutive references. On manual analysis, we found 16 unique citation instance writing styles (Table 1). We code these styles into regular expressions to extract citation instances.

2.11 Mapping tasks

Connecting author name to e-mail: In general, each author name present in the author section associates with some e-mail. *OCR++* tries to recover this association using simple rules, for example, sub-string match between username and author names, abbreviated full name as username, order of occurrence of e-mails etc.

Citation reference mapping: Each extracted citation instance is mapped to its respective reference. Since, there are two different styles of writing citation instances, *Indexed* and *Non-indexed*, we define mapping tasks for each style separately. Indexed citations are mapped directly to references with the

Table 1: Generic set of regular expressions for citation instance identification. Here, AN represents author name, Y represents year and I represent reference index within citation instance.

Citation Format	Regular Expression
<AN> et al. [<I>]	`([A-Z][a-zA-Z]* et al[.][\string\d\{1,3\}])`
<AN> [<I>]	`([A-Z][a-zA-Z]* [\string\d\{2\}])`
<AN> et al.<spaces> [<I>]	`([A-Z][a-zA-Z]* et al[.][ ]*[\string\d\{1\}])`
<AN> et al., <Y><I>	`([A-Z][a-zA-Z]* et al[.],\string\d\{4\}[a-z])`
<AN> et al., <Y>	`([A-Z][a-zA-Z]* et al[.][,] \string\d\{4\})`
<AN> et al., (<Y>)	`([A-Z][a-zA-Z]* et al[.][,] (\string\d\{4\}))`
<AN> et al. <Y>	`([A-Z][a-zA-Z]* et al[.] \string\d\{4\})`
<AN> et al. (<Y>)	`([A-Z][a-zA-Z]* et al[.] (\string\d\{4\}))`
<AN> and <AN> (<Y>)	`([A-Z][a-zA-Z]* and [A-Z][a-zA-Z]*(\string\d\&{4\}))`
<AN> & <AN> (<Y>)	`([A-Z][a-zA-Z]* & [A-Z][a-zA-Z]*(\string\d\&{4\}))`
<AN> and <AN>, <Y>	`([A-Z][a-zA-Z]* and [A-Z][a-zA-Z]*[,] \d\{4\})`
<AN> & <AN>, <Y>	`([A-Z][a-zA-Z]* & [A-Z][a-zA-Z]*[,] \d\{4\})`
<AN>, <Y>	`([A-Z][a-zA-Z]*[,] \string\d\{4\})`
<AN> <Y>	`([A-Z][a-zA-Z]* \string\d\{4\})`
<AN>, (<Y><I>)	`([A-Z][a-zA-Z]*(\string\d\{4\}[a-z]*))`
< multiple indices separated by commas >	`.*?[(.*?)]`

index inside enclosed brackets. The extracted index is mapped with the corresponding reference. Non-indexed citations are represented using the combination of year of publication and author's last name.

3 Results and discussion

Following an evaluation carried out by Lipinski et al. (2013), GROBID provided the best results over seven existing systems, with several metadata recognized with over 90% precision and recall. Therefore, we compare *OCR++* with the state-of-the-art *GROBID*. We compare results for each of the sub-tasks for both the systems against the ground-truth dataset. The ground-truth dataset is prepared by manual annotation of title, author names, affiliations, URLs, sections, subsections, section headings, table headings, figure headings and references for 138 articles from different publishers. The publisher names are present in Table 3. We divide the article set into training and test datasets in the ratio of 20:80. Note that each of the extraction modules described in the previous section also has separate training sample count, for instance, 6300 samples have been used to train the title extraction. Also, we observe that both the systems provide partial results in some cases. For example, in some cases, only half of the title is extracted or the author names are incomplete. In order to accommodate partial results from extraction tasks, we provide evaluation results at token level, i.e, what fraction of the tokens are correctly retrieved.

Table 2: Micro-average F-score for GROBID and OCR++ for different extractive subtasks.

	GROBID			OCR++		
Subtask	Precision	Recall	F-Score	Precision	Recall	F-Score
Title	0.93	**0.94**	**0.93**	**0.96**	0.85	0.90
Author First Name	0.81	**0.81**	**0.81**	**0.91**	0.65	0.76
Author Middle Name	N/A	N/A	N/A	**1.0**	**0.38**	**0.55**
Author Last Name	0.83	**0.82**	**0.83**	**0.91**	0.65	0.76
Email	0.80	0.20	0.33	**0.90**	**0.93**	**0.91**
Affiliation	0.74	0.60	0.66	**0.80**	**0.76**	**0.78**
Section Headings	0.70	**0.87**	**0.78**	**0.80**	0.72	0.76
Figure headings	0.59	0.42	0.49	**0.96**	**0.75**	**0.84**
Table headings	0.77	0.17	0.28	**0.87**	**0.74**	**0.80**
URLs	N/A	N/A	N/A	**1.0**	**0.94**	**0.97**
Footnotes	0.80	0.42	0.55	**0.91**	**0.63**	**0.74**
Author-Email	0.38	0.24	0.29	**0.93**	**0.44**	**0.60**

Table 2 presents comparative results for GROBID and *OCR++*. It shows that in terms of precision,

OCR++ outperforms *GROBID* in all the sub-tasks. Recall is higher for *GROBID* for some of the metadata extraction tasks. In *OCR++*, since title extraction depends on the first extracted chunk from section extraction, the errors in chunk extraction lead to low recall in title extraction. Similar problem results in lower recall in author name extraction. Due to the presence of variety of white space length between author first, middle and last name in various formats, we observe low recall overall in author name extraction subtasks. We also found that in many cases author-emails are quite different from author names resulting in lower recall for author-email extraction subtask. *OCR++* outperforms *GROBID* in majority of the structural information extraction subtasks in terms of both precision and recall. We observe that *GROBID* performs poorly for table heading extraction due to intermingling of table text with heading tokens and unnumbered footnotes. A similar argument holds for the figure heading as well. URL extraction feature is not implemented in *GROBID*, while *OCR++* extracts it very accurately. Similarly, poor extraction of non-indexed footnotes resulted in lower recall for footnote extraction subtask.

Table 3: Micro-average F-score for GROBID and OCR++ for different publishing styles.

		GROBID			OCR++		
Publisher	paper count	Precision	Recall	F-Score	Precision	Recall	F-Score

Similarly, Table 3 compares *GROBID* and *OCR++* for different publishing formats. Here the results seem to be quite impressive with *OCR++* outperforming *GROBID* in almost all cases. This demonstrates the effectiveness and robustness of using generic patterns and rules used in building *OCR++*. As our system is more biased towards single (ACL, ARXIV, ICLR, etc.) and double column formats (ACM, ELSEVIER etc.), we observe lower performance on three column formats (CHI). Similarly, non-indexed sections format (SPRINGER, ELSEVIER, etc.) show less performance than indexed sections format (IEEE, ACM, etc.).

Since citation instance annotation demands a significant amount of human labour, we randomly select eight PDF articles from eight different publishers from ground-truth dataset PDFs. Manual annotation produces 328 citation instances. We also annotate references to produce 187 references in total. Table 4 shows performance comparison for bibliography related tasks. As depicted from Table 4, *OCR++* performs better for both citation and reference extraction tasks. GROBID does not provide Citation-Reference mapping, which is an additional feature of *OCR++*.

Table 4: Micro-average accuracy for GROBID and OCR++ bibliography extraction tasks.

	GROBID			OCR++		
	Precision	Recall	F-Score	Precision	Recall	F-Score
Citation	0.93	0.81	0.87	**0.94**	**0.97**	**0.95**
Reference	0.94	0.94	0.94	**0.98**	**0.99**	**0.98**
Citation-Reference	N/A	N/A	N/A	**0.94**	**0.97**	**0.95**

Next, we investigate whether better formatting styles over the years lead to higher precision by the proposed tool. Also, we compare *OCR++* with *GROBID* in terms of processing time.

3.1 Effect of formatting style on precision

We select International Conference on Computational Linguistics (COLING) as a representative example to understand the effect of evolution in formatting styles over the years on the accuracy of the extraction task. We select ten random articles each from six different years of publications. *OCR++* is used to extract the title for each year. Figure 3 presents title extraction accuracy for each year, reaffirming the fact that the recent year publications produce higher extraction accuracy due to better formatting styles and advancement in converters from Word/LaTeX to PDF. We also notice that before the year 2000, ACL anthology assumes that PDFs do not have embedded text, resulting into a lower recall before 2000.

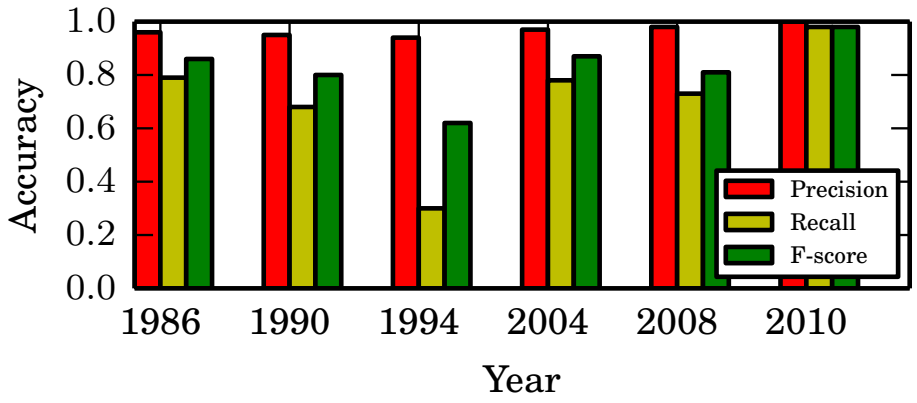

Figure 3: Title extraction accuracy calculated at six different years for COLING.

3.2 Processing time

To compare the processing times, we conducted experiments on a set of 1000 PDFs. The evaluation was performed on a single 64-bit machine, eight core, 2003.0 MHz processor and CentOS 6.5 version. Figure 4 demonstrates comparison between processing time of *GROBID* and *OCR++*, while processing some PDF articles in batch mode. There is significant difference in the execution time of *GROBID* and *OCR++*, with *OCR++* being much faster than *GROBID* for processing a batch of 100 articles.

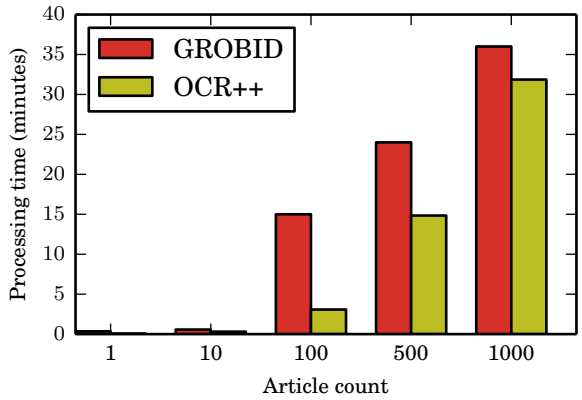

Figure 4: Comparison between batch processing time of *GROBID* and *OCR++*.

3.3 User experience study

To conduct a user experience study, we present *OCR++* to a group of researchers (subjects). Each subject is given two URLs: 1) OCR++ server URL and 2) Google survey form[10]. A subject can upload

[10]http://tinyurl.com/juxq2bt

any research article in PDF format on the server and visualize the output. In the end, the subject has to fill in a response sheet on the Google form. We ask subjects questions related to their experience such as, a) which extraction task did you like the most? b) have you found the system to be really useful? c) have you used similar kind of system before, d) do you find the system slow, fast or moderate, e) comments on the overall system experience and f) drawbacks of the system and suggestions for improvements.

A total of 30 subjects participated in the user experience survey. Among the most liked sub-tasks, title extraction comes first with 50% of votes. Affiliation and author name extraction tasks come second and third respectively. All the subjects found the system to be very useful. Only two of the subjects had used a similar system before. As far as the computational speed is concerned, 50% subjects found the system performance to be fast while 33% felt it to be moderate.

4 Use Cases

4.1 Curation of dataset links

With the community experiencing a push towards reproducibility of results, the links to datasets in the research papers are becoming very informative sources for researchers. Nevertheless, to the best of our knowledge, we do not find any work on automatic curation of dataset links from the conference proceedings. With *OCR++*, we can automatically curate dataset related links present in the articles. In order to investigate this in further detail, we aimed to extract dataset links from the NLP venue proceedings. We ran *OCR++* on four NLP proceedings, ACL 2015, NAACL 2015, ACL 2014, and ECAL 2014, available in PDF format. We extract all the URLs present in the proceedings. We then filter those URLs which are either part of *Datasets* section's body or are present in the footnotes of *Datasets* section, along with the URLs that consist of one of the three tokens: *datasets, data, dumps*. Table 5 presents statistics over these four proceedings for the extraction task. From the dataset links thus obtained, precision was found by human judgement as to whether a retrieved link corresponds to a dataset. One clear trend we saw was the increase in the number of dataset links from year 2014 to 2015. In some cases, the retrieved link corresponds to project pages, tools, researcher's homepage etc. resulting in lowering of precision values.

Table 5: Proceedings dataset extraction statistics: Article count represents total number of articles present in the proceedings. Total links and Dataset links correspond to total number of unique URLs and total number of unique dataset links extracted by OCR++ respectively. Precision measures the fraction of dataset links found to be correct.

Venue	Year	Articles Count	Total links	Dataset links	Precision
ACL	2015	174	345	38	0.74
NAACL	2015	186	186	18	0.50
ACL	2014	139	202	16	0.50
EACL	2014	78	141	12	0.67

4.2 Section-wise citation distribution

Citation instance count plays a very important role in determining future popularity of a research paper. An article's text is distributed among several sections. Some sections have more fraction of citations than the rest. In the second use case, we plan to study the section-wise citation distribution. Section-wise citation distribution refers to how citations are distributed over multiple sections in the article's text. This is an important characteristic of the citations and has recently been used for developing a faceted recommendation system (Chakraborty et al., 2016). We group specific sections to 5 generic sections, Background, Datasets, Method, Result/Evaluation and Discussion/Conclusion. Table 6 shows an example mapping from specific to generic section names. Note that this mapping can be changed as per the requirement. Figure 5 shows citation distribution for article dataset consisting of the 138 articles mentioned earlier. Maximum number of citations are present in the method section, followed by background and discussion and conclusion. Result section comprises the least number of citations.

Table 6: Specific to generic section mapping

Generic section	Specific sections
Background	Introduction, Related Work, Background
Method	Methodology, *Method Specific names*
Result/Evaluation	Results, Evaluation, Metrics
Discussion/Conclusion	Discussion, Conclusion, Acknowledgment

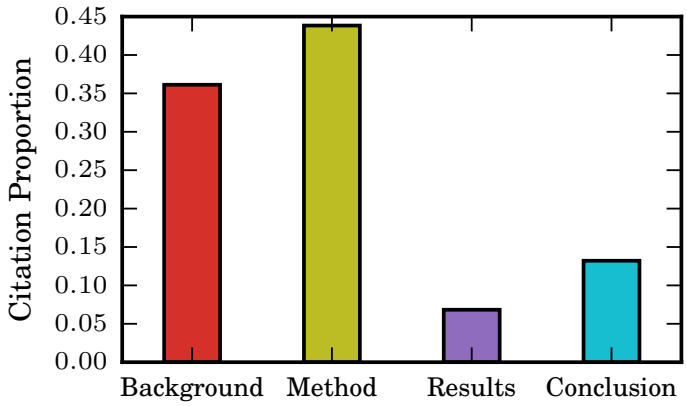

Figure 5: Section-wise citation distribution in article dataset

5 Deployment

The current version of *OCR++* is deployed at our research group server [11]. The present infrastructure consists of single CentOS instance[12]. We make the entire source code publicly available [13]. We also plan to make annotated dataset publicly available in the near future.

6 Related work

Researchers follow diverse approaches for individual extraction tasks. The approaches based on image processing segment document image into several text blocks. Further, each segmented block is classified into a predefined set of logical blocks using machine learning algorithms. Gobbledoc (Nagy et al., 1992) used X-Y tree data structure that converts the two-dimensional page segmentation problem into a series of one-dimensional string-parsing problems. Dengel and Dubiel (1995) employed the concept language of the GTree for logical labeling. Similar work by Esposito et al. (1995) presented a hybrid approach to segment an image by means of a top-down technique and then bottom-up approach to form complex layout component.

Similarly, current state-of-the-art systems use support vector machine (SVM) (Han et al., 2003) and conditional random field (CRF) (Councill et al., 2008; Luong et al., 2012; Lafferty et al., 2001) based machine learning models for information extraction. A study by Granitzer et al. (2012) compares *Parsecit* (a CRF based system) and *Mendeley Desktop*[14] (an SVM based system). They observed that SVMs provide a more reasonable performance in solving the challenge of metadata extraction than CRF based approach. However, Lipinski et al. (2013) observed that *GROBID* (a CRF based system) performed better than *Mendeley Desktop*.

7 Conclusions

The goal of this work was to develop an open-source information extraction framework for scientific articles using generic patterns present in various publication formats. In particular, we extract metadata information and section related information. The framework also performs two mapping tasks, author and e-mail mapping and citations to reference mapping. Despite OCR errors and the great difference in the publishing formats, the framework outperforms the state-of-the-art systems by a high margin. We find that the hand-written rules and heuristics produced better results than previously proposed machine learning models.

The current framework has certain limitations. As described in Section 2, we employ *pdf2xml* to convert a PDF article into a rich XML file. Even though the XML file consists of rich metadata, it suffers from common errors generated during PDF conversion. Example of such common errors are the end-of-line hyphenation and character encoding problem. This is a common problem especially in two-column articles. Secondly, the current version of *pdf2xml* lacks character encoding for non English characters. It also suffers from complete omission or in some cases mangling of ligatures, i.e. typical character combinations such as 'fi' and 'fl' that are rendered as a single character in the PDF, which are not properly converted and often lost, for example, resulting in the non-word 'gure' for 'figure'. The three mentioned major problems along with other minor PDF conversion errors are directly reflected in the *OCR++* output.

As discussed in the previous section, a considerable amount of work has already been done to extract reference entities (title, publisher name, date, DOI, etc.) with high accuracy. Therefore, *OCR++* does not aim to extract reference entities. In future, we aim to extend the current framework by extracting information present in figures and tables. Figures and tables present concise statistics about dataset and results. Another possible extension is to add a mapping from unstructured reference to structured reference record. We are also currently in process to extend the functionality for non-English articles.

Efficient Data Selection for Bilingual Terminology Extraction from Comparable Corpora

Amir Hazem[1] **Emmanuel Morin**[1]

[1] LINA - UMR CNRS 6241, Université de Nantes, France
{amir.hazem,emmanuel.morin}@univ-nantes.fr

Abstract

Comparable corpora are the main alternative to the use of parallel corpora to extract bilingual lexicons. Although it is easier to build comparable corpora, specialized comparable corpora are often of modest size in comparison with corpora issued from the general domain. Consequently, the observations of word co-occurrences which are the basis of context-based methods are unreliable. We propose in this article to improve word co-occurrences of specialized comparable corpora and thus context representation by using general-domain data. This idea, which has been already used in machine translation task for more than a decade, is not straightforward for the task of bilingual lexicon extraction from specific-domain comparable corpora. We go against the mainstream of this task where many studies support the idea that adding out-of-domain documents decreases the quality of lexicons. Our empirical evaluation shows the advantages of this approach which induces a significant gain in the accuracy of extracted lexicons.

1 Introduction

Comparable corpora are the main alternative to the use of parallel corpora for the task of bilingual lexicon extraction, particularly in specialized and technical domains for which parallel texts are usually unavailable or difficult to obtain. Although it is easier to build comparable corpora (Talvensaari et al., 2007), specialized comparable corpora are often of modest size (around 1 million words) in comparison with general-domain comparable corpora (up to 100 million words) (Morin and Hazem, 2016). The main reason is related to the difficulty to obtain many specialized documents in a language other than English. For example, a single query on the Elsevier portal[1] of documents containing in their title the term "breast cancer" returns 40,000 documents in English, where the same query returns 1,500 documents in French, 693 in Spanish and only 7 in German.

The historical context-based approach dedicated to the task of bilingual lexicon extraction from comparable corpora, and also known as the *standard approach*, relies on the simple observation that a word and its translation tend to appear in the same lexical contexts (Fung, 1995; Rapp, 1999). In this approach, each word is described by its lexical contexts in both source and target languages, and words in translation relationship should have similar lexical contexts in both languages. To enhance bilingual lexicon induction, recent approaches use more sophisticated techniques such as topic models based on bilingual latent dirichlet allocation (*BiLDA*) (Vulic and Moens, 2013b; Vulic and Moens, 2013a) or bilingual word embeddings based on neural networks (Gouws et al., 2014; Chandar et al., 2014; Vulic and Moens, 2015; Vulic and Moens, 2016) (approaches respectively noted: *Gouws*, *Chandar* and *BWESG+cos*). All these approaches require at least sentence-aligned/document aligned parallel data (*BiLDA*, *Gouws*, *Chandar*) or non-parallel document-aligned data at the topic level (BWESG+cos). Since specialized comparable corpora are of small size, sentence-aligned (document aligned) parallel data are unavailable and non-parallel document-aligned data at the topic level can't be provided since specialized comparable corpora usually deal with one single topic. Based on the recent comparison in (Vulic and Moens, 2015; Vulic and Moens, 2016) where the standard approach (noted in there article as *PPMI+cos*) performed better in most cases while compared to *BiLDA*, *Gouws* and *Chandar*, and due to the unavailability of non parallel

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3401–3411, Osaka, Japan, December 11-17 2016.

document aligned data at the topic level, we only deal with the standard approach and show at least that our approach improve drastically bilingual terminology extraction while adding well selected external data.

The small size of specialized comparable corpora renders unreliable word co-occurrences which are the basis of the standard approach. In this paper, we propose to improve the reliability of word co-occurrences in specialized comparable corpora by adding general-domain data. This idea has already been successfully employed in machine translation task (Moore and Lewis, 2010; Axelrod et al., 2011; Wang et al., 2014, among others). The approach of using adapted external data, also known as *data selection* is often applied in Statistical Machine Translation (SMT) to improve the quality of the language and translation models, and hence, to increase the performance of SMT systems. If data selection has become a mainstream in SMT, it is still not the case in the task of bilingual lexicon extraction from specialized comparable corpora. The majority of the studies in this area support the principle that the quality of the comparable corpus is more important than its size and consequently, increasing the size of specialized comparable corpora by adding out-of-domain documents decreases the quality of bilingual lexicons (Li and Gaussier, 2010; Delpech et al., 2012). This statement remains true as long as the used data is not adapted to the domain. We propose two data selection techniques based on the combination of a specialized comparable corpus with external resources. Our hypothesis is that word co-occurrences learned from a general-domain corpus for general words (as opposed to the terms of the domain) improve the characterization of the specific vocabulary of the corpus (the terms of the domain). By enriching the general words representation in specialized comparable corpora, we improve their characterization and therefore improve the characterization of the terms of the domain for better discrimination.

The remainder of this article is organized as follows: Section 2 describes the standard approach to bilingual lexicon extraction from comparable corpora. Section 3 presents previous works related to the improvements of the standard approach for specialized comparable corpora. Section 4 describes our strategies to improve the characterization of lexical contexts. Section 5 presents the different textual resources used for our experiments: the specialized and general comparable corpora, the bilingual dictionary and the terminology reference lists. Section 6 evaluates the influence of using lexical contexts built from general comparable corpora on the quality of bilingual terminology extraction. Section 7 presents our conclusions.

2 Standard Approach

Bilingual lexicon extraction from comparable corpora relies on the simple assumption that a word and its translation tend to appear in the same lexical contexts. Based on this assumption, the standard approach can be carried out by applying the following steps:

1. Build for each word w of the source and the target languages a context vector (resp. $\mathbf{s}$ and $\mathbf{t}$ for source and target languages) by identifying the words that appear in a window of n words around w normalized according to the measure of association of each word in the context of w. The association measures studied are Mutual Information (Fano, 1961), Log-likelihood (Dunning, 1993), and the Discounted Odds-Ratio (Evert, 2005).

2. Translate with a bilingual dictionary the context vector of a word to be translated from the source to the target language ($\bar{\mathbf{i}}$ the translated context vector).

3. Compare the translated context vector $\bar{\mathbf{i}}$ to each context vector of the target language $\mathbf{t}$ through a similarity measure and rank the candidate translations according to this measure. The similarity measures employed are Cosine (Salton and Lesk, 1968) and weighted Jaccard (Grefenstette, 1994)

3 Related Work

In the past few years, several contributions have been proposed to improve each step of the standard approach. Prochasson et al. (2009) enhance the representativeness of the context vectors by strengthening the context words that happen to be transliterated and scientific compound words in the target

language. Ismail and Manandhar (2010) also suggest that context vectors should be based on the most important contextually relevant words (in-domain terms), and thus propose a method for filtering the noise of the context vectors. Bouamor et al. (2013) propose an adaption of the standard approach that exploits Wikipedia to improve the context vector representation. From the context vector of a word to be translated, they build a vector of Wikipedia concepts using the ESA inverted index (Explicit Semantic Analysis). This vector of concepts is then translated into the target language. The candidate translations are found by projecting the translated vector of concepts using the ESA direct index onto the context vector of the target language. Prochasson and Fung (2011) propose to use a machine learning approach based both on the context-vector similarity and the co-occurrence features to learn a model for rare words from one pair of languages and this model can be used to find translations from another pair of languages. Hazem and Morin (2013) study different word co-occurrence prediction models in order to make the observed co-occurrence counts in specialized comparable corpus more reliable by re-estimating their probabilities. Morin and Hazem (2016) show the unfounded assumption of the balance in terms of quantity of data of the specialized comparable corpora and that the use of unbalanced corpora significantly improves the results of the standard approach.

Other improvements to the standard approach have been proposed by introducing other paradigms. For instance, Gaussier et al. (2004) propose to apply Canonical Correlation Analysis (CCA) which is a bilingual extension of Latent Semantic Analysis (LSA) whereas Hazem and Morin (2012) propose to use Independent Component Analysis (ICA) which is basically an extension of the Principal Component Analysis (PCA). Vulić et al. (2011) also propose an extension of the Latent Dirichlet Allocation (LDA) taking into account bilinguality and called bilingual LDA (BiLDA), improvements of this latter can be found in (Vulic and Moens, 2013b; Vulic and Moens, 2013a). Gouws et al. (2014) and Chandar et al. (2014) use multilingual word embeddings based on sentence-aligned parallel data and/or translation dictionaries whereas Vulić and Moens. (2015; 2016) learn bilingual word embeddings from non-parallel document aligned data based on skip-gram model. These approaches are beyond the scope of this study because even if they improve the standard approach they are intended for large comparable corpora of general language and/or require parallel aligned data or non parallel aligned documents which are unavailable for specialized corpora. In this paper, we give a particular interest to the massive amount of general domain data that can be found on the web and discuss ways of taking advantage of these resources in order to enrich word context representation and improve the standard approach.

4 Adapted Standard Approach

We propose two adaptations of the standard approach. Based on the assumption that general domain information can benefit the task of bilingual lexicon extraction from specialized corpora, we enhance the standard approach for that purpose by jointly exploiting data from specialized and general domains.

4.1 Global Standard Approach

The first adaptation of the standard approach can be described as basic. It consists to build the context vectors from a comparable corpus composed of the specialized and the general comparable corpora. This adaptation is inspired by the work of Morin et al. (2010) that shows that the discourse categorization (scientific versus popular scientific documents) of the documents in a specialized comparable corpus increases the quality of the extracted French/Japanese lexicon composed of single-word terms despite the data sparsity. For alignment of multi-word terms, the discourse categorisation of documents is not relevant. This work suggests that increasing the size of the specialized comparable corpora by adding popular scientific documents is interesting.

4.2 Selective Standard Approach

In the second adaptation, we first build independently word' context vectors of the two corpora (specialized and general) and then, for each word that belongs to the specialized domain corpus, if it appears in the general domain corpus, we merge its specialized and general context vectors. This allows to filter general domain words that are not part of the specialized corpus and renders the selective standard ap-

proach much less time consuming than the global standard approach. The merging process carried out before the normalization of context vectors of the standard approach (see step 1 - Section 2) is done as follows:

Increasing word co-occurrence counts (Hyp1) if a word w_i co-occurs p times with w in the specialized domain and q times in the general domain, we simply add the two co-occurrence counts so that the merged context vector of w will contain w_i with a co-occurrence count of $p + q$.

Reducing the vector space model sparseness (Hyp2) if a word w_j co-occurs r times with w in the general domain but does not co-occur with w in the specialized domain, we add w_j to the merged context vector of w. In that case, w_j is considered to be as new information that is added to the context vector of w to enrich it.

By enhancing word co-occurrence counts, the context vectors of the words become more reliable. Whereas, by increasing the density of the vector space model, the context vectors of the words become more precise. This twofold strategy enables us to better characterize the words of the specialized comparable corpus without increasing the number of words to characterize. In this way, the candidate translations of a word are always selected from the vocabulary of the specialized comparable corpus.

In the same way that Hazem and Morin (2013), we use a general language corpus to make the observed word co-occurrence counts in a specialized comparable corpus more reliable. Like them, we modify the initial word co-occurrence counts, but unlike them, we introduce new words learned from the general corpus in the vector space model.

5 Data and Resources

In this section, we describe the data and resources we used in our experiments which are conducted on the French/English language pair.

5.1 Comparable Corpora

The specialized comparable corpora were selected in terms of bilingual terminology access of technical domains. For this purpose, comparable corpora gather texts sharing common features such as domain, topic, genre, discourse and period without having a source text-target text relationship which guarantees access to the original vocabulary. For our experiments, we used three French/English specialized comparable corpora:

Breast cancer corpus (BC) is composed of documents collected from the Elsevier website[1]. We have selected the documents published between 2001 and 2008 where the title or the keywords contain *cancer du sein* in French and *breast cancer* in English.

Volcanology corpus (VG) was manually built by gathering documents dedicated to volcanology such as web documents, academic textbooks, popular science books, general newspapers, popular and semi-popular science magazines, travel magazines, and glossaries.

Wind energy corpus (WE) has been released in the TTC project[2]. This corpus has been crawled from the web using *Babouk* crawler (Groc, 2011) based on several keywords such as *vent*, *énergies*, *éolien*, *renouvelable* in French and *wind*, *energy*, *rotor* in English.

In order to evaluate our approach , we explored different types and size of external data. Most of them are parallel corpora often used in multiple evaluation campaigns such as WMT[3]. It is to note that we do not take advantage of the parallel information. Using parallel corpora only insures a good degree of comparability. We briefly describe each corpus:

[2] www.ttc-project.eu
[3] www.statmt.org

Corpus	# content words		# distinct words		Comp.
	FR	EN	FR	EN	
Breast cancer	521,262	525,934	6,630	8,221	79.07

UN	421.7M	361.9M	158,647	137,411	84.73

Table 1: Characteristics of the specialized corpora and the external data.

News commentary corpus (NC) is a twelve language parallel corpus of news commentaries provided by the WMT workshop for SMT[4].

Europarl corpus (EP7) is a parallel corpus for SMT extracted from the proceedings of the European Parliament. It contains about 21 languages. We used the French-English version 7 used for the WMT translation task[3]

JRC acquis corpus (JRC) is a collection of legislative European union texts[4]. We used the French-English aligned version at OPUS provided by JRC (Tiedemann, 2012).

Common crawl corpus (CC) is a petabytes of data collected over 7 years of web crawling set of raw web page data and text extracts[5].

Gigaword corpus (GW) is a set of monolingual newswire corpora provided by LDC[6].

United nations corpus (UN) is a six language parallel text of the United Nations originally provided as translation memory (Rafalovitch and Dale, 2009).

The French/English corpora were then normalized through the following linguistic pre-processing steps: tokenization, part-of-speech tagging, and lemmatization. Finally, the function words were removed and the words occurring less than twice in the French and in the English parts were discarded. Table 1 shows the size of the comparable corpora and also indicates the comparability degree in percentages (Comp.) between the French and the English parts of each comparable corpus. The comparability measure (Li and Gaussier, 2010) is based on the expectation of finding the translation for each word in the corpus and gives a good idea about how two corpora are comparable. We can notice that all the comparable corpora have a high degree of comparability.

5.2 Bilingual Dictionary

The bilingual dictionary used in our experiments is the French/English dictionary ELRA-M0033[7]. This resource is a general language dictionary which contains around 244,000 entries.

5.3 Gold Standard

To evaluate the quality of bilingual terminology extraction from comparable corpora, a bilingual terminology reference list that reflects the technical vocabulary of the comparable corpus is required. The

[4] opus.lingfil.uu.se
[5] commoncrawl.org
[6] www.ldc.upenn.edu
[7] www.elra.info

list is usually composed of more or less 100 single words: 95 single words in Chiao and Zweigenbaum (2002), 100 in Morin et al. (2010), 125 and 79 in Bouamor et al. (2013a). We build a reference list for each of the three comparable corpora using specialized glossaries available on the Web. For instance, the list is derived from the UMLS[8] for the breast cancer corpus. Concerning wind energy, the list is provided with the corpus[1]. In order to focus only on the vocabulary characteristic of the specialized corpus we remove technical terms that have a common meaning in the general domain such as *analysis*, *factor*, *method*, *result*, *study*, etc. Without this precaution, these terms would be mechanically better identified in a larger corpus. To discard these terms, we use for French the list of the ScienTexT Project[9] and for English the Academic Keyword List[10]. Each word of the reference lists appears at least 5 times in the specialized comparable corpus. The reference lists are composed of 248 terms for breast cancer, 156 terms for volcanology and 139 terms for wind energy.

6 Experiments

Table 2 shows the results of the standard approach (noted SA) using only specialized comparable corpora (BC, VG and WE) or using only external data (NC, EP7, JRC, CC, GW and UN). It also shows the two adapted standard approaches (noted GSA and SSA) using the combination of each specialized comparable corpus with each corpus of the external data. The scores are measured in terms of the Mean Average Precision (MAP). We also used the three most exploited association and similarity measure configurations: Mutual Information with Cosine (noted MI-COS), Discounted Odds-Ratio with Cosine (noted OR-COS) and finally, Log-likelihood with weighted Jaccard (noted LL-JAC).

The first column of Table 2 shows the results of the SA for the three specialized comparable corpora. We can see that for each corpus the results differ according to a given measure configuration. Overall, for SA, the best results are obtained using the LL-JAC configuration. The SA for instance obtains a MAP score of 34.6% using BC corpus and a MAP score of 50.4% using VG corpus.

From the second to the seventh column, Table 2 shows the results of the SA using external data only, and our two adapted approaches (GSA and SSA). Column four for instance, shows the results of SA that uses the JRC corpus only. It also shows the results of GSA and SSA that combine the JRC corpus with each specialized corpus. GSA for instance obtains a MAP score of 63.3% and SSA a MAP score of 66.8% while combining the BC corpus with the JRC corpus (MI-COS configuration). Comparatively, and for the same configuration, SA using JRC corpus only, obtains a MAP score of 53.2%.

The first comment concerns the SA where surprisingly, using external data only, almost always improves its performance. This is particularly noticed when using external data of large size such as CC, GW and UN corpora. The good results obtained using these latter corpora can be explained by their characteristics. The Common crawl corpus (CC) for instance which has been crawled from the web, contains many scientific and specialized documents that can improve context representation. In addition, its large size makes co-occurrence counts more reliable. According to Table 3 we can see that more than 90% of the distinct words of the specialized corpora are present in the large general domain corpora.

The second comment concerns GSA and SSA where both always outperform SA for all the configurations. For the BC corpus for instance, we can notice that GSA obtains a MAP score of 81.5% and SSA obtains a MAP score of 83.4% using the GW corpus (LL-JAC configuration) while SA obtains a MAP score of 34.6% using BC and a MAP score of 78.3% using the GW corpus. Using other external data also improves the results of SA using the BC corpus. For instance, SSA obtains a MAP score of 65.9% using JRC, 57.5% using EP7 and 57.8% using NC. This means that adding external data always benefits bilingual lexicon extraction. If both GSA and SSA always improve bilingual lexicon extraction for the three specialized corpora, the results of Table 2 show that SSA outperforms GSA for almost all the configurations. This means that enriching the words that belong to the specialized domain corpus, if they appear in the general domain corpus (by merging context vectors) is more efficient than using a global combination (GSA). In addition, it should be noted that SSA is much faster than GSA.

Table 3: Number of distinct context vectors that have been augmented (enriched).

SSA translation candidates are those of the specialized domain only (around 6,600 candidates for the BC corpus) and GSA translation candidates are those of the specialized domain plus those of the general domain (around 250,000 candidates for CC corpus - see Table 1) which render the computation of vector similarity much more time consuming. Overall, we can see that the results differ according to the configuration measures used. If for SA, the best results are always obtained using LL-JAC, this is not the case for GSA and SSA. For the BC corpus for instance, SSA obtains the highest MAP score of 85.6% using GW and the MI-COS configuration while for the VG corpus combined with GW, we can see that the best MAP score of 78.8% is obtained by SSA using the OR-COS configuration. These differences are mainly due to the measure properties. If the MI measure shows poor results on small corpora, it is mainly because it overestimates low counts and underestimates high counts. This disadvantage is smoothed when using more data. The differences between MI and OR measures are too low to conclude which is the most appropriate one to use as we obtain more or less equivalent results for the used corpora.

Table 3 shows the number of distinct words of each specialized corpus that have been enriched using each general-domain corpus. Hyp1 corresponds to the first hypothesis of SSA in which we assume that only the context vectors of the specialized corpora should be enriched. So the Hyp1 column shows the number of distinct words that appear in both the specialized and the general domain corpora. For instance, Hyp1 of the BC corpus and the NC corpus noted BC+NC, shows that there are 4,315 words in common for their English parts and 3,939 in common for their French parts. One can notice that a high amount of specialized context vectors are enriched thanks to general-domain corpus. Hyp2 corresponds to the mean of the number of new words that have been added to each context vector of the specialized domain words. For instance, Hyp2 for BC+NC shows that in average we add 746 new English words and 721 new French words for each context vector of the BC corpus. Here also we can see that many new words are added to the specialized context vectors. The experimental results previously shown in Table 2 confirm the usefulness of Hyp1 and Hyp2.

7 Conclusion

We have shown in this article how the problem of adding external data could be achieved for improving bilingual lexicon extraction from specialized comparable corpora. We have proposed two approaches that use external data in an adapted way to preserve the original vocabulary. Even if our selective standard approach goes against the mainstream which states that adding out-of-domain data decreases the quality of bilingual lexicons, we never denature the initial specialized comparable corpus. The results obtained

by the selective standard approach show significant improvements for alignment of single-word terms while using any of the external data and confirm the usefulness of exploiting as much data as we have to better characterize context vector representation and thus bilingual lexicon extraction.

Acknowledgments

The research leading to these results has received funding from the French National Research Agency under grant ANR-12-CORD-0020 (CRISTAL project) and the French Projet OCEAN (Outil de Concordance bilinguE libre pour l'Aide la traductioN) of the General Delegation for the French Language and in languages of France.

Abstract

In this paper we present a newly developed tool that enables researchers interested in spatial variation of language to define a geographic perimeter of interest, collect data from the Twitter streaming API published in that perimeter, filter the obtained data by language and country, define and extract variables of interest and analyse the extracted variables by one spatial statistic and two spatial visualisations. We showcase the tool on the area and a selection of languages spoken in former Yugoslavia. By defining the perimeter, languages and a series of linguistic variables of interest we demonstrate the data collection, processing and analysis capabilities of the tool.

1 Introduction

Geographic distribution of linguistic features is traditionally studied in dialectology (regarding closely-related varieties) and in language typology (regarding different languages and language families), with the goal of identifying the patterns of language change. The potential for studying the geographic spread of linguistic features increased with the development of computer-mediated-communication (CMC). Short and long texts produced by the users of social media communication platforms constitute large samples of authentic language use that can be automatically retrieved and analysed to address a range of questions about human behavior, including spatial linguistic patterns analysed in this paper.

The social network Twitter made an especially important contribution to the development of new methods of collecting linguistic data from the Internet by allowing access to the content produced by their users through an API (application programming interface). One interesting feature of Twitter is that tweets are often associated with spatial information, explicitly (GPS coordinates) or implicitly (place names). The data collected from Twitter can either be used as a valuable complement to linguistic data already collected by traditional means or, if traditional data is not available, as a replacement. This opportunity, however, comes with considerable challenges. First, using the data collection interface requires technical skills that researchers interested in studying language variation usually cannot be expected to have. Second, once collected, the data often turns out to be noisy, difficult to annotate and unevenly distributed in space. Observing patterns therefore requires advanced processing methods, such as spatial statistics and geographic information science (GIScience).

In this paper, we present a tool set that combines computational linguistics and GIScience methods in order to facilitate the collection, visualisation and analysis of georeferenced tweets. Our major goal is to allow the wider linguistic research community access to data automatically collected from the Internet (Twitter data in this particular case). We provide a configurable tool set for speeding up the research process without limiting researchers in their choice of input data and analysis techniques. The user is, for instance, free to specify language(s), regions, and linguistic features of interest. Spatial analysis tools

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3412–3421, Osaka, Japan, December 11-17 2016.

can be applied to the extracted and annotated data for visualization and as a help in reasoning about the spatial patterns. In short, we present a tool intended to enable researchers with basic programming skills to perform advanced computational and spatial linguistic analysis.

Throughout the paper, we illustrate the functioning of the tool on an example data set collected for the territory of former Yugoslavia. We choose this region as a case where collecting new linguistic data is especially important. Due to the recent linguistic proliferation,[1] the current situation in this region provides an opportunity for all interested researchers to observe the impact of historical developments on language change. Collecting and analysing samples of computer-mediated-communication becomes particularly important since conducting large-scale linguistic surveys is impeded by the current political and economical situation.

2 Related Work

Computational analyses of the geographic distribution of linguistic features have a long tradition in dialectological research. The data for studying the spread of linguistic features are traditionally collected through questionnaires and field work: a number of potentially informative categories are selected and their realisations are elected from a number of informants selected to represent a linguistic variety in a particular area. Data collected in this way are then stored in databases that can be queried and used for different kinds of quantitative analyses (Nerbonne, 2009; Bauernschuster et al., 2014; Szmrecsanyi, 2012; Wieling et al., 2011). The knowledge about the distribution of linguistic features on the world-wide scale has recently become available in the form of databases. For instance, the data stored in a well-known typological database, WALS (Dryer and Haspelmath, 2013) is often used in large-scale computational studies of language universals (Dunn et al., 2011).

The trends in computational analysis of spatial linguistic data sets led to the development of specialised software such as GeoLing[2], a tool, written in Java, that enables researchers to visualise the spatial distribution of linguistic features using methods such as kernel density estimation (for smoothing data points representation on maps), factor analysis (for reducing the dimensionality) and clustering (for grouping similar areas). This tool requires a previously prepared data set, which can be collected using traditional methods.

User-generated content available on the Internet is used in computational linguistics mostly to study demographic characteristics of speakers based on the linguistic variety they use (Eisenstein et al., 2011; Nguyen et al., 2011; Danescu-Niculescu-Mizil et al., 2013), often including a geographic component (Doyle, 2014; Hovy and Johannsen, 2016). We concentrate here on the work where associated software was made available. Doyle (2014), proposes a method based on conditional probability to estimate the geographical distribution of linguistic features using Twitter. This method can be used to overcome the problem of uneven geographic distribution of collection points.[3] The software associated with this work is SeeTweet[4], a Python tool that uses the Twitter search API to collect tweets containing terms of interest, as well as base terms used for estimating the prior spatial frequency of tweets. The tool does not perform any visualisation of the collected data or any inference.

A recently developed web-based tool called Humboldt[5] (Hovy and Johannsen, 2016) provides a search interface that allows the user to query for lexical phenomena in five languages, and to get both statistical analysis and map representations of the results along two demographic factors: age and sex. This tool uses a data set previously collected by the authors from one source of online reviews of companies.

The tool that we propose in this article differs from the existing tools in its scope and flexibility. Previous tools are mostly focused either on data collection (SeeTweet) or analysis (GeoLing, Humboldt). We integrate these two components allowing the researchers to set up their own criteria both for collecting

[1] Following the war and the separation of SFR Yugoslavia's constitutive republics in the nineties, one of the official languages, Serbo-Croatian, was divided into four languages: Croatian, Bosnian, Montenegrin, and Serbian.

[2] `https://www.uni-ulm.de/en/mawi/geoling/home.html`.

[3] Note that the problem of uneven distribution does not concern traditional data collection methods, where balanced sampling (based on ZIP codes, for instance) is usually part of the design.

[4] `https://github.com/gabedoyle/seetweet`.

[5] `http://www.languagevariation.com`

and analysing data sets depending on their hypotheses. With our tool, the user can define a wide range of potential features to be extracted from a large set of messages. Unlike SeeTweet, where data collection is limited to searching for specific terms, we provide the possibility for capturing the whole (available) data stream, storing all the messages produced in a given region during the collection time. The extraction of the features of interest is again controlled by the user who applies predefined generic functions on his linguistic description of specific phenomena, consisting of either regular expressions or a lexical resource. Regarding the analysis, our tool offers flexibility by allowing users to dynamically switch between spatial summary statistics, simple visualisations and more sophisticated analysis. Importantly, all analysis steps are independent from the underlying spatial distribution of the collected data. This is important since CMC geo-encoded data is known to be biased towards places with high population and sparse in rural regions (Hecht and Stephens, 2014).

In the following three sections we describe the tool and the research set-up that it supports. Each section describes one of the three main components of the tool. With an example data set we illustrate how each component is configured and what it gives as a result. The tool, accompanied with the exemplary dataset, is made available on GitHub[6].

3 Data Collection

The data collection component communicates with the Public Twitter Streaming API and stores the messages to a given location.

It is written in Python and relies on the *tweepy* Twitter API wrapper. In order to start data collection, the user needs to edit the configuration file by entering his Twitter API credentials (obtained from the Twitter Developer site), the project name (arbitrarily defined by the user) and the perimeter of interest (defined by the longitude and latitude bounds). Once the process is launched, a database is created and all the messages obtained from the Public Streaming API are stored. Messages not containing explicit longitude and latitude are discarded.[7]

Each of the retrieved objects is stored in an *sqlite* database as a BLOB structure. Parts of these structures, the `lang` and `screen_name` attributes, are also explicitly stored in the database outside the BLOB for reporting purposes. From these entries, the user can get a collection update at any time, specifying the number of tweets collected, the number of speakers (Twitter users) who published the tweets, and the head of the frequency distribution of tweets per speaker and tweets per the `lang` attribute value.

For our use case we started the data collection procedure in January 2016. For illustration purposes, we use the data collected up to July 2016, while continuing to run the collection process. We defined the perimeter over the countries of former SFR Yugoslavia, namely Slovenia, Croatia, Bosnia, Montenegro, Serbia and FYR Macedonia. During the 6 month period we collected 526,658 tweets from 50,783 speakers.

4 Data Processing

The data processing module is written in Python. Its two main functionalities are data filtering and extraction of linguistic variables.

4.1 Data Filtering

At this point, we provide three speaker-level (i.e. Twitter-user-level) filtering criteria:

- the minimum number of tweets published by a speaker,
- the most prominent language(s) used by a speaker, and
- the most prominent countries from which the speaker tweets.

[6] `https://github.com/clarinsi/tweetgeo`

[7] There are two ways of encoding spatial information on Twitter, explicit position (longitude, latitude), or a location (ranging from a town to a country). We discard the latter as in many areas locations are too general to be useful for spatial analysis.

While implementing the first and last filtering functionalities was quite straightforward (the country from which the tweet was sent can be obtained directly from the `Status` object), the language filtering functionality required additional engineering. Namely, although Twitter messages are tagged with the `lang` attribute, this attribute is known to be very unreliable, especially for the so called smaller languages. To filter only the messages in the language(s) of interest, we perform additional language identification on the level of speaker by applying the off-the-shelf language identification tool *langid.py*[8] (Lui and Baldwin, 2012) on a concatenation of all tweets of a speaker. Before performing language identification, we remove mentions, hashtags and URLs , as such elements were not seen in the language identification training data.

Only the tweets produced by the speakers that satisfy the language constraints are passed to the variable extraction module.

The language filtering criteria are set in a configuration file which is shared with the feature extraction process. In our use case we allowed three languages known to *langid.py*: Croatian, Bosnian and Serbian. While we were collecting data published in Slovenia and FYR Macedonia as well, in this analysis we are not interested in Slovene nor Macedonian data, but want to retain the speakers of the languages of interest from these countries. For this use case we did not define any restrictions regarding the minumum number of tweets per user, and we allowed tweets from our countries of interest and their neighbouring countries.

By running the speaker-level language identification over the fifty thousand Twitter users in our example collection, we have identified 3,854 speakers of the languages of interest. Given that only 7% of the total of collected speakers were identified as writing in the defined languages, we have performed an evaluation of the language identification output by manually checking 200 random entries. While the precision on this sample was 1.0 (16 out of 200 cases), recall was 0.89 as two users were not identified as speakers of the languages of interest. However, each of the two missed users actually produced just one tweet consisting of two words beside smileys and mentions, making the loss negligible.

While there are four times more English speakers than those of the languages of interest, there is a comparable number of Italian speakers and a smaller number of Russian, Spanish, Turkish and Slovene speakers.

4.2 Variable Extraction

Variables represent the user's linguistic features of interest. Our tool allows for a great flexibility in defining the variables, allowing the researchers to express their theoretical insight and creativity in formal description of the linguistic phenomena, putting more weight on individual linguistic insights than it is usually the case in quantitative approaches which tend to use aggregate linguistic data. Deeper exploration of linguistic features and their interactions is in line with the current trends in spatial linguistic research (Wieling and Nerbonne, 2015).

We showcase the variable extraction module on five nominal variables relevant for our area of interest. The first variable, *yat* (illustrated in Table 1), covers the Proto-Slavic vowel which has a different reflex in different dialects, having two levels, *e* for text containing forms of the Ekavian dialect (*dete*, 'child') and *je* for that containing forms of the Jekavian dialect (*dijete*). The second variable, *štošta* focuses on the variation in the interrogative pronoun *what*, with two levels, Standard Croatian *što* and Standard Serbian *šta*. The third variable *daje* covers two levels of variation in the interrogative clitics, *je li* prescribed in Standard Croatian, and *da li* allowed in the remaining varieties. The fourth variable, *month* covers a two-level lexical variation, where Croatian contains specific names for months (*siječanj*, *veljača*...) encoded via variable level *hr*, while the remaining varieties use international ones (*januar*, *februar*...) encoded via variable level *int* (see Table 1 for some examples). The fifth variable, *rdrop* (also given in Table 1), covers the frequent drop of the ending *r* in Standard Serbian like *jučer* (encoded with level *r*) vs. *juče* (encoded with level *nor*).

Our variable extraction component is defined in the configuration file mentioned in the previous subsection in the form of four lists of functions.

[8] `https://github.com/saffsd/langid.py`

yat		month		rdrop	
Word	Value	Word	Value	Word	Value
dječak	je	juni	int	juče	nor
dečak	e	lipanj	hr	jučer	r
dječaka	je	august	int	naveče	nor
dečaka	e	kolovoz	hr	navečer	r

Table 1: A sample of a feature extraction lexicons; each column represent one file used by the extraction function.

The first list of functions operates on the `Status` object of the *tweepy* module, enabling extraction of metadata such as the number of retweets, posting time, whether the tweet is a reply to another tweet etc. The formalism requires for the user to define the location of the metadata in the *tweepy* `Status` object, like `user.screen_name` for the speaker's screen name or `favorited_count` for the number of times a status was favorited. The user can additionally define a function to be applied on the metadata value, such as extracting the posting year from the posting time, like `lambda x:str(x.year)`.

The remaining three function lists operate on the text of the tweet. While the second list of functions operates on the original text of the tweet, the third list of functions operates on the lowercased text, and the fourth one on the normalised text of the tweet.

The normalisation process can be defined by the user and covers, in our use case, removal of repeating characters, generalising spaces and removal of diacritics.

The choice of the text representation level from which the variable will be extracted depends on how important the literal representation of the writing is for extracting a particular variable. For instance, when idetifying the *što* pronoun, we use second level text representation – lowercased text. We want to easily take into account titlecased or uppercased versions of the pronoun, but do not want for diacritics to be removed as the form *što* clashes with the numeral *one hundred*. On the other side, when identifying names of months, we use the third level of text representation, covering with the form *ozujak* various forms like *Ožujak*, *ozujak* or *ožuJAAAAAK*.

The functions that can be run on any of the three mentioned text representations are divided into two types: the `lexicon_choice` and the `regex_choice` function.

4.2.1 Lexicon Choice

In the functions of the `lexicon_choice` type, the desired feature to be extracted is encoded by the user in the form of a lexicon file, where each line consists of a (word, value) pair. An example of such a lexicon in our use case is the lexicon of words containing the already mentioned Proto-Slavic vowel *yat*, as illustrated in the first column of the Table 1.

The *e* reflex is characteristic in the eastern variants (mostly Serbian), while the *je* reflex is found more to the western side of our target perimeter (Croatian, Bosnian, Montenegrin).

The lexicon illustrated in Table 1 was automatically generated from the Croatian and Serbian inflectional morphological lexicons hrLex and srLex (Ljubešić et al., 2016) by searching for pairs of words having the same morphosyntactic description and the word forms identical except the transformations (*ije* vs. *e*) or (*je* vs. *e*)), and both word forms having just one possible canonical form (lemma).

The `lexicon_choice` function iterates through the tokens of each of the collected tweets. If any of the tokens matches any word in the lexicon, the variable value associated with the word is added to the set of potential values. If, at the end of the tweet, there is only one value in the set of potential values, the function assigns that value to the tweet. In all other cases (no coverage, multiple values) the function returns the `NA` value.

The tokenisation function can be also modified by the user. It currently considers tokens to be hashtags, mentions, URLs or greedy alphanumeric sequences.

Similar lexicons can be specified by the user to extract any lexical variation features. Such lexicons can be written by hand or extracted automatically from other resources such in our case. Once they are stored in a location required by the function, they can be used for extraction.

In our use case, we have extracted four such lexicons, illustrated in Table 1. We have chosen these variables based on their varied use, as discussed in comparisons of the language varieties (Meša, 2011). Detailed documentation of the extracted variables is available in the tool documentation.

4.2.2 Regex Choice

The `regex_choice` function operates similarly to the `lexicon_choice` function, it just does not rely on a lexicon, but a list of pairs of regular expressions and variable values. If a regular expression is applicable to the text of a tweet, the corresponding variable value is added to the set of potential values. The decision which value should be returned is identical as in the `lexicon_choice` function. An example of such a function in our use case is the variation of the particles *je li* and *da li*, each being covered by the corresponding regular expressions `"\bje li\b"` and `"\bda li\b"`. These regular expressions are applied on the third level of text representation, namely normalised text.

5 Data Analysis

The analysis module is written in R, an open-source programming language which incorporates a wealth of packages for spatial data handling. At this level of the tool development we decided to limit ourselves to three functionalities: point visualisation, spatial trend detection and the identification of dominant regions per variable level. In the remainder of this section, each of the three functionalities is illustrated.

Here we stress one more time that in this analysis we only consider tweets associated with explicit geolocation, which is only given for some 1-3% of all Twitter messages (Leetaru et al., 2013). We do not attach geolocation to unlocated tweets by, for instance, using the place of domicile of the user location prediction procedures, as it has been shown that such procedures can lead to wrong assumptions (Hahmann et al., 2014).

5.1 Point Visualisation

The point visualisation allows to gain an initial impression of the spatial distribution of all levels of a linguistic feature. It can thus be considered a visual analytics tool (Andrienko et al., 2010).

For visualisation we use the leaflet framework [9], which allows to dynamically change the spatial focus by zooming and panning. This functionality proves to be vital for representing tweets as spatial points, due to the uneven spatial distribution discussed above. On small scales (e.g. country level) tweets are cluttered in populated places and it is thus often difficult to identify the exact distribution of feature levels without having the option of dynamically changing the scale and extent of the map.

Additionally, leaflet allows to activate an HTML popup option, which we use to allow access to the text content of each tweet through mouseclick. The user can for instance iterate through a subsample of the data and thus gain an impression on the data quality in terms of the spatial precision or linguistic variable extraction.

This functionality is also intended to be used alternately with the variable extraction module. Namely, besides analysing the output of the variable extraction process in pure text format, it is often easier to analyse the extracted variables in space and therefore get a faster insight in potential problems in the variable extraction process.

Examples of point visualisation on the *yat* and *štošta* variables can be seen on the left side of Figure 1 and Figure 2.

5.2 Spatial Trend Detection

Spatial linguistic analysis is often concerned with first-order effects, such as distributional patterns in the data (Diggle, 2014). With the spatial trend detection tool we intended to go one step further and introduce a simple measure that allows to quantify the spatial dependency in the data, often referred to as spatial autocorrelation or second-order effect. The quantification of spatial autocorrelation for continuous variables (e.g. temperature) is well established and measures such as *Moran's I* can be used (Moran, 1950). Quantifying spatial autocorrelation in nominal data, which we deal with in this paper, is

[9] `http://leafletjs.com/`

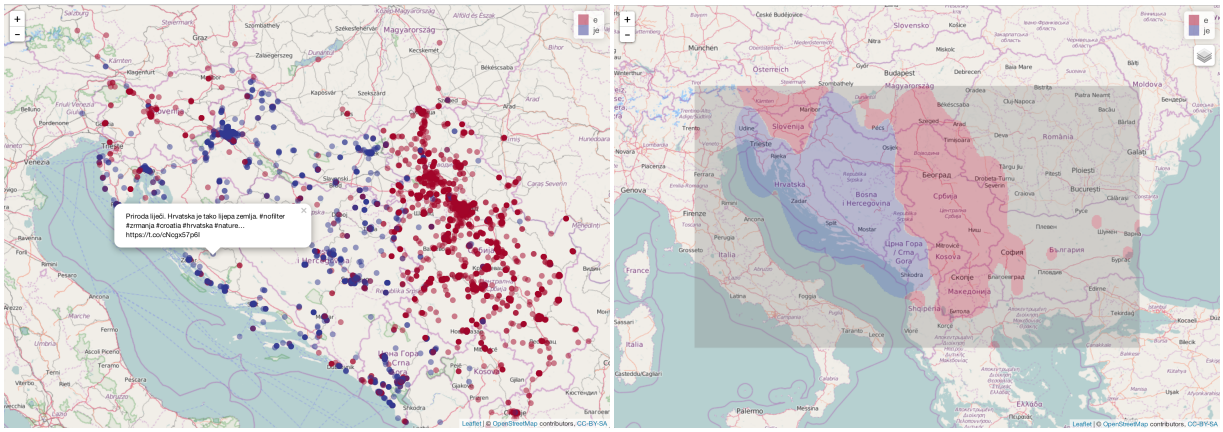

Figure 1: Result of point visualisation (left) and dominance map (right) for the variable *yat*

variable	level	spatial trend	frequency
yat	e	0.457	3298
	je	0.812	1702
stosta	što	1.079	1097
	šta	0.961	2205
daje	dali	0.902	497
	jeli	1.684	58
month	hr	1.252	16
	int	0.906	416
rdrop	r	0.402	79
	nor	0.713	619

Table 2: Statistical description of each variable and level

slightly less common. We compare the spatial distances as computed between all tweets of one linguistic feature (expected distances) with the distances as calculated for each feature level separately (observed distances). Aggregating these two sets of distances into what we call a *relative distance measure* allows us to distinguish feature levels that are spatially clustered (observed distance $<$ expected distance) from levels that are scattered in space (observed distance $>$ expected distance).

The results of the spatial trend detection applied to our five features is given in Table 2. We can observe that two variables having a strong spatial trend (low value equals strong trend), namely *yat* and *rdrop*.

In the *yat* variable the *e* level shows a higher spatial trend than the *ije* level, mostly due to the fact that the use of Ekavian is focused around Belgrade while the use of Jekavian is much more scattered around. This trend can also (partially) be observed in the point visualisation in Figure 1.

In the *rdrop* variable, the *r* level shows a much stronger spatial trend, which goes back to the fact that these variants are mostly used in Croatia only while in the remainder of the region the *nor* variants are used.

A somewhat surprising spatial trend is that of the *month* variable for which we would expect to have a strong spatial trend especially the *hr* level as Croatian month names are used in Croatia only. This result can be followed back to a low observation frequency of the variable in general, especially of the *hr* level. This result shows that, as most measures, the spatial trend heuristic is prone to outliers for small sample sizes.

The remaining two variables, *štošta* and *daje* show an expected weak spatial trend (higher is weaker) as these variants are used intermittently in the whole area of interest.

As shown with these examples, the spatial trend detection tool serves as a simple heuristic for deciding which linguistic features bear the potential of segregating space into larger linguistic areas. Ideally,

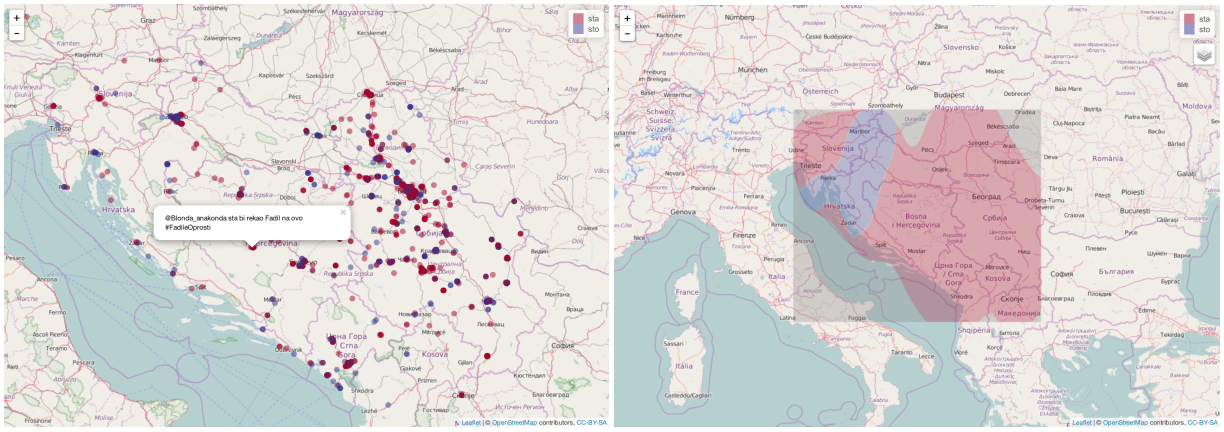

Figure 2: Result of point visualisation (left) and dominance map (right) for the variable *štošta*

candidate features will be passed forward to the dominance map tool, described in the next section.

5.3 Dominance Maps

The dominance map functionality provides the means for calculating continuous surfaces from point observations, in our case georeferenced tweets. Surfaces are calculated for each feature level separately, using kernel density estimation (KDE), a well established method for representing point observations as density surfaces. The local value of a density surface represents the number of observations of the respective feature level proximate to this location. A kernel function is applied for smoothing the signal and to thus account for local noise. The application of KDE to linguistic data is well represented in literature, e.g. (Bart et al., 2013). After computing density surfaces for each feature level individually, local intensities are compared and only the level with maximum local intensity is preserved and mapped as the dominant level. Hence, the dominance map function visually represents linguistic areas *dominated* by individual feature levels.

The two variables presented via point visualisation on the left side of Figure 1 and Figure 2 have their dominance maps depicted on the right side of the respective figures. While for the *yat* variable the point visualisation was already informative, due to a strong spatial trend as reported in Table 2, for the *štošta* variable, showing a weaker spatial trend, the visual identification of regionally dominant levels turns out to be considerably difficult. Therefore the dominance map comes in very handy, showing that only in central Croatia the *što* level is dominant while in the rest of the study area *šta* dominates.

For both variables the dominance map shows that the value dominant in Bosnia and Serbia is also dominant in Slovenia. This is due to large Bosnian and Serbian communities living in this country.

The results of the analysis of the *štošta* variable will benefit from more extensive data collection as the point visualisation shows that the areas of Croatia and Bosnia are only sparsely covered. We would therefore like to emphasize the preliminary nature of these results.

6 Conclusion and Future Work

In this paper, we have presented a configurable, flexible tool set for working with geo-encoded linguistic data automatically collected from Twitter. We have demonstrated through a use case how the tool facilitates to monitor language use in a region of interest. We have extracted a sample of five features with varied linguistic properties (phonetic, lexical, syntactic) and analysed their spatial distribution using spatial methods of varied complexity.

The results of our initial analyses indicate that the flexibility offered by our tool is important for gaining important insights into the data: higher level analyses and visualisation can reveal patterns not visible in a simpler point visualisation (as in the case of the *štošta* variable). On the other hand, point visualisation can serve as a good tool for manual checkups of the reliability of both the extracted data and higher-level analyses. With the possibility to obtain different representations quickly and in a relatively simple

way, researchers can use our tool to address important questions regarding geographical distributions of linguistic features. As the tool is written in popular languages, it is also easy to extend.

In future work, we will use the presented tool to perform further analyses of the language use in the region addressed in our initial study. We will address some of the key points in the ongoing debate about the differences between Bosnian, Croatian, Montenegrin and Serbian and the potential process of linguistic separation.

Furthermore we will continue extending the presented TweetGeo tool with additional analysis capabilities, as well as work on merging the tool with previously developed tools – TweetCat[10] (Ljubešić et al., 2014) which focuses on data acquisition through the Twitter Search API, and TweetPub[11] which is meant for preparing linguistically annotated Twitter collections for publishing while following the Twitter Developer agreement – into a unified toolkit for gathering, analysing and redistributing Twitter data.

While the presented tool is designed for spatial linguistic analysis, we would argue that it is also suited for studying the spatial distribution of other phenomena that can be studied using Twitter and associated metadata. Examples are demographic characteristics, relations between the speakers or particular ways of using the social network. We would therefore argue that without major changes, our tool could be applied to the broader context of the humanities.

Acknowledgements

We would like to thank our collaborator Dolores Batinić for her help in the linguistic part of our work. The work presented in this paper was supported by the URPP 'Language and Space' individual grant and by the Swiss National Science Foundation grant No. 160501.

Abstract

WordNet is probably the best known lexical resource in Natural Language Processing. While it is widely regarded as a high quality repository of concepts and semantic relations, updating and extending it manually is costly. One important type of relation which could potentially add enormous value to WordNet is the inclusion of collocational information, which is paramount in tasks such as Machine Translation, Natural Language Generation and Second Language Learning. In this paper, we present ColWordNet (CWN), an extended WordNet version with fine-grained collocational information, automatically introduced thanks to a method exploiting linear relations between analogous sense-level embeddings spaces. We perform both intrinsic and extrinsic evaluations, and release CWN for the use and scrutiny of the community.

1 Introduction

The embedding of cues about how we perceive concepts and how these concepts relate and generalize across different domains gives knowledge resources the capacity of generalization, which lies at the core of human cognition (Yu et al., 2015) and is also central to many Natural Language Processing (NLP) applications (Jurgens and Pilehvar, 2015). It is general practice to identify and formalize conceptual relations using a reference knowledge repository. As such a repository, WordNet (Miller et al., 1990) stands out as the *de facto* standard lexical database, containing over 200k English senses with 155k word forms. Over the years, WordNet has become the cornerstone of agglutinative resources such as BabelNet (Navigli and Ponzetto, 2012) and Yago (Suchanek et al., 2007). It is also used in semantically intensive tasks such as Word Sense Disambiguation (Navigli, 2009), Query Expansion and IR (Fang, 2008), Sentiment Analysis (Esuli and Sebastiani, 2006), semantic similarity measurement (Pilehvar et al., 2013), development and evaluation of word embeddings models (Huang et al., 2012; Faruqui et al., 2015), and Taxonomy Learning Evaluation (Bordea et al., 2015).

While the value of WordNet for NLP is indisputable, it is generally recognized that enriching it with additional information makes it an even more valuable resource. Thus, there is a line of research aimed at extending it with novel terminology (Jurgens and Pilehvar, 2016), cross-predicate relations (Lopez de la Calle et al., 2016), and so forth. Nonetheless, one type of information has been largely neglected so far: collocations, i.e., idiosyncratic binary lexical co-occurrences. As a standalone research topic, however, collocations have been the focus of a substantial amount of work, e.g. for automatically retrieving them from corpora (Choueka, 1988; Church and Hanks, 1989; Smadja, 1993; Kilgariff, 2006; Evert, 2007; Pecina, 2008; Bouma, 2010; Gao, 2013), and for their semantic classification according to different typologies (Wanner et al., 2006; Gelbukh and Kolesnikova., 2012; Moreno et al., 2013; Wanner et al., 2016). However, to the best of our knowledge, no previous work attempted the automatic enrichment of WordNet with collocational information. The only related attempt consisted in designing a schema for

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3422–3432, Osaka, Japan, December 11-17 2016.

the manual inclusion of lexical functions from Explanatory Combinatorial Lexicology (ECL) (Mel'čuk, 1996) into the Spanish EuroWordNet (Wanner et al., 2004).

Given the importance of collocations for a series of NLP applications (e.g. machine translation, text generation or paraphrasing), we propose to fill this gap by putting forward a new methodology which exploits intrinsic properties of state-of-the-art semantic vector space models and leverages the transformation matrix introduced by Mikolov et al. (2013b) in a word-level machine translation task. As a result, we release an extension of WordNet with detailed collocational information, named ColWordNet (CWN). This extension is carried out by means of the inclusion of *novel edges*, where each edge encodes a *collocates-with* relation, as well as the semantics of the collocation itself. For example, given the pair of synsets `desire.n.01` and `ardent.a.01`, a novel relation $\xrightarrow[x]{col:intense}$ is introduced, where 'intense' is the *semantic category* denoting *intensification*, and x is the confidence score assigned by our algorithm.

The remainder of the paper is organized as follows: In Section 2, we provide some background on collocations and the vector space models on which we base our approach. Section 3 describes the methodology followed to construct CWN. Then, Section 4 presents both intrinsic and extrinsic experimental results. And, finally, Section 5 summarizes the main contributions of our paper and outlines potential avenues for future work.

2 Background

In what follows, we first present relevant background on the semantic categories of collocations we use in our work (Section 2.1) and then on the resources used in our experiments (Section 2.2).

2.1 Collocations

Collocations are restricted lexical co-occurrences of two syntactically related lexical items, the base and the collocate. In a collocation, the base is freely chosen by the speaker, while the choice of the collocate depends on the base; see, e.g., (Cowie, 1994; Mel'čuk, 1996; Kilgariff, 2006) for a theoretical discussion. For instance, in the collocations *take* [*a*] *step*, *solve* [*a*] *problem*, *pay attention*, *deep sorrow*, and *strong tea*, *step*, *problem*, *attention*, *sorrow* and *tea* are the bases and *take*, *solve*, *pay*, *deep* and *strong* their respective collocates.

Besides a syntactic dependency, between the base and the collocate a semantic relation holds. Some of these semantic relations, such as 'intense', 'weak', 'perform', 'cause', etc. can be found across a large number of collocations. For instance, an 'intense' *applause* is a *thundering applause*, an 'intense' *emotion* is *deep*, 'intense' *rain* is *heavy*, and so on. In our experiments, we focused on the subset of the most prominent eight semantic collocation relations (or categories), which are listed in the first column of Table 1. These semantic categories are a generalization of the *lexical functions* (LFs) from ECL already used in Wanner et al. (2004). We have decided to use somewhat more generic categories instead of LFs because, on the one hand, some of the LFs differ only in terms of their syntactic structure (i.e. they capture the same semantic relation), and, on the other hand, LFs pose a great challenge for annotation due to their syntactic granularity.

2.2 Resources

The CWN lexical database is generated thanks to the exploitation of word and sense-based vector space models stemming from BabelNet (Navigli and Ponzetto, 2012),[1] which currently constitutes the largest semantic repository of both concepts and named entities.[2] In BabelNet, just like in WordNet, concepts are represented as *synsets* (i.e., set of synonym senses[3]). This allows us to exploit BabelNet's direct mapping with WordNet so that when our algorithm yields a candidate collocate $synset^{n}_{bn}$, we may retrieve

[1] `http://babelnet.org/`

[2] In its 3.6 release version, BabelNet is composed of 6.1M concepts and 7.7M named entities.

[3] For example, the concept defined as *principal activity in your life that you do to earn money* is represented by the synset {*occupation, business, job, line of work, line*}, where *occupation*, *business*, *job*, *line of work*, and *line* are senses/lexicalizations of the given synset.

its corresponding $synset^n_{wn}$, provided there exists one. In what follows, we briefly describe two different vector space models that are used in this paper for the task of synset-level collocation discovery.

SENSEMBED[4] (Iacobacci et al., 2015) is a knowledge-based approach for obtaining latent continuous representations of individual word senses based on Word2Vec (Mikolov et al., 2013a). Unlike other sense-based embeddings approaches, such as, e.g., Huang et al. (2012), which address the inherent polysemy of word-level representations relying solely on text corpora, SENSEMBED exploits the structured knowledge of BabelNet along with distributional information gathered from the Wikipedia corpus. In this paper, we used SENSEMBED for automatically disambiguating our training data, and as our **bases model**.

SHAREDEMBED. For this model we exploit distributional information from a 3B-word corpus extracted from the web (Han et al., 2013),[5] arguably richer in collocations than the encyclopedic style of Wikipedia. Similarly to SENSEMBED, this model is based on a pre-disambiguation of text corpora using BabelNet as sense inventory. However, unlike SENSEMBED, which learns vector representations for individual word senses, for this model we are interested in obtaining fine-grained information in the form of both plain text words and synsets[6] in a shared vector space (see Section 3.2 for the motivation behind this choice, and its application). To this end, we follow Chen et al. (2014) and modify the objective function of Word2Vec,[7] so that words and synsets can be learned jointly in a single training. The output is a vector space of word and synset embeddings that we use as **collocates model**.

3 Methodology

In this section, we provide a detailed description of the algorithm behind the construction of CWN. The system takes as input the WordNet lexical database and a set of collocation lists pertaining to predefined semantic categories, and outputs CWN. First, we collect training data and perform automatic disambiguation (Section 3.1). Then, we use this disambiguated data for training a linear *transformation matrix* from the base vector space, i.e., SENSEMBED, to the collocate vector space, i.e., SHAREDEMBED (Section 3.2). Finally, we exploit the WordNet taxonomy to select input base collocates to which we apply the transformation matrix in order to obtain a sorted list of candidate collocates (Section 3.3).

3.1 Collecting and Disambiguating Training Data

As is common in previous work on semantic collocation classification (Moreno et al., 2013; Wanner et al., 2016), our training set consists of a list of manually annotated collocations. For this purpose, we randomly selected nouns from the Macmillan Dictionary and manually classified their corresponding collocates with respect to their semantic categories.[8] Note that there may be more than one collocate for each base. Since collocations with different collocate meanings are not evenly distributed in language (e.g., we may tend to use more often collocations conveying the idea of 'intense' and 'perform' than 'begin to perform'), the number of instances per category in our training data also varies significantly (see Table 1).

Our training dataset consists at this stage of pairs of plain words, with the inherent ambiguity this gives raise to. We surmount this challenge by applying a disambiguation strategy based on the notion that, from all the available senses for a collocation's base and collocate, their correct senses are those which are most similar. This is a strategy that has been proved effective in previous concept-level disambiguation tasks (Delli Bovi et al., 2015). Formally, let us denote the SENSEMBED vector space as $\mathcal{S}$, and our original text-based training data as $\mathbf{T}$. For each training collocation $\langle b, c \rangle \in \mathbf{T}$ we consider all the available lexicalizations (i.e., senses) for both the base b and the collocate c in $\mathcal{S}$, namely $L_b = \{l^1_b ... l^n_b\}$, and $L_c = \{l^1_c ... l^m_c\}$, and their corresponding set of sense embeddings $\mathbf{V}_b = \{\vec{v}^1_b, ..., \vec{v}^n_b\}$ and $\mathbf{V}_c =$

[4] We downloaded the pre-trained sense embeddings at `http://lcl.uniroma1.it/sensembed/`.

[5] `ebiquity.umbc.edu/blogger/2013/05/01/umbc-webbase-corpus-of-3b-english-words/`

[6] As explained above, a synset is a set composed of synonym senses.

[7] We used the Continous Bag-Of-Words (CBOW) model with standard hyperparameters: 300 dimensions and a window size of 8 words.

[8] We do not consider phrasal verb collocates, e.g. *stand up*, *give up* or *calm down*.

Sem. Category	Example	# instances
'intense'	*absolute certainty*	586
'weak'	*remote chance*	70
'perform'	*give chase*	393
'begin to perform'	*take up a chase*	79
'increase'	*improve concentration*	73
'decrease'	*limit* [*a*] *choice*	73
'create', 'cause'	*pose* [*a*] *challenge*	195
'put an end'	*break* [*the*] *calm*	79

Table 1: Semantic categories and size of training set

$\{\vec{v}_c^1, ..., \vec{v}_c^m\}$. Our aim is to select, among all possible pairs of senses, the pair $\langle l'_b, l'_c \rangle$ that maximizes the cosine similarity between the corresponding embeddings v'_b and v'_c, which is computed as follows:

$$\langle \vec{v}'_b, \vec{v}'_c \rangle = \text{argmax}_{\vec{v}_b \in \mathbf{V}_b,\, \vec{v}_c \in \mathbf{V}_c} \frac{\vec{v}_b \cdot \vec{v}_c}{\|\vec{v}_b\| \, \|\vec{v}_c\|} \quad (1)$$

Our disambiguation strategy yields a set of disambiguated pairs **D**. This is the input for the next module of the pipeline, the learning of a *transformation matrix* aimed at retrieving WordNet synset collocates for any given WordNet synset base.

3.2 Training a Sense-Level Transformation Matrix for each Semantic Category

Among the many properties of word embeddings (Mikolov et al., 2013a; Mikolov et al., 2013c) that have been explored so far in the literature (e.g., modeling analogies or projecting similar words nearby in the vector space), the most pertinent to this work is the linear relation that holds between semantically similar words in two analogous spaces (Mikolov et al., 2013b). Mikolov et al.'s original work learned a linear projection between two monolingual embeddings models to train a word-level machine translation system between English and Spanish. Other examples include the exploitation of this property for language normalization, i.e. finding *regular English* counterparts of Twitter language (Tan et al., 2015), or hypernym discovery (Espinosa-Anke et al., 2016).

In our specific case, we learn a linear transformation from $\vec{v}'_b$ to $\vec{v}'_c$, aiming at reflecting an inherent condition of collocations. Since collocations are a linguistic phenomenon that is more frequent in the narrative discourse than in formal essays, they are less likely to appear in an encyclopedic corpus (recall that SENSEMBED vectors, which we use, are trained on a dump of the English Wikipedia). This motivates the use of $\mathcal{S}$ as our *base space*, and our SHAREDEMBED $\mathcal{X}$ as the *collocate model*, as it was trained over more varied language such as blog posts or news items.

Then, we construct our linear transformation model as follows: For each disambiguated collocation $\langle l'_b, l'_c \rangle \in \mathbf{D}$, we first retrieve the corresponding base vectors $\vec{v}'_b$. Next, we exploit the fact that $\mathcal{X}$ contains both BabelNet synsets and words, and derive for each l'_c two items, namely the vectors associated to its lexicalization (word-based) and its BabelNet synset. For example, for the training pair $\langle$`ardent_bn:00097467a`, `desire_bn:00026551n`$\rangle \in \mathbf{D}$, we learn two linear mappings, namely `ardent_bn:00097467a` $\mapsto$ `desire` and `ardent_bn:00097467a` $\mapsto$ `bn:00026551n`. We opt for this strategy, which doubles the size of the training data in most lexical functions (depending on coverage), due to the lack of resources of manually-encoded classification of collocations. By following this strategy we obtain an extended training set $\mathbf{D}* = \{\vec{b}_i, \vec{c}_i\}_{i=1}^n$ ($\vec{b}_i \in \mathcal{X}$, $\vec{c}_i \in \mathcal{S}, n \geq |\mathbf{D}|$). Then, we construct a *base matrix* $\mathbf{B} = \left[\vec{b}_1 \dots \vec{b}_n\right]$ and a collocate matrix $\mathbf{C} = [\vec{c}_1 \dots \vec{c}_n]$ with the resulting set of training vector pairs. We use these matrices to learn a linear transformation matrix $\Psi \in \mathbb{R}^{d_\mathcal{S} \times d_\mathcal{X}}$, where $d_\mathcal{S}$ and and $d_\mathcal{X}$ are, respectively, the number of dimensions of the base vector space (i.e., SENSEMBED) and the collocate vector space (SHAREDEMBED).[9] Following the notation in Tan et al. (2015), this transformation can be depicted as:

[9] In our setting the numbers of dimensions are $d_\mathcal{S} = 400$ and $d_\mathcal{X} = 300$.

$$\mathbf{B}\Psi \approx \mathbf{C}$$

As in Mikolov et al.'s original approach, the training matrix is learned by solving the following optimization problem:

$$\min_{\Psi} \sum_{i=1}^{n} \|\vec{b}_i - \vec{c}_i\|^2$$

Having trained Ψ, the next step of the pipeline is to apply it over a subset of WordNet's base concepts and their hyponyms. For each synset in this branch, we apply a scoring and ranking procedure which assigns a *collocates-with* score. If such score is higher than a predefined threshold, tuned over a development set, this relation is included in CWN.

3.3 Retrieving and Sorting WordNet Collocate Synsets

During the task of enriching WordNet with collocational information, we first gather a set of base WordNet synsets by traversing WordNet hypernym hierarchy starting from those base concepts that are most fit for the input semantic category.[10] Then, the *transformation matrix* learned in Section 3.2 is used to find candidate WordNet synset collocates (mostly verbs or adjectives) for each base WordNet synset.

As explained in Section 3, WordNet synsets are mapped to BabelNet synsets, which in turn map to as many vectors in SENSEMBED as their associated lexicalizations. Formally, given a base synset b, we apply the transformation matrix to all the SENSEMBED vectors $\mathbf{V}_b = \{\vec{v}_b^1, ..., \vec{v}_b^n\}$ associated with its lexicalizations. For each $\vec{v}_b^i \in \mathbf{V}_b$, we first get the vector $\vec{\psi}_b^i = \vec{v}_b^i\Psi$ obtained as a result of applying the transformation matrix and then we gather the subset $W_b^i = \{\vec{w}_b^{i,1} \dots \vec{w}_b^{i,10}\}$ ($\vec{w}_b^{i,j} \in \mathcal{X}$) of the top ten closest vectors by cosine similarity to $\vec{\psi}_b^i$ in the SHAREDEMBED vector space $\mathcal{X}$. Each $\vec{w}_b^{i,j}$ is ranked according to a scoring function $\lambda(\cdot)$, which is computed as follows[11]: $\lambda(\vec{w}_b^{i,j}) = \frac{cos(\vec{\psi}_b^i, \vec{w}_b^{i,j})}{j}$. This scoring function takes into account both the cosine similarity as well as the relative position[12] of the candidate collocate with respect to other neighbors in the vector space. Apart from sorting the list of candidate collocates, this scoring function is also used to measure the confidence of the retrieved collocate synsets in CWN.

4 Evaluation

We evaluate CWN both intrinsically and extrinsically. Our intrinsic evaluation consists of a manual scoring of the correctness of the newly introduced relations (Section 4.1). Extrinsic evaluation assesses the quality of CWN as an input resource for introducing collocational information into a word embeddings model (Section 4.2).

4.1 Intrinsic: Precision of Collocate Relations

Sampling and evaluation are carried out as follows. First, for each semantic category, we retrieve 50 random bases included in the aforementioned base concepts (see Section 3.3) and all their hyponym branch. This results in an evaluation set $Test$ of 800 collocations, as for each base we retrieve the 5 highest scoring candiates. These collocations are evaluated in terms of correctness, i.e., if the associated synset is an appropriate collocate for the input base. Note that not all bases in the test set may be suitable for the given semantic category, and that is why we also perform an evaluation on the test data restricted to only those bases manually selected for being suitable for having at least one collocate. We denote the restricted test data as $Test*$. For example, the base synset `putt.n.01` defined as *hitting a golf ball*

[10] These are: For 'intense' and 'weak', `attitude.n.01`, `feeling.n.01` and `ability.n.02`. For the rest of them, we select `cognition.n.01`, `act.n.02` and `action.n.01`.

[11] If $w_b^{i,j}$ appears in a different W_b^j set ($j \neq i$), its scores are averaged.

[12] Position is arguably an important factor as there may be dense areas where cosine similarity alone may not reflect entirely the fitness of a candidate.

Table 2: Summary of the manual evaluation of the performance of CWN and of the baseline

that is on the green using a putter does not admit any 'decrease' collocate, and therefore its collocations are not considered in $Test*$.

Since our algorithm returns a list of candidate collocate synsets for an input base synset, the task naturally becomes that of a ranking problem, and therefore ranking metrics such as Precision@K (P@K), Mean Average Precision (MAP) and Mean Reciprocal Rank (MRR) are appropriate for evaluating this experiment. These measures provide insights on different aspects of the outcome of the task, e.g. how often valid collocates were retrieved in the first positions of the rank (MRR), and if there were more than one valid collocate, whether this set was correctly retrieved, (MAP and R-P)[13]. In Table 2 we provide a detailed summary of the performance of our system (CWN), as compared with a competitor unsupervised baseline which exploits word analogies (as in $\vec{man} - \vec{king} + \vec{woman} = \vec{queen}$). This baseline, which we deploy on the SHAREDEMBED space, takes as input a prototypical collocation of a given semantic category (e.g. *thunderous applause* for 'intense') and an input base, and collects the top 10 Nearest Neighbours (NNs) to the vector resulting of the aforementioned analogy operation. This approach was recently used in a similar setting (Rodríguez-Fernández et al., 2016). Due to the difficulty of the task, and the restriction it imposes for collocates to be disambiguated synsets rather than any text-based word, the unsupervised approach fails short when compared to our supervised method, which is capable to find more and better disambiguated collocates.

Note that for half of the semantic categories under evaluation, our approach correlated well with human judgement, with the highest ranking candidates being more often correct than those ranked lower. This is the case of 'put an end', 'decrease', 'create/cause' and 'weak'. In fact, it is in 'put an end', where our system achieves the highest MRR score, which we claim to be the most relevant measure, as it rewards cases where the first ranked returned collocation is correct without measuring in the retrieved collocates at other positions. Moreover, let us highlight the importance of two main factors. First, the need for a well-defined semantic relation between bases and collocates. It has been shown in other tasks that exploit linear transformations between embeddings models that even for one single relation there may be clusters that require certain specificity in the *domain* or *semantic* of the data (see Fu et al. Fu et al. (2014) for a discussion of this phenomenon in the task of taxonomy learning). Second, the importance of having a reasonable amount of training pairs so that the model can learn the idiosyncrasies of the semantic relation that is being encoded (e.g., Mikolov et al. (2013b) report a major increase in performance as training data increases in several orders of magnitude). This is reinforced in our experiments, where we obtain the highest MAP score for 'intense', the semantic category for which we have the largest training data available.

[13] See Bian et al. (2008) for an in-depth analysis of these metrics.

Table 3: Comparison of collocational sensitivity between original and retrofitted embeddings models over four semantic categories.

4.2 Extrinsic evaluation: Retrofitting Vector Space Models to CWN

We complement our manual evaluation with an extrinsic experiment, where we assess the extent to which our newly generated lexical resource can be used to *introduce collocational sensitivity* to a generic word embeddings model.[14] To this end, we extract collocation clusters by extracting all the synsets associated lemmas (e.g. for *heavy.a.01 rain.n.01*, we would extract the cluster [*heavy*, *rain*, *rainfall*]). These are used as input for the Retrofitting Word Vectors algorithm (Faruqui et al., 2015).[15] This algorithm takes as input a vector space and a semantic lexicon which may encode any semantic relation, and puts closer in the vector space words that are related in the lexicon.

Previous approaches have encoded semantic relations by introducing some kind of bias into a vector space model (Yu et al., 2015; Pham et al., 2015; Mrkšić et al., 2016; Nguyen et al., 2016). For instance, Yu et al. (2015) encode (term, hypernym) relations by grouping together terms and their hypernyms, rather than semantically related items. In this way, their *biased* model puts closer to *jaguar* terms like *animal* or *vehicle*, while an unbiased model would put nearby terms such as *lion*, *bmw* or *jungle*. We aim at introducing a similar bias, but in terms of collocational information. This is achieved, for each lexical function and each synset in CWN-*st*, by obtaining its top 3 collocate candidates and incorporate information on their *collocationality* into the model.

4.2.1 Collocational Sensitivity

In this experiment, we assess the extent to which a retrofitted model with collocational bias is able to discriminate between a correct collocation and a random combination of the same base with an unrelated collocate. To this end, we manually constructed two datasets, one for *noun+adjective* ('intense' and 'weak' semantic categories) and one for *noun+verb* combinations, which we evaluate on the two most productive semantic categories, namely 'perform' and 'create/cause'. The datasets consist of 50 bases and one of their correct collocates according to the Macmillan Collocations Dictionary, accompanied by four *distractor* (*dist.* in Table 3) collocates. For instance, given the correct 'perform' collocation *make a pledge*, we expect our 'perform'-wise retrofitted model to increase the score in $\vec{make} + \vec{pledge}$ substantially more than a combination $\vec{pledge} + \vec{distractor}$. For each evaluated semantic category, we computed the average increase of the cosine similarity between all correct collocations and all distractors (*diff.* in Table 3). As shown in Table 3, there is a consistent increase over the four evaluated semantic categories, namely 'intense', 'weak', 'perform' and 'create/cause'. This proves the potential of our retrofitted model to discern between correct and wrong collocates. In the following section, we explore the possibility to use this vector space for finding collocates giving a base as input.

4.2.2 Exploring Nearest Neighbours for Collocate Discovery

Inspired by Yu et al.'s (2015) work on introducing hypernymic bias into a word embeddings model, we explore the extent to which our retrofitted models can be used to discover *alternative collocates* given the composition of the words involved in a collocation as input. In order to discover these collocates, we compose the base and the collocate by averaging their respective word embeddings and retrieve its closest words in the vector space according to cosine similarity. In Table 4, we show a sample of five NNs for several input adjective+noun collocations. These examples reveal how the vector space model retroffited using our collocations tends to bring closer in the space modifiers (i.e., collocates), providing

[14] We use the Google News pre-trained Word2Vec vectors, available at `code.google.com/archive/p/word2vec/`, as input for retrofitting.

Note the increase in plausible collocates in retrofitted models (in bold). NamedEntity refers to noisy entities appearing among the top 5 NNs.

an interesting method for automatic collocation discovery. Despite its simplicity, this collocational discovery approach extracts a considerable amount of suitable fine-grained collocates for a given base. For example, given the collocation *intense sympathy*, the retrofitted space extracts *considerable*, *tremendous*, *enormous* and *immense* as candidate collocates of intensity among the five nearest neighbours. As future work we plan to further exploit and evaluate the impact of this property.

5 Conclusions and Future Work

We have described a system for an automatic enrichment of the WordNet lexical database with fine-grained collocational information, yielding a resource called ColWordNet (CWN). Our approach is based on the intuition that there is a linear transformation in vector spaces between bases and collocates of the same *semantic category*, e.g. between *heavy* and *rain*, or between *ardent* and *desire*. We have exploited sense-based embedding models to train an algorithm designed to retrieve valid collocates for a given input base. This pipeline is carried out at the *sense* level (rather than the word level), by leveraging models which use BabelNet as a reference sense inventory. We evaluated CWN both intrinsically and extrinsically, and verified that our algorithm is able to encode fine-grained *collocates-with* relations at synset level.

Release. We release CWN at several different confidence levels. The version with the highest confidence includes over 100k collocational edges, which connect over 8k unique base and collocate WordNet synsets. These connections are further enriched by two pieces of information, namely (1) the type of collocation (e.g. 'intense' or 'perform'), and (2) a confidence score derived from our approach. Moreover, in addition to CWN, we also release four modified versions of the well-known Word2Vec Google News vector space model, retrofitted with collocational information, which we constructed for the extrinsic evaluation of CWN. These models can be exploited both for assessing the correctness of a collocation and for the discovery of alternative collocates for a given collocation. Finally, we also make available the evaluation datasets built as part of the Collocational Sensitivity experiment. All data associated with this publication is publicly available at http://www.taln.upf.edu/colwordnet.

Future work. In the future, we plan to design a method to retrieve the best *bases* for a given semantic category, which would allow us not to rely on predefined manually built base concepts. Finally, we are currently investigating the potential of applying neural approaches recasting the task as a sequence classification problem for including collocational information in WordNet clusters.

A News Editorial Corpus for Mining Argumentation Strategies

<firstname>.<lastname>@uni-weimar.de

Abstract

Many argumentative texts, and news editorials in particular, follow a specific strategy to persuade their readers of some opinion or attitude. This includes decisions such as when to tell an anecdote or where to support an assumption with statistics, which is reflected by the composition of different types of argumentative discourse units in a text. While several argument mining corpora have recently been published, they do not allow the study of argumentation strategies due to incomplete or coarse-grained unit annotations. This paper presents a novel corpus with 300 editorials from three diverse news portals that provides the basis for mining argumentation strategies. Each unit in all editorials has been assigned one of six types by three annotators with a high Fleiss' κ agreement of 0.56. We investigate various challenges of the annotation process and we conduct a first corpus analysis. Our results reveal different strategies across the news portals, exemplifying the benefit of studying editorials—a so far underresourced text genre in argument mining.

1 Introduction

News editorials define a genre of written argumentative discourse whose main goal is persuasiveness. In a news editorial, an author states and defends a thesis that conveys his or her stance on a controversial topic usually related to the public interest. Editorials do not only aim to persuade readers of some opinion, but they often also propagate particular ideologies or recommend certain attitudes to the community, e.g., a specific action towards an upcoming event (van Dijk, 1992). To achieve persuasion, a news editorial follows a particular *argumentation strategy* that the author expects to be most suitable for the target audience, i.e., the author composes a series of claims, assumptions, and different types of evidence while using argumentative language and structure (van Dijk, 1995). This does not only cover the resort to quantitative features of text (e.g., related to lexical style, cohesion, or rhetorical structure), but it also refers to the roles, positions, flows, and relations of specific argumentative discourse units.

The study of news editorials is beneficial for several tasks, such as the creation of persuasive writing strategies for writing assistance systems and qualitative media content analysis. At the same time, the rapid expansion of online news portals increases the need for algorithms that can analyze an editorial's discourse *automatically*. The needed analyses include argumentation mining and evidence detection, both of which are studied in computational argumentation, an emergent area of computational linguistics. While several text corpora for such analyses have recently been published for different domains and genres, a respective resource with news editorials is missing to this day. Moreover, existing corpora stick to coarse-grained and/or incomplete annotations of the units of an argumentative discourse (see Section 2 for details), which renders the mining of an author's argumentation strategy impossible.

In this paper, we present a novel corpus with 300 news editorials evenly selected from three diverse online news portals: *Al Jazeera*, *Fox News*, and *The Guardian*. The aim of the corpus is to study (1) the mining and classification of fine-grained types of argumentative discourse units and (2) the analysis of argumentation strategies pursued in editorials to achieve persuasion. To this end, each editorial contains manual type annotations of all units that capture the role that a unit plays in the argumentative discourse,

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3433–3443, Osaka, Japan, December 11-17 2016.

Figure 1: Example news editorial from the presented corpus. Each argumentative discourse unit of all 300 editorials in the corpus has been manually assigned one of six types, four of which are shown here.

such as *assumption* or *statistics*. The corpus consists of 14,313 units of six different types, each annotated by three professional annotators from the crowdsourcing platform *upwork.com*. Figure 1 shows the type annotations of one editorial in the corpus. The editorial has been taken from The Guardian.

Based on the results of the annotation process, we analyze the agreement between annotators in order to scrutinize the major cases of disagreement as well as to designate the complex issues that humans face in classifying types of argumentative discourse units in editorials. Considering the number and complexity of the types, the obtained inter-annotator agreement of 0.56 in terms of Fleiss' κ can be seen as high. In a first brief statistical analysis of the corpus, we investigate differences in the type distribution between the three portals, which indicate divergent argumentation strategies.

To conclude, the contribution of this paper is three-fold: (1) We propose the first annotation scheme for mining argumentation strategies that captures the type of each unit of an argumentative text. Unlike previous schemes, it relies on a complete annotation of the text on a fine-grained level. (2) We introduce a novel corpus with 300 news editorials which are manually annotated according to the scheme. Despite the resort to a so far under-resourced text type, the corpus contains a considerably larger number of unit annotations than comparable existing corpora. In addition, we provide a detailed analysis of the inter-annotator agreement and of the reliability of the resulting annotations. The corpus is freely available in order to foster research on computational argumentation.[1] (3) We present insightful findings that indicate the potential of our corpus for analyzing the argumentation strategies of news editorials. As far as we know, our corpus is the first which allows studying such strategies in monological opinionated text.

2 Related Work

Many recent publications in the area of computational argumentation are concerned with the construction of annotated resources, which is as a fundamental step towards building automatic systems that analyze the argumentative structure of texts. Unlike most previous corpora, the annotations of our corpus provide a classification of argumentative units based on their content. In the most simple case, other works distinguish only argumentative discourse units from other text, as we do in (Al-Khatib et al., 2016). Some

[1] Webis-Editorials-16 corpus, http://www.uni-weimar.de/en/media/chairs/webis/corpora/

corpora contain unit annotations based on the role units take in arguments, e.g., premise or conclusion (Stab and Gurevych, 2014; Habernal and Gurevych, 2015). Such annotations represent the general argumentative structure, but they do not encode the means an author uses to persuade the readers.

Previous corpora that contain content-based unit annotations are not suitable for analyzing argumentation strategies due to their annotation method or to the genre of the contained texts. Similar to our corpus, the CE corpus of Wikipedia articles (Aharoni et al., 2014; Rinott et al., 2015) also considers types of evidence (anecdotes, statistics, and testimony). However, evidence is annotated only where it relates to a set of given topics, so no complete annotation of the article's discourse is provided. Park and Cardie (2014) use annotations to distinguish verifiable from non-verifiable evidence, which is not related to argumentation strategies. The corpus of Habernal and Gurevych (2016) includes logos and pathos annotations. While this would be appropriate for studying argumentation strategies, the corpus consists of short forum discussions, which follow no strategic plan.

Several corpora serve to study relations between the argumentative discourse units in a text (Boltužić and Šnajder, 2014; Ghosh et al., 2014; Peldszus and Stede, 2015; Stab and Gurevych, 2014), e.g., whether a unit supports or attacks another unit or the thesis of the text. Some patterns of such relations would certainly be relevant for an analysis of argumentation strategies, like the rebuttal of a common ground that seems to counter the author's stance. However, similar to the low number of attack relations in persuasive essays (Stab and Gurevych, 2014), we found few insightful patterns of this kind in editorials.

While we focus on the argumentation strategy of an entire text, the 60 schemes of Walton et al. (2008) can be seen as representing the strategy of single arguments, although at a much finer granularity. Annotating a complete argumentative text according to all these schemes is very difficult. The only available resource with scheme annotations we are aware of, the Araucaria corpus (Reed and Rowe, 2004), contains annotations of single arguments but not of whole texts.

The construction of the corpus introduced in this paper has already been sketched in (Kiesel et al., 2015). Due to the pure form of argumentation found in news editorials, we discuss suitability of the corpus as a resource for shared tasks on argument mining there. Most existing work on news editorials in computational linguistics studies sentiment and opinions (Yu and Hatzivassiloglou, 2003; Wilson and Wiebe, 2003; Bal, 2009). A first conceptual study of the relation between the opinions in a news editorial and its argumentative structure is described in (Bal and Saint-Dizier, 2009). Besides, to our knowledge, the only work in this regard is the very recent work of Chow (2016) on Chinese editorials. Unfortunately, the annotation of this corpus is restricted to the argumentativeness of paragraphs as a whole, which makes the corpus unsuitable for analyzing argumentation strategies.

3 Model

We now introduce the model (in terms of annotation scheme) that we propose for analyzing the argumentation strategy of a news editorial. The model is focused on the sequential structure of argumentative discourse, which benefits a reliable statistical recognition of strategy patterns. To this end, we separate an editorial into argumentative discourse units of six different types where each type represents a particular role in the discourse. While our model is in line with related work on evidence types (Rinott et al., 2015), we assign a type to each unit in order to capture an editorial's overall argumentation strategy.

In particular, we see argumentative discourse units as the smallest elements of the argumentative discourse of an editorial. They represent the propositions stated by the editorial's author to discuss, directly or indirectly, his or her thesis. In general, propositions affirm or deny that certain entities have certain attributes. An entity may be an object (e.g., *milk*), a being (e.g., *Obama* or *we*), or an abstract concept (e.g., *learning to cooperate*). Technically, we define a unit based on the notion of propositions as follows:

> **Argumentative Discourse Unit:** An argumentative discourse unit is the minimum text span that completely covers one or more propositions. It always includes a subject (or a placeholder, such as "which") and a verb, and it needs to include an object if grammatically required. It spans at most one sentence.

The units of a news editorial play different roles in the editorial's argumentative discourse. E.g., some

represent knowledge or beliefs of the author or other people, and some serve as evidence in favor or against the truth of other units. We assume each unit to refer to exactly one of six types:

1. **Common Ground:** The unit states common knowledge, a self-evident fact, an accepted truth, or similar. It refers to general issues, not to specific events. Even if not known in advance, it will be accepted without proof or further support by all or nearly all possible readers.

   Example: *"History warns us what happens when empires refuse to teach known values that strengthen societies and help protect them from enemies intent on their destruction."*

2. **Assumption:** The unit states an assumption, conclusion, judgment, or opinion of the author, a general observation, possibly false fact, or similar. To make readers accept it, it is, or it would need to be supported by other units.

   Example: *"For too long young people have relied on adults who have done too little to stop the violation of the rights of the children for whom they were responsible."*

3. **Testimony:** The unit gives evidence by stating or quoting that a proposition was made by some expert, authority, witness, group, organization, or similar.

   Example: *"According to The Yazidi Fraternal Organization (YFO), thousands of young Yazidi women and children are being used by ISIL as sex slaves."*

4. **Statistics:** The unit gives evidence by stating or quoting the results or conclusions of quantitative research, studies, empirical data analyses, or similar. A reference may but needs not always be given.

   Example: *"Of the total of 779 men and boys that have been detained at Guantanamo Bay since 2002, only nine have been convicted of any crime."*

5. **Anecdote:** The unit gives evidence by stating personal experience of the author, an anecdote, a concrete example, an instance, a specific event, or similar.

   Example: *"In 1973, it deployed 18,000 troops with 300 tanks to save Damascus during the 'October War'."*

6. **Other:** The unit does not or hardly adds to the argumentative discourse or it does not match any of the above classes.

   Example: *"Happy New Year!"*

Our hypothesis is that these six types suffice to capture the main structural characteristics of argumentation strategies in news editorials. At the same time, they define an annotation scheme for a fine-grained mining of argumentative discourse units. This scheme represents the basis for the corpus we constructed.

4 Corpus Construction

This section describes the construction and annotation process of the news editorial corpus based on the proposed model (Section 3). The purpose of the corpus is to study different argumentation strategies in news editorials in terms of the argumentative discourse units they use.

4.1 Data Acquisition and Preparation

Before the annotation, the editorials are selected from three diverse news portals and decomposed into clause-like segments in order to ease the annotation process to achieve scale.

Selection of Argumentative News Editorials The corpus consists of editorials from *aljazeera.com*, *foxnews.com*, and *theguardian.com*. This selection of news portals cover diverse cultures and styles. They are internationally well-known and have separate editorial sections. We randomly selected 100 editorials from each portal that (1) are published within the same short time interval (December 2014 and January 2015) to facilitate a topical overlap, (2) sparked at least a small discussion (had at least 5 comments), and (3) contain at least 250 words (to filter out texts that just pose a question instead of arguing).

Type	Editorials	Total	Mean	Std. dev.	Median	Min	Max
Tokens	**All editorials**	**287364**	**957.88**	**257.28**	**932**	**298**	**1894**
	Al Jazeera	106430	1064.30	236.05	1033	440	1671
	Fox News	86415	864.15	226.36	855	298	1613
	Guardian	94519	945.19	267.13	906	481	1894
Sentences	**All editorials**	**11754**	**39.18**	**13.00**	**37**	**12**	**114**
	Al Jazeera	3962	39.62	10.55	38	16	75
	Fox News	3912	39.12	13.45	39	12	104
	Guardian	3880	38.80	14.65	36	18	114
Paragraphs	**All editorials**	**4664**	**15.55**	**6.48**	**15**	**2**	**45**
	Al Jazeera	1896	18.96	5.15	19	7	33
	Fox News	1689	16.89	6.71	16	2	45
	Guardian	1079	10.79	4.29	10	5	31
Segments	**All editorials**	**35665**	**118.88**	**38.21**	**116**	**28**	**309**
	Al Jazeera	11521	115.21	31.68	113	32	218
	Fox News	11315	113.15	35.4	112	28	231
	Guardian	12829	128.29	44.58	122	59	309

Table 1: Distribution of tokens, sentences, paragraphs, and segments in the corpus before annotation.

Pre-Segmentation of Argumentative Discourse Units To allow for an annotation at larger scale, we automatically segmented the editorials before the annotation but then allowed annotators to merge adjacent segments to discard incorrect unit boundaries. In this setup, the annotators do not have to choose the exact unit boundaries, which simplifies the annotation process while making the evaluation of the annotator-agreement more intuitive. A similar manual approach was used by Park and Cardie (2014).

In detail, the applied segmentation algorithm, which we will make publicly available, starts a new segment at the beginning or end of every clause not preceded by a relative pronoun. Clauses were identified using a state-of-the-art dependency parser (Manning et al., 2014) and the clause tags from the Penn Treebank Guidelines (Bies et al., 1995). The heuristic behind the segmentation was chosen based on a careful analysis of news editorials as well as of the persuasive essays corpus from (Stab and Gurevych, 2014), since essays resemble editorials in the way they compose argumentative discourse units. An evaluation of the segmentation algorithm on that corpus yielded very satisfying results: The algorithm segmented the 90 essays into 5132 segments. Only nine of these segments should have been split further, as they overlapped with several ground-truth units from the essay corpus. On the other hand, the segmentation was somewhat too fine-grained, namely, the 1552 ground-truth units were split into 3637 segments. In our setup, however, the annotators then perform the necessary segment merges. Table 1 shows statistics about the size of the corpus and its three sub-corpora after segmentation.

4.2 Annotation Process

Given the 300 selected news editorials, an annotation process was performed in order to identify all argumentative discourse units in each newspaper editorial, including an assignment of one of the six types from Section 3 to each unit. The main steps of this process are summarized in the following.

Task Definition First, each editorial had to be read as whole in order to understand the main topic and to follow the stance of the editorial's author.

As the annotation task, one out of eight classes had to be chosen for each segment of each editorial (see pre-segmentation above): (1–6) Any of the six types of argumentative discourse units of our model from Section 3, (7) *no unit*, when the segment does not belong to a unit, and (8) *continued*, when the segment needs to be merged with subsequent segments in order to obtain a unit. In case (8), the class assigned to the last segment determines the class of the merged unit.

The annotation guidelines given to the annotators contained the type definitions from Section 3 and a few clear and controversial examples for each type. In addition, we pointed out that the correct classification of a segment may require looking at surrounding segments. Also, no distinction should be made between true and false propositions (e.g., a wrong testimony should still be classified as testimony).

	Common ground	Assumption	Anecdote	Testimony	Statistics	Other	No unit	Continued	Overall
Fleiss' κ	0.114	0.613	0.399	0.591	0.582	0.152	0.365	0.684	**0.560**

Table 2: Inter-annotator agreement in the main annotation process, quantified in terms of Fleiss' κ.

Pilot Annotation Study A pilot study was conducted on nine editorials to evaluate the guidelines and to select the annotators. For this, three editorials were chosen from each portal. They are not part of the corpus, but were acquired and segmented in the same fashion.

We decided to conduct the annotation process via the professional crowdsourcing platform *upwork.com* in order both to increase scalability and to obtain independent annotators. The list of candidate annotators comprised ten freelancers. All of them were native English speakers, had at least a bachelor's degree, and had already knowledge about argumentation theories from their education.

Seven annotators completed all nine editorials, taking around 30 minutes per editorial on average. The Fleiss' κ agreement score for all seven annotators was a moderate 0.433 (J. Richard Landis, 1977). As we observed remarkable drops in the agreement caused by either of three specific annotators, we decided to exclude those annotators and keep the remaining four for the main annotation study.

An error analysis of the annotation of the four annotators revealed insightful hard cases. For instance, the annotators had difficulties to distinguish between *common ground* and *anecdote* for units discussing a specific event that is well-known universally. Also, there was notable disagreement between *common ground* and *assumption*. This was expected, though, since the distinction of these two types appears more subjective than for other type combinations. Nevertheless, the agreement between the four annotators for all types was substantial with $\kappa = 0.606$. Therefore, we decided not to modify our scheme, but only to clarify the type definitions and to add some additional examples that clarify these hard cases.

Main Annotation Process The 300 corpus editorials were evenly distributed among the four annotators. Each annotator got 225 editorials to annotate, 75 from each news portal. Accordingly, each editorial was annotated by three annotators.

4.3 Annotation Results

We analyzed the results of the annotation process in order to examine (1) the reliability of the corpus and (2) the major disagreements in units and types between the annotators. Our main findings are as follows:

Inter-Annotator Agreement In terms of Fleiss' κ, the overall agreement is 0.56. As broken down in Table 2, however, the types *common ground* and *other* have only a slight agreement, while the annotators achieved fair agreement for *no unit* and *anecdote* as well as moderate or substantial agreement for the remaining four types. Moreover, for 94.4% of all segments at least two of three annotators agree on one type, suggesting that a resort to majority agreement is very adequate. Considering that the annotators had to decide among eight different classes for every segment, such agreement seems high in overall terms. Therefore, we conclude that the annotations of the corpus can be seen as reliable.

Disagreement Analysis To analyze the disagreement between the annotators, we created the confusion probability matrix (CPM, Cinková et al. (2012)) for all classes shown in Table 3. Each matrix cell shows the probability of choosing the column's class, given that another annotator chose row's class. Table 3 reveals the five class-pairs where annotators are most confused between:

1. Disagreement between *other* and *assumption* (0.324). An explanation may be that the annotators interpreted the intention of the author of a respective editorial differently in some segments.

   An example unit that led to confusion is *"I just don't get it"* after another unit *"the rave reviews for the first episode make me feel like a teetotaller at a lock-in"*. The first unit could be interpreted as an implicit assumption about the reviews in the second unit, say, that the review is corrupt or hard to understand. However, it could also simply be seen as an interjection not belonging to any argument.

2. Disagreement between *common ground* and *assumption* (0.562). Although we revised our guidelines to resolve the ambiguity of these types, their distinction still seems to be hard in practice.

	Common ground	Assumption	Testimony	Statistics	Anecdote	Other	No unit	Continued
Common ground	0.129	**0.562**	0.012	0.005	**0.163**	0.012	0.075	0.042
Assumption	0.035	0.701	0.017	0.010	0.075	0.014	0.066	0.083
Testimony	0.006	0.134	0.618	0.016	0.087	0.002	0.034	0.104
Statistics	0.006	0.195	0.042	0.603	0.074	0.002	0.037	0.040
Anecdote	0.037	0.277	0.041	0.013	0.451	0.016	0.059	0.104
Other	0.018	**0.324**	0.006	0.003	0.101	0.166	**0.310**	0.073
No unit	0.008	0.114	0.008	0.003	0.027	0.023	0.440	**0.377**
Continued	0.001	0.036	0.006	0.001	0.012	0.001	0.094	0.849

Table 3: Probability confusion matrix for all pairs of annotated types of argumentative discourse units.

For example, the unit *"To see a movie legally you must leave your house, queue up, ask someone for a ticket and then sit down in the company of others"* can be viewed as *common ground* if the annotator believes that most people agree with this statement, meaning there is no need for justification. In contrast, it is viewed as an *assumption* if people are assumed to disagree to some extent, e.g., because a DVD can be bought and watched legally at home.

3. Disagreement between *common ground* and *anecdote* (0.163). Confusion between these types occurred in cases where there was a distinct fact that the editorial's author uses to support his stance.

   For example, *Iraq's Sunnis were the leading force within the Iraqi army since its foundation on January 6, 1921*. This declaration was used to support the author's claim that the Sunnis respect their army and see it as a national institution of unrivaled prestige.

4. Disagreement between *other* and *no unit* (0.310). Without clear reason, these classes seem to have been used interchangeably sometimes.

5. Disagreement between *no unit* and *continued* (0.377). The main reason for such disagreement was that the annotators dealt with discourse markers and connectives inconsistently.

   E.g., in case of the subsequent segments (1) *"According to the administration"* and (2) *"the film by Nakoula Basseley Nakoulahad sparked spontaneous riots to defend Muhammad's honor"*, the first was partly seen as *no unit*, although our guideline specified to consider such segments as one unit.

Post-Processing of the Annotations For the final version of the corpus, the corpus segments were consolidated using the *majority vote* for each segment: If at least two workers agreed on the class of a segment, the segment was classified accordingly. Else, one of this paper's authors selected one of three suggested classes. Based on the disagreement analysis and a manual inspection of the annotations, we found a few general misclassifications that could be fixed semi-automatically. While overruling some decisions of the annotators, we thereby achieve a more consistent annotation, which is crucial for learning based on the corpus. In particular, we conducted the following post-processing steps:

- A considerable number of segments was annotated as *no unit*, although it should have been merged with the next segment. We reviewed several instances of this problem, such as conditional statements (e.g., of the form "if A then B") or relations that are not argumentative but temporal or spatial (e.g., of the form "when A then B"). Where necessary, we then merged the respective segments.

- According to our definitions, only non-rhetorical questions should be labeled as *no unit*. However, many rhetorical questions were also classified as *no unit*, even though they had, in our view, a clear argumentative function: most times implicitly conveying claims, recommendations, or similar. Following our definitions, we reclassified them as *assumption*.

- Second person voice segments were often classified as *no unit*, possibly due to the unintended interpretation that a unit requires an *explicit* subject. Nearly all of them are appeals, recommendations, or similar. As above, we thus reclassified them as *assumption*.

In addition to the corrections above, we excluded periods, commas, or similar punctuation at the end of segments and put them in separate *no unit* segments. This is important to prevent unit type classifiers from misleadingly learning to identify particular types based on these characters.

Type	Total	Mean	Std. dev.	Median	Min	Max	Percent
Common ground	241	0.80	1.53	0	0	13	1.7%
Assumption	9792	32.64	12.42	32	3	86	68.4%
Anecdote	2603	8.68	9.12	7	0	77	18.2%
Testimony	1089	3.63	5.42	2	0	44	7.6%
Statistics	421	1.40	2.76	0	0	19	2.9%
Other	167	0.56	1.64	0	0	24	1.2%
All units	14313	47.71	14.28	46	14	132	100%

Table 4: The distribution of types of argumentative discourse units in the created corpus.

4.4 The Corpus

Table 4 presents some statistics of the final corpus, obtained after post-processing. We observe that the most frequent type of argumentative discourse unit is *assumption* covering almost 68.4% of all units. The *anecdote* type represents about 18.2%, surpassing the *testimony* (7.6%), *statistics* (2.9%), and *common ground* (1.7%). *Other*, finally, only refers to a very low percentage of units (1.2%). On one hand, this supports the hypothesis that editorials are a rich source for argumentation. On the other hand, it serves as strong evidence that the six proposed types of units cover most units found in editorials.

5 Argumentation Strategies

Aside from the general use of our corpus for the development and evaluation of approaches to argumentation mining, the corpus serves to investigate how authors argue in news editorials in order to persuade the readers. We do not actually analyze such argumentation strategies here. Rather, we present some basic findings that indicate the potential of our corpus for analysis in this regard.

In particular, Table 5 shows detailed statistics about the types of argumentative discourse units in the corpus. Overall, we see that the length of news editorials is quite stable across the three news portals, with a mean between 48.76 (*The Guardian*) and 52.34 units (*Fox News*). Some very short (minimum 14 units) and very long editorials (maximum 132 units) exist, though.

Regarding the distribution of the types, some general tendencies as well as some insightful differences can be observed. Generally, more than two third of an editorial usually comprises assumptions. This is not surprising, as the type *assumption* covers both claims and any other propositions that may require justification. While *The Guardian* has the highest proportion of assumptions (71.7%), it represents the median for most other types. Fox News more strongly relies on *common ground*, with more than one unit of that type on average. Even more clearly, 8.7% of all units in Fox News editorials is *testimony* evidence, about twice as many on average as in The Guardian (4.55 vs. 2.53). In contrast, Al Jazeera seems to put more emphasis on *anecdote*. At least, it spreads anecdotes across more units (21.0% of all). Interestingly, all three portals behave very similar in their resort to *statistics* at the same time.

Altogether, these numbers suggest that our corpus is worthy of being analyzed regarding argumentation strategies. While we leave such analyses to future research, we expect that especially the sequence of types of argumentative discourse units in an editorial can be decisive. Similar findings have been reported for the impact of discourse functions on the quality of essays (Persing et al., 2010), the inference of intentions from rhetorical moves (Teufel, 2014), and the generality of sentiment flows across review domains (Wachsmuth et al., 2015). Possibly, an adequate granularity (editorial level vs. paragraph level) and abstraction (all types vs. majority in paragraphs vs. ...) may have to be found for editorials, though, because the high average number of units allows for significant variance in respective sequences.

6 Discussion and Conclusion

Although news editorials are considered as one of the purest forms of argumentative text, so far few works exist in computational linguistics that study them. In this paper, we have presented the development of an annotated corpus for the mining of an editorial's argumentative discourse and the analysis of its argumentation strategy. We expect that such an analysis will contribute to the computational assessment of the quality and persuasiveness of monological argumentation. In recent work, we have analyzed the argumentative structure of persuasive essays in order to assess their argumentation quality (Wachsmuth

Type	Editorials	Total	Mean	Std. dev.	Median	Min	Max	Percent

Table 5: Distribution of types of argumentative discourse units in the complete corpus and in the subcorpus of each news portal. Percentages refer to the proportions of units in the respective (sub-) corpus.

et al., 2016). While we focused on the logos means of persuasion there, argumentation strategies actually bring together logos, pathos, and ethos (Aristotle, 2007).

Our corpus is based on a fine-grained model (in terms of an annotation scheme) that we propose for capturing the different types of argumentative discourse units found in news editorials and in similar argumentative texts. We have detailed the annotation process and we have presented empirical evidence for typical characteristics of editorials and their variance across news portals. While not being considered in the model, we point out that units sometimes may have different types, e.g., they may represent both testimonial and statistical evidence. To create a clear classification setting, we decided to assign exactly one type to each unit, though, and to give the annototators guidelines about what type to prefer in what context. Partly, they are already encoded in the presented type definitions. Aside from that, we observed rather low agreement for the infrequent type *common ground*. Still, the resulting annotations may be valuable for research questions related to argumentation quality or persuasiveness. For instance, some authors use specific terms such as "in fact" or "for sure" before assumptions to let them appear as common ground. Our corpus helps to detect such cases.

In general, there is room to extend our corpus in future work. Most evidently, a deeper analysis of the argumentative discourse of news editorials will need to consider the relations between units that make up arguments. Among others, the relations will also reveal what are the main claims of an editorial. Unlike related text genres such as persuasive essays, however, editorials usually have no clear hierarchical argumentative structure, partly due to a frequent resort to enthymemes. This makes a consistent annotation of relations very challenging. We thus decided to focus on the types of units in the given form of the corpus, thereby ending up with a reliable corpus of reasonable size that we will make freely available. Recently, the need for according benchmark corpora was discussed in the emerging community of computational argumentation in order to allow for shared tasks and similar (Gurevych et al., 2016).

Abstract

The Universal Dependencies (UD) project was conceived after the substantial recent interest in unifying annotation schemes across languages. With its own annotation principles and abstract inventory for parts of speech, morphosyntactic features and dependency relations, UD aims to facilitate multilingual parser development, cross-lingual learning, and parsing research from a language typology perspective. This paper presents the Turkish IMST-UD Treebank, the first Turkish treebank to be in a UD release. The IMST-UD Treebank was automatically converted from the IMST Treebank, which was also recently released. We describe this conversion procedure in detail, complete with mapping tables. We also present our evaluation of the parsing performances of both versions of the IMST Treebank. Our findings suggest that the UD framework is at least as viable for Turkish as the original annotation framework of the IMST Treebank.

1 Introduction

The Universal Dependencies (UD)[1] project is an international collaborative project to make cross-linguistically consistent treebanks available for a wide variety of languages. Currently in version 1.3, the UD project covers 40 languages, including two Turkic languages: Kazakh, which was annotated from scratch, and Turkish, the creation of which is described in this paper.

The universal annotation guidelines of UD are based on the Google Universal Part-of-Speech Tagset (Petrov et al., 2012) for parts of speech, the Interset framework (Zeman, 2008) for morphological features, and Stanford Dependencies (De Marneffe et al., 2006; Tsarfaty, 2013; De Marneffe et al., 2014) for dependency relations. The objective of harmonizing annotation guidelines as far as possible is to make comparison of parsing results and investigating cross-linguistic methods across languages easier. This is achieved by a number of principles, including the primacy of content words, distinguishing core arguments from modifiers and distinguishing clausal constituents from nominals.

The IMST-UD Treebank was first released in UD version 1.3 and became the first Turkish treebank to be included in a UD release. The treebank was created by automatic conversion of the IMST

Treebank (Sulubacak et al., 2016), which is itself a reannotation of the METU-Sabancı Turkish Treebank (Oflazer et al., 2003; Atalay et al., 2003). Although the annotation framework of the IMST Treebank was revised, it is still fundamentally similar to that of the METU-Sabancı Treebank and radically different from the UD framework in both morphology and syntax.

In this paper, we describe the procedures employed in converting the annotation schemes of the IMST Treebank to the corresponding UD-compliant schemes. We also provide comparative statistics on the composition of the IMST Treebank before and after the conversion. Afterwards, we report our initial parsing results on the new IMST-UD Treebank in comparison with the original IMST Treebank. The paper is structured as follows: Section 2 discusses the conversion procedure, Section 3 describes the IMST Treebank and the relevant statistics, Section 4 explains the parsing tests and their analysis, and finally, Section 5 presents the conclusion.

2 Mapping

In this section, we describe the procedure we employed in mapping the original IMST Treebank to a UD-compliant framework. The UD-compliant grammatical representations to which we mapped the original annotation schemes were largely adapted from previous work in the subject (Çöltekin, 2015; Çöltekin, 2016). The original treebank was available in the CoNLL-X data format (Buchholz and Marsi, 2006), where sentences are bounded by empty lines, and every word has a separate row, each containing a tab-delimited array of morphosyntactic data pertaining to the word. In compliance with the UD standard, the converted sentences were output in the CoNLL-U format.[2]

The sections to follow present explanations and discussions on the procedures of mapping morphological and syntactic data, as well as some idiosyncratic linguistic phenomena. Quick reference tables were also provided where applicable, showing what conditions on the *source* unit are required to assign which properties to the *target* unit.

2.1 Segmentation

The inflectional group (IG) formalism (Oflazer, 1999; Hakkani-Tür et al., 2002) was designed to make the highly agglutinative typology of Turkish tractable for language processing. Since then, it has seen usage in many influential works (Oflazer, 2003; Eryiğit and Oflazer, 2006) and has become the de facto standard in parsing Turkish. According to the formalism, orthographic tokens are divided into morphosyntactic words from *derivational boundaries*.[3] These units are called the inflectional groups (IGs) of the token. The IG formalism establishes these, rather than orthographic tokens, as the syntactic units of the sentence.

The original IMST treebank also follows its predecessors in using the IG formalism. The rightmost IG governs the word, while every other IG depends on the next one in line with the exclusive relation DERIV. Though a computationally effective representation, IGs are in contradiction with the UD principles. The representation dictates that the rightmost IG (which is, more often than not, a function word) be the head, whereas the leftmost IG (which is always a content word) is made to be the deepest dependent. As this does not comply with the principle of the primacy of content words, IGs have been removed during the conversion to UD. As a substitute, some derivational morphemes were treated as unbound enclitics, segmented off of their host words, assigned parts of speech such as ADP and AUX, and made to depend on their stems. Other morphemes were merged with their stems and were either fully lexicalized or marked for complex morphology. By a lexicalized derivation we mean tokens for which the grammatical process of derivation is not represented, and the result of the derivation is considered to be the lemma. An example for this is shown with *küreselleşme* in Figure 1.

Table 1a outlines the derivations that were segmented off of their stems. The surface forms for each such segment was constructed with the help of a morphological synthesizer, by 1) compiling the morphological analysis of the whole token, then 2) removing the part that corresponds to the derivation and any

[2]The CoNLL-U format is itself a revised version of the CoNLL-X data format. A description of the format is maintained (at the time of writing) on the official UD website (`http://universaldependencies.org/format.html`).

[3]In this context, a *derivational boundary* is the boundary between a POS-changing derivational suffix (or zero morpheme) and the stem that it is added to.

following inflection, and finally 3) synthesizing the new form from this partial analysis. The segments were also assigned the lemmas and parts of speech given in the LEMMA and UPOSTAG columns of the table, and made to depend on their stems with the relation specified in the DEPREL column.

The derivations given in Tables 1a, 1b and 3 are made via the addition of various derivational suffixes. Each of these suffixes has several allomorphs according to vowel harmony (e.g. the agent-deriving suffix may have the following 16 forms: *–cı, –ci, –cu, –cü, –çı, –çi, –çu, –çü, –ıcı, –ici, –ucu, –ücü, –yıcı, –yici, –yucu, –yücü*), and sometimes there is no overt suffix (as in the third person singular copula, which is a zero morpheme). Moreover, words are often further inflected after derivation, or may be multiply derived, and the analysis of these cascading and overlapping suffixes is an ambiguous and unreliable process. Therefore, instead of derivational morphemes, the minor part-of-speech tags assigned to each word (given in the POSTAG column) were used to identify derivations.

Table 1b lists the derivations that were not considered sufficiently productive and merged with their stems. Although these derivations have varying degrees of productivity, words derived by them are largely confined to a limited group of fairly common derivations. The fact that these words were more often than not lexicalized in the original treebank served as our justification for the lexicalization. The *lexicalized token* was made to inherit the surface form, lemma, and all morphological and syntactic data from the *derivation*, as well as its dependents, before replacing both the *stem* and the *derivation*.

Table 3 summarizes the participle (verbal adjective), transgressive (verbal adverb) and gerund (verbal noun) derivations in the same manner. In compliance with the UD standard of encoding verb forms, the *merged token* was made to inherit the lemma of the *stem*, as well as the surface form, the CASE, PERSON[PSOR], NUMBER[PSOR] and TENSE features, the head index, and the dependents of the

derivation. The *merged token* was also assigned a VERBFORM feature as designated by the mapping, along with ASPECT, MOOD, TENSE and NEGATIVE features, before replacing the *stem* and the *derivation*.

In addition to the derivations discussed previously in this section, there were some zero derivations in the original treebank that were immediately derived into other parts of speech without any inflection inbetween, such as when adjectives were derived into zero nouns before copular (verbal) derivations. These intermediate derivations held no morphosyntactic information and were eliminated in conversion.

2.2 Part-of-Speech Tags

The mapping of the UD part-of-speech tags are displayed in Table 2. Most parts of speech were mapped in a straightforward, one-to-one fashion, with a small number of exceptions. In some cases, extra morphological features were used for an expressive conversion.

2.3 Morphological Features

Table 4 shows the mapping of the morphological features. Derivational information was mostly kept in the minor part of speech (POSTAG) field in the original IMST Treebank. These tags were retained in the XPOSTAG field in the CoNLL-U output after the conversion. Using either a directly corresponding UD feature or a combination of other UD features, we were able to represent most of the information kept in these fields.

The TENSE, ASPECT and MOOD features are closely related and often fused in Turkish. In some cases, a multiply derived token may have more than one value for one of these features. Moreover, although the UD guidelines enforce these features for finite verbs, they were occasionally omitted in the IMST Treebank so that they would defer to a neutral value. Whenever one of these features had more than one corresponding value, we concatenated these values with a hyphen delimiter, except for multiple occurrences of the same feature value, and the cases specified in Table 4. If one of these features had no directly corresponding value, we assigned the implied default value (TENSE=PRES, ASPECT=PERF, and MOOD=IND). For instance, the feature sequence HASTILY | PROG1 was converted to ASPECT=PROG-RAPID | MOOD=IND | TENSE=PRES.

Table 4: Morphological feature mapping.

2.4 Dependency Relations

The mapping rules used in converting dependency relations are outlined in Tables 5, 6, 7, and 8. The conditions for these mapping rules are considerably more complex than for the parts of speech and the morphological features. More often than not, besides the original dependency relations, additional morphosyntactic and lexical data must be considered for an accurate mapping. Furthermore, the entire analysis of a given dependent may sometimes not suffice, and further data pertaining to the head token that governs that dependent must be considered as well (as specified under columns with *(head)* labels).

Table 5 shows the mappings for dependency relations that are essentially types of modifiers and determiners. The mapping conditions are exactly as arranged on the table, except for the mapping to the ADVCL relation, where if the word had the feature VERBFORM=GER, it was also required to have an adpositional dependent with a CASE dependency. This means having a CASE dependent on a verbal head, which is incompatible with the UD guidelines for the moment. However, as this is an issue that will be discussed in the future, we decided to wait and see whether a change in the guidelines will be made. Table 6 displays the rules for dependencies that denote multiword expressions and other compounds. Multiword expressions (MWEs) were mapped to five different UD relations dependending on their context. The remaining MWEs were converted according to their syntactic role in the sentence. For both of the groups covered in Tables 5 and 6, certain cases were only distinguishable by their lemmas. These cases are given in additional rows below each table.

Tables 7 and 8 show the mappings for the remaining dependency relations. These tables also give exact mapping conditions, except for tokens with OBJECT dependencies (Table 7), which were still mapped to CCOMP dependencies without a VERBFORM=GER feature if they had a copular dependent with a COP dependency. Table 8 is reserved for dependency conversions whose head indices were adjusted

along with their dependency relations. For the mappings marked **SWAP** in the HEAD column, the direction of the dependency was also reversed. The original dependent became the new head and vice versa, and the dependents of these tokens were swapped. For those marked **CLAUSAL**, the head of the dependency (usually the sentence root in the original IMST Treebank) was updated to the head of the clause in which the token occurs. If no such clause exists, the head of the sentence was assigned instead.

Table 8: Dependency mapping: Other dependencies, adjusting the typology.

For any remaining tokens whose dependencies were not updated by any of the given mapping rules, a catch-all UD relation was assigned according to its converted part of speech. Tokens with the part-of-speech tags ADP, CONJ, INTJ and PUNCT were respectively attached the dependency relations CASE, CC, VOCATIVE and PUNCT. Those with the tags ADJ, ADV, DET and NUM were respectively given the AMOD, ADVMOD, DET and NUMMOD relations. Any other token was assigned the NMOD relation.

2.5 Postprocessing

After the adjustments to segmentation and the conversion of part-of-speech tags, morphological features and dependency relations, we applied postprocessing routines to each sentence to ensure they constitute valid dependency trees. This step was also necessary in order to circumvent some cases in the original IMST Treebank where sentences did not have a unique token with the sentence root as the head. These cases were often due to dependencies such as CONJUNCTION, PUNCTUATION and VOCATIVE, which depended on the sentence root in certain contexts as required by the dependency grammar. Otherwise, a small number of annotation errors which broke the unique root constraint were also present in the original treebank, and these warranted addressing as well.

Initially, every token depending on the sentence root with a non-ROOT dependency was reassigned the clausal head (or, if not applicable, the sentential head) as its new head. The remaining sentences that still broke the constraint were artifacts of annotation errors. For these sentences, an additional treeification procedure was applied to break all cycles and ensure the possibility of reaching the root from any token.

For sentences with no rooted token (and at least one obligatory cycle), the rightmost token that was part of a cycle was considered the sentential head and connected to the sentence root with the dependency relation ROOT. For any other cycles, the token with the most dependents in the cycle was considered a clausal head and connected to the sentential head, keeping its original dependency relation. Finally, if a sentence had multiple rooted tokens, the rightmost rooted token with a VERB category (or, in the absence of rooted VERB tokens, simply the rightmost rooted token) was considered the sentential head, and the other rooted tokens were connected to that token with the dependency relation CONJ.

3 The IMST Treebank

The IMST Treebank is a Turkish dependency treebank of well-edited sentences from a wide range of domains, fully annotated for morphological analyses and dependency relations. The treebank underwent substantial changes since its unofficial conception in 2014 and was at version 1.3 when it was officially released.[4]

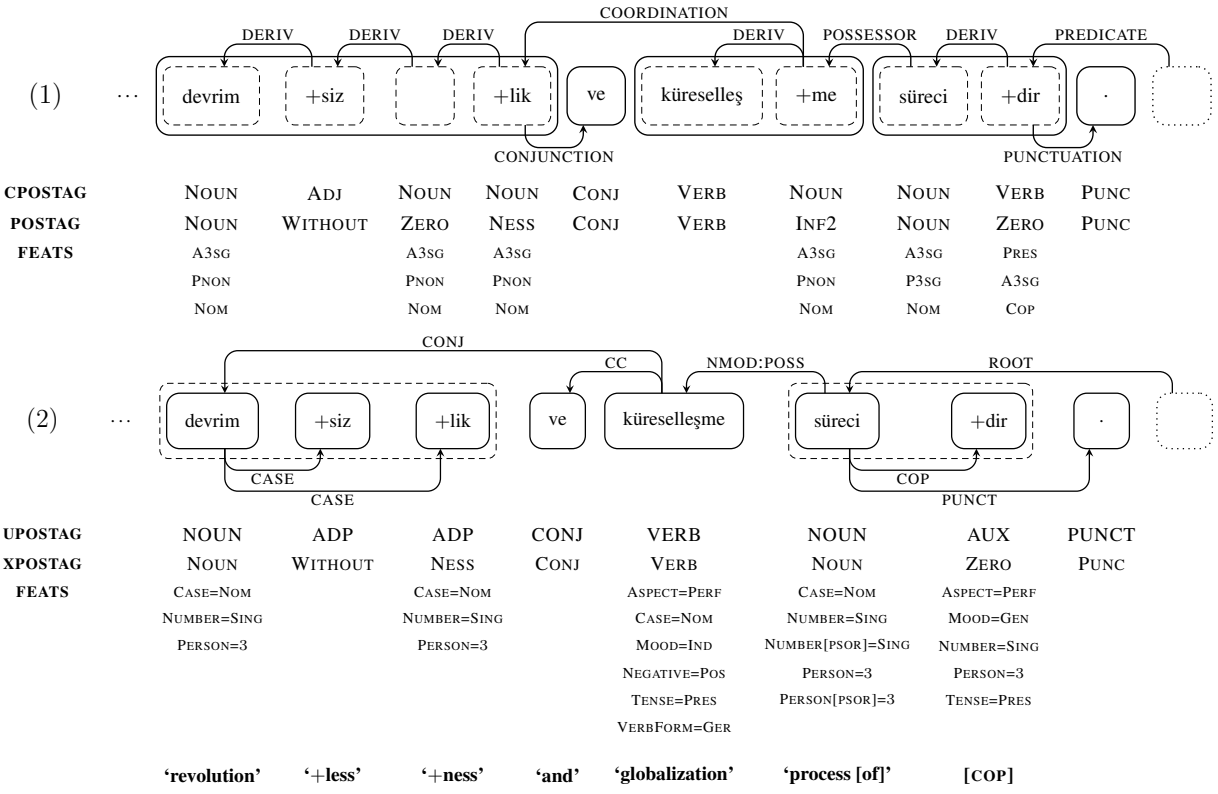

Figure 1: An example of a partial sentence, "*...devrimsizlik ve küreselleşme sürecidir.*" ("**...is the process of revolutionlessness and globalization.**"), before (1) and after (2) the conversion, extracted from the IMST and IMST-UD treebanks.

The IMST Treebank was annotated using its own annotation framework, which is based on that of the METU-Sabancı Treebank and radically different from the UD framework. Figure 1 compares a partial sentence from the IMST Treebank before and after the conversion. The + sign is used for convenience as a suffix marker, and does not actually occur in the treebank. The token enclosures denote either IG sets (in the original treebank sentences) or multi-word tokens (in converted sentences). As shown in the example, these multi-word groups were converted to a head-first typology, whereas coordination structures remained head-final. This is because the final token in a coordination structure always retains all inflection, whereas suffixes shared by all the tokens may be dropped in the others.

Table 9 presents a selection of comparative statistics, including the total numbers of sentences, tokens and dependency counts as well as the counts of unique part-of-speech tags, morphological features and dependency relations for the baseline and converted versions of the IMST Treebank, as a preamble to the parsing tests described in Section 4. We use the treebank's version 1.3.1 as the baseline for the UD conversion. For this reason, the statistics provided in this section are slightly different from those given in the IMST Treebank's original publication (Sulubacak et al., 2016).

Table 9: Comparative statistics for the IMST Treebank and the IMST-UD Treebank.

4 Evaluation

In this section, we present our statistical analysis on the parsing performances of the original and converted versions of the IMST Treebank.

4.1 Preliminaries

For our parsing tests, we employ the same MaltParser (Nivre et al., 2007) configuration as in many previous studies on the METU-Sabancı Treebank (Eryiğit, 2006; Eryiğit et al., 2008; Eryiğit et al., 2011; Sulubacak and Eryiğit, 2013) and the IMST Treebank (Sulubacak et al., 2016). In compliance with the parsing procedures used in the cited studies, we eliminate non-projective sentences from each training set, as this practice was shown to boost overall performance[5] (Eryiğit et al., 2008; Eryiğit et al., 2011).

In further accordance with the cited studies, we use the conventional labeled and unlabeled attachment scores as our evaluation metrics. Although both scores are essentially based on the ratio of correct predictions to all tokens, they differ in which predictions they accept as correct. While a correct prediction of the head token suffices for the unlabeled attachment score (UAS), the labeled attachment score (LAS) also requires the dependency relation to be correctly predicted. Furthermore, dependencies with the relation DERIV[6] are excluded from evaluation for the baseline version, as they are considered trivial.

4.2 Parsing Scores

The parsing scores given in Table 10 were calculated via ten-fold cross-validation on the baseline *(left)* and the UD *(right)* versions of the IMST Treebank. A comparison of the scores before and after the conversion to UD shows that there has been a noticeable improvement in the labeled attachment score, despite the consequential increase in the number of unique POS tags, morphological features and dependency labels, as previously shown in Table 9. However, there has been no apparent progress in the unlabeled attachment score. Since head indices had also been adjusted as part of the mapping procedure, the similarity in the scores is likely a favorable coincidence. Considering both scores, it is evident that the UD framework has been more accommodating for the IMST Treebank over the current parsing setup.

	IMST	IMST–UD
LAS	$75.4 \pm 0.2\%$	$77.1 \pm 0.2\%$
UAS	$83.8 \pm 0.3\%$	$83.8 \pm 0.2\%$

Table 10: Attachment scores.

[5] We tested this on the UD version of the IMST Treebank as well, and including non-projective sentences in training indeed caused a drop of 2.9 percentage points in the average labeled attachment score compared to training without non-projective sentences.

[6] The DERIV relation is used in the annotation framework of the original IMST Treebank to mark intra-token dependencies between morphosyntactic units. Each such unit depends on the next, and the rightmost unit is considered to be the head.

5 Conclusion

In this paper, we described our procedure for converting the morphological and syntactic tagset of the IMST Treebank to comply with the UD standard. In doing so, we presented a specific application of the UD guidelines to the annotation of parts of speech, morphological features and dependency relations in Turkish. We also introduced the IMST-UD Treebank, which was automatically converted from the IMST Treebank and became the first Turkish treebank to be in a UD release. We also evaluated the parsing performances on the IMST and IMST-UD treebanks and found that there is a noticeable improvement in parsing performances after conversion, which suggests that the UD framework is at least as viable for Turkish as the original annotation framework of the IMST Treebank.

Acknowledgements

We would like to thank Birsel Karakoç, Hüner Kaşıkara and Tuğba Pamay for their valuable insights and discussions, and the Uppsala University for kindly hosting a meeting for us during the initial stages of our effort. We would also like to offer our gratitude to our anonymous reviewers for meticulously proofreading our manuscript.

Creating Resources for Dialectal Arabic from a Single Annotation: A Case Study on Egyptian and Levantine

Ramy Eskander, Nizar Habash†, Owen Rambow and Arfath Pasha
Columbia University, USA

rambow@ccls.columbia.edu, arfath@ccls.columbia.edu

Abstract

Arabic dialects present a special problem for natural language processing because there are few Arabic dialect resources, they have no standard orthography, and they have not been studied much. However, as more and more written dialectal Arabic is found on social media, natural language processing for Arabic dialects has become an important goal. We present a methodology for creating a morphological analyzer and a morphological tagger for dialectal Arabic, and we illustrate it on Egyptian and Levantine Arabic. To our knowledge, these are the first analyzer and tagger for Levantine.

1 Introduction

The goal of this paper is to show how a particular type of annotated corpus can be used to create a morphological analyzer and a morphological tagger for a dialect of Arabic, without using any additional resources. A morphological analyzer is a tool that returns all possible morphological analyses for a given input word taken out of any context. A morphological tagger is a tool that identifies the single morphological analysis which is correct for a word given its specific context in a text. We illustrate our work using Egyptian Arabic and Levantine Arabic. Egyptian Arabic is in fact relatively resource-rich compared to other Arabic dialects, but we use a subset of available data to simulate a resource-poor dialect.

For Arabic and its dialects, we are faced with a set of well-known challenges (Habash, 2010): they have a rich morphology, the orthography encourages ambiguity, and the dialects do not have standard orthographies (and are generally not well documented linguistically). However, we can also exploit similarities among the dialects and between Dialectal Arabic (DA) and Modern Standard Arabic (MSA), and in fact the writing system, while encouraging ambiguity, also reduces the differences between these variants.

The approach we present in this paper is based on the morphological annotation of a text corpus. The annotator provides for each word a conventional orthography, a segmentation, a set of features, and a lemma. We use this information to hypothesize unseen morphological forms, and use all forms to build an analyzer for the new dialect. Because of the close relationship among the variants of Arabic, we also make use of an existing analyzer for MSA, and (in the case of Levantine), an existing Egyptian analyzer. The resulting analyzer is then used in a tagger, which uses the annotated corpus to learn classifiers that choose among all possible analyses. Crucially, we do not require the corpus to be fully annotated, allowing the annotator to concentrate on the most frequent words. We are currently annotating five more dialects with this sort of corpus, with initial corpora available for two dialects (Al-Shargi et al., 2016).

The primary contribution of this paper is that we describe a methodology for creating morphological analyzers and taggers for any Arabic dialect. We show the effectiveness of our approach by measuring performance based on training corpora of different sizes. A secondary contribution of this paper is that we present new resources for Levantine Arabic (a morphological analyzer and a morphological tagger), which to our knowledge are the first of their kinds.

While we restrict our attentions to Arabic and its dialects, we believe our approach may be relevant to other situations in which we face a large number of related low-resource languages or language variants.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3455–3465, Osaka, Japan, December 11-17 2016.

This paper is structured as follows: Section 2 presents related work. Section 3 presents the data we use. Section 4 discusses the creation of morphological analyzers, and Section 5 the morphological taggers. Section 6 evaluates the morphological analysis and tagging. Finally, Section 7 concludes and outlines future plans.

2 Related Work

There has been a considerable amount of research on MSA morphological analysis, disambiguation, part-of-speech (POS) tagging, tokenization, lemmatization and diacritization, see for example (Habash and Rambow, 2005; Zitouni et al., 2006; Diab et al., 2007; Pasha et al., 2014).

In the early efforts on DA processing, researchers focused on exploiting MSA resources and tools. Duh and Kirchhoff (2005) adopted a minimally supervised approach that requires raw data from several DAs, and an MSA morphological analyzer. They reported a POS accuracy of $\sim 71\%$ on a coarse-grained POS tagset (17 tags). Similarly, Chiang et al. (2006) were the first to attempt to do parsing on Arabic dialects using MSA training data. Other notable efforts to create dialectal morphological analyzers using MSA morphological analyzers include work reported by Abo Bakr et al. (2008) and Salloum and Habash (2011).

In the last few years, an important shift in the research on DA processing occurred, as researchers started to create resources that target DA and focused less on exploiting MSA resources. This can be seen in the rise of dialectal corpora and annotations (Gadalla et al., 1997; Diab et al., 2010; Al-Sabbagh and Girju, 2012b; Mohamed et al., 2012; Maamouri et al., 2014; Bouamor et al., 2014; Jarrar et al., 2014; Masmoudi et al., 2014; Smaïli et al., 2014; Voss et al., 2014; Khalifa et al., 2016).

In the context of morphological analysis and tagging for Arabic dialects, recent efforts focused principally on Egyptian Arabic (Mohamed et al., 2012; Al-Sabbagh and Girju, 2012a; Habash et al., 2012b; Habash et al., 2013). Mohamed et al. (2012) annotated a small corpus of Egyptian Arabic for morphological segmentation and learned tokenization models using memory-based learning (Daelemans and van den Bosch, 2005). Their system achieves a 91.90% accuracy on the task of morpheme-segmentation. Al-Sabbagh and Girju (2012a) describe a supervised tagger for Egyptian Arabic social media corpora using transformation-based learning (Brill, 1995). They report 87.6% on POS tagging. Finally, we previously created a morphological analyzer for Egyptian (Habash et al., 2012b) using the lexicon of Kilany et al. (2002); then we used this analyzer to create a morphological tagger (Habash et al., 2013). Our previous work used rich Egyptian-specific resources — the lexicon derived from the CallHome corpus for Egyptian Arabic (Kilany et al., 2002) and the Egyptian Arabic Treebank (Maamouri et al., 2014). In contrast, we now wish to explore how much can be done with a small annotation effort. In both our previous work and our new one, we use an analyze-and-choose approach to morphological tagging, following the work of Hajič (2000) (also used by Habash and Rambow (2005) for MSA). We also compare against our previous work in our evaluation.

3 Data

3.1 Orthography

Arabic dialects do not have a standard orthography. This is a big challenge to the annotation process as it allows the coexistence of uninteresting orthographic variations. To address this challenge, we previously developed the *Conventional Orthography for Dialectal Arabic* (CODA) (Habash et al., 2012a). The CODA choices aim at reducing differences between variants (DA and MSA) when possible while maintaining the distinctive morphological inventories of the different variants. The first CODA specifications were developed for Egyptian Arabic (henceforth EGY) and utilized in the EGY corpus which we also use (Maamouri et al., 2012). The EGY CODA guidelines were extended to Levantine Arabic (henceforth LEV) by the creators of the LEV corpus we use (Jarrar et al., 2014). Since the LEV corpus was annotated without diacritics, all diacritics were also stripped from the EGY corpus for the study we present in this paper. The only exception is that lemmas are represented using diacritics in the corpora for both dialects so that fine-grained distinctions between different lexemes can be made.

Word	CODA	Lemma	Gloss	BW Tag	POS	POS5	Stem
سألو sÂlw	سأله sÂlh	saÂal	ask	PV+PVSUFF_SUBJ:3MS+PVSUFF_DO:3MS	verb	VRB	sÂl
ابوه Abwh	ابوه Abwh	Ab	father	NOUN+POSS_PRON_3MS	noun	NOM	Ab
ليش lyš	ليش lyš	layš	why	INTERROG_ADV	adv_interrog	PRT	lyš
اتأخرت AtÂxrt	اتأخرت AtÂxrt	AitÂax∼ar	be late	PV+PVSUFF_SUBJ:2MS	verb	VRB	AtÂxr
لهلوكت lhlwkt	لهالوقت lhAlwqt	waqt	time	PREP+DEM_PRON+DET+NOUN	noun	NOM	wqt
؟ ?	؟ ?	?	?	PUNC	punc	PNX	?

Table 1: An example Levantine sentence سألو ابوه ليش اتأخرت لهلوكت؟ *sÂlw Abwh lyš AtÂxrt lhlwkt?* 'His father asked him why he was late?'. The various columns are for the CODA spelling and different morphological features: lemma, gloss, Buckwalter POS tag, two reduced POS tags and stem.

3.2 Egyptian Data

Corpus We use the Egyptian Arabic corpora developed by the Linguistic Data Consortium (LDC) (Maamouri et al., 2012; Eskander et al., 2013a). The corpora are morphologically annotated in a similar style to the annotations done at the LDC for MSA. Words are provided with contextually appropriate CODA form, lemmas, POS tags (Buckwalter, 2004), and English glosses.

We ran the EGY corpus through our EGY morphological analyzer CALIMA$_{\text{Egy}}$ (Habash et al., 2012b) in order to generate morphological features similar to the ones described in MADAMIRA (Pasha et al., 2014). In this process, we replaced the human-annotated corpus analysis by the closest CALIMA$_{\text{Egy}}$ analysis when it does not match any of the CALIMA$_{\text{Egy}}$ analyses for a given word. In the cases where CALIMA does not produce an analysis, a word is analyzed as a proper noun as a back-off. The back-off happened in 4.9% of the words. Finally, we removed diacritics from the corpus except for the lemmas as described above.

Data Splits We follow the corpus splits described in (Diab et al., 2013). The whole DEV (45K words) and TEST (46K words) are used, while only a portion of 135K words of TRAIN is utilized for the purpose of this work.

3.3 Levantine Data

Corpus We use the Curras Corpus of Palestinian Arabic developed at Birzeit University (Jarrar et al., 2014) as the LEV data. Palestinian Arabic is a sub-dialect of Levantine Arabic. The Corpus is around 57,000 words, half of which come from transcripts of a TV show and the rest of which comes from a mix of sources such as Facebook, Twitter, blogs and web forums.

The corpus is morphologically annotated in a similar style to the annotations in the EGY corpus. Procedurally, the developers of the Curras Corpus used MADAMIRA Egyptian (Pasha et al., 2014) to provide a starting point for the manual annotation. In this paper, we used a version of Curras that is only 82% manually annotated. Gaps in annotation exist only in the training corpus, but not in the development or test corpora, which are fully manually annotated. At the time of this publication, the Curras corpus is fully annotated.

Table 1 presents an example of a single Levantine sentence with the following associated annotations:[1] the CODA spelling, the lemma, its gloss, the full Buckwalter POS tag, two POS tags from different tagsets of Arabic and the stem. We discuss them further and evaluate against them in Section 6.

Data Splits We divided the provided corpus into three data sets; TRAIN, DEV and TEST, corresponding to 78% (45K words), 11% (6K words) and 11% (6K words) of the corpus size, respectively. DEV is selected to be the first 371 sentences of the Facebook threads in Curras, in addition to the first four documents from the TV show *Watan Aa Watar*, while TEST represents the rest of the Facebook threads and the next four documents from the TV show. The remaining part of the Curras corpus forms TRAIN.

[1] Arabic transliteration in this paper is presented in the Habash-Soudi-Buckwalter scheme (Habash et al., 2007).

4 Creating the Morphological Analyzers

We build two morphological analyzers, one for EGY and one for LEV, based on the corpus annotations. The two analyzers are built in the same manner based on completing the inflectional classes (ICs) generated from TRAIN. We follow our work on the automatic extraction of morphological lexicons from corpora to build morphological analyzers given the corpus annotations (Eskander et al., 2013b). However, the work described in (Eskander et al., 2013b) was performed only on verbs with no clitics. This would not allow us to build wide-coverage morphological analyzers. In this paper, we extend the work to cover words of any POS types, whether with clitics or without, so that we obtain complete morphological analyzers. We also apply the approach to Levantine for the first time.

For each POS, we collect all the possible morphosyntactic feature combinations found in TRAIN for words of that POS. This list of feature combinations defines the set of slots for inflected forms found in all inflectional classes (ICs) for lemmas with that POS. For each lemma in TRAIN and for all of its inflected forms found in TRAIN, we then create an inflectional class (IC) that lists the prefix, stem and suffix information in the appropriate slots in the IC. Typically, many slots remain empty for these ICs. The stem is represented as an abstraction, where the letters in the stem are replaced by placeholders, except for the letters ا *A*,أ *Â*, إ *Ǎ*, آ *Ā*, ؤ *ŵ*, ئ *ŷ*, ء *'*, و *w*, ي *y* and ى *ý*. This approach simulates in a simple manner the templatic (or "root and pattern") morphology of Semitic langauges. We then automatically complete the ICs to fill in the missing slots, and obtain all inflections of all the lexemes. Each IC in this set of complete ICs is associated with a set of compatible roots, such that each lexeme corresponds to a root and an IC. We do the completion process for each POS type separately (a total of 33 POS types), as every POS type has its own set of features with which it is compatible.

After completing the ICs, we create ALMOR databases (Habash, 2007) that represent the EGY and LEV morphological analyzers. The list of prefixes and suffixes are generated directly from the ICs. For the construction of the stems, each of the roots associated to an IC is plugged into the stem templates to generate the concrete stems. Finally, the compatibility tables are generated according to the correlation among the prefixes, stems and suffixes in the ICs.

We create morphological analyzers for different training sizes. In the case of EGY, the sizes of the analyzers are 5K, 15K, 45K and 135K, while the sizes of the LEV analyzers are 5K, 15K and 45K. Thus, we can evaluate the performance of the EGY and LEV analyzers at different sizes and compare them. Additionally, the big EGY analyzer of 135K words allows us to see the performance when more data is available.

The orthographic transformations between the input words and the surface-form annotations that appear in TRAIN are added into the analyzers as extensions. This allows the analyzers to convert a input in spontaneous orthography that is not in CODA into a CODA-compliant form that the analyzers know how to handle. The orthographic extensions are added for each of the prefix, stem and suffix entries, separately. However, a transformation that only appears once in TRAIN is omitted. This avoids having over-generating extensions that are due to infrequent typos.

If an input word is not given an analysis by the analyzer, we perform a back-off to a proper-noun analysis. In this case, the lemma, CODA, and stem are given the form of the input word.

5 Creating the Morphological Taggers

The morphological taggers were created by extending MADAMIRA for the EGY data and for LEV. MADAMIRA (Pasha et al., 2014) is a system for morphological analysis and disambiguation of Arabic text. It utilizes a morphological analysis component, a feature modeling component and an analysis ranking component to produce a list of analyses for each word in a given sentence. The morphological analyzer returns a list of all possible analyses (independent of context) for each word. The feature modeling component applies classifiers to derive predictions for the word's morphological features in context. The analysis ranking component then scores each word analysis list based on how well each analysis agrees with the model predictions, and then sorts the analyses based on that score.

For the purpose of this paper, two sets of MADAMIRA systems were developed using EGY and LEV

analyzers and classifiers built from different sizes of data sets, as described in Section 4. We note that a MADAMIRA system already exists for EGY, which uses a large amount of training data. In this paper, we do not use that system, and artificially reduce the amount of training data to simulate a resource-poor dialect.

Each system is trained on the TRAIN sets described in 3. Tuning of the individual classifiers was conducted by randomly selecting about 10% of the total word volume from TRAIN to be used as a tuning set. The tuning set was used to generate a set of feature weights that are required by the Analysis Ranking component. The tuning set was later merged back into TRAIN and the classifiers were then trained using all the training data.

6 Evaluation

6.1 Components of the Evaluation

In our evaluations for both the morphological analyzer and the tagger, we evaluate for the following components of the output of the analyzer or tagger:

- **POS** is the core POS tag of the word. We use the stem tagset in MADAMIRA, whose size is 36.
- **POS5** is a reduced tag set: *NOM* (all nominals including adjectives and adverbs), *PROP* (proper nouns), *VRB* (verbs), *PRT* (all particles), and *PNX* (punctuation). This tagset is a variant of the Columbia Arabic Treebank tagset, which is based on traditional Arabic grammar (Habash et al., 2009).
- **Lemma** is the fully diacritized lemma.
- **CODA** is the undiacritized conventional spelling of the input word with normalized Alifs (Habash et al., 2012a).
- **Stem** is the undiacritized stem of the word with normalized Alifs. The evaluation of this component represents the ability of the analyzer or tagger to segment a word into three parts, corresponding to all prefixes conjoined, a stem, and all suffixes conjoined.
- **ALL** represents the conjunction of all five preceding metrics, i.e., they all need to be correct in the same answer.

We describe the specific evaluations for the analyzers and for the taggers in the next subsections.

6.2 Evaluating the Analyzers

We now present the evaluation of the dialectal morphological analyzers created from the annotated corpora and compare them to existing state-of-the-art analyzers. Tables 2 and 3 present the results on DEV for EGY and LEV, respectively.

Metrics We use several evaluation metrics to measure the effectiveness of the analyzers. First is the **Analyzer Token Recall**, which measures for each token and for each analysis criterion whether the hand-tagged analysis is generated by the morphological analyzer (possibly among others). It is an upper limit on our ability to correctly tag a word. As the name implies, this metric counts all tokens, not just unique types. We apply this metric to all components listed in Section 6.1. The second metric is **OOV**, which represents the cases that are not recognizable by the analyzer, i.e., out of vocabulary. Finally, we present the number of **Analyses per Word**. This is a measure of the degree of ambiguity that should be considered together with the other two (recall and OOV). Overall we want the recall to be high, but we want the ambiguity and OOV rates to be low. Recall that if a word is OOV, a proper-noun back-off analysis is assigned, where the lemma, CODA and stem are given the form of the input word.

Systems For both EGY and LEV, we compare the use of the SAMA analyzer (Graff et al., 2009) (our MSA baseline); a rule-based dialect-affix extended version of SAMA (SAMA$_{ext}$) based on the work of Salloum and Habash (2014); and a combination of CALIMA$_{\text{Egy}}$ with SAMA$_{ext}$. For EGY, the latter is a state-of-the-art comparison point that we do not expect to beat in all of the metrics since it was carefully

developed over years, and using more data than we are. For LEV, we expect CALIMA$_{\text{Egy}}$+SAMA$_{ext}$ to be a very good baseline (because of the similarities between EGY and LEV), but we expect to improve on it.

For both EGY and LEV, we compare different training data sizes, namely 5K, 15K and 45K words. For EGY only, we add an extra step of 135K words since more data is available. For each training size, we compare three settings: (a) a **Lookup** baseline that assumes no learning by paradigm completion, (b) a **ParaFill** setting, which uses paradigm completion as discussed in Section 4, and (c) a combination of **ParaFill** with additional pre-existing resources. The additional resources we use for **ParaFill** differ by dialect. In the case of EGY, we only use SAMA$_{ext}$ (since we are using EGY to simulate a low-resource dialect, we cannot use CALIMA$_{\text{Egy}}$); but we use the CALIMA$_{\text{Egy}}$ analyzer and also SAMA$_{ext}$ for LEV (since for dialects other than EGY, we can always make use of the richer resources available for EGY).

		Analyzer Token Recall

	ParaFill$_{\text{Lev}}$+CALIMA$_{\text{Egy}}$+SAMA$_{ext}$	92.3	96.5	92.8	95.7	95.4	87.0	3.1	16.0

Table 3: LEV Morphological Analysis Recall on DEV

Results For DEV, for both EGY and LEV, as expected, among the pre-existing systems, SAMA$_{ext}$ outperforms SAMA; and CALIMA$_{\text{Egy}}$+SAMA$_{ext}$ does best of the three options. Also, across all training sizes, paradigm completion outperforms lookup; and using a combination of paradigm completion with a pre-existing state-of-the-art system for MSA (in the case of EGY) or for MSA and EGY (in the case of LEV) does best in terms of token recall. There is of course no guarantee that the tagger later on will select the analysis correctly: while we see that the search space is expanding as needed, we also see that as the training size increases and as additional resources are added, the number of analyses per word increases, adding more ambiguity for the tagger to select from.

System		All	OOV	$\frac{Analyses}{Word}$

Table 6: EGY Tagger Results on DEV and TEST

For some metrics, such as CODA and POS5, the baseline is rather high. Our EGY system trained on 45K words in conjunction with SAMA$_{ext}$ beats the highly engineered CALIMA$_{\text{Egy}}$ system on all metrics. In the case of LEV, our baselines are lower and we can incorporate CALIMA$_{\text{Egy}}$ as a pre-existing system. Our best system beats the best baseline on all metrics starting with 5K training data. We now discuss the performance on the harsh All metric, which is really the best indicator of quality overall, in more detail. For EGY, using paradigm completion on only 5K training data improves above the SAMA and SAMA$_{ext}$ baselines. By 15K we are able to beat the state-of-the-art system CALIMA$_{\text{Egy}}$+SAMA$_{ext}$ and consistently provide less ambiguity than it. This is due to the power of paradigm completion, which adds thousands of unseen inflected forms. We also get a very similar pattern for Levantine, where the error rate in All token recall can be cut by 30% against the high CALIMA$_{\text{Egy}}$+SAMA$_{ext}$ baseline by using a combination of paradigm completion and existing systems at the 5K level; and by 42% at the 45K level.

Tables 4 and 5 present the TEST results for EGY and LEV, respectively (only showing the All results). The results on TEST have the same pattern as those on DEV.

6.3 Evaluating the Taggers

We now discuss the performance of the morphological taggers that we build.

Metrics We use a single metric, **Accuracy**, where we ask whether our predicted result is correct. The evaluation was conducted across all the components described in 6.1 at the word token level.

Systems For each of EGY and LEV, we trained two sets of MADAMIRA systems using classifiers built from different sizes of data sets as described in Section 5. The two sets differed in the underlying

		DEV						TEST

	$\text{ParaFill}_{\text{Lev}}$++	78.2	85.9	74.6	89.9	85.6	60.6	78.5	85.9	74.0	90.0	86.1	61.1
Train 45K	$\text{ParaFill}_{\text{Lev}}$	75.7	80.2	69.2	89.9	83.7	61.6	75.6	79.7	69.7	89.7	83.7	62.9
	$\text{ParaFill}_{\text{Lev}}$++	81.8	89.4	77.8	91.7	88.4	65.5	82.3	89.2	77.2	91.7	88.5	65.7

Table 7: LEV Tagger Results on DEV and TEST; $\text{ParaFill}_{\text{Lev}}$++ refers to $\text{ParaFill}_{\text{Lev}}$+$\text{CALIMA}_{\text{Egy}}$+$\text{SAMA}_{ext}$

morphological analyzer: the result of paradigm completion only ($\text{ParaFill}_{\text{Egy}}$ or $\text{ParaFill}_{\text{Lev}}$), or this system augmented with additional resources from other variants (MSA for EGY, MSA and EGY for LEV). These are the same analyzers evaluated above in Section 6.2. In addition, evaluations were conducted on MADAMIRA-MSA and MADAMIRA-EGY in order to compare the performance of the EGY and LEV systems to the standard systems. Note that for EGY, MADAMIRA-EGY represents a carefully engineered contrastive system, while for LEV, it represents a plausible alternative to dialect-specific efforts and thus a true baseline.

Results The results for EGY are shown in Table 6 for DEV and TEST. Looking at the DEV results, we see as expected that MADAMIRA-EGY provides a high level of performance across the components of the evaluation. We do not beat this system on POS even with 135K training data. However, we beat it on POS5 and CODA at 135K; 45K is enough training data to beat MADAMIRA-EGY on Stem, and 15K is enough on Lemma and All. We see that performance increases with more training data, as expected. Interestingly, the increase in performance from 45K to 135K (a substantial amount of additional annotation) is much smaller than the previous increments, for all evaluation criteria. We also see that the addition of SAMA_{ext} to the morphological analyzer helps only at the medium amount of 15K (on All); we suspect that this is because at 5K, there is not enough training data to counteract the increased ambiguity that comes from adding these additional analyses, while at larger amounts of training data, the analyzer based on paradigm completion alone generates sufficiently rich databases. Results are roughly similar on TEST.

The results for LEV are shown in Table 7 for DEV and TEST. For LEV, MADAMIRA-EGY represents a baseline. Our system beats this baseline even with only 5K training data, however only if we include +$\text{CALIMA}_{\text{Egy}}$+$\text{SAMA}_{ext}$ (and not on POS). In fact, the results for using the $\text{ParaFill}_{\text{Lev}}$+$\text{CALIMA}_{\text{Egy}}$+$\text{SAMA}_{ext}$ analyzer are consistently better than those for $\text{ParaFill}_{\text{Lev}}$ analyzer alone (the one we get from paradigm completion), though this effect is stronger at smaller training sizes. This shows that the tagger is able to make the right choice despite the steep increase in ambiguity (as seen in Table 3), for example from 2.2 analyses per word for $\text{ParaFill}_{\text{Lev}}$ to 14.2 for $\text{ParaFill}_{\text{Lev}}$+$\text{CALIMA}_{\text{Egy}}$+$\text{SAMA}_{ext}$ at 15K training data. Finally, we see again that more data helps, and we do not see a major flattening of the learning curve at 45K words yet. As with EGY, the results on TEST mirror the ones on DEV for LEV.

Error Analysis We conducted error analyses for the $\text{ParaFill}_{\text{Egy}}$ and $\text{ParaFill}_{\text{Lev}}$ taggers, trained on 45K-word TRAIN and tested on DEV. For EGY, 20.7% of the errors occur because the gold answer is not provided by the morphological analyzer. An additional 5.6% of the errors are back-off cases at the time of preparing the data where $\text{CALIMA}_{\text{Egy}}$ does not produce an answer. OOV cases contribute a further 2.6% of the errors. The rest of the errors are cases where the analyzer provides the correct analysis, but the tagger fails to pick it in context. For LEV, the absence of the gold answer in the analyzer and the OOV entries contribute to 21.7% and 6.6% of the errors, respectively. The other errors occur as the tagger fails to select the correct answer provided by the analyzer.

7 Conclusions and Future Work

This paper has presented a methodology for deriving a morphological analyzer and a morphological tagger for an Arabic dialect. We have shown that this can be done successfully, even with a small amount of data. The approach requires a single type of annotation: a morphological annotation on running text which identifies the normalized spelling, the segmentation, the morphological features, and the lemma for each word. Both the analyzer and the tagger evaluations show the importance of using the paradigm completion approach to creating full inflectional classes: we obtain important error reductions over using just the morphological information supplied in the annotation. Furthermore, we have shown that for Levantine, using Egyptian resources helps performance in both analysis and tagging, even though using such resources greatly increases ambiguity, thus making the tagging task harder.

This paper has also presented a morphological analyzer and a morphological tagger for Levantine. To our knowledge, these are the first of their kind. We plan on using the complete version of the Levantine corpus and then making these resources available.

Our error analysis showed that most of the errors in the tagger come from the tagger itself, not the analyzer. This is understandable, as usually taggers are trained on much larger corpora. In future work, we will investigate whether we can improve the performance of the tagger by training the classifiers on combinations of Levantine text with Egyptian and/or MSA tagged text. Furthermore, we will also apply this methodology to other Arabic dialects; we are currently preparing annotations in the same style for five additional dialects from across the Arab world (see (Al-Shargi et al., 2016) for Moroccan and Sanaani Yemeni), and we will follow exactly the same methodology as laid out in this paper.

Abstract

Semantic Role Labeling (SRL) is the task of identifying the predicate-argument structure in sentences with semantic frame and role labels. For the English language, the Proposition Bank provides both a lexicon of all possible semantic frames and large amounts of labeled training data. In order to expand SRL beyond English, previous work investigated automatic approaches based on parallel corpora to automatically generate Proposition Banks for new target languages (TLs). However, this approach heuristically produces the frame lexicon from word alignments, leading to a range of lexicon-level errors and inconsistencies. To address these issues, we propose to manually *alias* TL verbs to existing English frames. For instance, the German verb *drehen* may evoke several meanings, including "turn something" and "film something". Accordingly, we alias the former to the frame TURN.01 and the latter to a group of frames that includes FILM.01 and SHOOT.03. We execute a large-scale manual aliasing effort for three target languages and apply the new lexicons to automatically generate large Proposition Banks for Chinese, French and German with manually curated frames. We present a detailed evaluation in which we find that our proposed approach significantly increases the quality and consistency of the generated Proposition Banks. We release these resources to the research community.

1 Introduction

Semantic role labeling (SRL) is the task of labeling predicate-argument structure in sentences with shallow semantic information. The prominent labeling scheme for the English language is the Proposition Bank (Palmer et al., 2005), which provides a lexicon of possible *frames* for English verbs. Each frame corresponds to one semantic interpretation and comes with frame-specific *role* labels and descriptions. Over the past decade, large amounts of text data have been annotated based on these guidelines (Palmer et al., 2005; Hovy et al., 2006; Bonial et al., 2014). They enable the training of statistical SRL systems, which have proven useful for downstream applications such as information extraction (IE) (Fader et al., 2011), question answering (QA) (Shen and Lapata, 2007; Maqsud et al., 2014) and machine translation (Lo et al., 2013).

However, such manual efforts are known to be highly costly. Possible frames need to be manually determined, their roles individually described, and large volumes of text data annotated accordingly. For this reason, Proposition Banks do not exist for most languages.

Annotation projection. Recent research has explored the possibility of using annotation projection to automatically generate Proposition Banks from parallel corpora for new target languages (TL) (Padó and Lapata, 2009; Van der Plas et al., 2011; Akbik et al., 2015). This approach requires a large word-aligned corpus of English sentences and their TL translations. An English SRL system predicts semantic labels for the English sentences. These labels are then transferred along word alignments to automatically annotate the TL corpus. Recent work has shown that such auto-generated Proposition Banks can be used to train semantic role labelers for a wide range of languages (Akbik and Li, 2016).

Heuristically generated frame lexicon. However, a major drawback of such approaches is that the frame lexicon is heuristically produced from available alignments, which leads to a range of errors and inconsistencies. Consider the German verb *drehen*. In the English-German portion of the OPENSUB-

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3466–3474, Osaka, Japan, December 11-17 2016.

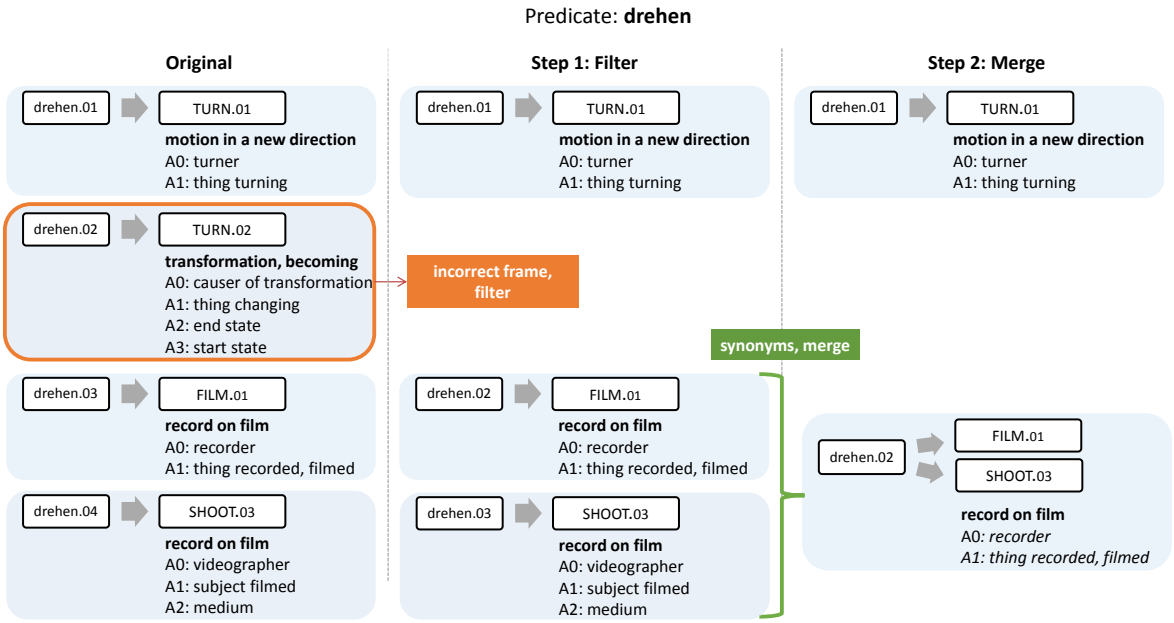

Figure 1: Illustration of merging and filtering steps over heuristically produced frame lexicon. This process reduces the number of distinct frames for the verb *drehen* from 4 to 2.

TITLES2016 parallel corpus (Lison and Tiedemann, 2016), this verb is aligned to many different English frames, four of which are illustrated in Figure 1. Previous annotation projection approaches treat each alignment as a separate and valid frame of the TL verb. In this example, it is therefore heuristically determined that *drehen* may evoke four separate frames, namely TURN.01, TURN.02, FILM.01 and SHOOT.03. See Figure 1 (left pane) for an illustration and explanation of the four frames. The example illustrates the two main problems in heuristically produced lexicons:

Incorrect frames The first problem is posed by errors in the frame lexicon. For instance, the German verb *drehen* cannot evoke the frame TURN.02 (transformation). The corresponding entry in the lexicon is therefore incorrect. This lexicon-level error has a significant impact on the generated Proposition Bank since every TL sentence with this annotation is incorrectly labeled. Therefore, as the middle pane in Figure 1 illustrates, we wish to filter out such lexicon-level errors.

Redundant frames The second problem is posed by redundancy that occurs if multiple entries for a TL verb are in fact synonyms. For instance, *drehen* is heuristically determined to evoke SHOOT.03 (record on film) and FILM.01 (record on film) as two separate meanings. However, the TL usages of *drehen* in these contexts are clearly identical. This lexicon-level error causes inconsistent annotation of the same semantics throughout the generated Proposition Bank. Therefore, as the right pane in Figure 1 illustrates, we wish to merge these two entries into a single entry comprising both frames.

In this paper, we propose to address these issues by manually curating incorrect alignments and grouping synonymous English frames with a process of filtering and merging as illustrated in Figure 1. With this approach, we effectively follow a process of *aliasing* TL verbs to English frames (Bonial et al., 2014; Jagfeld and van der Plas, 2015). Our goal is to remove lexicon-level errors and redundancies in order to generate higher quality TL Proposition Banks with consistent annotation and salient verb senses.

Contributions Our contributions are: 1) We propose a method for manually curating a heuristically determined frame lexicon and discuss our curation guidelines. 2) We execute our method over large-scale parallel data for three target languages (Chinese, French and German) to automatically generate Proposition Banks with curated frame lexicons. 3) We present an experimental evaluation in which we find that our proposed approach significantly increases the quality of automatically generated Proposition Banks and greatly reduces redundancy. 4) We analyze the verb coverage of the generated lexicons and

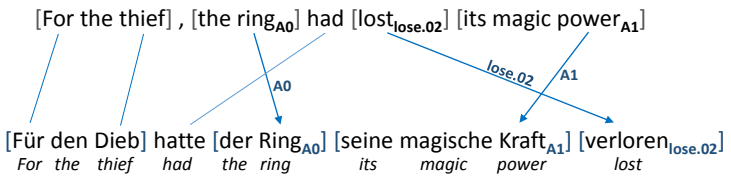

Figure 2: Example of annotation projection for an English-German sentence pair. English frame (LOSE.02) and role labels (A0, A1) are projected onto aligned German words.

conduct a comparison of our work against manual efforts to create Proposition Banks. 5) Finally, we release all resources to the research community for the training of multilingual SRL and the study of crosslingual semantics[1].

2 Related Work

Annotation projection Annotation projection takes as input a word-aligned parallel corpus of English sentences and their target language (TL) translations. An English semantic role labeler is used to predict semantic labels for the English sentences. These labels are then projected onto aligned TL words, automatically producing a TL corpus annotated with English frame and role labels. Refer to Figure 2 for illustration.

The use of annotation projection to train parsers for new languages was first introduced in the context of learning a PoS tagger (Yarowsky et al., 2001). Initial work on projecting semantic labels used FrameNet (Padó and Lapata, 2009), but subsequent work has focused on PropBank annotation due to its broader coverage and the availability of high quality semantic role labelers for English (Van der Plas et al., 2011; van der Plas et al., 2014). Recent work has focused on increasing the accuracy of projected labels by scaling up projection to larger corpora and retraining SRL models (Van der Plas et al., 2011; van der Plas et al., 2014) as well as using filtering techniques to block labels most likely affected by translation shift (Akbik et al., 2015). The latter found that the largest portion of errors in generated PropBanks results from incorrectly predicted labels for English sentences, which are then projected onto TL sentences, thereby propagating this error.

Consistency of the frame lexicon. However, so far, previous work has not investigated the overall correctness and consistency of the frame lexicon. All previous annotation projection efforts treat each distinct global alignment as a different sense of each verb, which, as argued in section 1, is not the case. In this paper, we specifically address this issue.

Aliasing Our work is similar to recent efforts in *aliasing*, in which existing English verb frames are reused for new types of frame evoking elements (Bonial et al., 2014). One advantage of this approach is that it reduces the effort required to define new frames. More importantly, this ensures consistent annotation for different syntactic elements that evoke the same semantics. An example is the verb frame FEAR.01 that is reused for the noun *fear* (as in *I have a fear of spiders*) and the adjective *afraid* (as in *I am afraid of spiders*). Recent work has proposed a method to automatically identify aliases for verbal complex predicates using a distributional model over parallel corpora (Jagfeld and van der Plas, 2015).

Unlike previous works that exclusively consider English, we consider a multilingual setting in which we alias English frames to verbs in other languages. We also allow multiple aliases for each TL verb. We pursue this approach not only to define a frame lexicon, but also to increase the quality and consistency of Proposition Banks generated with annotation projection.

3 Method

Our approach curates a frame lexicon of a Proposition Bank generated with annotation projection. The approach has two curation steps: filtering (section 3.1) and merging (section 3.2). We then make a final pass to add human readable explanations to the curated frame lexicon (section 3.3).

[1]Please contact the first author of this paper for access to the data.

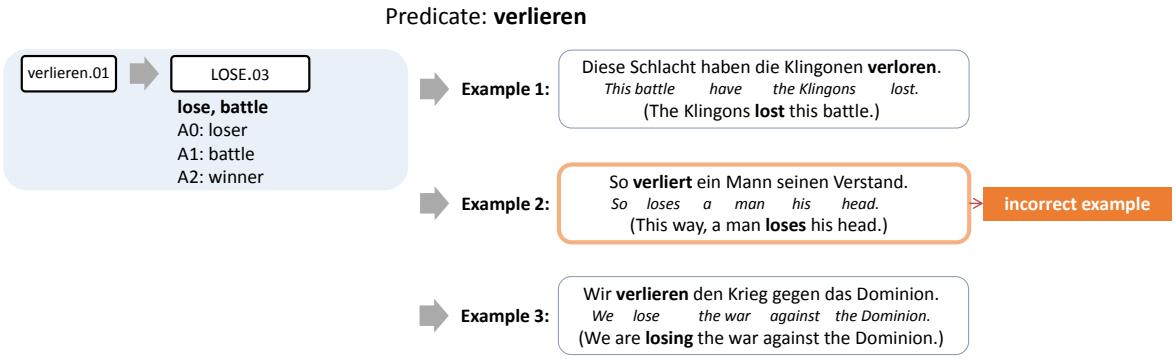

Figure 3: Filtering task example. A curator is shown one lexicon entry, consisting of a TL verb (*verlieren*) and an English frame (LOSE.03, as in *lose a battle*). In addition, the curator is shown five example sentences (only three displayed in this image). While examples 1 and 3 are correct, example 2 does not evoke the *lose a battle* sense.

3.1 First Curation Task: Filtering

The first task is to identify all incorrect frames for TL verbs. For each entry in the lexicon, curators must make a binary decision on whether the entry is correct or not. In order to make this decision, curators are presented with the following information: 1) The TL verb. 2) A description of the English frame and its roles. 3) A sample of TL sentences annotated with this frame. Refer to Figure 3 for illustration.

Given this information, curators must answer two questions (detailed below). If the answers to both questions are *yes*, the entry is considered valid. If one of the questions is answered with *no*, this entry must be removed from the lexicon.

Q1: Is the English frame a valid sense for the TL verb? The first question concerns the semantic validity of the English frame for the TL verb. To answer this question, curators only consider the English frame description. If the description refers to semantics that the TL verb clearly cannot evoke, the answer to this question is *no*. We encountered such a case in section 1 with the verb *drehen* that cannot evoke frame TURN.02. In all other cases, the answer is *yes*. Notably, we do not ask if an English frame is a perfect fit in semantics. At this point in the process, we are only interested in filtering out clear errors.

Q2: Does the TL verb accurately reflect the English frame description in the sample sentences? Even if an entry is valid in principle, it may still be subject to errors in practice. We find that some entries are correct judging from their description, but are never correctly detected in the corpus due to errors made by the English SRL. This problem disproportionally affects frames for which only limited English training data is available. For this reason, we require the curator to inspect a sample of 5 TL sentences per entry and determine whether they are correctly labeled. Refer to Figure 3 examples for both cases: Sentence 1 and 3 correctly invoke LOSE.03 (lose a battle), whereas Sentence 2 evokes LOSE.02 (lose an item). If a majority of example sentence is incorrectly labeled, this question must be answered with *no*.

3.2 Second Curation Task: Merging

The second task addresses the issue of redundancy caused by multiple entries for TL verbs that evoke the same semantics. For each pair of entries for the same TL verb, a curator must decide whether they are synonymous and need to be merged into a single entry. This task therefore effectively decides the semantic granularity of the lexicon entries for each TL verb.

We base merging decisions on the annotation guidelines of the English Proposition Bank, which specify that new frames need to be created to reflect different syntactic usages of a verb. In addition, new frames are created for broadly different meanings of a verb even if the syntactic subcategorization is the same (Palmer et al., 2005).

For each merging decision, we present curators with the following information: 1) The TL verb. 2) The two frames and their descriptions. 3) A set of TL sample sentences for each frame. The latter is the most important since sample sentences illustrate how the TL verb is used in related contexts when labeled with a specific frame. Refer to Figure 4 for example.

Given this information, curators must answer two questions (explained below). If the answer to any

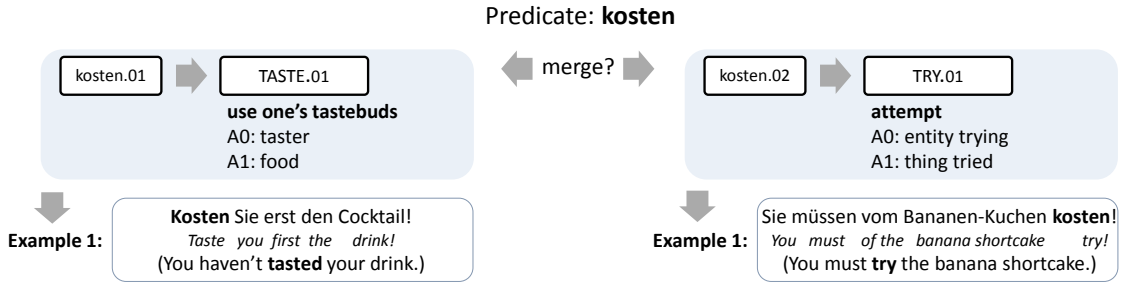

Figure 4: Information presented to curator for merge decisions: Two frames, their descriptions and example sentences.

of these questions is *no*, the two entries should not be merged.

Q1: Are the two entries usage-synonyms? We define *usage-synonyms* as target language usage synonyms. To illustrate the difference to regular synonyms, consider the example in Figure 4 in which curators must decide whether TASTE.01 and TRY.01 should be merged. While the two English frames are clearly not synonymous, their target language usages are. As lexicon entries for the German verb *kosten*, they are both solely used in the context of tasting food and are therefore usage-synonyms, illustrated by the sample sentences for each frame in Figure 4. If two entries are clearly not usage-synonyms, the answer to this question is *no*. In all other cases, the answer is *yes*.

Q2: Do the two entries represent syntactically different usages? We found a number of cases in which curators disagreed on whether two entries are usage-synonyms or not. An example of this were entries which partially overlapping semantics, such as the frame pair WRAP.01 (*enclose*) and PACK.01 (*fill, load*). To address this, we created a guideline to compare syntactic usage of TL verbs. We ask curators to build the *dictionary expansion* for both entries, which we define as the default syntactic expansion that one might find in a dictionary. An English example for the verb *turn* is *to turn something* for TURN.01 and *to turn into something* for TURN.02. However, we ask curators to create this form for TL verbs[2]. If the TL dictionary expansion is different, the answer to this question is *no*.

3.3 Final Pass: Dictionary Forms and Comments

After curators complete both tasks, we rerun annotation projection using the created lexicon to filter out incorrect entries and merge redundant entries. This produces a Proposition Bank with manually curated TL frames. To complete the curation process, we ask curators to inspect each entry in the dictionary and add comments or explanations, as well as dictionary expansions. This information is intended for human consumption. The purpose of this annotation is to make apparent the distinctions between multiple entries for the same TL verb and explain our aliasing decisions. The entire curation process thus produces an annotated Proposition Bank with salient, manually curated frames for each TL verb.

4 Evaluation

We present a set of large-scale experiments over three languages to evaluate our proposed approach. We first evaluate the curation process itself in terms of curator agreement scores, the required effort and the impact on the frame lexicons. We then present a detailed analysis of the auto-generated Proposition Banks in which we evaluate their quality in terms of precision, recall and F1 score both before and after curation. We further evaluate the curated Proposition Banks with regards to verb coverage and conduct a qualitative comparison against the manually created, official Chinese Proposition Bank (Xue and Palmer, 2005). Based on this analysis, we discuss the challenges and potential of combining large-scale annotation projection and manual aliasing to generate Proposition Banks for new target languages.

Experimental setup. We pre-generate Proposition Banks with the approach described in Akbik et. al (2015) for Chinese, French and German using parallel text from the OPENSUBTITLES2016

[2]In the example discussed in Figure 4, the dictionary expansion of *kosten* the same for both entries: *etwas kosten* ("*to taste/try something*"). This indicates that both entries take a direct object and are syntactically similar. They must therefore be merged only if the entries are also usage-synonyms.

		Proposition Bank				Evaluation		
Language	Parallel Corpus	Type	#Verbs	#Frames	#Sentences	P	R	F_1
Chinese	OpenSubtitles	projected	1,094	1,472	87,953	0.87	0.94	0.91
	(9 million sentences)	curated	942	1,003	68,829	0.93	0.96	**0.94**
French	OpenSubtitles	projected	1,323	2,249	175,636	0.82	0.94	0.87
	(15 million sentences)	curated	1,208	1,370	130,579	0.91	0.94	**0.93**
German	OpenSubtitles	projected	1,552	2,441	191,816	0.83	0.92	0.87
	(13 million sentences)	curated	1,532	1,717	150,949	0.90	0.93	**0.91**

Table 1: Annotation projection statistics for all three target languages: Number of parallel sentences available for each language, total number of covered verbs in auto-generated PropBanks as well as the total number of frames. The number of frames is higher because many verbs evoke more than one frame.

project (Lison and Tiedemann, 2016). This data is automatically mined from movie subtitles and thus covers a large array of topics (dramas, documentaries, science fiction etc.), reflecting verb usage in common speech. We execute annotation projection over 9-15 million parallel sentences for each target language, generating lexicons that cover over 1,000 verbs, respectively, as well as labeled corpora spanning over 100,000 sentences. For a full breakdown of our annotation projection numbers, refer to Table 1 (the uncurated PropBanks are marked as "PROJECTED").

These generated PropBanks are the starting point for our curation process. We had two persons each curate the French lexicon, while Chinese and German were curated by one person each. On average, for each language and each person about 60 person hours were required for the full curation process for all lexicon entries. All curators in our experiment have expert knowledge in semantic role labeling.

Using the curated lexicons, we generate the final generated Proposition Banks, marked as "CURATED" in Table 1. Following earlier evaluation practice, we randomly selected 100 sentences from each Proposition Bank before and after curation. We manually evaluated these sentences in order to get an understanding of precision, recall and F_1-score for the generated resources.

4.1 Evaluation Results

Refer to Table 1 for an overview of all three generated Proposition Banks before and after curation with our proposed process. We make a number of observations:

Curation significantly improves Proposition Bank quality. We find that incorporating the curated frame lexicons into annotation projection significantly boosts overall quality. For German, we estimate an F_1 of 0.91 (↑ 4pp), for French 0.93 (↑ 6pp), and for Chinese 0.91 (↑ 4pp). This indicates that a large number of errors are caused by incorrect entries in the frame lexicon, which can be handled globally at moderate effort using our proposed approach.

Curation reduces the amount of labeled data and covered verbs. We also note that filtering incorrect entries reduces the number of annotated sentences in the generated resource, since all affected projections are removed. For Chinese, French and German, a total of 18k, 20k and 36k sentences are affected by incorrect annotations and are therefore filtered out. Our approach therefore generates slightly smaller Proposition Banks with a higher overall quality. We also note that for some TL verbs all entries in the lexicon were deemed incorrect. These verbs are therefore no longer covered in the curated PropBanks. This reduces the amount of verbs included in the TL lexicons by 20 for German, 115 for French and 152 for Chinese, which seems to correspond to their linguistic distance to English: German, the closest relative to English, has the largest number of covered verbs while Chinese has the lowest.

Curation significantly reduces redundancy. We note that our approach significantly reduces the number of distinct frame entries for each language. Whereas in uncurated versions, every alignment is interpreted as a distinct verb frame, the filtering and merging process removes hundreds of incorrect and redundant entries. The curated Chinese, French and German PropBanks evoke 1,003 (↓ 32%), 1,370 (↓ 39%), and 1,717 (↓ 30%) frames respectively. We note that the highest difference is observed for French, for which the largest number of parallel sentences was available. It seems that greater amounts of parallel data lead to greater redundancies and more incorrect alignments.

FRENCH	SOURCE	#AL.	ERROR CLASS	GERMAN	SOURCE	#AL.	ERROR CLASS
rentrer	go	9,070	CP: *go home*	möchten	want	26,996	DI
ressembler	look	6,160	CP: *look like*	sollen	suppose	12,849	CP: *be supposed to*
naître	bear	5,937	LE: *be born*	sollen	want	12,619	CP: *want sb. to do sth.*
pouvoir	be	4,541	CP: *be able to*	herausfinden	find	7,756	CP: *find out*
asseoir	sit	4,300	LE: *s'assoir*	beschützen	protect	6,416	DI
adorer	love	3,391	DI	fällen	like	5,846	LE
pouvoir	get	3,325	CP: *get to do something*	mitnehmen	take	5,604	CP: *take along*
rentrer	come	2,813	CP: *come home*	kennenlernen	meet	5,254	CP: *get to know sb.*.
appartenir	belong	2,745	DI	übernehmen	take	4,029	CP: *take over*
enfermer	lock	2,143	DI	erledigen	do	3,914	CP: *get sth. done*

Table 2: Top 10 unlabeled verbs for French and German, with English source verbs and alignment counts in the parallel corpus. Error classes are lemmatiation error (LE), dictionary incomplete (DI) and complex predicates (CP).

4.2 Curation Guidelines

In order to assess our curation guidelines, we asked two curators to independently execute the curation process for the French lexicon. We produce two independently curated French Proposition Banks using the two lexicons. We compared both versions and found that curators had agreed on 1,317 out of 1,370 (96%) of all curated entries. This speaks to the deterministic nature of our guidelines.

One contributing factor to our high agreement score is that we discussed and determined representative cases of disagreement in early iterations of the curation process. In the filtering task, for instance, we encountered initial disagreements on theoretically correct entries that were incorrectly recognized in practice (see section 3.1). In the merging task, we also had initial difficulties concerning semantically related frames that were neither clear usage-synonyms nor clearly distinct (see section 3.2). As previously illustrated, we defined deterministic rules for these cases.

Disagreements. Some disagreement remained in the merging task: Some entries have syntactically similar usage and partially overlapping semantics. This often affects merging questions in which one entry is a highly specialized usage of the other. This frequently involves slang language. For example, the French verb *secher* (to dry) can also be used in spoken language to indicate "cutting class" as in not attending class in school. Due to the lack of a more appropriate English frame, this sense is aligned to the frame CUT.01 (slice or injure). Such cases required further discussion by curators.

4.3 Qualitative Evaluation of Curated Proposition Banks

The curated Proposition Banks give us the opportunity to gain insights on verb coverage and to compare annotation projection against manual annotation efforts. We present results of a qualitative inspection of common TL verbs that are absent in generated frame lexicons and a qualitative comparison of our generated resource for Chinese against the official Chinese Proposition Bank (Xue and Palmer, 2005).

Verb coverage. From the parallel corpora, we retrieve the most common TL verbs that are not contained in our frame lexicon. We manually inspect the 100 most common unlabeled verbs to determine reasons for lack of coverage. We find that lack of coverage can be traced back to one of three reasons: 1) The translation dictionary we use to filter out translation shift errors is incomplete (DI). 2) The lemmatizer is unable to correctly lemmatize certain verbs (LE). 3) The TL verb meaning can only be rendered in English as a complex predicate (CP). We list the top 10 most common unlabeled verbs for French and German in Table 2.

Complex phrasal constructions. A crucial error class are TL verbs that cannot be expressed with a single verb in English. Consider the French verb *rentrer*, which frequently expresses the meaning of "returning home", rendered in English with the LVCs *go home* or *come home*. Another example is *pouvoir*, which in English needs to be rendered with the adverb *able* as in *be able to*. A German example for this phenomenon is *sollen*, rendered as *to be supposed to* or *to want someone to do something*. This represents a limitation of our current verb-based projection approach. However, there are ongoing efforts to expand the English Proposition Bank with frames for complex predicates. We believe that this will allow us to address this source of verb coverage loss in future work.

Comparison to Chinese PropBank We randomly sample 100 Chinese verbs from our lexicon and compare all entries against the official Chinese Proposition Bank. We find an encouragingly high agreement, which 94.6% of our lexicon entries corresponding to senses in the Chinese PropBank. We also find 7 lexicon entries that do not exist in the Chinese PropBank, indicating that annotation projection with manual frame curation may be used to increase coverage of existing Proposition Banks. We also find 4 instances in which valid entries for a verb in the two PropBanks are complimentary. However, we point out that we conduct this study only in one direction. The official Chinese Proposition Bank contains frames for all types of frame evoking elements, including verbs, nouns and complex predicates (Xue, 2006; Xue and Palmer, 2009). Their coverage is therefore significantly larger than our current approach. Nevertheless, we find the significant overlap in both frame lexicons encouraging.

5 Discussion and Conclusion

We presented an approach for addressing lexicon-level inconsistencies in automatically generating Proposition Banks using annotation projection. Our approach manually curates the heuristically determined frame lexicon in two steps: A filtering and a merging step. We executed the approach on large-scale parallel data to generate Proposition Banks with curated frames. Our evaluation shows that our approach significantly increases the quality of the generated resources, while reducing redundancy and inconsistency in the frame lexicon.

Our evaluation also revealed TL verbs that require complex predicates in English as a natural limitation of our current verb-based approach. Accordingly, future work will investigate this issue by expanding the range of projections from verbs to other types of frame-evoking elements. We aim to expand our frame lexicon to include not only TL verbs, but also nouns, adjectives and eventually complex TL predicates.

Another avenue for future work is to investigate the use of SRL trained over projected Proposition Banks in applications. As previous work has shown information extraction and question answering to benefit from SRL, we aim to investigate multilingual applications in these tasks.

We release the Proposition Banks created with our approach in order to encourage discussion with the research community. We believe this resource to potentially be valuable for investigating crosslingual semantics and for training statistical SRL systems for Chinese, French and German.

Abstract

This paper contributes to a growing body of evidence that—when coupled with appropriate machine-learning techniques—linguistically motivated, information-rich representations can outperform one-hot encodings of linguistic data. In particular, we show that phonological features outperform character-based models using the PanPhon resource. PanPhon is a database relating over 5,000 IPA segments to 21 subsegmental articulatory features. We show that this database boosts performance in various NER-related tasks. Phonologically aware, neural CRF models built on PanPhon features are able to perform comparably to character-based models on monolingual Spanish and Turkish NER tasks. On transfer models (as between Uzbek and Turkish) they have been shown to perform better. Furthermore, PanPhon features also contribute measurably to Orthography-to-IPA conversion tasks.

1 Introduction

This paper introduces PanPhon[1], a resource consisting of a database that relates over 5,000 IPA segments (simple and complex) to their definitions in terms of 21 articulatory features (see Tab. 1) as well as a Python package for interacting with this database and manipulating the representations that it provides. While our previous publications (summarized in §4) have described experiments using it, this is the first full description of PanPhon. Combined with a sister package, Epitran[2], it allows the conversion of

Table 1: Illustration of IPA segments and feature vectors from PanPhon

orthographic texts to sequences of articulatory feature vectors. The Epitran-Panphon pipeline is illustrated in Fig. 1. The input to Epitran consists of word tokens in orthographic representation. Take, for example, the Spanish word *Madrid*. Epitran converts this string to a phonemic (not phonetic) representation in IPA, in this case /madɾid/. Epitran then calls a PanPhon function to convert this IPA string into a sequence of feature vectors. It then returns this sequence, aligned with the orthographic representation, capitalization, and Unicode character category features.

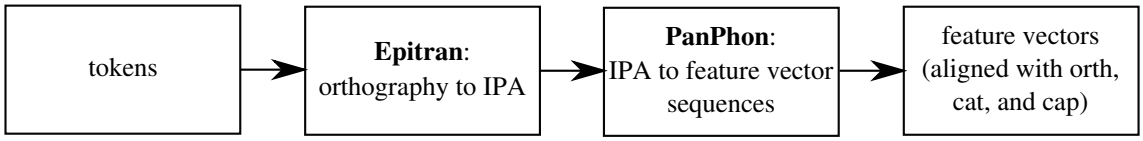

Figure 1: Feature vector pipline

This paper also shows that subsegmental features, as encoded in PanPhon, are useful in NLP tasks. The specific tasks for which PanPhon has been shown to improve performance are named entity recognition and conversion of lossy orthographies[3] to IPA.

Phonologists have long held that articulatory features play a role in three central aspects of phonology: **contrast**, **distribution**, and **alternation**. These constitute the distinctiveness of speech sounds, the restrictions on where they can occur in the speech-stream, and the phonologically-derived differences in the various realizations of the same morpheme. These may be illustrated through examples from Turkish (Lees, 1963) as illustrated in Tab. 2. The difference between /i/ and /e/ is sufficient to distinguish two

NOM.SG	GEN.SG	NOM.PL	GEN.PL	gloss
ip	ip-**in**	ip-**ler**	ip-**ler-in**	'rope'
el	el-**in**	el-**ler**	el-**ler-in**	'hand'
kɪz	kɪz-**ɪn**	kɪz-**lar**	kɪz-**lar-ɪn**	'girl'

Table 2: Turkish vowel harmony (NOM = nominative, GEN = genitive, SG = singular, and PL = plural)

words, evidence that the feature [±high][4] is contrastive (sufficient to make lexical contrasts) in Turkish. The vowels in the suffixes (*-ler*/*-lar* and *-in*/*-ın*) alternate to assimilate in quality to the preceding vowel. This can be easily expressed in terms of the phonological feature [±back]: The vowels ⟨i⟩ and ⟨e⟩ are [−back] while ⟨a⟩ and ⟨ɪ⟩ are [+back][5]. The alternation consists of the smallest change that allows agreement in the specification of this feature between the vowels in the root at the vowel in the suffix. In this way, phonological features allow a degree of generalization, even over orthographic patterns, that purely character-based (and also phoneme-based) models do not. Finally, the static observation that, in all but a minority of "disharmonic" words, each vowel in a word shares the same specification for [±high] and [±back] is a matter of distribution. These linguistic insights behind articulatory features translate into practical benefits for NLP systems.

The usefulness of articulatory features in natural language processing, this paper will show, is most valuable for replacing character-level models where characters bear some predictable relationship to phonemes or phones. In such a scenario, treating characters as atomic entities is rather like treating the chords of a musical score as unanalyzable units. While this approach may be adequate for many purposes, we will argue that it ignores aspects of phonological structure that have demonstrable utility. Articulatory features represent the parts in a layered articulatory score. Operations on this score target these individual features, not the segment as a whole ("the chord"), contrary to the assumption made in strictly character-based approaches. We have found, from a variety of perspectives, that exploiting these components can improve the performance of relevant NLP systems.

2 Past Use of Phonological Features in NLP

Within both formal and empirical linguistics, it is rare to encounter discussion of structural patterns in sounds without some mention of phonological features. Even radically empirical phonologists, rather than denying the existence of such phonological features, tend to simply deny that there is a universal

[3]"Lossy orthographies" are ambiguous writing systems that lose segmental information present in the speech stream.

[4]In the linguistic subfield of phonology, features are often represented in square brackets with the name on the right and the value presented as +, −, or ± (indicating that the feature is binary but that the value is not known).

[5]Note that alternate feature systems use the feature [±front] to account for this contrast.

and innate feature inventory (Mielke, 2008). Likewise, in the speech sciences and speech technology, phonological features have been the subject of widespread inquiry (Bromberg et al., 2007; Metze, 2007). This contrasts with NLP, where phonological features have been subject to less experimentation, perhaps because of the perceived lower relevance of phonology than morphology, syntax, and semantics to NLP tasks. However, some promising NLP results have been achieved using phonological features.

In one of the more widely-cited cases of this kind, Gildea and Jurafsky (1996) added phonological biases—stated in terms of phonological features—to aid the OSTIA (the Onward Subsequential Transducer Inferance Algorithm) in learning phonological rules. Subsequently , Tao et al. (2006) used hand-weighted articulatory feature edit distance (augmented with "pseudofeatures") to facilitate the transliteration of named entities. This feature-based system outperformed a temporal algorithm on a English/Hindi language pair and contributed to the performance of the best model the authors tested. In a successor study, Yoon et al. (2007) employed the model of Tao et al. (2006) but with features weighted by the winnow algorithm rather than by hand; they achieved comparable results without engineered weights. In a related strain of research, Kondrak and Sherif (2006) explored phonological similarity measures based, in some cases, on a kind of phonological feature system (but with a multivalued place feature unlike the binary and ternary features integral to PanPhon).

3 PanPhon and Its Functionality

PanPhon facilitates further experimentation with phonological (specifically, articulatory) features. Our goal in implementing PanPhon was not to implement a state-of-the-art feature system (from the standpoint of linguistic theory) but to develop a methodologically solid resource that would be useful for NLP researchers. Contemporary feature theories posit hierarchical and non-linear feature structures; they cannot be easily expressed in terms of vectors of binary or ternary values like the earlier-vintage system represented in PanPhon. Linear phonological models like that instantiated in PanPhon are arguably less explanatory than non-linear and feature-geometric models, but they can also be said to hew closer to the empirical ground. One limitation of PanPhon involves the representation of tone, one area in which non-linear representations are almost universally conceded to hold the upper hand. PanPhon is segmental by design and tone is suprasegmental by nature.

In constructing PanPhon, our approach was to start with a subset of the International Phonetic Alphabet (or IPA) where every segment represents a sound that is distinct from the others. Contrary to its design principles, the IPA allows multiple transcriptions for the same sound in a variety of cases. An attempt was made, using consensus definitions, to classify each of these segments according to binary (and occasionally, ternary) features. This consensus feature set and the accompanying definitions were based on a survey of the phonological literature.

PanPhon's contribution lies in the following attributes:

Universal. PanPhon will, when queried with a legal, segmental Unicode IPA string, return a sequence of valid vectors of articulatory feature values. Currently, it defines 5,395 simple and complex IPA characters in terms of 21 articulatory features.

Empirically verified. The general feature system used in PanPhon has been widely tested by linguists across a great range of phenomena and languages and found to be effective at modeling the phonological and morphophonological patterns of the world's languages.

Unicode compliant. PanPhon uses the Unicode encoding of the International Phonetic Alphabet both internally and externally. This provides human readability (or, at least, readability to human linguists) in a way that ASCII mappings of all or part of the IPA, like ARPAbet, WorldBet, SAMPA, and X-SAMPA do not. Compare German *müde* 'tired' in ARPAbet /M <no_symbol> D AH/, WordBet /m y: d &/, SAMPA /m y: d @/, X-SAMPA /m y: d @/ with IPA /myːdə/. The development of convenient input methods and appropriate rendering technologies for IPA mitigate much of the past difficulty involved in using it in computing applications.

Open source. Unlike many existing phonological feature resources[6], PanPhon is freely available under a liberal license (MIT).

PanPhon consists of a collection of components:

1. A database relating unmodified IPA segments to vectors of 21 features. These form the core of the database. The features are listed here in the canonical order in which they appear in the database:

   syl [±syllabic]. Is the segment the nucleus of a syllable?
   son [±sonorant]. Is the segment produced with a relatively unobstructed vocal tract?
   cons [±consonantal]. Is the segment consonantal (not a vowel or glide, or laryngeal consonant)?
   cont [±continuant]. Is the segment produced with continuous oral airflow?
   delrel [±delayed release]. Is the segment an affricate?
   lat [±lateral]. Is the segment produced with a lateral constriction?
   nas [±nasal]. Is the segment produced with nasal airflow?
   strid [±strident]. Is the segment produced with noisy friction?
   voi [±voice]. Are the vocal folds vibrating during the production of the segment?
   sg [±spread glottis]. Are the vocal folds abducted during the production of the segment?
   cg [±constricted glottis]. Are the vocal folds adducted during the production of the segment?
   ant [±anterior]. Is a constriction made in the front of the vocal tract?
   cor [±coronal]. Is the tip or blade of the tongue used to make a constriction?
   distr [±distributed]. Is a coronal constriction distributed laterally?
   lab [±labial]. Does the segment involve constrictions with or of the lips?
   hi [±high]. Is the segment produced with the tongue body raised?
   lo [±low]. Is the segment produced with the tongue body lowered?
   back [±back]. Is the segment produced with the tongue body in a posterior position?
   round [±round]. Is the segment produced with the lips rounded?
   tense [±tense]. Is the segment produced with an advanced tongue root.

   Feature vectors from PanPhon for a few example segments (both simple and complex) are shown in Tab. 1.

2. A collection of rules, written in user-editable YAML, that describe diacritics and modifiers—the Unicode codepoint of the modifier, the feature specifications that provide the necessary context for adding the diacritic or modifier, and the feature specifications changes that take place if the diacritic or modifier is added to a segment. An example of one of these YAML rules is shown below:

Listing 1: Diacritic rule

```
- marker: ʷ
  name: Labialized
  position: post
  conditions:
    - syl:  "-"
  exclude:
    - w
    - ʍ
    - ɥ
  content:
    round: "+"
    back:  "+"
    hi:  "+"
```

[6]But see also PHOIBLE's phonological feature set (Moran et al., 2014).

This example shows a rule (named "Labialized") that adds the modifier (marker) "ʷ" after a segment—post(fix), if the segment has the feature [−syllabic] and is not /w/, /ʍ/, or /ɥ/. The new segment has the same features as the input segment except that is it [+round], [+back], and [+hi].

3. A script for applying diacritics and modifiers, as defined in 2, to segments, as defined in 1 and the comprehensive segment database produced by this script.

4. A set of Python convenience functions and classes for accessing, manipulating, and employing the phonological feature vectors associated with any segment, whether simple or complex:

   (a) Greedily parsing IPA strings into segments defined in the database.
   (b) Converting such a sequence of segments into a sequence of articulatory feature vectors.
   (c) Querying sets of segments based upon their features.
   (d) Pattern matching against strings using feature specifications to define character classes.
   (e) Computing phonological distance: weighted and unweighted feature edit distance.
   (f) Computing phonological distance: Levenshtein distance between strings with collapsed, phonologically-based segment equivalence classes.

In some applications, PanPhon is used with a sister library, Epitran, or another—more specialized—package for converting orthography to IPA. Epitran provides a simple interface for quickly implementing grapheme to phoneme mappings for languages with phonemically adequate orthographies. It includes mappings for a variety of languages including Spanish, Dutch, Turkish, and Uyghur.

4 Empirical Evaluation of PanPhon

It is not simply the case that the articulatory features available through PanPhon are well founded in terms of linguistic theory. It is also true that they have been demonstrated to improve the performance of certain machine learning models at certain NLP tasks. This section summarizes the contribution of PanPhon to two classes of tasks: orthography-to-IPA character transduction and named entity recognition (NER). While the second set of experiments (on NER) were prompted by a need to test a particular class of model—phonologically aware LSTM-CRFs—the first set were motivated by the need to solve a particular problem: how best to convert Sorani Kurdish (a Northwestern Iranian language of Iraq and Iran) from orthographic to IPA representation.

4.1 Orthography-IPA Character Transduction

As part of a NER system for the low-resource Sorani Kurdish language, we developed a Sorani-orthography-to-IPA converter Littell et al. (2016). This was challenging because the Sorani orthography, like many Perso-Arabic scripts, badly underdetermines the equivalent phonetic representation. The following steps summarize the workflow behind building the Sorani-to-IPA converter:

1. Human linguists identify the orthographic units (i.e., characters and multigraphs) in the script.

2. Human linguists identify the possible IPA representations of each orthographic unit, using knowledge of the language and the writing system.

3. The system generates all possible hypotheses for a subset of tokens of the language using the mapping developed in the previous step.

4. Human linguists generate training data using a grammar and lexicon (Thackston, 2006) by picking one or more valid pronunciations (or, if unknown, one or more likely hypotheses) for a selection of tokens.

5. Character-level chain conditional random field (CRF) is trained (Lafferty et al., 2001; Dyer et al., 2010) on resulting data.

The hypothesis space within which the CRF operates was determined by the symbol-level IPA map developed in the first step of our work-flow. It is important to note that we allowed many-to-many mapping between orthographic input character sequences and IPA output character sequences in the sense that a single input character can be mapped to multiple IPA symbols and an input multigraph (consisting of multiple orthographic characters) can be mapped to a single IPA symbol.

PanPhon feature vectors were used to create one set of features that were consumed by the CRF. This move was motivated by the insight that phonotactic patterns—patterns in the sequences of speech sounds—tend to be based around the very sorts of classes that phonological features are intended to describe. For the purposes of these experiments, we divided these features into six classes which correspond largely to classes widely used by phonologists:

- **Major Class** features—represent the major classes of sounds: [±syllable], [±sonorant], [±consonantal], [±continuant].
- **Laryngeal** features—specify the glottal states of sounds: [±voice], [±spread glottis], [±constricted glottis].
- **Major place** features—focus on the place of articulation: [±anterior], [±coronal], [±labial] and [±distributed][7].
- **Minor Place** features—related to the position of the dorsum in the tongue: [±high], [±low] and [±back].
- **Manner** features—categorize IPA symbols according to their manner of articulation: [±nasal], [±lateral], [±delayed release] and [±strident].
- **Minor Manner** features—the attributes in this group were [±round] and [±tense].

We then generated the training data with 244 instances (types)[8] and report performance of their IPA predictor on 402 instances. In Table 3 (adapted from Littell et al. (2016)), we compare the accuracy and character error rate (CER) of the predictor, when using PanPhon features compared to, and along with:

- **Basic** features pertaining to the usage of orthography-to-IPA symbol translation rules, and whether the IPA symbols were identified as consonants and vowels[9].
- **Phon** features derived from the PanPhon IPA-to-feature-vector package.
- **Kurmanji** features derived from a 4-gram language model, built using SRILM (Stolcke, 2002), from the IPA-ized Kurmanji corpus. Kurmanji is a "sister" language of Sorani having a phonologically unambiguous orthography.
- **Tajik** features, derived as above, from the IPA-ized Tajik corpus. Tajik is a close cousin of Sorani having a phonologically unambiguous orthography.

While the single most important class of features, all told, were those derived from the Kurmanji language model, the inclusion of PanPhon features gave similar gains to the inclusion of the Tajik features, and the best results overall came from the inclusion of both Kurmanji and PanPhon features. This is a welcome result—while not all languages have a close sister variety with an unambiguous orthography, PanPhon-based features are universally available.

Among the PanPhon features, the most valuable features for this task were the *major class features*, *laryngeal features*, and *place features*. Unsurprisingly, having a language model from a sister language (in this case, Kurmanji) is the most useful single source of features for IPA conversion. However, it is surprising to find that just having the universal features derived from PanPhon vectors were as useful as having a language model from a cousin language (in this case, Tajik).

[7]Phonologists do not generally consider the feature [±distributed] to be a major place feature. This appears to have been an error in our implementation of the feature classes.

[8]It is worth noting that when reducing the training set to a quarter of this, we observed only slightly worse results, suggesting that very little manual effort would be necessary to generate training data for a task like this.

[9]The consonant/vowel feature should have been largely equivalent to the feature [±syllabic].

Features	Accuracy	CER
Basic	0.635	0.237
Basic+phon.	0.669	0.234
Basic+Kurmanji	0.701	0.223
Basic+Kurmanji+phon.	0.721	0.221
Basic+Tajik	0.661	0.231
Basic+Tajik+phon.	0.664	0.228
All features	0.721	0.221

4.2 NER with Phonologically-Aware Neural Models

We subsequently experimented with PanPhon—and its sister package, Epitran—in performing NER with a character-based LSTM-CRF architecture (Bharadwaj et al., 2016). We made this architecture phonologically-aware by substituting phonological feature vectors from PanPhon for characters. We used the resulting features in a series of NER experiments in both monolingual and transfer scenarios. As a baseline, we employed a character based LSTM-CRF NER system with features from pre-trained word vectors.

In a series of monolingual experiment using CoNLL 2002 data from Spanish (see Tab. 4, adapted from (Bharadwaj et al., 2016)) it was found that substituting PanPhon and phonological attention features for orthographic and orthographic attention features (in a model also incorporating word vector, capitalization, and Unicode character category features) raised F1 from 85.25 to 85.81 and yielded the best-performing model in the series. In a second series of monolingual experiments using the LDC2014E115 BOLT Turk-

ish Language Pack, Bharadwaj et al. (2016) found that the best model incorporated PanPhon as well as orthographic features (see Tab. 5. The second-best scoring model uses only PanPhon features and phonological attention features (in addition to pretrained word vectors) and because it is character-independent, it is more suitable for cross-lingual transfer. Finally, Bharadwaj et al. (2016) conducted a series of Uzbek-to-Turkish cross-lingual transfer experiments using the LDC2015E89 BOLT data pack for Uzbek and the

LDC2014E115 BOLT data pack for Turkish. Unsurprisingly, monolingual models with no training data achieve an F1 of zero. In a transfer situation, with no Turkish training data, word vectors alone give an F-score of 2.09. However, using phonological features and phonological attention features with zero training data in the target language (but training in the transfer language) yields an F-score of 11.9. Adding capitalization and Unicode category features allowed the resulting model to achieve an F1 of 26.92 in a zero-shot scenario.

S-LSTM (Lample et al., 2016)		0	15.41	39.33	42.99	51.92	51.55	56.58

Table 6: Model transfer from Uzbek to Turkish at different target data availability thresholds compared to monolingual Turkish baseline, also at different data availability thresholds; factors are pre-trained word vectors (WVec), PanPhon features (Phon), phonological attention features (PhonAttn), capitalization features (Cap), and Unicode category features (Cat)

What do these experiments reveal about the value of PanPhon for NER? The monolingual experiments may not seem compelling, but they drive home an important point: even though conversion from orthography to PanPhon vectors entails a significant loss of information, it does not seem to entail a loss of performance. It is even possible that phonological features facilitate NER in the monolingual case by helping a neural NER system to identify phonologically aberrant tokens which are more likely to reflect borrowed lexical items which, in turn, are more likely to be named entities. The real benefit of using phonological feature representations in NER, however, is manifest in transfer scenarios like the Uzbek-Turkish transfer scenario we explored in Bharadwaj et al. (2016). By projecting both the source and target language into a common phonological space, similarities that would be masked in an orthographic space become accessible to a neural NER system. The value of such an approach is most obvious when it is applied to relatively closely-related languages that are written in different orthographies like Uzbek and

Turkish[10].

5 Conclusion

This paper has reported the creation of a new resource, PanPhon, a database of IPA segment-phonological feature correspondences with a collection of code for exploiting these relationships. Additionally, we briefly documented the PanPhon database and modules. Most significantly, we showed that PanPhon features can improve performance in two NLP tasks: orthography-to-IPA conversion and NER. At this point, the PanPhon feature mapping has still not be tested against other phonological feature implementations (which have typically not been made widely available) in these tasks, so it cannot be claimed that PanPhon boosts performance more than these other databases. However, it can be said conclusively that systems *like* PanPhon are a useful component in some NLP systems.

Abstract

Recurrent Neural Network (RNN) is one of the most popular architectures used in Natural Language Processsing (NLP) tasks because its recurrent structure is very suitable to process variable-length text. RNN can utilize distributed representations of words by first converting the tokens comprising each text into vectors, which form a matrix. And this matrix includes two dimensions: the time-step dimension and the feature vector dimension. Then most existing models usually utilize one-dimensional (1D) max pooling operation or attention-based operation only on the time-step dimension to obtain a fixed-length vector. However, the features on the feature vector dimension are not mutually independent, and simply applying 1D pooling operation over the time-step dimension independently may destroy the structure of the feature representation. On the other hand, applying two-dimensional (2D) pooling operation over the two dimensions may sample more meaningful features for sequence modeling tasks. To integrate the features on both dimensions of the matrix, this paper explores applying 2D max pooling operation to obtain a fixed-length representation of the text. This paper also utilizes 2D convolution to sample more meaningful information of the matrix. Experiments are conducted on six text classification tasks, including sentiment analysis, question classification, subjectivity classification and newsgroup classification. Compared with the state-of-the-art models, the proposed models achieve excellent performance on 4 out of 6 tasks. Specifically, one of the proposed models achieves highest accuracy on Stanford Sentiment Treebank binary classification and fine-grained classification tasks.

1 Introduction

Text classification is an essential component in many NLP applications, such as sentiment analysis (Socher et al., 2013), relation extraction (Zeng et al., 2014) and spam detection (Wang, 2010). Therefore, it has attracted considerable attention from many researchers, and various types of models have been proposed. As a traditional method, the bag-of-words (BoW) model treats texts as unordered sets of words (Wang and Manning, 2012). In this way, however, it fails to encode word order and syntactic feature.

Recently, order-sensitive models based on neural networks have achieved tremendous success for text classification, and shown more significant progress compared with BoW models. The challenge for textual modeling is how to capture features for different text units, such as phrases, sentences and documents. Benefiting from its recurrent structure, RNN, as an alternative type of neural networks, is very suitable to process the variable-length text.

RNN can capitalize on distributed representations of words by first converting the tokens comprising each text into vectors, which form a matrix. This matrix includes two dimensions: the time-step dimension and the feature vector dimension, and it will be updated in the process of learning feature representation. Then RNN utilizes 1D max pooling operation (Lai et al., 2015) or attention-based operation (Zhou et al., 2016), which extracts maximum values or generates a weighted representation over

the time-step dimension of the matrix, to obtain a fixed-length vector. Both of the two operators ignore features on the feature vector dimension, which maybe important for sentence representation, therefore the use of 1D max pooling and attention-based operators may pose a serious limitation.

Convolutional Neural Networks (CNN) (Kalchbrenner et al., 2014; Kim, 2014) utilizes 1D convolution to perform the feature mapping, and then applies 1D max pooling operation over the time-step dimension to obtain a fixed-length output. However the elements in the matrix learned by RNN are not independent, as RNN reads a sentence word by word, one can effectively treat the matrix as an 'image'. Unlike in NLP, CNN in image processing tasks (LeCun et al., 1998; Krizhevsky et al., 2012) applies 2D convolution and 2D pooling operation to get a representation of the input. It is a good choice to utilize 2D convolution and 2D pooling to sample more meaningful features on both the time-step dimension and the feature vector dimension for text classification.

Above all, this paper proposes Bidirectional Long Short-Term Memory Networks with Two-Dimensional Max Pooling (BLSTM-2DPooling) to capture features on both the time-step dimension and the feature vector dimension. It first utilizes Bidirectional Long Short-Term Memory Networks (BLSTM) to transform the text into vectors. And then 2D max pooling operation is utilized to obtain a fixed-length vector. This paper also applies 2D convolution (BLSTM-2DCNN) to capture more meaningful features to represent the input text.

The contributions of this paper can be summarized as follows:

- This paper proposes a combined framework, which utilizes BLSTM to capture long-term sentence dependencies, and extracts features by 2D convolution and 2D max pooling operation for sequence modeling tasks. To the best of our knowledge, this work is the first example of using 2D convolution and 2D max pooling operation in NLP tasks.

- This work introduces two combined models BLSTM-2DPooling and BLSTM-2DCNN, and verifies them on six text classification tasks, including sentiment analysis, question classification, subjectivity classification, and newsgroups classification. Compared with the state-of-the-art models, BLSTM-2DCNN achieves excellent performance on 4 out of 6 tasks. Specifically, it achieves highest accuracy on Stanford Sentiment Treebank binary classification and fine-grained classification tasks.

- To better understand the effect of 2D convolution and 2D max pooling operation, this paper conducts experiments on Stanford Sentiment Treebank fine-grained task. It first depicts the performance of the proposed models on different length of sentences, and then conducts a sensitivity analysis of 2D filter and max pooling size.

The remainder of the paper is organized as follows. In Section 2, the related work about text classification is reviewed. Section 3 presents the BLSTM-2DCNN architectures for text classification in detail. Section 4 describes details about the setup of the experiments. Section 5 presents the experimental results. The conclusion is drawn in the section 6.

2 Related Work

Deep learning based neural network models have achieved great improvement on text classification tasks. These models generally consist of a projection layer that maps words of text to vectors. And then combine the vectors with different neural networks to make a fixed-length representation. According to the structure, they may divide into four categories: Recursive Neural Networks (RecNN[1]), RNN, CNN and other neural networks.

Recursive Neural Networks: RecNN is defined over recursive tree structures. In the type of recursive models, information from the leaf nodes of a tree and its internal nodes are combined in a bottom-up manner. Socher et al. (2013) introduced recursive neural tensor network to build representations of phrases and sentences by combining neighbour constituents based on the parsing tree. Irsoy and Cardie

[1]To avoid confusion with RNN, we named Recursive Neural Networks as RecNN.

(2014) proposed deep recursive neural network, which is constructed by stacking multiple recursive layers on top of each other, to modeling sentence.

Recurrent Neural Networks: RNN has obtained much attention because of their superior ability to preserve sequence information over time. Tang et al. (2015) developed target dependent Long Short-Term Memory Networks (LSTM (Hochreiter and Schmidhuber, 1997)), where target information is automatically taken into account. Tai et al. (2015) generalized LSTM to Tree-LSTM where each LSTM unit gains information from its children units. Zhou et al. (2016) introduced BLSTM with attention mechanism to automatically select features that have a decisive effect on classification. Yang et al. (2016) introduced a hierarchical network with two levels of attention mechanisms, which are word attention and sentence attention, for document classification. This paper also implements an attention-based model BLSTM-Att like the model in Zhou et al. (2016).

Convolution Neural Networks: CNN (LeCun et al., 1998) is a feedforward neural network with 2D convolution layers and 2D pooling layers, originally developed for image processing. Then CNN is applied to NLP tasks, such as sentence classification (Kalchbrenner et al., 2014; Kim, 2014), and relation classification (Zeng et al., 2014). The difference is that the common CNN in NLP tasks is made up of 1D convolution layers and 1D pooling layers. Kim (2014) defined a CNN architecture with two channels. Kalchbrenner et al. (2014) proposed a dynamic k-max pooling mechanism for sentence modeling. (Zhang and Wallace, 2015) conducted a sensitivity analysis of one-layer CNN to explore the effect of architecture components on model performance. Yin and Schütze (2016) introduced multichannel embeddings and unsupervised pretraining to improve classification accuracy. (Zhang and Wallace, 2015) conducted a sensitivity analysis of one-layer CNN to explore the effect of architecture components on model performance.

Usually there is a misunderstanding that 1D convolutional filter in NLP tasks has one dimension. Actually it has two dimensions (k, d), where k, $d \in \mathbb{R}$. As d is equal to the word embeddings size d^w, the window slides only on the time-step dimension, so the convolution is usually called 1D convolution. While d in this paper varies from 2 to d^w, to avoid confusion with common CNN, the convolution in this work is named as 2D convolution. The details will be described in Section 3.2.

Other Neural Networks: In addition to the models described above, lots of other neural networks have been proposed for text classification. Iyyer et al. (2015) introduced a deep averaging network, which fed an unweighted average of word embeddings through multiple hidden layers before classification. Zhou et al. (2015) used CNN to extract a sequence of higher-level phrase representations, then the representations were fed into a LSTM to obtain the sentence representation.

The proposed model BLSTM-2DCNN is most relevant to DSCNN (Zhang et al., 2016) and RCNN (Wen et al., 2016). The difference is that the former two utilize LSTM, bidirectional RNN respectively, while this work applies BLSTM, to capture long-term sentence dependencies. After that the former two both apply 1D convolution and 1D max pooling operation, while this paper uses 2D convolution and 2D max pooling operation, to obtain the whole sentence representation.

3 Model

As shown in Figure 1, the overall model consists of four parts: BLSTM Layer, Two-dimensional Convolution Layer, Two dimensional max pooling Layer, and Output Layer. The details of different components are described in the following sections.

3.1 BLSTM Layer

LSTM was firstly proposed by Hochreiter and Schmidhuber (1997) to overcome the gradient vanishing problem of RNN. The main idea is to introduce an adaptive gating mechanism, which decides the degree to keep the previous state and memorize the extracted features of the current data input. Given a sequence $S = \{x_1, x_2, \ldots, x_l\}$, where l is the length of input text, LSTM processes it word by word. At time-step t, the memory c_t and the hidden state h_t are updated with the following equations:

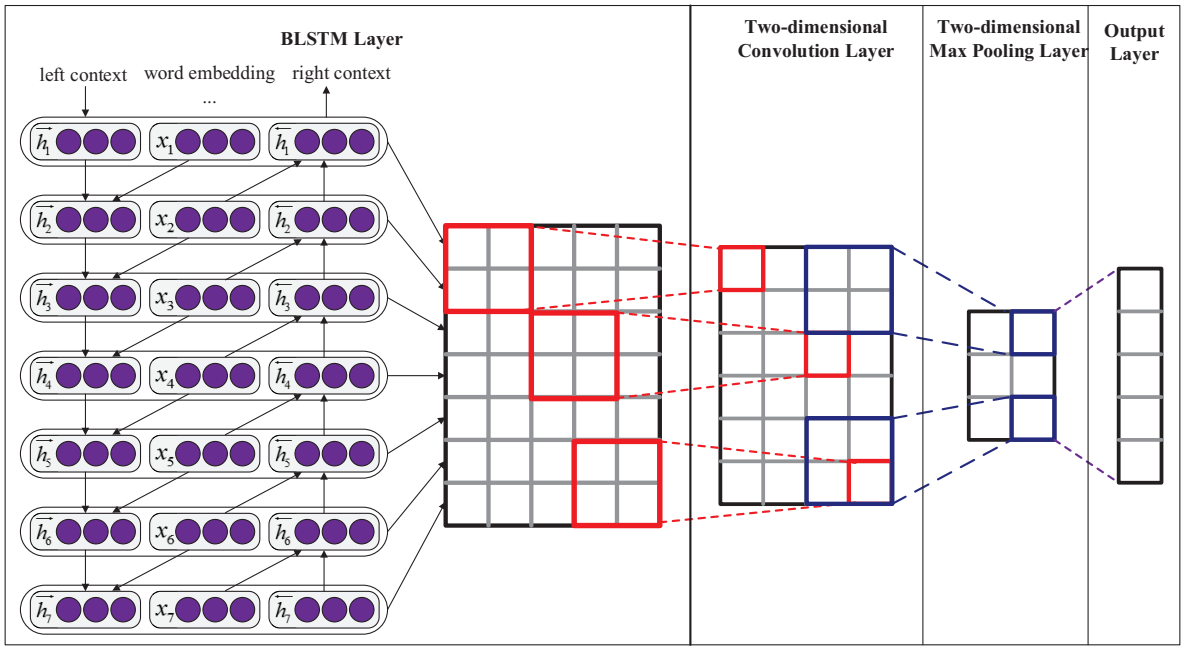

Figure 1: A BLSTM-2DCNN for the seven word input sentence. Word embeddings have size 3, and BLSTM has 5 hidden units. The height and width of convolution filters and max pooling operations are 2, 2 respectively.

$$\begin{bmatrix} i_t \\ f_t \\ o_t \\ \hat{c}_t \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \\ \tanh \end{bmatrix} W \cdot [h_{t-1}, x_t] \tag{1}$$

$$c_t = f_t \odot c_{t-1} + i_t \odot \hat{c}_t \tag{2}$$

$$h_t = o_t \odot \tanh(c_t) \tag{3}$$

where x_t is the input at the current time-step, i, f and o is the input gate activation, forget gate activation and output gate activation respectively, $\hat{c}$ is the current cell state, σ denotes the logistic sigmoid function and $\odot$ denotes element-wise multiplication.

For the sequence modeling tasks, it is beneficial to have access to the past context as well as the future context. Schuster and Paliwal (1997) proposed BLSTM to extend the unidirectional LSTM by introducing a second hidden layer, where the hidden to hidden connections flow in opposite temporal order. Therefore, the model is able to exploit information from both the past and the future.

In this paper, BLSTM is utilized to capture the past and the future information. As shown in Figure 1, the network contains two sub-networks for the forward and backward sequence context respectively. The output of the i^{th} word is shown in the following equation:

$$h_i = [\overrightarrow{h_i} \oplus \overleftarrow{h_i}] \tag{4}$$

Here, element-wise sum is used to combine the forward and backward pass outputs.

3.2 Convolutional Neural Networks

Since BLSTM has access to the future context as well as the past context, h_i is related to all the other words in the text. One can effectively treat the matrix, which consists of feature vectors, as an 'image', so 2D convolution and 2D max pooling operation can be utilized to capture more meaningful information.

3.2.1 Two-dimensional Convolution Layer

A matrix $H = \{h_1, h_2, \ldots, h_l\}$, $H \in \mathbb{R}^{l \times d^w}$, is obtained from BLSTM Layer, where d^w is the size of word embeddings. Then narrow convolution is utilized (Kalchbrenner et al., 2014) to extract local features over H. A convolution operation involves a 2D filter $\mathbf{m} \in \mathbb{R}^{k \times d}$, which is applied to a window of k words and d feature vectors. For example, a feature $o_{i,j}$ is generated from a window of vectors $H_{i:i+k-1,\, j:j+d-1}$ by

$$o_{i,j} = f(\mathbf{m} \cdot H_{i:i+k-1,\, j:j+d-1} + b) \tag{5}$$

where i ranges from 1 to $(l - k + 1)$, j ranges from 1 to $(d^w - d + 1)$, $\cdot$ represents dot product, $b \in \mathbb{R}$ is a bias and an f is a non-linear function such as the hyperbolic tangent. This filter is applied to each possible window of the matrix H to produce a feature map O:

$$O = [o_{1,1}, o_{1,2}, \cdots, o_{l-k+1, d^w-d+1}] \tag{6}$$

with $O \in \mathbb{R}^{(l-k+1)\times(d^w-d+1)}$. It has described the process of one convolution filter. The convolution layer may have multiple filters for the same size filter to learn complementary features, or multiple kinds of filter with different size.

3.2.2 Two-dimensional Max Pooling Layer

Then 2D max pooling operation is utilized to obtain a fixed length vector. For a 2D max pooling $p \in \mathbb{R}^{p_1 \times p_2}$, it is applied to each possible window of matrix O to extract the maximum value:

$$p_{i,j} = down(O_{i:i+p_1,\, j:j+p_2}) \tag{7}$$

where $down(\cdot)$ represents the 2D max pooling function, $i = (1, 1 + p_1, \cdots, 1 + (l - k + 1/p_1 - 1) \cdot p_1)$, and $j = (1,\ 1 + p_2, \cdots, 1 + (d^w - d + 1/p_2 - 1) \cdot p_2)$. Then the pooling results are combined as follows:

$$h^* = [p_{1,1}, p_{1,1+p_2}, \cdots, p_{1+(l-k+1/p_1-1)\cdot p_1, 1+(d^w-d+1/p_2-1)\cdot p_2}] \tag{8}$$

where $h^* \in \mathbb{R}$, and the length of h^* is $\lfloor l - k + 1/p_1 \rfloor \times \lfloor d^w - d + 1/p_2 \rfloor$.

3.3 Output Layer

For text classification, the output h^* of 2D Max Pooling Layer is the whole representation of the input text S. And then it is passed to a softmax classifier layer to predict the semantic relation label $\hat{y}$ from a discrete set of classes Y. The classifier takes the hidden state h^* as input:

$$\hat{p}(y|s) = softmax\left(W^{(s)} h^* + b^{(s)}\right) \tag{9}$$

$$\hat{y} = \arg\max_y \hat{p}(y|s) \tag{10}$$

A reasonable training objective to be minimized is the categorical cross-entropy loss. The loss is calculated as a regularized sum:

$$J(\theta) = -\frac{1}{m} \sum_{i=1}^{m} t_i \log(y_i) + \lambda \|\theta\|_F^2 \tag{11}$$

where $\boldsymbol{t} \in \mathbb{R}^m$ is the one-hot represented ground truth, $\boldsymbol{y} \in \mathbb{R}^m$ is the estimated probability for each class by softmax, m is the number of target classes, and λ is an L2 regularization hyper-parameter. Training is done through stochastic gradient descent over shuffled mini-batches with the AdaDelta (Zeiler, 2012) update rule. Training details are further introduced in Section 4.3.

Data	c	l	m	train	dev	test	$\|V\|$	$\|V_{pre}\|$
SST-1	5	18	51	8544	1101	2210	17836	12745

20Ng	4	276	11468	7520	836	5563	51379	30575

Table 1: Summary statistics for the datasets. c: number of target classes, l: average sentence length, m: maximum sentence length, train/dev/test: train/development/test set size, $|V|$: vocabulary size, $|V_{pre}|$: number of words present in the set of pre-trained word embeddings, **CV**: 10-fold cross validation.

4 Experimental Setup

4.1 Datasets

The proposed models are tested on six datasets. Summary statistics of the datasets are in Table 1.

- **MR**[2]: Sentence polarity dataset from Pang and Lee (2005). The task is to detect positive/negative reviews.

- **SST-1**[3]: Stanford Sentiment Treebank is an extension of MR from Socher et al. (2013). The aim is to classify a review as fine-grained labels (very negative, negative, neutral, positive, very positive).

- **SST-2**: Same as SST-1 but with neutral reviews removed and binary labels (negative, positive). For both experiments, phrases and sentences are used to train the model, but only sentences are scored at test time (Socher et al., 2013; Le and Mikolov, 2014). Thus the training set is an order of magnitude larger than listed in table 1.

- **Subj**[4]: Subjectivity dataset (Pang and Lee, 2004). The task is to classify a sentence as being subjective or objective.

- **TREC**[5]: Question classification dataset (Li and Roth, 2002). The task involves classifying a question into 6 question types (abbreviation, description, entity, human, location, numeric value).

- **20Newsgroups**[6]: The 20Ng dataset contains messages from twenty newsgroups. We use the bydate version preprocessed by Cachopo (2007). We select four major categories (comp, politics, rec and religion) followed by Hingmire et al. (2013).

4.2 Word Embeddings

The word embeddings are pre-trained on much larger unannotated corpora to achieve better generalization given limited amount of training data (Turian et al., 2010). In particular, our experiments utilize the GloVe embeddings[7] trained by Pennington et al. (2014) on 6 billion tokens of Wikipedia 2014 and Gigaword 5. Words not present in the set of pre-trained words are initialized by randomly sampling from uniform distribution in $[-0.1, 0.1]$. The word embeddings are fine-tuned during training to improve the performance of classification.

[7]http://nlp.stanford.edu/projects/glove/

4.3 Hyper-parameter Settings

For datasets without a standard development set we randomly select 10% of the training data as the development set. The evaluation metric of the 20Ng is the Macro-F1 measure followed by the state-of-the-art work and the other five datasets use accuracy as the metric. The final hyper-parameters are as follows.

The dimension of word embeddings is 300, the hidden units of LSTM is 300. We use 100 convolutional filters each for window sizes of (3,3), 2D pooling size of (2,2). We set the mini-batch size as 10 and the learning rate of AdaDelta as the default value 1.0. For regularization, we employ Dropout operation (Hinton et al., 2012) with dropout rate of 0.5 for the word embeddings, 0.2 for the BLSTM layer and 0.4 for the penultimate layer, we also use l2 penalty with coefficient 10^{-5} over the parameters.

These values are chosen via a grid search on the SST-1 development set. We only tune these hyper-parameters, and more finer tuning, such as using different numbers of hidden units of LSTM layer, or using wide convolution (Kalchbrenner et al., 2014), may further improve the performance.

5 Results

5.1 Overall Performance

This work implements four models, BLSTM, BLSTM-Att, BLSTM-2DPooling, and BLSTM-2DCNN. Table 2 presents the performance of the four models and other state-of-the-art models on six classification tasks. The BLSTM-2DCNN model achieves excellent performance on 4 out of 6 tasks. Especially, it achieves 52.4% and 89.5% test accuracies on SST-1 and SST-2 respectively.

BLSTM-2DPooling performs worse than the state-of-the-art models. While we expect performance gains through the use of 2D convolution, we are surprised at the magnitude of the gains. BLSTM-CNN beats all baselines on SST-1, SST-2, and TREC datasets. As for Subj and MR datasets, BLSTM-2DCNN gets a second higher accuracies. Some of the previous techniques only work on sentences, but not paragraphs/documents with several sentences. Our question becomes whether it is possible to use our models for datasets that have a substantial number of words, such as 20Ng and where the content consists of many different topics. For that purpose, this paper tests the four models on document-level dataset 20Ng, by treating the document as a long sentence. Compared with RCNN (Lai et al., 2015), BLSTM-2DCNN achieves a comparable result.

Besides, this paper also compares with ReNN, RNN, CNN and other neural networks:

- Compared with ReNN, the proposed two models do not depend on external language-specific features such as dependency parse trees.
- CNN extracts features from word embeddings of the input text, while BLSTM-2DPooling and BLSTM-2DCNN captures features from the output of BLSTM layer, which has already extracted features from the original input text.
- BLSTM-2DCNN is an extension of BLSTM-2DPooling, and the results show that BLSTM-2DCNN can capture more dependencies in text.
- AdaSent utilizes a more complicated model to form a hierarchy of representations, and it outperforms BLSTM-2DCNN on Subj and MR datasets. Compared with DSCNN (Zhang et al., 2016), BLSTM-2DCNN outperforms it on five datasets.

Compared with these results, 2D convolution and 2D max pooling operation are more effective for modeling sentence, even document. To better understand the effect of 2D operations, this work conducts a sensitivity analysis on SST-1 dataset.

5.2 Effect of Sentence Length

Figure 2 depicts the performance of the four models on different length of sentences. In the figure, the x-axis represents sentence lengths and y-axis is accuracy. The sentences collected in test set are no

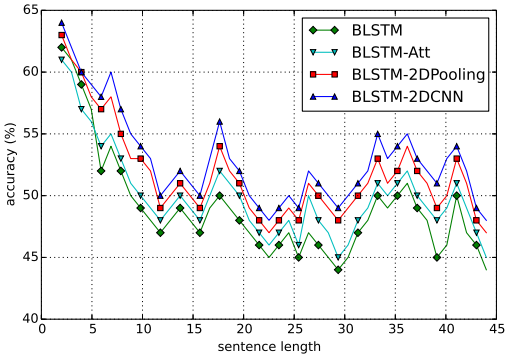

Figure 2: Fine-grained sentiment classification accuracy vs. sentence length.

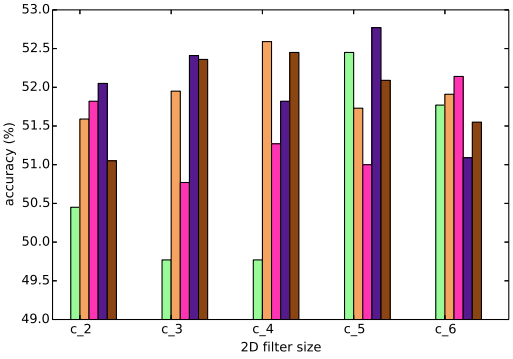

Figure 3: Prediction accuracy with different size of 2D filter and 2D max pooling.

longer than 45 words. The accuracy here is the average value of the sentences with length in the window $[l-2, l+2]$. Each data point is a mean score over 5 runs, and error bars have been omitted for clarity.

It is found that both BLSTM-2DPooling and BLSTM-2DCNN outperform the other two models. This suggests that both 2D convolution and 2D max pooling operation are able to encode semantically-useful structural information. At the same time, it shows that the accuracies decline with the length of sentences increasing. In future work, we would like to investigate neural mechanisms to preserve long-term dependencies of text.

5.3 Effect of 2D Convolutional Filter and 2D Max Pooling Size

We are interested in what is the best 2D filter and max pooling size to get better performance. We conduct experiments on SST-1 dataset with BLSTM-2DCNN and set the number of feature maps to 100.

To make it simple, we set these two dimensions to the same values, thus both the filter and the pooling are square matrices. For the horizontal axis, c means 2D convolutional filter size, and the five different color bar charts on each c represent different 2D max pooling size from 2 to 6. Figure 3 shows that different size of filter and pooling can get different accuracies. The best accuracy is 52.6 with 2D filter size (5,5) and 2D max pooling size (5,5), this shows that finer tuning can further improve the performance reported here. And if a larger filter is used, the convolution can detector more features, and the performance may be improved, too. However, the networks will take up more storage space, and consume more time.

6 Conclusion

This paper introduces two combination models, one is BLSTM-2DPooling, the other is BLSTM-2DCNN, which can be seen as an extension of BLSTM-2DPooling. Both models can hold not only the time-step dimension but also the feature vector dimension information. The experiments are conducted on six text classificaion tasks. The experiments results demonstrate that BLSTM-2DCNN not only outperforms RecNN, RNN and CNN models, but also works better than the BLSTM-2DPooling and DSCNN (Zhang et al., 2016). Especially, BLSTM-2DCNN achieves highest accuracy on SST-1 and SST-2 datasets. To better understand the effective of the proposed two models, this work also conducts a sensitivity analysis on SST-1 dataset. It is found that large filter can detector more features, and this may lead to performance improvement.

More is not always better: balancing sense distributions for all-words Word Sense Disambiguation

Abstract

Current Word Sense Disambiguation systems show an extremely poor performance on low frequent senses, which is mainly caused by the difference in sense distributions between training and test data. The main focus in tackling this problem has been on acquiring more data or selecting a single predominant sense and not necessarily on the meta properties of the data itself. We demonstrate that these properties, such as the volume, provenance, and balancing, play an important role with respect to system performance. In this paper, we describe a set of experiments to analyze these meta properties in the framework of a state-of-the-art WSD system when evaluated on the SemEval-2013 English all-words dataset. We show that volume and provenance are indeed important, but that approximating the perfect balancing of the selected training data leads to an improvement of 21 points and exceeds state-of-the-art systems by 14 points while using only simple features. We therefore conclude that unsupervised acquisition of training data should be guided by strategies aimed at matching meta properties.

1 Introduction

The task of automatically selecting the meaning of a word in a linguistic context, known as Word Sense Disambiguation (WSD), has been and is one of the main challenges for NLP. Despite the huge amount of research that has been carried out to analyze and tackle this problem, it is nevertheless still considered unsolved. The best performances on the SemEval-2013 task 12: "Multilingual Word Sense Disambiguation" English all-words subtask (from now on *sem2013-aw*) (Navigli et al., 2013) was 72.28 (Weissenborn et al., 2015)) out of competition and 64.7 in competition (Gutiérrez et al., 2013), exceeding the naive Most Frequent Sense (MFS) baseline by only 10 points at most.

Supervised machine learning systems have been successful for WSD and it is commonly believed that the problem of the low performance can be solved by providing more (manually annotated) training data. However, in addition to the sparseness of training data, another aspect of the problem is the Zipfian distribution of word senses (McCarthy et al., 2007). In both training data and test data, the same single sense of a word tends to heavily dominate, making the MFS not only a baseline that is difficult to beat (Kilgarriff, 2004), but also being used as a fall-back option by many systems.

Given the Zipfian distribution of word senses, it comes as no surprise that WSD systems have a bias towards assigning the MFS (Preiss, 2006). Building upon this observation, Postma et al. (2016) analyzed systems participating in previous Senseval and SemEval competitions with respect to their performance on the MFS and on all other senses, which are called the less frequent senses (LFS). This study convincingly showed that systems excel at identifying MFS instances, but that all systems underperform on LFS instances. For instance on the sem2013-aw task, systems performed on average around 80% in accuracy on the MFS instances, but they hardly achieved on average 20% accuracy for the LFS instances.

The main challenge for WSD is therefore not only to acquire more training data, but to also address the overfitting towards the majority case in order to boost the performance for the LFS cases. Assuming that

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3496–3506, Osaka, Japan, December 11-17 2016.

their low performance is due to both the sparseness of training data and differences in sense distributions, the challenge is how to acquire more training data and obtaining the right distribution. In this paper, we therefore investigate the following research questions:

1. **Volume**: What is the influence of using more training data without distinguishing between MFS and LFS cases?
2. **LFS**: What is the influence of only adding more LFS training examples?
3. **Provenance**: What is the effect of training using manually annotated data versus automatically annotated data?
4. **Balancing**: What is the effect of mimicking the perfect target distribution in the training data?

By providing evidence for each research question, we firstly demonstrate that more data has a small impact on the performance of a state-of-the-art supervised system (It Makes Sense (IMS), (Zhong and Ng, 2010)). Interestingly enough, the type of data has a bigger impact, more specifically, adding silver data with a better fit to the test set with respect to time and genre appears to be better than adding more manually annotated data. Our biggest contribution is however that a perfect balance of data has a major impact on the performance. Balancing the training data according to the sense distribution of the test data boosts the results for the LFS cases while maintaining the high performance for the MFS instances. Following this assumption, our experiments presented in this paper reach an overall accuracy of 86.8 as an upper ceiling. This points towards the conclusion that the evaluation data sets have so-called "long-tail details" that need to be modeled to obtain a high-performance in addition to the properties of the head of the distribution. We therefore conclude that the distributional effect is more complex than suggested in (McCarthy et al., 2004a), who focus only on the predominant sense, but also has a larger potential if acquisition is guided by strategies to match meta properties.

The paper is structured as follows: in Section 2 we discuss related work, following by a description of the resources and the evaluation framework (Section 3). The experiments and the results are presented in Section 4. Finally, we discuss the results in Section 5 and conclude the paper in Section 6. All the training data, system output files and scripts required to fully reproduce the experiments presented in this paper have been made publicly available at: `https://github.com/cltl/MoreIsNotAlwaysBetter`.

2 Related Work

Many natural phenomena can be described by power laws (Newman, 2005), ranging from city populations to name frequencies. Word sense distributions are no exception to this interesting phenomenon and also show Zipfian characteristics (McCarthy et al., 2007; Kilgarriff, 2004). This means that, given any document or collection of documents, one sense of a lemma is usually overrepresented, while the other senses are barely used. The MFS consequently plays a critical role in the task of WSD and establishes a challenge for systems. In evaluation, the MFS is usually used as a hard to beat baseline and it is therefore also used as a fallback strategy by systems.

In general, WSD systems perform well on the MFS instances, whereas their performance drops dramatically for the LFS instances (Postma et al., 2016). This is not surprising considering the Zipfian distribution of senses which has a big impact on supervised approaches. Given the dominance of MFS examples in the training data, this results in better sense representations for these cases. This unbalance contributes to the system bias towards the MFS. For unsupervised approaches, in particular graph-based approaches, the MFS of a lemma also appears to have a higher connectivity in the graph (Calvo and Gelbukh, 2015), hence also favoring it in the sense assignment phase of a WSD system. Overall, less attention has been paid to the less represented and less frequent senses, despite the fact that these provide the biggest room for improvement (Postma et al., 2016).

Although the MFS in the training data often coincides with the MFS of the task, this is not always the case, specially in cross-domain or genre scenarios. A system able to detect the predominant sense of a lemma within a target document would obtain a vast increase in accuracy. McCarthy et al. (2004b) and Koeling et al. (2005) provided the first proof of concepts in order to demonstrate this. They collected for

each target word k nearest neighbors using distributional similarity, where the similarity between each sense of the target word and the nearest neighbors is determined by WordNet similarity measures. The sense with the highest similarity is chosen as the predominant sense. Building upon the same idea, Chan and Ng (2005) apply two algorithms, a confusion matrix algorithm and an Expectation-maximization-based algorithm, to determine the sense distribution of the test data. This information is fed into the systems to improve the sense assignment.

Similar approaches have been used to tackle the task of Word Sense Induction. The work presented in Lau et al. (2012) introduces a Topic Modeling approach based on LDA (Blei et al., 2003) and HDP (Teh et al., 2012) for deriving clusters that can be identified for different senses of a word. As an intermediate outcome, the authors also provide the expected predominant senses in the target corpus. Similarly, Boyd-Graber and Blei (2007) apply a model that considers the words of a document generated coherently to the topic distribution of that document. The most likely sense for each instance of a word is predicted from this topic distribution considering the words in the context. Finally, Lau et al. (2014; 2012) focused on the detection of novel senses, which might be considered as an extreme case of unbalanced acquisition with respect to training and evaluation distributions.

Mismatches between the training and test data have been of central interest to research on domain adaptation (Daume III, 2007; Carpuat et al., 2013; Jiang and Zhai, 2007). The 2010 edition of the SemEval series (SemEval-2010) proposed a task called "All-words Word Sense Disambiguation on a Specific Domain" (Agirre et al., 2010). The aim was to analyze to what extent WSD systems are sensitive to specific domains when there is no annotated data available for that domain. In the same direction, another goal was to investigate how a general domain WSD system should be adapted to perform properly when the sense distribution is unknown and different to the sense distribution of traditional corpora used for training machine learning models. This evaluation showed that the most successful approaches included knowledge from the specific domain in different forms. For example, Kouno et al. (2015) present a framework for WSD where an unsupervised approach is applied to abstract the features across different domains and then feeds these features into a Support Vector Machine. A semi-supervised framework is introduced by Agirre and Lopez de Lacalle (2008). Several domains are used to establish cross-domain experiments, where two supervised machine learning WSD systems (k-NN and SVM) are applied on one domain and evaluated on a different one. Singular Value Decomposition (SVD) is employed to find correlations between terms, alleviate the scarcity of data, and extract examples from unlabeled data. The authors show an improvement on the cross-domain setting when including the SVD technique to add training data of the target domain.

The importance of the MFS bias in training data was already highlighted in previous work. For instance, Agirre and Martinez (2004) try to overcome the problem of this skewness by automatically acquiring examples from the Internet using an heuristic based on monosemous words. Improvement is achieved on the Senseval-2 task for nouns with less than 10 examples in SemCor (Miller et al., 1993).

Finally, researchers combined the task of WSD with Entity Linking to improve the performance on the disambiguation part. For example, Weissenborn et al. (2015) jointly disambiguate nouns and entities by exploiting the links between them in BabelNet (Navigli and Ponzetto, 2012). In addition, the Babelfy system (Moro et al., 2014) goes one step further by also making use of interlingual relations.

Despite these efforts to either acquire more data or adapt the distributions, none of these systems gained an improvement big enough to consider the problem as solved. Our work differs from these approaches mainly in that we analyze more precisely the contribution of the volume, nature, and distribution of the training data in relation to the properties of the test data. The experiments are designed to isolate each phenomenon and be able to extract meaningful conclusions. For example, whereas Agirre and Martinez (2004) acquire more data for all senses of low frequent words, we focus on adding more examples for the less frequent senses instead. Just by obtaining more examples for a word does not imply that we are able to create better sense representations for all the senses of this word. Similarly, whereas McCarthy et al. (2004b) and Koeling et al. (2005) restrict the system to find a deterministic predominant sense, we propose that the probabilities of the target data need to be used to obtain a more fine-grained behavior. We show that properly balancing the probabilities of the acquired data gives a

major improvement even using a straight-forward machine learning system with a basic set of features.

3 Methodology

In this section we describe our training and evaluation framework: which WSD system has been selected, what corpora have been used to create our models and how these models have been evaluated. We have set up the framework in such a way that we can systematically vary the type of training data used, the volume of training data and the sense distribution in this data. The impact of the variables is then tested using the same state-of-the-art supervised WSD system. We measure the overall performance in addition to the performance on the MFS and LFS cases and also generate some statistics to highlight the characteristics of the training data.

3.1 Training data sets

In our experiments, we exploit three sources of English sense annotated data: SemCor, Princeton WordNet Gloss Corpus, and what we have called "Wordnet2Wikipedia". The last corpus was created as part of the experiments and hence its creation will be described in more detail below.

Semcor (SC) The Semantic Concordance (Miller et al., 1993), or SemCor (SC), is a corpus containing approximately 240,000 sense annotated words. The tagged documents originate from the Brown corpus (Francis and Kucera, 1979) and cover various genres. The corpus contains annotations for more than 20,000 lemmas. The creators note that the main focus when creating the corpus was on word frequencies, and not on sense frequencies. This might explain why the proportion of the MFS on the total amount of annotated senses in this corpus is (unnaturally) high: more than 70%.

Princeton WordNet Gloss Corpus (GC) The Princeton WordNet Gloss Corpus, or GC, is a special sense annotated corpus. It does not contain annotations of natural text in documents but of the WordNet glosses (Fellbaum, 1998). The corpus contains more than 310,000 annotated words, which is significantly more than in SemCor. Annotations exist for approximately 15,000 lemmas, which is less than in SemCor. The MFS proportion is around 55%, which makes sense given that glosses are tagged and not natural text.

Wordnet2Wikipedia (WW) For the last source of sense annotated data, WordNet2Wikipedia, or WW, we exploit the existing relation between WordNet and Wikipedia as present in BabelNet 2.5 (Navigli and Ponzetto, 2012). BabelNet 2.5 contains the relations *direct* and *redirect*, which link a WordNet sense to a Wikipedia entry. This relation only exists for nouns in the resource. For each target sense of a target lemma: 1. we check whether a link to Wikipedia exists for this target sense. 2. if so, we extract all sentences from the Wikipedia article with the target lemma and tag the target lemmas with the target sense. By exploiting this relation in BabelNet, we are able to extract 43,000 training examples for the 751 lemmas of the sem2013-aw competition. In addition, on average, 63% of the examples we extract are examples of LFS instances.

3.2 The WSD System

We used the "It makes sense" (IMS) WSD system in our experiments (Zhong and Ng, 2010). There are several reasons for choosing IMS. First of all, IMS has shown to achieve a very high performance in the Senseval and SemEval all-words tasks. Secondly, it is an open source system that provides a flexible framework, allowing us to train and evaluate it with different kinds and amounts of data. Finally, IMS is based on a Support Vector Machine (SVM) learning engine, which is a linear classifier known to suffer not as much from unbalanced training as other learning paradigms (e.g. probabilistic learning paradigms like Naive Bayes).[1]

IMS uses three features in its default setting: surrounding words, part-of-speech tags, and collocations in a certain window around the target word. We used the system with the default setting in terms of features and learning parameters. IMS creates word experts, which means that one single classifier is

[1] http://www.win-vector.com/blog/2015/02/does-balancing-classes-improve-classifier-performance

built for a specific lemma (with the corresponding part-of-speech tag). We could easily adapt the specific word experts by manipulating the input training data while keeping all the other settings the same.[2]

3.3 Evaluation framework

For evaluation, we selected the test set from SemEval-2013, task 12: Multilingual Word Sense Disambiguation (**sem2013-aw**, (Navigli et al., 2013)). The task consisted of two disambiguation tasks: Entity Linking and Word Sense Disambiguation for English, German, French, Italian, and Spanish. We focused on the WSD part using WordNet as a sense repository. The test set contains 13 articles obtained from previous editions of the workshop on Statistical Machine Translation.[3] The articles cover different domains, ranging from sports to financial news. With respect to the English WSD part, there are 1,644 test instances in total, all nouns. The sense repository used to tag these instances is WordNet version 3.0. Based on this sense repository, we computed the number of instances annotated with the MFS, and the number of instances annotated with one of the LFS. Out of the 1,644 test instances, the MFS applies in 1,035 cases, while one of the LFS applies in the rest of 609 cases. This gives a baseline of 62.96% for the MFS heuristic.

3.4 Experiments

In order to gain insight into system performance with respect to the quality, quantity, and distribution of the training data, four main research questions have been formulated, which we will repeat here for the sake of clarity:

1. **Volume**: What is the influence of using more training data without distinguishing between MFS and LFS cases?
2. **LFS**: What is the influence of only adding more LFS training examples?
3. **Provenance**: What is the effect of training using manually annotated data versus automatically annotated data?
4. **Balancing**: What is the effect of mimicking the perfect target distribution in the training data?

We use several selection techniques to test each research question. We distinguish between a *Base* corpus from which we add all training instances available, and an *Expansion* corpus, from where subsets of instances are extracted by applying different selection techniques. SemCor (**SC**) is used as a Base and the WordNet gloss-corpus (**GC**) and the WordNet-Wikipedia corpus (**WW**) as Expansions, representing both more Volume and different types of annotation (Provenance). In addition, we defined the following selection techniques when expanding the training data:

All: all instances, both MFS and LFS, are added. This technique will allow us to provide evidence for the **Volume** and **Provenance** research questions.

LFS: only the LFS instances are added, which provides insight into the **MFS** versus **LFS** research question.

Top-down: to provide evidence for this question, we use the sense distribution of the test data starting from the MFS. For every lemma in the test set, we attempt to fit the training distribution as much as possible to the test sense distribution. In this *top-down* approach, we start with the sense with the highest relative frequency in the test set and determine the number of examples in our experiment for this sense. We then calculate the number of examples for the other senses relative to the number of examples for the sense with the highest relative frequency. When a sense does not occur in the test set, we assign to this sense a default number of 1 (top-down-1) or 5 (top-down-5) training examples, which makes sure that we perform balancing instead of filtering. Without the assignment of the default number of senses for missing senses in the test data, we would on average reduce the average polysemy to almost one, which would make the task almost solved.

[2]During our experiments, we noticed that IMS produces exceptions when using larger training sets than SemCor. We solved this by including a number of checks in the source code and by modifying two files with respect to the original IMS distribution. These files are included under the folder *ims_amended_files* in the data and scripts package delivered together with the paper. The installation script will take care of copying them to the proper place in the IMS project structure and recompile the full library. The changes have been documented in the README file.

[3]`http://www.statmt.org`

Bottom-up: to provide evidence for this question, we use the sense distribution of the test data starting from the LFS. This approach is almost identical to the *Top-down* approach but now we use the number of examples for the sense of a lemma with the lowest relative frequency in the test set as a starting point. When a sense does not occur in the test set, we assign a default number of 1 (Bottom-up-1) or 5 (Bottom-up-5) examples to the sense. Both the **Bottom-up** technique and the **Top-down** technique provide evidence for the **Balancing** research question.

To allow replication of our results and stimulate further research, all the data and scripts for training and evaluating the models have been made publicly available. There is an installation script to take care of the downloading and installation of the required libraries and data sets. There is also one main script that runs all the experiments described in Section 4. The package can be found here: `https://github.com/cltl/MoreIsNotAlwaysBetter`.

4 Results

Table 1 presents the results for all our experiments. Each experiment has been defined to analyze one of our research questions and is hence based on a certain training dataset, which is the result of applying various selection techniques, which include the type of data, the volume, and the sense distribution. For each run of an experiment (**ID**), we present the Base corpora (**Base**), the Expansion Corpora (**Expansion**), the selection technique used on the Expansion corpora (**Technique**), the overall accuracy (**Acc**), the accuracy on the MFS instances (Acc_{mfs}), the accuracy on the LFS instances (Acc_{mfs}), the micro average between the accuracy on the MFS and LFS instances (**MicroAV**), the number of training instances (**#**), the average number of training instances per lemma (**Avg#**), and the average percentage of MFS instances per lemma (Dom_{mfs}). The last three values provide information about the quantitative characteristics of the training data.

				WSD results				**Training stats**		
ID	Base	Expansion	Technique	Acc	Acc_{mfs}	Acc_{lfs}	MicroAV	#	Avg#	Dom_{mfs}
1	SC	-	-	65.60	**95.60**	14.80	55.20	22k	43	70
2	SC	GC	All	66.80	89.10	29.10	59.10	60k	110	59
3	SC	GC+WW	All	68.90	90.30	**32.50**	**61.40**	102k	187	52
4	SC	WW	All	**69.30**	**92.80**	29.40	61.10	65k	120	54
5	SC	GC	LFS	63.20	75.70	41.90	58.80	38k	71	43
6	SC	GC+WW	LFS	62.00	70.50	**47.60**	59.05	65k	120	31
7	SC	WW	LFS	**67.50**	**87.50**	33.30	**60.40**	49k	91	44
8	-	SC+GC+WW	Bottom-up1	85.40	95.90	67.50	81.70	46k	87	56

Table 1: Results of our experiments on SemEval-2013 dataset

Volume and Provenance Experiments *1*, *2*, *3*, and *4* provide insight into the Volume and Provenance research questions. We observe a clear trend that more training data indeed improves the performance. By only adding the GC corpus, the accuracy improves by 1.3 points, and if we add both GC and WW by 3.4 points. These experiments are not solely increasing the number of training examples, they also lower the MFS dominance per lemma as shown in the last column (SC scoring 70, and the expansions scoring lower 59, 42, and 54, respectively) and thus change the balancing or distribution of the senses in the training data. Both factors seem to contribute to the improved overall accuracy. Surprisingly, the best result is not found by using all of the available sense annotated data, as shown by experiment 4. By only adding the WW corpus to SC, we improve the baseline by 3.7 points despite the fact that the examples are extracted automatically (silver) compared to 1.2 points gain when adding an equal amount of data from the manual annotation of GC to SC. We suspect that the WW corpus is more similar to the test data with respect to creation time and genre since they come from Wikipedia whereas the SemCor texts go back to 1961. The GC corpus contains usage examples and definitions, which are older than the test data and timeless while also being more formal in style, written for a different purpose. Finally,

the experiments 2, 3, and 4 all dramatically improve the performance on the LFS instances by more than 15(!) points compared to the baseline in experiment 1. The price for this can be found in a slight drop on the MFS instances. In order to get a better understanding of the improvement of our best run (experiment 4), compared to the baseline, we computed the accuracy per sense rank class, as shown in Figure 1. We can observe a clear improvement of the sense rank classes 2, 3, 4, and 10+ among the LFS cases.

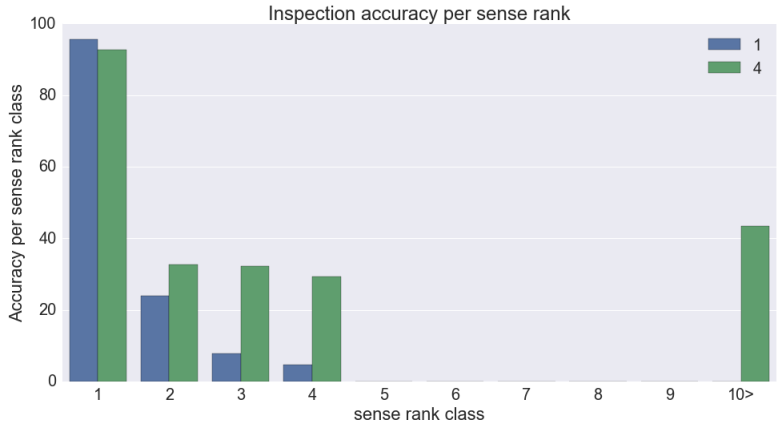

Figure 1: Performance of run 1 (left column) and 4 (right column) with respect to the performance per sense rank class.

LFS What is the effect of only adding LFS instances? We know that some senses of WordNet annotated in the test set are not annotated in SemCor, so they are not available for the training of the IMS system. What will happen if senses with few or no training data get boosted? Experiments 5 to 7 provide evidence to answer these questions. We note that the dominance of the MFS in the training instances now drops to 30-40%. On the other hand, this also results in very impressive performances on the LFS instances, between 33.33% and 47.62%. What we gain on one side, we lose on the other and the only experiment that is able to beat the baseline is run 7, which beats the baseline by 1.9 points.

Balancing Apparently the trick is to find the proper balancing between the MFS and LFS to maintain the high performance of the former and still gain in the performance of the latter. To demonstrate the potential of proper balancing, we apply the Top-down and Bottom-up balancing strategies on the training data using the test data as an approximation of the perfect balance. This can be seen as approximating the upper bound for systems being aware of the sense distribution of the test data. We see in experiments 8, 9, 10, and 11 that properly balancing the distribution gives us the highest gain (21 points) up to an overall accuracy of even 86.8. We see that it enormously boosts the accuracy of the LFS to levels normally achieved for the MFS and it also improves the accuracy of the MFS to 96.52. Note that the system still needs to make a choice between senses in this setting since all senses are represented in the model, including senses that do not occur in the test data. We also see that defining a lower bound for senses not occurring in the test set makes a difference. If we define the lower bound to 5, performance drops by 4 to 5 points, confirming the earlier experiment in which we just boost the LFS cases.

5 Discussion

In general, we note that adding more training data, obtained through manual annotation or unsupervised learning, will lead to results that exceed the standard system trained on SemCor, but will not transcend the performance to a level where we would consider the task solved. Interestingly, balancing the distribution to the task turns out to be very effective to boost the accuracy to an upper bound of around 85%, which is close to what other NLP tasks, such as entity detection and linking, achieve. In addition, the amount of training data to achieve this can be kept relatively low and can be acquired automatically. The main conclusion we draw from this is that test sets appear to contain very specific idiosyncratic details (long-tail details) when it comes to semantic tasks (as opposed to for instance syntactic tasks). These details are difficult to capture using the available training data in general. Just providing more does not help.

What helps is determining the semantic specifics of the test data. We believe that this is not just a matter of finding the predominant sense as argued by McCarthy et al. (2004a), since the distribution of both predominant and nondominant senses play a role. We have seen that also MFS distributions continue to play a role as they show shifts that need to be captured as well. We thus expect that acquisition, and likewise modeling, should be considered as problem-driven tasks rather than applying bulk acquisition. This is exactly what Figure 2 indicates. The improvements are for very specific low frequent senses and not for others. We believe that each test set has a unique long tail profile that needs to be captured by the system. In future work, we hope to perform well on this task without any prior knowledge on the sense distribution of the task, but by analyzing the properties of the texts.

The results from our experiment show that a lot of recent silver data results in better performance than a small amount of old manually-annotated data. It would be interesting to perform experiments with old silver data and manually annotated recent data. The practical obstacle towards achieving this is the availability of the data. For manual annotation, this would require a big annotation effort. For silver data, this would require an innovative approach that is different from recent approaches, which are mostly based on Wikipedia, e.g. Babelfied Wikipedia (Scozzafava et al., 2015).

One could argue that our system just uses the prior probabilities and that the machine learning is not adding anything on top of this. This is undeniable a factor but we also see that the Provenance of the training data has some impact, as the WW data help more than the GC data. Furthermore, it is not the case that the lemmas in the test set only occur in a single sense. The system does need to make a choice between different instances of a lemma in the test set for 41.4% of the lemmas.

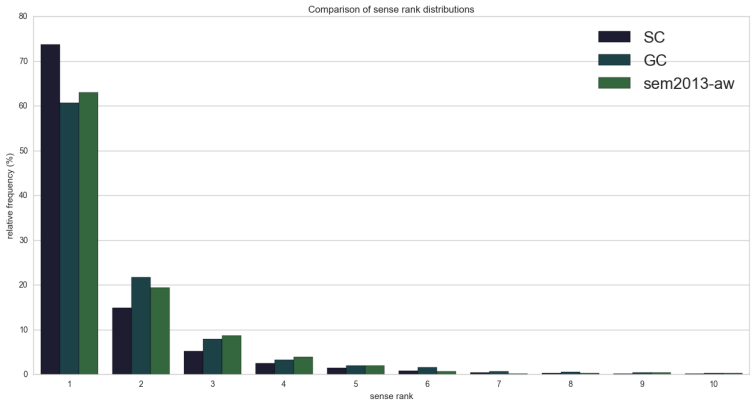

Figure 2: Comparison of sense rank distributions from the corpora: SC (left column), GC (middle column), and sem2013-aw (right column) for the sense ranks 1 till 10.

To our knowledge, only two systems (out-of-competition) achieved a better accuracy score on the **sem2013-aw** competition compared to our best run, experiment 4, from the unbalanced systems (experiments 1 to 7). The Game-Theoretic approach to WSD in Tripodi and Pelillo (2016) leads to an accuracy of 70.8, which is achieved by not only relying on the sentence as the context, but on the full document. Weissenborn et al. (2015) achieve the best result to date with an accuracy of 72.28%. The improvement is mainly due to the joint disambiguation of nouns and entities. Besides the fact that our system is more basic and uses a poorer context, we also see that even a simple system as ours can achieve far better results if we would know the distribution of the test set. We can expect that more advanced systems such as Tripodi and Pelillo (2016) and Weissenborn et al. (2015) may even exceed our best results of 86.8 with perfect balancing.

For future work, we hence intend to develop models that are problem-driven and attempt to obtain meta properties of the target data to estimate better sense distributions. An interesting starting point is a Word Sense Induction system called HCA-WSI (Bennett et al., 2016). This system could be used to determine the sense distributions of the time period in which a document in the test data was written, which would remove the dependence on sense distributions from manually annotated corpora.

6 Conclusions

We addressed the problem that most WSD systems perform well on the MFS and extremely poorly on the LFS, due to the skewness of the training data to the MFS. We analyzed the impact of adapting the training data with regard to this skewed performance: more data, better data, and balanced data. In general, we observe that more training data does indeed improve the results. However, the provenance of the data proved to be more important than the volume. We observed that automatically-acquired training data that was closer to the test data with respect to time and genre yielded better results than manually-created training data from the WordNet glosses. Finally, the real improvement was found by mimicking the sense distribution of the test data in the training data, which lead to results close to where we would consider the task solved. Hence, we argue that the solution to the task can be found in problem-driven approaches that attempt to adapt their models with respect to properties of the test set. In future work, we will focus on unsupervised methods to identify the meta properties of a test set and to capture its idiosyncratic long-tail details.

Abstract

We study the role of the second language in bilingual word embeddings in monolingual semantic evaluation tasks. We find strongly and weakly positive correlations between down-stream task performance and second language similarity to the target language. Additionally, we show how bilingual word embeddings can be employed for the task of semantic language classification and that joint semantic spaces vary in meaningful ways across second languages. Our results support the hypothesis that semantic language similarity is influenced by both structural similarity as well as geography/contact.

1 Introduction

Word embeddings derived from context-predicting neural network architectures have become the state-of-the-art in distributional semantics modeling (Baroni et al., 2014). Given the success of these models and the ensuing hype, several extensions over the standard paradigm (Bengio et al., 2003; Collobert and Weston, 2008; Mikolov et al., 2013; Pennington et al., 2014) have been suggested, such as retro-fitting word vectors to semantic knowledge-bases (Faruqui et al., 2015), multi-sense (Huang et al., 2012; Neelakantan et al., 2014), and multi-lingual word vectors (Klementiev et al., 2012; Faruqui and Dyer, 2014; Hermann and Blunsom, 2014; Chandar et al., 2014; Lu et al., 2015; Gouws et al., 2015; Gouws and Søgaard, 2015; Huang et al., 2015; Šuster et al., 2016).

The models underlying the latter paradigm, which we focus on in the current work, project word vectors of two (or multiple) languages into a joint semantic space, thereby allowing to evaluate semantic similarity of words from different languages; see Figure 1 for an illustration. Moreover, the resulting word vectors have been shown to produce on-par or better performance even in a *monolingual* setting, e.g., when using them for measuring semantic similarity in one of the two languages involved (Faruqui and Dyer, 2014).

While multilingual word vectors have been evaluated with respect to intrinsic parameters such as embedding dimensionality, empirical work on another aspect appears to be lacking: the second language involved. For example, it might be the case that projecting two languages with very different lexical semantic associations in a joint embedding space inherently deteriorates *monolingual* embeddings as measured by performance on an intrinsic monolingual semantic evaluation task, relative to a setting in which the two languages have very similar lexical semantic associations. To illustrate, the classical Latin word *vir* is sometimes translated in English as both 'man' and 'warrior', suggesting a semantic connotation, in Latin, that is putatively lacking in English. Hence, projecting English and Latin in a joint semantic space may invoke semantic relations that are misleading for an English evaluation task. Alternatively, it may be argued that heterogeneity in semantics between the two languages involved is beneficial for monolingual evaluation tasks in the same way that uncorrelatedness in classifiers helps in combining them.

Here, we study two questions (**main contributions**). On the one hand, we are interested in the effect of language similarity on bilingual word embeddings in a (Q1) **monolingual (intrinsic) semantic evaluation task**. Thus, our first question is: how does the performance of bilingual word embeddings

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3507–3518, Osaka, Japan, December 11-17 2016.

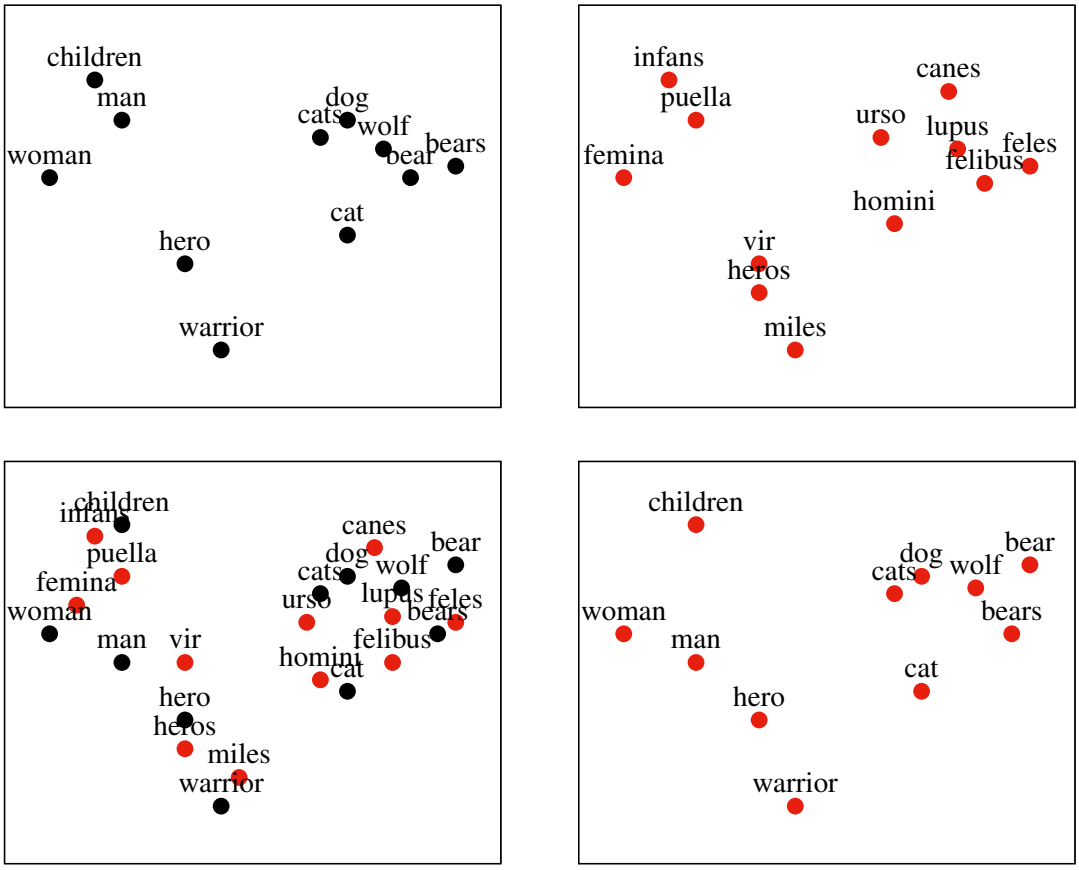

Figure 1: Monolingual embeddings (top left and top right) have been shown to capture semantic (as well as syntactic) properties of languages, here exemplarily: p = English and ℓ = Latin. Bottom left: The (idealized) goal of crosslingual embeddings is to capture these relationships across two or more languages. Bottom right: After projection in a joint semantic space, semantic (as well as syntactic) properties of words in language p have adapted to those of language ℓ. Note, in particular, the movement of *man* in these idealized plots, i.e., the different positions of *man* in top left vs. bottom right.

in monolingual semantic evaluation tasks depend on the second language involved?[1] Secondly, we ask how bilingual word embeddings can be employed for the task of semantic (Q2) **language classification**. Our approach here is simple: we project languages onto a common pivot language p so as to make them comparable. We directly use bilingual word embeddings for this. More precisely, we first project languages ℓ in a common semantic space with the pivot p by means of bilingual word embedding methods. Subsequently, we ignore language ℓ words in the joint space. Semantic distance measurement between languages then amounts to comparison of graphs that have the same nodes — pivot language words — and different edge weights — semantic similarity scores between pivot language words based on bilingual embeddings that vary as a function of the second language ℓ involved. This core idea is illustrated in Figures 1 and 2.

We show that joint semantic spaces induced by bilingual word embeddings vary in meaningful ways across second languages. Moreover, our results support the hypothesis that semantic language similarity is influenced by both genealogical language similarity and by aspects of language contact.

This work is structured as follows. Section 2 introduces our approach of constructing graphs from bilingual word embeddings and its relation to the two questions outlined. Section 3 describes our data,

[1]Our initial expectation was that bilingual word embeddings lead to better results in monolingual settings, at least for some second languages. However, this was not confirmed in any of our experiments. This may be related to our (small) data set sizes (see Section 3) or to other factors, but has no concern for the question (Q1) we are investigating.

which is based on the Europarl corpus (Koehn, 2005). Section 4 details our experiments, which we discuss in Section 5. We relate to previous work in Section 6 and conclude in Section 7.

2 Model

In this section, we formally outline our approach.

Given $N + 1$ languages, choose one of them, p, as *pivot language*. Construct N weighted networks $G_\ell^{(p)} = (V^{(p)}, E^{(p)}, \mathsf{w}_\ell^{(p)})$ as follows: nodes $V^{(p)}$ are the words of language p, graphs are fully connected, i.e., $E^{(p)} = V^{(p)} \times V^{(p)}$, and edge weights are $\mathsf{w}_\ell^{(p)}(u, v) = \mathsf{sim}(\mathbf{u}_{p,\ell}, \mathbf{v}_{p,\ell})$. The similarity function sim is, e.g., cosine similarity, and $\mathbf{u}_{p,\ell}, \mathbf{v}_{p,\ell} \in \mathbb{R}^d$ are *bilingual* word embeddings of words u and v, respectively, derived from any suitable method (see below). Here, ℓ ranges over the N *second languages*.

For (Q1) **monolingual semantic evaluation** in language p, choose p as pivot and consider $G_\ell^{(p)}$ for varying second languages ℓ. We can then evaluate semantic similarity between two language p words u and v by querying the edge weight $\mathsf{w}_\ell^{(p)}(u, v)$. This is the classical situation of (intrinsic) monolingual evaluation of bilingual word embeddings.

For (Q2) **language classification**, we compare the graphs $G_\ell^{(p)}$ across all second languages ℓ, and a fixed pivot p. Here, we have many choices how to realize distance measures between graphs, such as which metric we use and at which level we compare graphs (Bunke and Shearer, 1998; Rothe and Schütze, 2014). We choose the following: we first represent each node (pivot language word) in a graph as the vector of distances to all other nodes. That is, to $u \in V[G_\ell^{(p)}] = V^{(p)}$ we assign the vector $\mathbf{r}_u^{(\ell)} = \left(\mathsf{w}_\ell^{(p)}(u, v)\right)_{v \in V^{(p)}}$. The distance $d(G_\ell^{(p)}, G_{\ell'}^{(p)})$ between two graphs $G_\ell^{(p)}$ and $G_{\ell'}^{(p)}$ is then defined as the average distance (Euclidean norm) of the so represented nodes in the graphs: $d(G_\ell^{(p)}, G_{\ell'}^{(p)}) = \frac{1}{|V^{(p)}|} \sum_{u \in V^{(p)}} ||\mathbf{r}_u^{(\ell)} - \mathbf{r}_u^{(\ell')}||$. Finally, we define the *(syntacto-)semantic distance* $D(\ell, \ell')$ of two languages ℓ and ℓ' as the average graph distance over all $N - 1$ pivots (l and l' excluded):

$$D(\ell, \ell') = \frac{1}{N-1} \sum_{\tilde{p}} d(G_\ell^{(\tilde{p})}, G_{\ell'}^{(\tilde{p})}). \tag{1}$$

By summing over pivots, we effectively 'integrate out' the influence of the pivot language, leading to a 'pivot independent' language distance calculation. In addition, this ensures that the distance matrix D encompasses all languages, including all possible pivots.

Figure 2 illustrates our idea of projecting semantic spaces of different languages onto a common pivot.

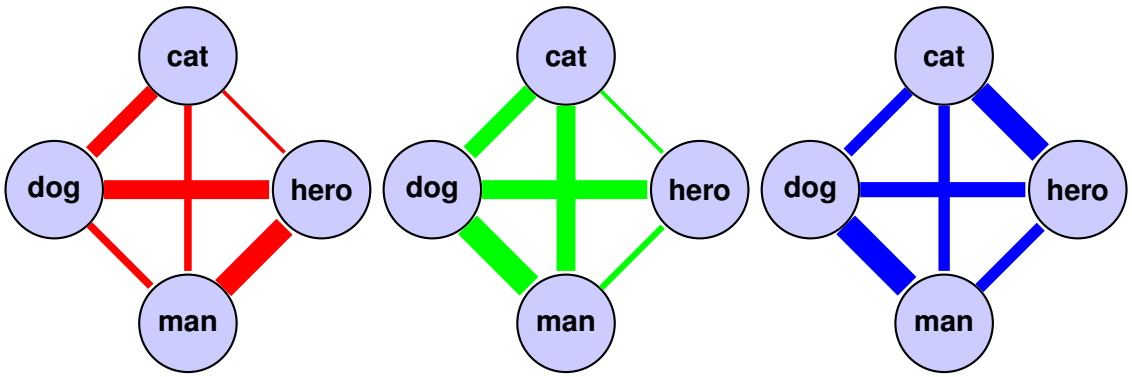

Figure 2: Schematic illustration of our approach. Repeating the "four-stage" process illustrated in Figure 1 for three different languages ℓ (marked by different colors) and the same pivot p. Edge strengths between pivot language words indicate their semantic similarity as measured by cosine distances in semantic spaces as in Figure 1 bottom right.

Bilingual embedding models: We consider two approaches to constructing bilingual word embeddings. The first is the canonical correlation analysis (**CCA**) approach suggested in Faruqui and Dyer

(2014). This takes *independently* constructed word vectors from two different languages and projects them onto a common vector space such that (one-best) translation pairs, as determined by automatic word alignments, are maximally linearly correlated. CCA relies on word level alignments and we use cdec for this (Dyer et al., 2010).

The second approach we employ is called BilBOWA (**BBA**) (Gouws et al., 2015). Rather than separately training word vectors for two languages and subsequently enforcing cross-lingual constraints, this model *jointly* optimizes monolingual and cross-lingual objectives similarly as in Klementiev et al. (2012):

$$\mathcal{L} = \sum_{\ell \in \{e,f\}} \sum_{w,h \in \mathfrak{D}^\ell} \mathcal{L}^\ell(w, h; \theta^\ell) + \lambda \Omega(\theta^e, \theta^f)$$

is minimized, where w and h are target words and their contexts, respectively, and θ^e, θ^f are embedding parameters for two languages. The terms $\mathcal{L}^\ell$ encode the monolingual constraints and the term $\Omega(\theta^e, \theta^f)$ encodes the cross-lingual constraints, enforcing similar words across languages (obtained from *sentence aligned* data) to have similar embeddings.

3 Data

For our experiments, we use the Wikipedia extracts available from Al-Rfou et al. (2013)[2] as monolingual data and Europarl (Koehn, 2005) as bilingual database. We consider two settings, one in which we take all 21 (`All21`) languages available in Europarl and one in which we focus on the 10 (`Big10`) largest languages. These languages are bg, cs, **da**, **de** , el, **en**, **es**, et, **fi**, **fr**, hu, **it**, lt, lv, **nl**, pl, **pt**, ro, sk, sl, **sv** (`Big10` languages highlighted). To induce a comparable setting, we extract in the `All21` setup: 195,842 parallel sentences from Europarl and roughly 835K (randomly extracted) sentences from Wikipedia for each of the 21 languages. In the `Big10` setup, we extract 1,098,897 parallel sentences from Europarl and 2,540K sentences from Wikipedia for each of the 10 languages involved. We note that the above numbers are determined by the minimum available for the respective two sets of languages in the Europarl and Wikipedia data, respectively. As preprocessing, we tokenize all sentences in all datasets and we lower-case all words.

4 Experiments

We first train $d = 200$ dimensional skip-gram word2vec vectors (Mikolov et al., 2013)[3] on the union of the Europarl and Wikipedia data for each language in the respective `All21` and `Big10` setting. For CCA, we then obtain bilingual embeddings for each possible combination (ℓ, ℓ') of languages in each of the two setups, by projecting these vectors in a joint space via word alignments obtained on the respective Europarl data pair. For BBA, we use the monolingual Wikipedias of ℓ and ℓ' for the monolinugal constraints, and the Europarl sentence alignments of ℓ and ℓ' for the bilingual constraints. We only consider words that occur at least 100 times in the respective data sets.

4.1 Monolingual semantic task (Q1)

We first evaluate the obtained BBA and CCA embedding vectors on monolingual $p =$ English evaluation tasks, for varying second language ℓ. The tasks we consider are WS353 (Finkelstein et al., 2002), MTurk287 (Radinsky et al., 2011), MTurk771,[4] SimLex999 (Hill et al., 2015), and MEN (Bruni et al., 2014), which are standard semantic similarity datasets for English, documented in an array of previous research. In addition, we include the SimLex999-de and SimLex999-it (Leviant and Reichart, 2015) for $p =$ German and $p =$ Italian, respectively. In each task, the goal is to determine the semantic similarity between two language p words, such as *dog* and *cat* (when $p =$ English). For the tasks, we indicate average Spearman correlation coefficients $\delta = \delta_{p,\ell}$ between

[2] https://sites.google.com/site/rmyeid/projects/polyglot.

[3] All other parameters set to default values.

[4] http://www2.mta.ac.il/ gideon/mturk771.html

- the predicted semantic similarity — measured in cosine similarity — between respective language p word pair vectors obtained when projecting p and ℓ in a joint embedding space, and

- the human gold standard (i.e., human judges have assigned semantic similarity scores to word pairs such as *dog,cat*).

Table 1 below exemplarily lists results for MTurk-287, for which p = English. We notice two trends. First, for BBA, results can roughly be partitioned into three classes. The languages pt, es, fr, it have best performances as second languages with δ values between 54% and close to 60%; the next group consists of da, nl, ro, de, el, bg, sv, sl, cs with values of around 50%; finally, fi, pl, hu, lv, lt, sk, et perform worst as second languages with δ values of around 47%. So, for BBA, the choice of second language has evidently a considerable effect in that there is ~26% difference in performance between best second language, ℓ = it, and worst second languages, ℓ = pl/sk/et. Moreover, it is apparently better to choose (semantically) similar languages — with reference to the target language p = English — as second language in this case. Secondly, for CCA, variation in results is much less pronounced. For example, the best second languages, et/lv, are just roughly 5.5% better than the worst second language, lt. Moreover, it is not evident, on first view, that performance results depend on language similarity in this case.[5]

	BBA	CCA		BBA	CCA
pt	56.54	57.48	sv	50.02	56.06
es	54.87	56.76	fi	47.41	56.76
fr	54.48	56.76	pl	47.12	56.47
it	59.70	57.12	cs	49.94	56.74
da	50.49	56.49	sl	52.96	57.05
nl	49.94	57.49	hu	48.84	56.46
ro	51.44	58.10	lv	47.55	58.81
de	50.08	58.24	lt	47.49	55.66
el	51.23	56.66	sk	47.22	57.17
bg	49.90	57.04	et	47.26	58.75

Table 1: Correlation coefficients $\delta = \delta_{p,\ell}$ in % on MTurk-287 for BBA and CCA methods, respectively, for various second languages ℓ. Second languages ordered by semantic similarity to p = English, as determined by Eq. (1); see §4.2 for specifics.

To quantify this, we systematically compute correlation coefficients τ between the correlation coefficients $\delta = \delta_{p,\ell}$ and the language distance values $D(p, \ell)$ from Eq. (1) (see §4.2 for specifics on $D(p, \ell)$). Table 2 shows that, indeed, monolingual semantic evaluation performance is consistently positively correlated with (semantic) language similarity for BBA. In contrast, for CCA, correlation is positive in eight cases and negative in six cases; moreover, coefficients are significant in only two cases. Overall, there is a strongly positive average correlation for BBA (75.75%) and a (very) weakly positive one for CCA (10.04%).

[5] As further results, we note *en passant*: CCA performed typically better than BBA, particularly in three — MEN, WS353, SimLex999 — out of our five English datasets as well as the non-English datasets. This could be due to the fact that we trained the vectors for the skip-gram model — the monolingual vectors that form the basis for CCA — on the union of Europarl and Wikipedia, while BBA used only Wikipedia as a monolingual basis. Other explanations could be the particular default hyperparameters chosen, which may have coincidentally favored CCA, or the fact that CCA uses only 1-best word alignments for projection; see Section 5 for further discussions. Moreover, in no case did we find that either BBA or CCA outperformed the purely monolingually constructed skip-gram vectors on the English evaluation task. On the one hand, this may be due to our rather small bilingual databases — containing just roughly 200K and 1,000K parallel sentences. On the other hand, while this finding is partly at odds with Faruqui and Dyer (2014), who report large improvements for bilingual word vectors over monolingual ones in some settings, it is (more) in congruence with Lu et al. (2015) and Huang et al. (2015).

Table 2: Correlation τ, in %, between language similarity and monolingual semantic evaluation performance. For example, on WS353 in the Big10 setup, the more a language, say ℓ = French, is (semantically) similar to p = English, the more is it likely that correlations $\delta_{p,\ell}$ are large, when word pair similarity of p = English words is measured from embedding vectors that have been projected in a joint French-English semantic embedding space. More precisely, the exact correlation values are 93.33% and 58.33%, respectively, depending on whether vectors have been projected via BBA or CCA. '***' means significant at the 0.1% level; '**' at the 1% level, '*' at the 5% level, '†' at the 10% level.

4.2 Language classification (Q2)

Finally, we perform language classification on the graphs $G_\ell^{(p)}$ as indicated in §2. Since we use two different methods for inducing bilingual word embeddings, we obtain two distance matrices.[6] Figure 3 below shows a two-dimensional representation of all 21 languages obtained from *averaging* the BBA and CCA distance matrices in the All21 setup, together with a k-means cluster assignment for $k = 6$. We note a grouping together of es, pt, fr, en, it; nl, da, de, sv; fi, et; ro, bg, el; hu, pl, cs, sk, sl; and lt, lv. In particular, {es, pt, fr, it, en} appear to form a homogeneous group with, consequently, similar semantic associations, as captured by word embeddings. Observing that fi is relatively similar to sv, which is at odds with genealogical/structural language classifications, we test another question, namely, whether the resulting semantic distance matrix is more similar to a distance matrix based on genealogical/structural relationships or to a distance matrix based on geographic relations. To this end, we determine the degree of structural similarity between two languages as the number of agreeing features (a feature is, e.g., *Number of Cases*) in the WALS[7] database of structural properties of languages divided by the number of total features available for the language pair (Cysouw, 2013a). For geographic distance, we use the dataset from Mayer and Zignago (2011) which lists distances between countries. We make the simplifying as-

[6] For All21, these two distance matrices have a correlation of close to 70% (Mantel test), and of 73% for Big10. Hence, overall, semantic language classification results produced by either of the two methods alone — BBA or CCA — are expected to be very similar.

[7] http://wals.info/

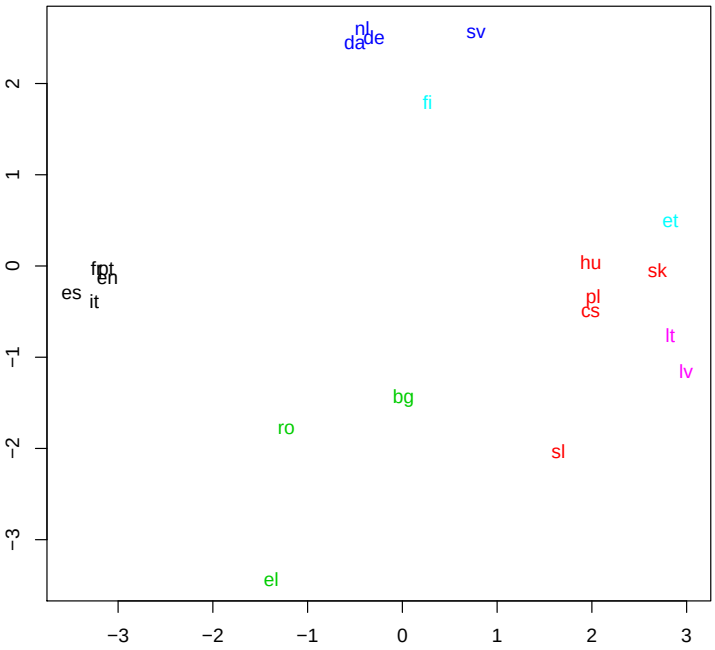

Figure 3: Two-dimensional PCA (principal component analysis) projection of average distance matrices as described in the text.

sumption that, e.g., language it and country Italy agree, i.e., it is spoken in Italy (exclusively). Table 3 shows that geographic distance correlates better with our semantic distance calculation than does WALS structural similarity under the Mantel test measure. This may hint at an interesting result: since semantics is changing fast, it may be more directly influenced by contact phenomena than by genealogical processes that operate on a much slower time-scale.

Note that our results are in accordance with the assumption that the probability of borrowing and geographical distance are inversely correlated (Cysouw, 2013b). In our case, this may relate to semantic loans (adopting the semantic neighborhoods of loaned words within the target language) rather than to structural or grammatical borrowings. That is, geographically related languages exhibit a higher probability to borrow words from each other together with the same range of semantic associations. At least, this hypothesis is not falsified by our experiment.

5 Discussion

Our initial expectation was that 'distant' second languages ℓ — in terms of language similarity — would greatly deteriorate monolingual semantic evaluations in a target language p, as we believed they would invoke 'unusual' semantic associations from the perspective of p. Such a finding would have been a word of caution regarding with which language to embed a target language p in a joint semantic space, if this happens for the sake of improving monolingual semantic similarity in p. We were surprised to find that only BBA was sensitive to language similarity in our experiments in this respect, whereas CCA seems quite robust against choice of second language. An explanation for this finding may be the different manners in which both methods induce joint embedding spaces: While CCA takes independently constructed vector spaces of two languages, BBA jointly optimizes mono- and bilingual constraints and may thus be more sensitive to the interplay, and relation, between both languages. Another plausible explanation is that CCA uses only *1-best* alignments for projecting two languages in a joint semantic space. Thus, it may be less sensitive to varying polysemous associations across different languages (cf. our *vir* example in Section 1), and hence less adequate for capturing cross-lingual polysemy.[8]

In terms of language similarity, we mention that our approach is formally similar to approaches as in

[8]Thus, we would also expect CCA to perform better in monolingual intrinsic evaluations (as our experiments have partly confirmed) and BBA to perform better in multilingual intrinsic evaluations. We thank one reviewer for pointing this out.

(Eger et al., 2015; Asgari and Mofrad, 2016) and others. Namely, we construct graphs, one for each language, and compare them to determine language distance. Compared to Eger et al. (2015), our approach differs in that they use translations in a second language ℓ to measure similarity between pivot language p words. This idea also underlies very well-known lexical semantic resources such as the paraphrase database (PPDB) (Bannard and Callison-Burch, 2005; Ganitkevitch et al., 2013); see also Eger and Sejane (2010). In contrast, we directly use bilingual embeddings for this similarity measurement by jointly embedding p and ℓ, which are arguably best suited for this task. Our approach also differs from Eger et al. (2015) in that we do not apply a random-surfer process to our semantic graphs.

We finally note that the linguistic problem of (semantic) language classification, as we consider, involves some vagueness as there is de facto no gold standard that we can compare to. Reasonably, however, languages should be semantically similar to a degree that reflects structural, genealogical, and contact relationships. One approach may then be to disentangle or, as we pursued here, (relatively) weigh each of these effects.

From an application perspective, our approach allows for enriching (automatically generated) lexica. This relates, for example, to the generation of sentiment lexica listing prior polarities for selected lexemes (Sonntag and Stede, 2015). Since the acquisition of such specialized information (e.g., by annotation) is cost-intensive, approaches are needed that allow for automatically generating or extending such resources especially in the case of historical languages (e.g., Latin). Here our idea is to start from pairs of semantically (most) similar languages in order to induce polarity cues for words in the target language as a function of their distances to selected seed words in the pivot language, for which polarities are already known. By averaging over groups of semantically related pivot languages, for which sentiment lexica already exist, the priority listings for the desired target language may stabilize. Obviously, this procedure can be applied to whatever lexical information to be annotated automatically (e.g., grammatical or semantic categories like agency, animacy etc. as needed, for example, for semantic role labeling (Palmer et al., 2010)).

A second application scenario relates to measuring (dis-)similarities of translations and their source texts (Baker, 1993): starting from our model of bilingual semantic spaces, we may ask, for example, whether words for which several alternatives exist within the target language tend to be translated by candidates that retain most of their associations within the source language – possibly in contradiction to frequency effects. Such a finding would be in line with Toury's notion of interference (Toury, 1995) according to which translations reflect characteristics of the source language – the latter leaves, so to speak, fingerprints within the former. Such a finding would bridge between the notion of interference in translation studies and distributional semantics based on deep learning.

6 Related work

Besides the mono- and multilingual word vector representation research that forms the basis of our work and which has already been referred to, we mention the following three related approaches to language classification. Koehn (2005) compares down-stream task performance in SMT to language family relationship, finding positive correlation. Cooper (2008) measures semantic language distance via bilingual dictionaries, finding that French appears to be semantically closer to Basque than to German, supporting our arguments on contact as co-determining semantic language similarity. Bamman et al. (2014) and Kulkarni et al. (2015b) study semantic distance between dialects of English by comparing region specific word embeddings.

Studying geographic variation of (different) languages is also closely related to studying temporal variation within one and the same language (Kulkarni et al., 2015a), with one crucial difference being the need to find a common representation in the former case. Word embeddings — in particular, monolingual ones — can also be used to address the latter scenario (Eger and Mehler, 2016; Hamilton et al., 2016).

In terms of classifying languages, the work that is closest to ours is that of Asgari and Mofrad (2016). A key difference between their approach and ours is that, in order to achieve a common representation between languages, they translate words. This has the disadvantage that translation pairs need to be known, which typically requires large amounts of parallel text. In contrast, bilingual word embeddings, which

form the basis of our experiments, can be generated from as few as ten translation pairs, as demonstrated in Zhang et al. (2016).

There is by now a long-standing tradition that compares languages via analysis of complex networks that encode their words and the (semantic) relationships between them (Cancho and Solé, 2001; Gao et al., 2014). These studies often only look at very abstract statistics of networks such as average path lengths and clustering coefficients, rather than analyzing them on a level of content of their nodes and edges. In addition, they often substitute co-occurrence as a proxy for semantic similarity. However, as Asgari and Mofrad (2016) point out, co-occurrence is a naive estimate of similarity; e.g., synonyms rarely co-occur.

7 Conclusion

Using English, German and Italian as pivot languages, we show that the choice of the second language may significantly matter when the resulting space is used for monolingual semantic evaluation tasks. More specifically, we show that the goodness of this choice is influenced by genealogical similarity and by (geographical) language contact. This finding may be important for the question which languages to integrate in multilingual embedding spaces (Huang et al., 2015). Moreover, we show that semantic language similarity — estimated on the basis of bilingual embedding spaces as suggested in this work — may be better predicted by contact than by genealogical relatedness. The validation of this hypothesis by means of bigger data sets will be the object of future work.

Word Embeddings, Analogies, and Machine Learning: Beyond $King$ - Man + $Woman$ = $Queen$

Abstract

Solving word analogies became one of the most popular benchmarks for word embeddings on the assumption that linear relations between word pairs (such as $king$:man :: $woman$:$queen$) are indicative of the quality of the embedding. We question this assumption by showing that the information not detected by linear offset may still be recoverable by a more sophisticated search method, and thus is actually encoded in the embedding.

The general problem with linear offset is its sensitivity to the idiosyncrasies of individual words. We show that simple averaging over multiple word pairs improves over the state-of-the-art. A further improvement in accuracy (up to 30% for some embeddings and relations) is achieved by combining cosine similarity with an estimation of the extent to which a candidate answer belongs to the correct word class. In addition to this practical contribution, this work highlights the problem of the interaction between word embeddings and analogy retrieval algorithms, and its implications for the evaluation of word embeddings and the use of analogies in extrinsic tasks.

1 Introduction

Discovering analogical relations is currently one of the most popular benchmarks for word embeddings. This trend started after (Mikolov et al., 2013b) showed that proportional analogies (a is to b as c is to d) can be solved by finding the vector closest to the hypothetical vector calculated as c - a + b (e.g. $king$ - man + $woman$ = $queen$). Many subsequent studies used this approach to evaluate the performance of word embeddings with the Google test set (Mikolov et al., 2013a); the top current result is over 80% accuracy (Pennington et al., 2014). The assumption is that a "good" word embedding encodes linguistic relations in such a way that they are identifiable via linear vector offset (see section 2).

Analogies are interesting not only as a benchmark, but also potentially as a method for discovering linguistic relations (Turney, 2008). They are already used for morphological analysis (Lavallée and Langlais, 2010), word sense disambiguation (Federici et al., 1997), semantic search (Cohen et al., 2015), and even for broad-range detection of both morphological and semantic features (Lepage and Goh, 2009). However, Mikolov's study was a demonstration of how word embeddings capture linguistic relations, rather than a proposal of linear vector offset as a method for their discovery. It was later shown to not work as well for a wider range of relations (Köper et al., 2015; Gladkova et al., 2016).

This study questions the underlying assumption that linguistic relations should translate to linear relations between vectors rather than a more complex correspondence pattern. We show that relations not detected by vector offset may be recoverable by other methods, and thus are actually encoded in the embedding. The method we propose is based on learning the target relation from multiple word pairs, since reliance on single word pair makes linear vector offset sensitive to word idiosyncrasies. A naive average-based baseline outperforms the state-of-the-art. A more sophisticated machine-learning algorithm achieves further improvement (up to 30% for some embeddings and linguistic relations) by combining similarity to a source word vector ($king$) with the estimate of whether a candidate answer ($queen$) belongs to the correct class of words ("woman").

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3519–3530, Osaka, Japan, December 11-17 2016.

2 State of the Art: Analogical Reasoning Based on the Offset of Word Vectors

The starting point for this study is (Mikolov et al., 2013a), the first work to demonstrate the possibility of capturing relations between words as the offset of their vectors. The answer to the question "a is to b as c is to ?" is represented by hidden vector d, calculated as $argmax_{d \in V}(sim(d, c - a + b))$. Here V is the vocabulary (excluding word vectors a, b and c), and sim is a similarity measure, for which Mikolov and most other researchers use angular distance between vectors u and v: $sim(u, v) = cos(u, v) = \frac{u \cdot v}{||u||||v||}$ We will refer to this method as **3CosAdd**. The intuition behind it is that the position of, e.g., vector man relative to $king$ should be roughly the same as the position of $woman$ relative to $queen$. Vylomova et al. (2016) use this method as a basis for learning lexical relations with spectral clustering and Support Vector Machines (SVM).

An alternative method was introduced by Levy and Goldberg (2014) who propose to calculate the hidden vector as $argmax_{d \in V}(cos(d - c, b - a))$. They report that this method produces more accurate results for some categories. Its essence is that it accounts for $d - c$ and $b - a$ to share the same direction and discards lengths of these vectors. We will refer to this method as **PairDistance**.

Linzen (2016) reports results of experiments with 6 more functions, including reversing the relation, returning simply the nearest neighbour of the c word, and the word most similar to both b and c. None of these functions outperformed 3CosAdd and PairDistance consistently. Reversal was beneficial for some relations, but it is only applicable to symmetrical one-on-one relations. Crucially, when the words a, b and c are not excluded from the set of possible candidates, the performance drops to zeroes, and for the singular-plural noun category the correct answers are obtained with 70% accuracy as simply the nearest neighbours of the c word.

3 The Alternative: Learning From Multiple Examples

3.1 Naive Approach

The vector offset approach relies on a single pair of words, which makes it sensitive to noise and word idiosyncrasies, such as differences in polysemy networks. Consider the above $king$:$queen$ example: depending on the corpus, there may be more differences in their vectors than just masculinity/femininity. $Queen$ is also a musical group, and therefore appears in many contexts in which $king$ does not appear.

The alternative is to learn the relation from a set of example pairs. The "naive" baseline would be a simple average of the offset between every pair of vectors in the training set: $argmax_{d \in V}(sim(d, c + avg\_offset))$, where $avg\_offset = \frac{\sum_{i=0}^{m} a_i}{m} - \frac{\sum_{i=0}^{n} b_i}{n}$ and a_i and b_i represents words from source and target classes. We refer to this method as **3CosAvg**. To the best of our knowledge, this has not been explored before - surprising as it is.

3.2 LRCos Method

We propose an alternative approach to discovering linguistic relations with analogies based on a set of word pairs that have the same relation, such as the country:capital relation shown in Table 1:

Source	Target
France	Paris
Japan	Tokyo
China	Beijing

Table 1: Example analogy pairs set: capitals

In this set the right-hand-side and left-hand-side elements represent coherent groups of words - in this example, "countries" and "capitals". We shall refer to the left-hand-side of such analogies as the "source class", and to the right-hand-side - as "target class". Given a set of such word pairs, the question "what is related to $France$ as $Tokyo$ is related to $Japan$?" can be reformulated as "what word belongs to the same class as $Tokyo$ and is the closest to $France$?"

We detect words belonging to the target class (e.g. "capitals") with logistic regression[1]. Given a set of word pairs (e.g. *Japan:Tokyo*), the available target words are used as positive samples, and source words, along with random words from the dictionary, as negative samples. The number of random words and other parameters of logistic regression such as regularization strength can affect the performance of the classifier, but in our pilot tests no set of parameters yielded significant gains over the default choices. In experiments reported below the number of random words was equal to the number of positive samples. We used logistic regression implementation from Python `linear_model.LogisticRegression` module from Python's sklearn module version 0.17.1 with default parameters[2].

The probability of a word being the correct answer for a given analogy is calculated by combining (in this study, multiplying) the probability of this word belonging to the target class, and its similarity with the vector a measured using angular distance. Theoretically this enables further optimization through different weighting schemes, although our test did not show significant gains over simple multiplication.

Both set-based methods (3CosAvg and LRCos) were evaluated in exclude-n scheme. Given a set of 50 word pairs, n of them are excluded, and remaining are used for obtaining the "rule" of transfer (this part differs by the method). Then each of the n pairs become the question, and the learned "rule" is used to try to derive the answer. Larger n speeds up the computation and can be used for larger datasets, while n=1 will maximize the number of training elements to obtain the "rule". In this study we used n=2.

3.3 Filtering Vector Dimensions

Performance of LRCos could theoretically benefit from forcing the similarity metric to ignore irrelevant features. Consider the task of identifying plural forms of nouns (e.g. *phone:phones*, *banana:bananas*). The two linguistic classes (in this case singular and plural nouns) necessarily introduce some dissimilarity between $phone$ and $phones$.

Assuming that this dissimilarity is shared by all word pairs, we can learn which features are responsible for it, and exclude them in the similarity estimation step. This should give an advantage to words from the target class. Ideally, when the "plurality" features are excluded, the $phones$ vector should be the most similar to the $phone$ vector. To implement this method we have additionally trained C-Support Vector Classifier (sklearn.svm.SVC) with a linear kernel to discriminate between "left" and "right" words and used complimentary values of the weights assigned to the features it learned to scale individual dimensions. We will refer to this "filtered" variant of LRCos method as LRCosF.

4 Corpora and Word Embeddings

Word embeddings represent words in the vocabulary as vectors that can be derived directly from co-occurrence counts ("explicit models") or learned implicitly by neural nets (see (Erk, 2012) for general overview of the field). It is currently debated whether explicit and implicit models are conceptually different (Levy and Goldberg, 2014), or whether the latter have an advantage over the former (Baroni et al., 2014). To contribute to the ongoing debate, this work explores both types of models.

The source corpus combines an English Wikipedia snapshot from July 2015 (1.8B tokens), Araneum Anglicum Maius (1.2B) (Benko, 2014) and ukWaC (2B) (Baroni et al., 2009) (uncased, words occurring less than 100 times were discarded). The resulting vocabulary size is 301,949 words.

The **SVD**-based explicit model is built upon co-occurrence matrix weighted by Positive Pointwise Mutual Information (PPMI, Church and Hanks (1990)). The co-occurrence matrix was computed using the co-occurrence extraction kernel by (Drozd et al., 2015) with a window size of 8. Singular Value Decomposition (SVD) transformation was used to obtain low-rank approximation of the sparse co-occurrence matrix. SVD factorizes $m \times n$ real or complex matrix M in a form $M = U\Sigma V^*$ (Golub and Van Loan, 1996), and embeddings can be obtained as $U\Sigma$. Σ is a diagonal matrix the elements of which reflect how much of a variance of original data is captured in a given dimension. We used the technique by (Caron, 2001) of rising Σ matrix element-wise to the power of a where $0 < a \leq 1$ to give a boost to dimensions

[1]We tried several other classification algorithms such as SVM with linear, polynomial and radial basis function kernels, but neither of them yielded higher classification accuracy, and they also were more computationally expensive. Building a classifier directly from the set of vector offsets of all word pairs was also not successful.

[2]Source code and additional materials are available at `http://vsm.blackbird.pw`

with smaller variance, with a =0.1 for 300-dimensional embeddings and a=0.6 for the rest. We have used embeddings of size 300 and 1000 for comparison with GloVe and Skip-Gram models, and sizes 100-1200 for studying the dimensionality effect. Finally, we have normalized each embedding vector individually, as we have found that it increases the performance of SVD-based embeddings.

As representatives of implicit models we used GloVe and Skip-Gram. The **GloVe** model was trained with the original software by (Pennington et al., 2014) with 300 dimensions, window size 8, 20 iterations, parameters x_{max}= 100, a = 3/4. **Skip-Gram** embeddings were trained with original software by Mikolov (Mikolov et al., 2013a) in skip-gram mode, with windows size 8, 25 negative samples, 5 iterations, "sample" parameter (for down-sampling of frequent words) equal to 1e-4. It is also worth noting that co-occurrences for the SVD model were collected with respect to sentence boundaries, while GloVe and Skip-Gram models disregard them.

The performance of word embeddings can be drastically affected by their parameters (Levy et al., 2015; Lai et al., 2015), which prompts parameter searching for different tasks. However, accuracy of solving word analogies also varies immensely for different linguistic relations (Gladkova et al., 2016). Optimizing for "average accuracy" on a diverse set of relations may not be meaningful, as it does not necessarily guarantee better performance on a particular relation. Therefore we did not attempt such parameter search for our models. However, in section 5.1 we will test our embeddings on the widely used Google analogy test to show that they are generally on the par with the previously reported results (Levy et al., 2015; Pennington et al., 2014), and not victims of some particularly unfortunate configuration.

5 Evaluation

5.1 The Google Test Set

3CosAdd is widely used for benchmarking word embeddings on the test known as the Google test set (Mikolov et al., 2013a). It contains 14 categories with 20-70 unique example pairs per category, which are combined in all possible ways to yield 8,869 semantic and 10,675 syntactic questions. The state-of-the-art on this test has over 65% average accuracy: 67.8% for DRRS (Garten et al., 2015), 70.64% for GCeWE (Zhou et al., 2015), and 75.6% for GloVe (Pennington et al., 2014).

The average accuracy for 3 models with 4 analogy detection methods is presented in table 2. We used logistic regression as a classification algorithm in the "exclude one" scheme, where the classifier is re-trained each time on all target class words excluding the one from the pair in question. Table 2 shows that LRCos clearly outperforms 3CosAdd and 3CosAvg, although for all methods accuracy varies between relations and models.

We compute both Mean_{all} (the number of correct answers divided by the total number of questions in the whole dataset) and Mean_{rel} (the average accuracy scores for all categories), and, for the latter, also SD (standard deviation) between categories. It is Mean_{all} that is typically reported (Mikolov et al., 2013a; Pennington et al., 2014), but table 2 suggests that Mean_{all} tends to be higher than Mean_{rel}. We attribute this to the fact that the Google test set is not balanced (20-70 unique pairs per category), and the more successful country:capital relations constitute the bulk of the semantic questions. Mean_{all} also can not represent the variation between categories, which in our experiments is between 17-28%.

Method	3CosAdd			PairDistance			3CosAvg			LRCos		
	Mean_{all}	Mean_{rel}	SD	Mean_{all}	Mean_{rel}	SD	Mean_{all}	Mean_{rel}	SD	Mean_{all}	Mean_{rel}	SD
SVD300	50.6%	45.1%	24%	22.7%	16.1%	17%	54.8%	51.2%	26%	68.2%	68.1%	23%
SVD1000	58.1%	49.4%	25%	23.6%	22.3%	17%	59.7%	54.0%	27%	74.6%	72.6%	21%
GloVe	**79.6%**	67.8%	26%	**33.5%**	**26.9%**	22%	79.1%	74.2%	28%	73.7%	70.9%	24%
Skip-Gram	75.1%	**66.6%**	23%	28.6%	24.2%	21.6%	**80.3%**	**78.3%**	17%	**79.8%**	**78.0%**	17%

Table 2: Average accuracy in the total dataset (Mean_{all}), between 14 categories (Mean_{rel}), and the standard deviation (SD) between categories in the Google test set.

Table 2 highlights the interaction between the method of discovering analogies and the word embedding itself. The results of GloVe and Skip-Gram improve with LRCos as compared to 3CosAdd, but the simple average 3CosAvg works even slightly better for them. However, SVD gets an over 15% boost

from LRCos, but not from 3CosAvg. This suggests that (a) the information not detected by 3CosAdd was actually contained in the SVD model, and (b) evaluating different embeddings with the same method might not be as meaningful as is commonly believed. Perhaps a better question to ask is why these embeddings behave so differently, and what does it tell us about them and the methods used.

5.2 The Bigger Analogy Test Set

The above results suggest that performance on the Google test set varies significantly between categories, and it was shown that some relations are in principle not detected successfully with 3CosAdd (Köper et al., 2015). Gladkova et al. (2016) developed the BATS analogy test set that is balanced across 4 types of linguistic relations (grammatical inflections, word-formation, lexicographical and world-knowledge relations), with 50 word pairs per category and 10 categories of each type (overall 2000 unique word pairs)[3]. This test presents a bigger challenge: the performance of GloVe is reported to drop from 80.4% on the Google test set to 28.5% on BATS due to difficulties with derivational and lexicographic categories.

Table 3 and figure 1 show that LRCos follows this overall trend, achieving only 47.7% average accuracy on BATS with Skip-Gram, the best-performing embedding. But it still outperforms the others: the best average for 3CosAdd is 28.1% (Glove), 7.5% for PairDistance (GloVe), 34.4% for 3CosAvg (GloVe). LRCosF is only slightly behind (47.2% for LRCosF on Skip-Gram).

Compared to 3CosAdd LRCos achieves up to 25% boost on encyclopedic relations (SVD model with 1000 dimensions), up to 8% boost on lexicographic relations (SVD), and, most significantly, up to 34% boost on the difficult derivational relations (for Skip-Gram). For inflectional morphology LRCosF yielded even better results (up to 28% for SVD).

Method	Encyclopedia			Lexicography			Inflectional Morphology			Derivational Morphology		
	SVD	GloVe	Skip-Gram	SVD	GloVe	Skip-Gram	SVD	GloVe	Skip-Gram	SVD	GloVe	Skip-Gram
PairDistance	11.8%	13.6%	12.4%	1.1%	1.0%	0.8%	12.8%	14.5%	14.9%	1.9%	0.8%	0.8%
3CosAdd	18.5%	31.5%	26.5%	10.1%	10.9%	9.1%	44.0%	59.9%	61.0%	9.8%	10.2%	11.2%
3CosAvg	30.0%	**44.8%**	34.6%	12.2%	13.0%	9.6%	51.2%	68.8%	69.8	13.0%	11.2%	15.2%
LRCos	39.3%	40.6%	**43.6%**	**18.0%**	16.8%	**15.4%**	65.2%	74.6%	87.2%	**30.4%**	17.0%	**45.6%**
LRCosF	**43.7%**	40.8%	42.6%	16.4%	**17.6%**	14.4%	**72.2%**	**75.0%**	**87.4%**	30.0%	**17.1%**	44.2%

Table 3: Average accuracy per relation type in BATS per method for SVD1000, GloVe and w2v models.

Figure 1 demonstrates variation in performance of 3CosAdd, 3CosAvg and LRCos on GloVe and SVD models by individual categories of BATS. LRCos almost always performs the best, but the pattern of results for GloVe and SVD is a little different. SVD did worse on inflectional morphology on SVD than on GloVe, so it benefitted more from LRCos - but it is interesting that (a) the benefit for the overall better-performing GloVe was overall smaller, and (b) LRCos almost never improves the results for categories where 3CosAdd already achieved near 80% accuracy. This suggests that there might be a certain limit on how accurate we can get on the test, at least for a given corpus.

Table 3 shows that different methods for discovering analogies do not perform uniformly across the whole set or different embeddings. LRCos and LRCosF are "preferred" by different types of relations (although the gap between them is not so large), and in one case the baseline actually performs better.

One of the possible explanations for why LRCos yields significant improvement for derivational morphology, but not for lexicographic relations, is that LRCos relies on the notion of "target word class". In case of suffixes and prefixes such a target class is relatively coherent ("all words with the suffix *-ness*"), but for, e.g., synonyms, BATS includes different parts of speech (e.g. *scream:cry*, *car:automobile*, *loyal:faithful*). In this case there is no clear target class, and LRCos should actually be at a disadvantage compared to 3CosAdd (although it still improves results for some of the more coherent categories).

5.3 Russian Morphological Categories

As an additional task we compiled a small set consisting of 6 Russian noun forms: nominative case paired with instrumental, dative and prepositional cases in singular and plural form, such as *yaponets : yapontsem* ("a Japanese": "by a Japanese"). As in BATS, each category contains 50 unique word pairs.

Figure 1: Performance of 3CosAdd, 3CosAvg and LRCos methods on BATS categories.

The overall accuracy on the SVD embedding with 1000 dimensions is **18.0%** with 3CosAdd method, **19.2%** with 3CosAvg and **43.1%** with LRCos. For GloVe the results are **28.1%**, **34.4%** and **39.4%**, respectively.

While this is not a comprehensive test like BATS, it is sufficient to see if the different methods of discovering analogical relations are equally successful on morphologically complex and simple languages. The problem with the former is that there are many more word forms per lemma (e.g., the English text of *Pride and Prejudice* contains 7266 tokens for 6576 lemmas, and its Russian translation – 17903 tokens for 7715 lemmas, i.e. almost three times more). For word-level word embeddings this means that there are more vectors from the same volume of text, that they are built with less information, and that there are more vectors that are very similar (which complicates the task for a method relying on cosine similarity).

For this test we built an SVD-based model from Araneum Russicum Maximum (Benko and Zakharov, 2016) - a web-corpus containing 13.4B tokens. The parameters are as follows: 1000 dimensions, window size 3, with PMI-weighted co-occurrence matrix and Σ raised to the power $a = 1$.

Fig. 2 shows that morphological complexity does increase difficulty for analogical reasoning with word embeddings. In English 3CosAdd scores over 50% on many morphological categories, but in Russian cases its performance is in the 20% range. LRCos performs significantly better, although not always on the par with English. Further research is needed to tell why, e.g., Russian prepositional case appears to be more difficult than instrumental.

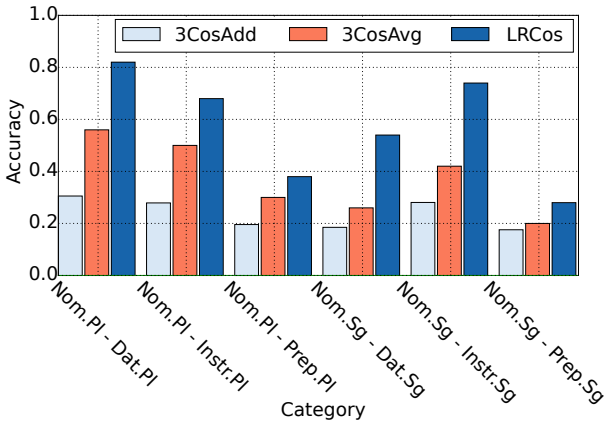

Figure 2: Accuracy of LRCos, 3CosAdd and 3CosAvg on Russian noun case forms.

6 Exploring LRCos

6.1 Effect of Training Set Size

Any method relying on supervised learning is only useful when there is sufficient data for learning. To use a method such as LRCos for practical analogical reasoning tasks we need to know how much data we would have to provide for each relation.

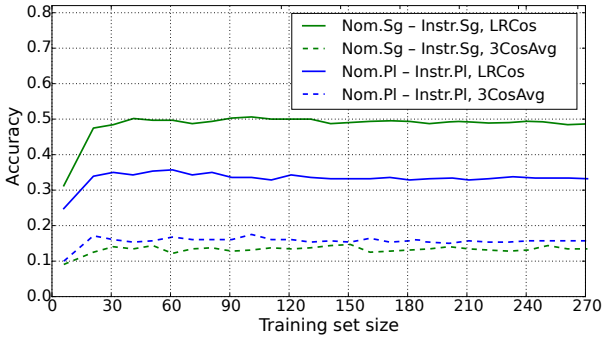

Figure 3: Effect of training set size.

We performed such an evaluation with our Russian morphology data, creating sets that contained up to a thousand word pairs. To estimate the optimal number of training samples we repeated the experiment multiple times, each time randomly selecting a subset of word pairs and observing how its size affects performance.

Two sample categories are shown in Figure 3 (LRCos and 3CosAvg methods). Our experiments suggest that accuracy for Russian morphological categories for both methods saturates at 50 pairs on average. While more tests are needed to determine if this number may be different for other types of relations or for other languages, such a range is feasible for LRCos to be used in practical tasks such as morphological parsing.

6.2 Effect of Vector Size

Our experiments suggest that although higher dimensionality implies more information about words being captured, it does not necessarily leads to better accuracy with the 3CosAdd method (a similar effect was observed by Cai et al. (2015) for similarity task). Some categories benefit slightly from higher dimensions, but for many there is no improvement, or there is even a slight degradation, while for

3CosAdd performance continues to rise. Data for four example categories are shown in Figure 4. One possible explanation for this phenomenon is that once the dimensions corresponding to the core aspects of a particular analogical relation are included in the vectors, adding more dimensions increases noise.

LRCos is not completely free from this negative effect, but it suffers less as the effect is mitigated by the fact that regression can assign near-zero weights to the dimensions which are not responsible for the target analogical relation. Thus algorithm performance continues to grow with larger vector sizes.

This result suggests that there is potential for LRCos to achieve even better results with combined models (Garten et al., 2015; Fried and Duh, 2014). For example, different window sizes are believed to be more beneficial for different tasks: larger windows for topical relations, smaller windows for morphological relations, as shown in (Lebret and Collobert, 2015). This would prevent any one model from achieving top performance on all tasks. However, we can have, e.g., a model that combines window 10 and window 2, and the extra dimensions will not become noise for LRCos method.

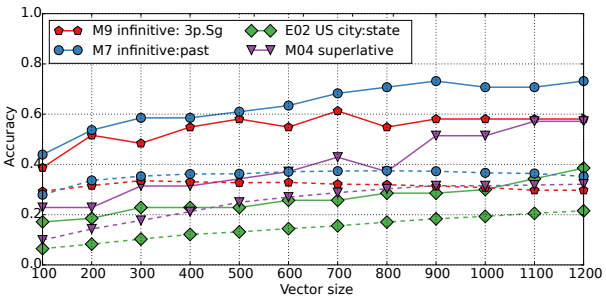

Figure 4: Effect of vector dimensionality on 3CosAdd (dashed lines) and LRCos (solid lines) methods

6.3 Effect of a Parameter

As described in section 4, we raise the elements of Σ matrix of factorization to the power of a to control the contribution of different singular vectors. If a is equal to 1, then each column in the transformed matrix is scaled proportionally to the variance in the original data it represents. Smaller values of a essentially boost the features which were less pronounced in the corpus in terms of co-occurrence patterns.

Figure 5 illustrates the impact of changing a for several example relations. Similarly to other model parameters, there is no value that provides the best results for all cases. The average accuracy is affected slightly, but certain relations may experience up to a two times decrease or improvement. This suggests that treating individual dimensions of embeddings independently could yield better results. While experimenting with the size of embeddings suggests that the LRCos method is better at selectively choosing useful dimensions for the embeddings, there is still a lot of room for improvement.

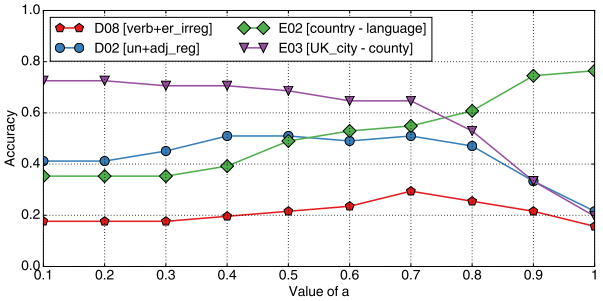

Figure 5: Effect of changing the value of α

7 Further Ways to Improve: Mistakes of 3CosAdd and LRCos

Since LRCos relies on both cosine similarity and degree to which the hypothetical answer belongs to the target class of words, it could be expected to yield a different pattern of mispredictions than 3CosAdd. To investigate the differences in the output of the two methods we manually annotated the incorrect answers by 3CosAdd and LRCos on 4 BATS categories: E05 (*Lincoln:president*), L05 (*parishioner:parish*), M05 (*follow:follows*) and WF05 (*create:recreate*). The evaluation was done with the SVD model at 1000 dimensions, window size 3. The results of this evaluation are summarized in table 4.

First of all, for both methods the ratio of "random" answers is insignificant; most of the wrong answers are morphologically, derivationally, collocationally, or semantically related to one or more of the source words – as can be expected for methods relying on cosine similarity. The problem, traditionally, is distinguishing between different types of relations.

When proposing the 3CosAdd method, Mikolov et al. (2013b) exclude the three source words from

Type of answer	Example	E05 name:occupation		L05 member: group		I05 infinitive: 3p.Sg		D05 re+verb	
		3CosAdd	LRCos	3CosAdd	LRCos	3CosAdd	LRCos	3CosAdd	LRCos
Correct answer	*hear: hears :: seem: seems*	10.62	52.00	0.97	4.08	35.1	78.00	26.24	48.00
Acceptable answer	*plato:philosopher :: hegel:?theorist*	1.42	6.00	1.75	6.12	-	-	-	-
Morphological relation	*define:redefine :: imagine: *imagining*	3.84	-	44.28	56.00	43.39	-	23.19	-
Misspelling of a source word	*confirm:reconfirm :: acquire:*aquire*	-	-	-	2.04	0.08	-	2.20	2.00
Derivational relation	*hear: hears :: seem: *seemingly*	0.94	-	1.25	-	0.82	-	1.55	2.00
Lexicographical relation	*include: includes:: appear: *seems*	61.6	22.00	27.69	4.08	4.53	4.00	14.04	8.00

Collocate of a source word	*protect: protects:: learn: *basics*	-	-	1.99	4.08	3.35	2.00	0.49	-
Mistake due to polysemy	*parishioner: parish :: relative: *density*	1.67	-	8.49	4.08	0.94	-	-	-
Partially correct answer	*protect: protects :: maintain: *ensures*	-	-	0.97	10.20	6.82	18.00	13.71	28.00
Unrelated word	*send: resend :: engage: *categorise*	2.37	4.00	2.63	-	1.39	4.00	8.28	2.00

* Several relations may be applicable to each case, so the sum for each column does not necessarily add up to 100%.

Table 4: Types of mistakes for 3CosAdd and LRCos methods in different linguistic relations.

the set of possible answers, because otherwise one of them is too likely to turn up to be the closest to the hypothetical vector. But even if they are excluded, these source vectors can still "misdirect" the method. The fact that in L05, I05, and D05 the most frequent type of mistakes are the wrong morphological forms of a source word is consistent with the finding of Linzen (2016) that in the noun plural category of the Google test set the nearest neighbor of the c word provides the correct answer in 70% of cases. The plurals-as-nearest-neighbors were the pitfall for our L05 *member:group* category, where the analogy *student:class :: bird:?(flock)* would yield the answer *birds*. Likewise, with the verbs in I05 and D05 we were getting many participles with *-ing* ending: *arrange:rearrange::grow:*growing* (expected: *regrow*), *create:creates::accept:*accepting* (expected: *accepts*).

Consider now the E05 category that seems to break the pattern of morphologically-related nearest-neighbor: here the most mistakes are "lexicographic'. E05 category has analogies such as *aristotle:philosopher::bach:?composer*. The typical mistake is a co-hyponym of the a or (usually) c word, i.e. another composer in this case. This is also explained by the fact that for the names of famous people their nearest neighbors frequently happen to be co-hyponyms: in our SVD model the nearest neighbors of *Bach* are *Haydn* and *Schubert*, and in GloVe - *Handel* and *Beethoven*. This means that in all the categories the basic source of mistakes is the same indiscriminateness of cosine similarity.

Unfortunately, this means that word analogies fail to provide sufficient "context" to words: ideally, *king:queen :: man:woman* and *king:kings :: queen:queens* should profile sufficiently different aspects of the $king$ vector to avoid the nearest-neighbor trap. However, it does not seem to work this way. This is particularly clear in mistakes resulting from polysemy of one of the source words. For example, in L05 we had: *crow:murder::fish:*killing* (expected: *school*), *lion:pride::bird:*ambition* (expected: *flock*).

In E05, D05 and I05 LRCos significantly improves over 3CosAdd by reducing this nearest-neighbor kind of mistake, but it is telling that this improvement comes with the increase of partially-correct answers: the model comes up with the correct target feature in an incorrect word, e.g. ask $asks$ + $happen$ = $realizes$ (expected: *$happens$). Such mistakes suggest that the contribution of classifier and cosine similarity could differ for different words, although it is not clear how to determine them dynamically.

Another observation from our data is that for both methods the margin of error is very thin. For example, in the E05 category LRCos gives *Depp:screenwriter* a total score of 0.36, and this incorrect answer beats the correct answer *Depp:actor* that is ranked 0.35. Average accuracy would be much higher if we allowed the answers to be in the top five nearest neighbors, although this, of course, brings up the problem of where analogies could be used in practice, and what level of precision that would require.

8 Discussion: Embeddings vs Methods

LRCos offers a significant boost in accuracy for detecting analogical relations over the most widely-used 3CosAdd method, including derivational relations where the latter does not perform well. However, LRCos is by no means perfect, and there is room for further improvement, especially with respect to lexicographic relations. This includes algorithms aimed at searching for complex patterns of correspondences between vectors rather than simple similarity. A different (and potentially more fruitful) approach is to investigate whether the target relations are at all reflected in the distributional properties of words.

Aside from the practical result for non-lexicographic relations, this work also brings up a theoretical question. We have shown that different methods of detecting analogies provide different results on different embeddings, and this means that low performance of a word embedding with, e.g., 3CosAdd method, does not prove that the embedding does not capture certain linguistic relations - only that they are not detectable with this particular method. This brings into question the validity of analogy detection with 3CosAdd as a benchmark for word embeddings, as it is frequently used (Pennington et al., 2014; Garten et al., 2015; Cui et al., 2014).

It could be argued that embeddings could be judged "good" as in "easy to work with"; in this sense a "good" embedding is an embedding that yields correct answers with simple rather than complex extraction methods. However, what is good for practical applications is not necessarily the same as what is good for a benchmark. In this case with analogies, 3CosAdd is at disadvantage with embeddings that encode a lot of extra (but useful) information in dimensions that are irrelevant to a particular relation, and thus misleads 3CosAdd. On the other hand, it could be argued that machine-learning-based methods should not be used for benchmarking because they could learn to ignore noise too well.

9 Conclusion

We presented LRCos, a method of analogical reasoning that is based on supervised learning from a group of examples. LRCos significantly outperforms the popular 3CosAdd method (based on offset for individual word pairs) on both the Google and BATS test sets, although the gain varies between embeddings and relation types. Importantly, LRCos achieves high accuracy in two areas where 3CosAdd mostly failed: word-formation in English and grammar in Russian, a morphologically rich language. Unlike 3CosAdd, LRCos is less sensitive to idiosyncrasies of individual word pairs, and does not suffer from higher vector dimensionality.

We compared 5 analogical reasoning methods on 40 types of linguistic relations with two word embeddings: explicit SVD model and neural-net-based GloVe. Both models yielded overall similar patterns of performance with different methods, offering further evidence for conceptual similarity of explicit and implicit word embeddings.

This work also makes a theoretical contribution in demonstrating the interaction between word embeddings, types of analogies, and different types of search algorithms: with LRCos our SVD-based model approaches the state-of-the-art performance for GloVe and Skip-Gram. This suggests that the information about linguistic relations from the test set was actually encoded in the SVD-based embedding, possibly in a different way. In that case we need to decide whether failure to detect a relation with 3CosAdd method actually indicates inferiority of a word embedding, and whether a "good" embedding should encode different kinds of relations in the same way - as the Google test set in conjunction with 3CosAdd is still one of the most popular benchmarks.

Abstract

We propose a novel semantic tagging task, *sem-tagging*, tailored for the purpose of multilingual semantic parsing, and present the first tagger using deep residual networks (ResNets). Our tagger uses both word and character representations, and includes a novel residual bypass architecture. We evaluate the tagset both intrinsically on the new task of semantic tagging, as well as on Part-of-Speech (POS) tagging. Our system, consisting of a ResNet and an auxiliary loss function predicting our semantic tags, significantly outperforms prior results on English Universal Dependencies POS tagging (95.71% accuracy on UD v1.2 and 95.67% accuracy on UD v1.3).

1 Introduction

A key issue in computational semantics is the transferability of semantic information across languages. Many semantic parsing systems depend on sources of information such as POS tags (Pradhan et al., 2004; Copestake et al., 2005; Bos, 2008; Butler, 2010; Berant and Liang, 2014). However, these tags are often customised for the language at hand (Marcus et al., 1993) or massively abstracted, such as the Universal Dependencies tagset (Nivre et al., 2016). Furthermore, POS tags are syntactically oriented, and therefore often contain both irrelevant and insufficient information for semantic analysis and deeper semantic processing. This means that, although POS tags are highly useful for many downstream tasks, they are unsuitable both for semantic parsing in general, and for tasks such as recognising textual entailment.

We present a novel set of semantic labels tailored for the purpose of multilingual semantic parsing. This tagset (i) abstracts over POS and named entity types; (ii) fills gaps in semantic modelling by adding new categories (for instance for phenomena like negation, modality, and quantification); and (iii) generalises over specific languages (see Section 2). We introduce and motivate this new task in this paper, and refer to it as *semantic tagging*. Our experiments aim to answer the following two research questions:

1. Given an annotated corpus of semantic tags, it is straightforward to apply off-the-shelf sequence taggers. Can we significantly outperform these with recent neural network architectures?

2. Semantic tagging is essential for deep semantic parsing. Can we find evidence that semtags are effective also for other NLP tasks?

To address the first question, we will look at convolutional neural networks (CNNs) and recurrent neural networks (RNNs), which are both highly prominent approaches in the recent natural language processing (NLP) literature. A recent development is the emergence of deep residual networks (ResNets), a building block for CNNs. ResNets consist of several stacked residual units, which can be thought of as a collection of convolutional layers coupled with a 'shortcut' which aids the propagation of the signal in a neural network. This allows for the construction of much deeper networks, since keeping a 'clean' information path in the network facilitates optimisation (He et al., 2016). ResNets have recently shown state-of-the-art performance for image classification tasks (He et al., 2015; He et al., 2016), and have

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3531–3541, Osaka, Japan, December 11-17 2016.

also seen some recent use in NLP (Östling, 2016; Conneau et al., 2016; Bjerva, 2016; Wu et al., 2016). However, no previous work has attempted to apply ResNets to NLP tagging tasks.

To answer our second question, we carry out an extrinsic evaluation exercise. We investigate the effect of using semantic tags as an auxiliary loss for POS tagging. Since POS tags are useful for many NLP tasks, it follows that semantic tags must be useful if they can improve POS tagging.

2 Semantic Tagging

2.1 Background

We refer to *semantic tagging*, or *sem-tagging*, as the task of assigning semantic class categories to the smallest meaningful units in a sentence. In the context of this paper these units can be morphemes, words, punctuation, or multi-word expressions. The linguistic information traditionally obtained for deep processing is insufficient for fine-grained lexical semantic analysis. The widely used Penn Treebank (PTB) Part-of-Speech tagset (Marcus et al., 1993) does not make the necessary semantic distinctions, in addition to containing redundant information for semantic processing. Let us consider a couple of examples.

There are significant differences in meaning between the determiners *every* (universal quantification), *no* (negation), and *some* (existential quantification), but they all receive the `DT` (determiner) POS label in PTB. Since determiners form a closed class, one could enumerate all word forms for each class. Indeed some recent implementations of semantic parsing follow this strategy (Bos, 2008; Butler, 2010). This might work for a single language, but it falls short when considering a multilingual setting. Furthermore, determiners like *any* can have several interpretations and need to be disambiguated in context.

Semantic tagging does not only apply to determiners, but reaches all parts of speech. Other examples where semantic classes disambiguate are reflexive versus emphasising pronouns (both POS-tagged as `PRP`, personal pronoun); the comma, that could be a conjunction, disjunction, or apposition; intersective vs. subsective and privative adjectives (all POS-tagged as `JJ`, adjective); proximal vs. medial and distal demonstratives (see Example 1); subordinate vs. coordinate discourse relations; role nouns vs. entity nouns. The set of semantic tags that we use in this paper is established in a data-driven manner, considering four languages in a parallel corpus (English, German, Dutch and Italian). This first inventory of classes comprises 13 coarse-grained tags and 75 fine-grained tags (see Table 1). As can be seen from this table and the examples given below, the tagset also includes named entity classes (see also Example 2).

(1) *These cats live in that house .*
`PRX CON ENS REL DST CON NIL`

(2) *Ukraine 's glory has not yet perished , neither her freedom .*
`GPE HAS CON ENT NOT IST EXT NIL NOT HAS CON NIL`

In Example 1, both *these* and *that* would be tagged as `DT`. However, with our semantic tagset, they are disambiguated as `PRX` (proximal) and `DST` (distal). In Example 2, *Ukraine* is tagged as `GPE` rather than `NNP`.

2.2 Annotated data

We use two semtag datasets. The Groningen Meaning Bank (GMB) corpus of English texts (1.4 million words) containing silver standard semantic tags obtained by running a simple rule-based semantic tagger (Bos et al., Forthcoming). This tagger uses POS and named entity tags available in the GMB (automatically obtained with the C&C tools (Curran et al., 2007) and then manually corrected), as well as a set of manually crafted rules to output semantic tags. Some tags related to specific phenomena were hand-corrected in a second stage.

Our second dataset is smaller but equipped with gold standard semantic tags and used for testing (PMB, the Parallel Meaning Bank). It comprises a selection of 400 sentences of the English part of a parallel corpus. It has no overlap with the GMB corpus. For this dataset, we used the Elephant tokeniser, which performs word, multi-word and sentence segmentation (Evang et al., 2013). We then used the

Table 1: Semantic tags used in this paper.

simple rule-based semantic tagger described above to get an initial set of tags. These tags were then corrected by a human annotator (one of the authors of this paper).

For the extrinsic evaluation, we use the POS annotation in the English portion of the Universal Dependencies dataset, version 1.2 and 1.3 (Nivre et al., 2016). An overview of the data used is shown in Table 2.

Table 2: Overview of the semantic tagging data (ST) and universal dependencies (UD) data.

3 Method

Our tagger is a hierarchical deep neural network consisting of a bidirectional Gated Recurrent Unit (GRU) network at the upper level, and a Convolutional Neural Network (CNN) and/or Deep Residual Network (ResNet) at the lower level, including an optional novel residual bypass function (cf. Figure 1).

3.1 Gated Recurrent Unit networks

GRUs (Cho et al., 2014) are a recently introduced variant of RNNs, and are designed to prevent vanishing gradients, thus being able to cope with longer input sequences than vanilla RNNs. GRUs are similar to the more commonly-used Long Short-Term Memory networks (LSTMs), both in purpose and implementation (Chung et al., 2014). A bi-directional GRU is a GRU which makes both forward and backward passes over sequences, and can therefore use both preceding and succeeding contexts to predict a tag (Graves and Schmidhuber, 2005; Goldberg, 2015). Bi-directional GRUs and LSTMs have been shown to yield high performance on several NLP tasks, such as POS tagging, named entity tagging, and chunking (Wang et al., 2015; Yang et al., 2016; Plank et al., 2016). We build on previous approaches by combining bi-GRUs with character representations from a basic CNN and ResNets.

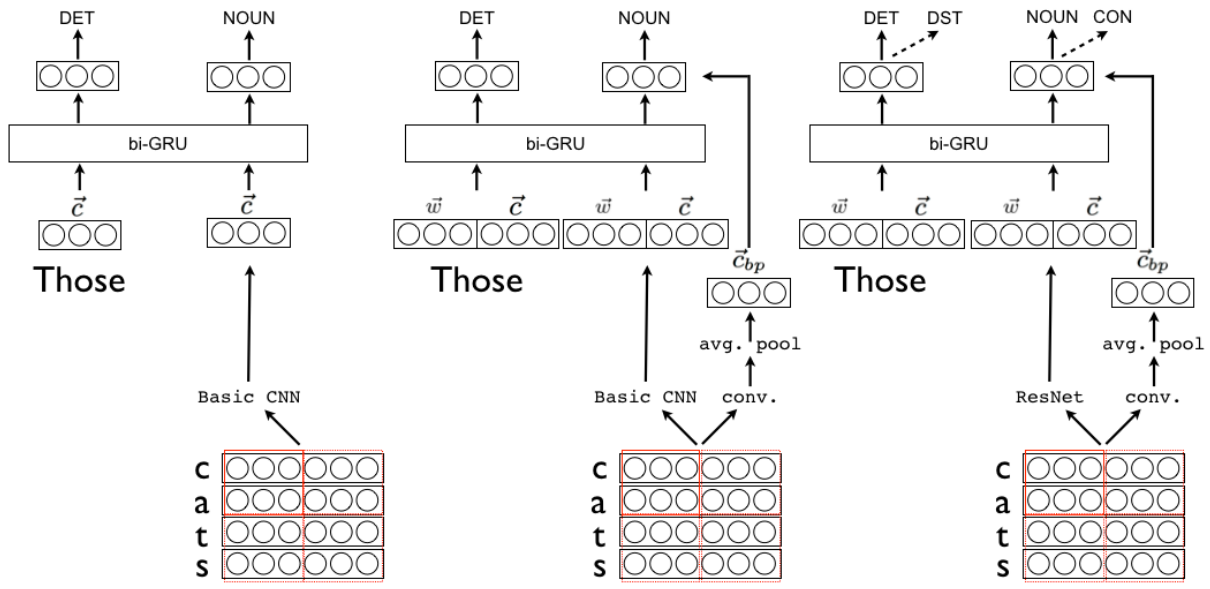

Figure 1: Model architecture. Left: Architecture with basic CNN char representations ($\vec{c}$), Middle: basic CNN with char and word representations and bypass ($\vec{c}_{bp} \wedge \vec{w}$), Right: ResNet with auxiliary loss and residual bypass ($+\text{AUX}_{bp}$).

3.2 Deep Residual Networks

Deep Residual Networks (ResNets) are built up by stacking residual units. A residual unit can be expressed as:

$$\begin{aligned} y_l &= h(x_l) + \mathcal{F}(x_l, \mathcal{W}_l), \\ x_{l+1} &= f(y_l), \end{aligned} \tag{3}$$

where x_l and x_{l+1} are the input and output of the l-th layer, $\mathcal{W}_l$ is the weights for the l-th layer, and $\mathcal{F}$ is a residual function (He et al., 2016), e.g., the identity function (He et al., 2015), which we also use in our experiments. ResNets can be intuitively understood by thinking of residual functions as paths through which information can propagate easily. This means that, in every layer, a ResNet learns more complex feature combinations, which it combines with the shallower representation from the previous layer. This architecture allows for the construction of much deeper networks. ResNets have recently been found to yield impressive performance in image recognition tasks, with networks as deep as 1001 layers (He et al., 2015; He et al., 2016), and are thus an interesting and effective alternative to simply stacking layers. In this paper we use the *assymetric* variant of ResNets as described in Equation 9 in He et al. (2016):

$$x_{l+1} = x_l + \mathcal{F}(\hat{f}(x_l), \mathcal{W}_l). \tag{4}$$

ResNets have been very recently applied in NLP to morphological reinflection (Östling, 2016), language identification (Bjerva, 2016), sentiment analysis and text categorisation (Conneau et al., 2016), as well as machine translation (Wu et al., 2016). Our work is the first to apply ResNets to NLP sequence tagging tasks. We further contribute to the literature on ResNets by introducing a residual bypass function. The intuition is to combine both deep and shallow processing, which opens a path of easy signal propagation between lower and higher layers in the network.

3.3 Modelling character information and residual bypass

Using sub-token representations instead of, or in combination with, word-level representations has recently obtained a lot of attention due to their effectiveness (Sutskever et al., 2011; Chrupała, 2013;

Zhang et al., 2015; Chung et al., 2016; Gillick et al., 2015). The use of sub-token representations can be approached in several ways. Plank et al. (2016) and Yang et al. (2016) use a hierarchical bi-directional RNN, first passing over characters in order to create word-level representations. Gillick et al. (2015) similarly apply an LSTM-based model using byte-level information directly. Dos Santos and Zadrozny (2014) construct character-based word-level representations by running a convolutional network over the character representations of each word. All of these approaches have in common that the character-based representation is passed through the entire remainder of the network. Our work is the first to combine the use of character-level representations with both deep processing (i.e., passing this representation through the network) and shallow processing (i.e., bypassing the network in our residual bypass function). We achieve this by applying our novel residual bypass function to our character representations, inspired by the success of ResNets. In particular, we first apply the bypass to a CNN-based model achieving large gains over a plain CNN, and later evaluate its effectiveness in a ResNet.

A core intuition behind CNNs is the processing of an input signal in a hierarchical manner (LeCun et al., 1998; Goodfellow et al., 2016). Taking, e.g., a 3-dimensional image ($width \times height \times depth$), the approach is typically to reduce spatial dimensions of the image while increasing depth. This hierarchical processing allows a CNN to learn high-level features of an input, essential to image recognition tasks. A drawback of this method, however, is that lower-level features are potentially lost in the abstraction to higher-level features. This issue is partially countered by ResNets, as information is allowed to flow more easily between residual blocks. However, this approach does not allow for simple and direct use of information in the network input in final layers. To alleviate this issue, we present a residual bypass function, which can be seen as a global residual function (depicted in Figure 1). This function allows both lower-level and higher-level features to be taken directly into account in the final layers of the network. The intuition behind using such a global residual function in NLP is that character information primarily ought to be of importance for the prediction of the current word. Hence, allowing these representations to bypass our bi-GRU might be beneficial. This residual bypass function is not dependent on the usage of ResNets, and can be combined with other NN architectures as in our experiments. We define the penultimate layer of a network with n layers, using a residual bypass, as follows:

$$y_{n-1} = h(x_{n-1}) + \mathcal{F}(x_i, \mathcal{W}_i), \tag{5}$$

where x_i and $\mathcal{W}_i$ are the input and weights of the i_{th} layer, $\mathcal{F}$ is a residual function (in our case the identity function), and $h(x_{n-1})$ is the output of the penultimate layer. In our experiments, we apply a residual bypass function to our convolutional character representations.

3.4 System description

The core of our architecture consists of a bi-GRU taking an input based on words and/or characters, with an optional residual bypass as defined in subsection 3.3. We experiment with a basic CNN, ResNets and our novel residual bypass function. We also implemented a variant of the *Inception* model (Szegedy et al., 2015), but found this to be outperformed by ResNets. Our system is implemented in Keras using the Tensorflow backend (Chollet, 2015; Abadi et al., 2016), and the code is available at `https://github.com/bjerva/semantic-tagging`.

We represent each sentence using both a character-based representation (S_c) and a word-based representation (S_w). The character-based representation is a 3-dimensional matrix $S_c \in \mathbb{R}^{s \times w \times d_c}$, where s is the zero-padded sentence length, w is the zero-padded word length, and d_c is the dimensionality of the character embeddings. The word-based representation is a 2-dimensional matrix $S_w \in \mathbb{R}^{s \times d_w}$, where s is the zero-padded sentence length and d_w is the dimensionality of the word embeddings. We use the English Polyglot embeddings (Al-Rfou et al., 2013) in order to initialise the word embedding layer, but also experiment with randomly initialised word embeddings.

Word embeddings are passed directly into a two-layer bi-GRU (Chung et al., 2014). We also experimented using a bi-LSTM. However, we found GRUs to yield comparatively better validation data performance on semtags. We also observe better validation data performance when running two consecutive forward and backward passes before concatenating the GRU layers, rather than concatenating after each forward/backward pass as is commonplace in NLP literature.

We use CNNs for character-level modelling. Our basic CNN is inspired by dos Santos and Zadrozny (2014), who use character-representations to produce local features around each character of a word, and combine these with a maximum pooling operation in order to create fixed-size character-level word embeddings. The convolutions used in this manner cover a few neighbouring letters at a time, as well as the entire character vector dimension (d_c). In contrast to dos Santos and Zadrozny (2014), we treat a word analogously to an image. That is to say, we see a word of n characters embedded in a space with dimensionality d_c as an image of dimensionality $n \times d_c$. This view gives us additional freedom in terms of sizes of convolutional patches used, which offers more computational flexibility than using only, e.g., $4 \times d_c$ convolutions. This view is applied to all CNN variations explored in this work.

A neural network is trained with respect to some loss function, such as the cross-entropy between the predicted tag probability distribution and the gold probability distribution. Recent work has shown that the addition of an auxiliary loss function can be beneficial to several tasks. Cheng et al. (2015) use a language modelling task as an auxiliary loss, as they attempt to predict the next token while performing named entity recognition. Plank et al. (2016) use the log frequency of the current token as an auxiliary loss function, and find this to improve POS tagging accuracy. Since our semantic tagging task is based on predicting fine semtags, which can be mapped to coarse semtags, we add the prediction of these coarse semtags as an auxiliary loss for the sem-tagging experiments. Similarly, we also experiment with POS tagging, where we use the fine semtags as an auxiliary information.

3.4.1 Hyperparameters

All hyperparameters are tuned with respect to loss on the semtag validation set. We use rectified linear units (ReLUs) for all activation functions (Nair and Hinton, 2010), and apply dropout with $p = 0.1$ to both input weights and recurrent weights in the bi-GRU (Srivastava et al., 2014). In the CNNs, we apply batch normalisation (Ioffe and Szegedy, 2015) followed by dropout with $p = 0.5$ after each layer. In our basic CNN, we apply a 4×8 convolution, followed by 2×2 maximum pooling, followed by 4×4 convolution and another 2×2 maximum pooling. Our ResNet has the same setup, with the addition of a residual connection. We also experimented with using average pooling instead of maximum pooling, but this yielded lower validation data performance on the semantic tagging task. We set both d_c and d_w to 64. All GRU layers have 100 hidden units. All experiments were run with early stopping monitoring validation set loss, using a maximum of 50 epochs. We use a batch size of 500. Optimisation is done using the ADAM algorithm (Kingma and Ba, 2014), with the categorical cross-entropy loss function as training objective. The main and auxiliary loss functions have a weighting parameter, λ. In our experiments, we weight the auxiliary loss with $\lambda = 0.1$, as set on the semtag auxiliary task.

Multi-word expressions (MWEs) are especially prominent in the semtag data, where they are annotated as single tokens. Pre-trained word embeddings are unlikely to include entries such as 'International Organization for Migration', so we apply a simple heuristic in order to avoid treating most MWEs as unknown words. In particular, the representation of a MWE is set to the sum of the individual embeddings of each constituent word.

4 Evaluation

We evaluate our tagger on two tasks: semantic tagging and POS tagging. Note that the tagger is developed solely on the semantic tagging task, using the GMB silver training and validation data. Hence, no further fine-tuning of hyperparameters for the POS tagging task is performed. We calculate significance using bootstrap resampling (Efron and Tibshirani, 1994). We manipulate the following independent variables in our experiments:

1. character and word representations ($\vec{w}, \vec{c}$);
2. residual bypass for character representations ($\vec{c}_{bp}$);
3. convolutional representations (Basic CNN and ResNets);
4. auxiliary loss (using coarse semtags on ST and fine semtags on UD).

We compare our results to four baselines:

1. the most frequent baseline per word (MFC), where we assign the most frequent tag for a word in the training data to that word in the test data, and unseen words get the global majority tag;
2. the trigram statistic based TNT tagger offers a slightly tougher baseline (Brants, 2000);
3. the BI-LSTM baseline, running the off-the-shelf state-of-the-art POS tagger for the UD dataset (Plank et al., 2016) (using default parameters with pre-trained Polyglot embeddings);
4. we use a baseline consisting of running our own system with only a BI-GRU using word representations ($\vec{w}$), with pre-trained Polyglot embeddings.

4.1 Experiments on semantic tagging

We evaluate our system on two semantic tagging (ST) datasets: our silver semtag dataset and our gold semtag dataset. For the +AUX condition we use coarse semtags as an auxiliary loss. Results from these experiments are shown in Table 3.

	BASELINES				BASIC CNN				RESNET					
	MFC	TNT	BI-LSTM	BI-GRU	$\vec{c}$	$\vec{c}_{bp}$	$\vec{c}_{bp} \wedge \vec{w}$	+AUX$_{bp}$	$\vec{c}$	$\vec{c} \wedge \vec{w}$	+AUX	$\vec{c}_{bp}$	$\vec{c}_{bp} \wedge \vec{w}$	+AUX$_{bp}$
ST Silver	84.64	92.09	94.98	94.26	91.39	90.18	94.63	94.53	94.39	95.14	94.23	94.23	**95.15**	94.58
ST Gold	77.39	80.73	82.96	80.26	69.21	65.77	76.83	80.73	76.89	**83.64**	74.84	75.84	82.18	73.73

Table 3: Experiment results on semtag (ST) test sets (% accuracy). MFC indicates the per-word most frequent class baseline, TNT indicates the TNT tagger, and BI-LSTM indicates the system by Plank et al. (2016). BI-GRU indicates the $\vec{w}$ only baseline. $\vec{w}$ indicates usage of word representations, $\vec{c}$ indicates usage of character representations, and $\vec{c}_{bp}$ indicates usage of residual bypass of character representations. The +AUX column indicates the usage of an auxiliary loss.

4.2 Experiments on Part-of-Speech tagging

We evaluate our system on v1.2 and v1.3 of the English part of the Universal Dependencies (UD) data. We report results for POS tagging alone, comparing to commonly used baselines and prior work using LSTMs, as well as using the fine-grained semantic tags as auxiliary information. For the +AUX condition, we train a single joint model using a multi-task objective, with POS and ST as our two tasks. This model is trained on the concatenation of the ST silver data with the UD data, updating the loss of the respective task of an instance in each iteration. Hence, the weights leading to the UD softmax layer are not updated on the ST silver portion of the data, and vice-versa for the ST softmax layer on the UD portion of the data. Results from these experiments are shown in Table 4.

	BASELINES				BASIC CNN				RESNET					
	MFC	TNT	BI-LSTM	BI-GRU	$\vec{c}$	$\vec{c}_{bp}$	$\vec{c}_{bp} \wedge \vec{w}$	+AUX$_{bp}$	$\vec{c}$	$\vec{c} \wedge \vec{w}$	+AUX	$\vec{c}_{bp}$	$\vec{c}_{bp} \wedge \vec{w}$	+AUX$_{bp}$
UD v1.2	85.06	92.66	95.17	94.39	77.63	83.53	94.68	95.19	92.65	94.92	**95.71**	92.45	94.73	95.51
UD v1.3	85.07	92.69	95.04	94.32	77.51	82.89	94.89	95.34	92.63	94.88	**95.67**	92.86	94.69	95.57

Table 4: Experiment results on Universal Dependencies (UD) test sets (% accuracy). Adding semtags as auxiliary tags results in the best results obtained so far on English UD datasets.

5 Discussion

5.1 Performance on semantic tagging

The overall best system is the ResNet combining both word and character representations $\vec{c} \wedge \vec{w}$. It outperforms all baselines, including the recently proposed RNN-based bi-LSTM. On the ST silver data, a significant difference ($p < 0.01$) is found when comparing our best system to the strongest baseline

(BI-LSTM). On the ST gold data, we observe significant differences at the alpha values recommended by Søgaard et al. (2014), with $p < 0.0025$. The residual bypass effectively helps improve the performance of the basic CNN. However, the tagging accuracy of the CNN falls below baselines. In addition, the large gap between gold and silver data for the CNN shows that the CNN model is more prone to overfitting, thus favouring the use of the ResNet. Adding the coarse-grained semtags as auxiliary task only helps for the weaker CNN model. The ResNet does not benefit from this additional information, which is already captured in the fine-grained labels.

It is especially noteworthy that the ResNet character-only system performs remarkably well, as it outperforms the BI-GRU and TNT baselines, and is considerably better than the basic CNN. Since performance increases further when adding in $\vec{w}$, it is clear that the character and word representations are complimentary in nature. The high results for characters only are particularly promising for multilingual language processing, as this allows for much more compact models (see, e.g., Gillick et al. (2015)), which is a direction we want to explore next.

5.2 Performance on Part-of-Speech tagging

Our system was tuned solely on semtag data. This is reflected in, e.g., the fact that even though our $\vec{c} \wedge \vec{w}$ ResNet system outperforms the Plank et al. (2016) system on semtags, we are substantially outperformed on UD 1.2 and 1.3 in this setup. However, adding an auxiliary loss based on our semtags markedly increases performance on POS tagging. In this setting, our tagger outperforms the BI-LSTM system, and results in new state-of-the-art results on both UD 1.2 (95.71% accuracy) and 1.3 (95.67% accuracy). The difference between the BI-LSTM system and our best system is significant at $p < 0.0025$.

The fact that the semantic tags improve POS tagging performance reflects two properties of semantic tags. Firstly, it indicates that the semantic tags carry important information which aids the prediction of POS tags. This should come as no surprise, considering the fact that the semtags abstract over and carry more information than POS tags. Secondly, it indicates that the new semantic tagset and released dataset are useful for downstream NLP tasks. In this paper we show this by using semtags as an auxiliary loss. In future work we aim to investigate the effect of introducing the semtags directly as features into the embedded input representation.

5.3 ResNets for sequence tagging

This work is the first to apply ResNets to NLP tagging tasks. Our experiments show that ResNets significantly outperform standard convolutional networks on both POS tagging and sem-tagging. ResNets allow better signal propagation and carry lower risk of overfitting, allowing for the model to capture more elaborate feature representations than in a standard CNN.

5.4 Pre-trained embeddings

In our main experiments, we initialised the word embedding layer with pre-trained polyglot embeddings. We also compared this with initialising this layer from a uniform distribution over the interval $[-0.05, 0.05)$. For semantic tagging, the difference with random initialisation is negligible, with pre-trained embeddings yielding an increase in about 0.04% accuracy. For POS tagging, however, using pre-trained embeddings increased accuracy by almost 3 percentage points for the ResNet.

6 Conclusions

We introduce a semantic tagset tailored for multilingual semantic parsing. We evaluate tagging performance using standard CNNs and the recently emerged ResNets. ResNets are more robust and result in our best model. Combining word and ResNet-based character representations helps to outperform state-of-the-art taggers on semantic tagging. Coupling this with an auxiliary loss from our semantic tagset yields state-of-the-art performance on the English UD 1.2 and 1.3 POS datasets.

A Supervised Approach for Enriching the Relational Structure of Frame Semantics in FrameNet

Shafqat Mumtaz Virk and **Philippe Muller** and **Juliette Conrath**
IRIT, Toulouse University
118 Route de Narbonne
31062 Toulouse, France

Abstract

Frame semantics is a theory of linguistic meanings, and is considered to be a useful framework for shallow semantic analysis of natural language. FrameNet, which is based on frame semantics, is a popular lexical semantic resource. In addition to providing a set of core semantic frames and their frame elements, FrameNet also provides relations between those frames (hence providing a network of frames i.e. FrameNet). We address here the limited coverage of the network of conceptual relations between frames in FrameNet, which has previously been pointed out by others. We present a supervised model using rich features from three different sources: structural features from the existing FrameNet network, information from the WordNet relations between synsets projected into semantic frames, and corpus-collected lexical associations. We show large improvements over baselines consisting of each of the three groups of features in isolation. We then use this model to select frame pairs as candidate relations, and perform evaluation on a sample with good precision.

1 Introduction

In the area of formal linguistics, frame semantics is a theory of meanings, which was introduced by Charles J. Fillmore and his colleagues back in the early 1980's. Frame semantic analysis (Das et al., 2014), which is based on frame semantics, itself is a type of shallow semantic analysis in which the focus is on predicates and their arguments. Frame semantic analysis is abstracting away from single verbal predicates, used in other semantic analysis approaches such as Propbank-based work (Kingsbury and Palmer, 2012), to "semantic frames" (Fillmore, 1982). The idea in frame semantics is to group predicates referring to similar events, processes, and/or object types under the umbrella term 'a semantic frame', which can be expressed with different parts of speech and with arguments that can have various syntactic realizations. For instance, the sentence in example (1-a) could be seen as introducing a commerce frame, indicated by the lexical unit *buy*. This frame has a set of necessary arguments, a *buyer*, some *goods*, and a *seller*, which are realized by role fillers *Lester*, *a car* and *Jimmy* in the example. Frames can be realized with different lexical units and syntactic constructions, so that sentences (1-b)-(1-c) would have a similar meaning with respect to the frame in question.

(1) a. $[\text{Lester}]_{\text{buyer}}$ $[\text{bought}]_{\text{commerce}}$ $[\text{a car}]_{\text{goods}}$ $[\text{from Jimmy}]_{\text{seller}}$.
b. $[\text{Jimmy}]_{\text{seller}}$ $[\text{sold}]_{\text{commerce}}$ $[\text{a car}]_{\text{goods}}$ $[\text{to Lester}]_{\text{buyer}}$.
c. $[\text{Lester}]_{\text{buyer}}$'s $[\text{purchase}]_{\text{commerce}}$ of $[\text{Jimmy}]_{\text{seller}}$'s $[\text{car}]_{\text{goods}}$ (...)

Most recent NLP work on such semantic frames are based on FrameNet (henceforth FN) (Baker et al., 1998), a resource listing frames, how they can be evoked, and their argument types. FrameNet also lists how the frames are organized with respect to each other, with a set of frame-to-frame relations. If FrameNet based analysis has proven useful for certain tasks such as information extraction (Surdeanu et al., 2003), question-answering (Shen and Lapata, 2007), or coreference resolution (Ponzetto and Strube, 2006), its frame structure is assumed to be useful on its own for semantic analysis (Burchardt et al.,

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3542–3552, Osaka, Japan, December 11-17 2016.

2005), or paraphrase extraction (Hasegawa et al., 2011). It also provides additional information for semantic analysis in contextual role linking, as demonstrated in (Li et al., 2015), or to improve prediction of roles, as in the work of Kshirsagar et al. (2015). The relations are also useful to build thesauri and to retrieve semantically related words (Ruppenhofer et al., 2006). However, one big issue with FrameNet is its partial coverage of the lexicon and the intended set of frames, which translates also into a partial coverage of frame relations. Numerous studies address FrameNet's lack of lexical coverage (Pennacchiotti et al., 2008; Das and Smith, 2012; Pavlick et al., 2015). In contrast, little work has been done on extending frame relations except by Ovchinnikova et al. (2010), in which cluster of frames are proposed based on collocation information, along with principles to be respected when adding new relations, or Pennacchiotti and Wirth (2009), which defines a generic notion of "relatedness" between frames, with no semantics to compare this to FrameNet relations. Both approaches are unsupervised, and provide little evaluation of the relevance to the intended FN structure.

We present a supervised approach to enrich FrameNet's relational structure by training a model on the existing set of frame relations and a rich set of features combining linguistic and structural information. Further, we also leverage external resources such as WordNet. The resulting model is used to predict new frame-to-frame relations whose validity is then manually evaluated. The rest of the paper is organized as follows: Section 2 presents in more detail FN frame relations, Section 3 presents our methodology and the three group of features we use for training a supervised model. Section 4 presents our experimental results based (1) on a separate test set taken from already existing FrameNet relations, and (2) a human evaluation of newly proposed relations.

2 FrameNet Relations

FrameNet is a lexical semantic resource which is based on the theory of frame semantics (Fillmore, 1982). A set of script-like descriptions, known as semantic frames, of real world situations is collected and maintained along with the participants of those situations. Each of the semantic frames has a set of associated words (known as frame evoking elements, FEE) which can evoke a particular predicate. The participants of a situation (called frame elements, FE instead of the more classical term 'semantic role') are also identified for each frame. In addition, each semantic frame is coupled with example sentences taken from naturally occurring natural language text. FrameNet-1.5 has 1230 semantic frames, 11829 lexical units, and 173018 example sentences.

As mentioned previously, FrameNet has defined a set of frame-to-frame relations, and has proposed connections of certain frames to certain other frames, thus providing a network. The backbone of this network is built on a hierarchy of predicate types, and typical sub-events of specific situations. Event participants, also called frame elements, of the connected frames may also have one-to-one connections. Some of these frames are introduced purely for the coherence of the structure and may not have associated lexical items ("unlexicalized frames"). The following is a list of relations defined between two frames X and Y:

- Subframe(X,Y): a complex scenario X, e.g. CRIMINAL_PROCESS, is composed of typical sub-events (e.g. Y can be TRIAL, SENTENCING...).
- Precedes(X,Y): X is before Y in a typical scenario, e.g. TRIAL precedes SENTENCING.
- Inheritance(X,Y): A relation between frames where one frame is a more specific version of another frame e.g. ANIMALS inherits from BIOLOGICAL_ENTITY.
- Causative_of(X,Y): X is a potential cause of Y, e.g AIMING is causative_of HIT_OR_MISS.
- Inchoative_of(X,Y): X is an inchoative of Y, e.g. ROTTING is inchoative of BEING_ROTTEN.
- Perspectivized_in(X,Y): X represents a specific perspective of Y, e.g. COMMERCE_BUY and COMMERCE_SELL are two different perspectives of COMMERCE_TRANSFER_GOODS.
- Using(X,Y): X somehow involves Y, e.g. PEOPLE_BY_AGE uses the AGE frame.

- See_also(X,Y): Frames that have some similarities, but need to be differentiated carefully (e.g. MEASURABLE_ATTRIBUTE and DIMENSION).

Figure (1) gives an example of a subset of relations around the CRIMINAL PROCESS Frame, that will be used for illustration in the rest of the paper.

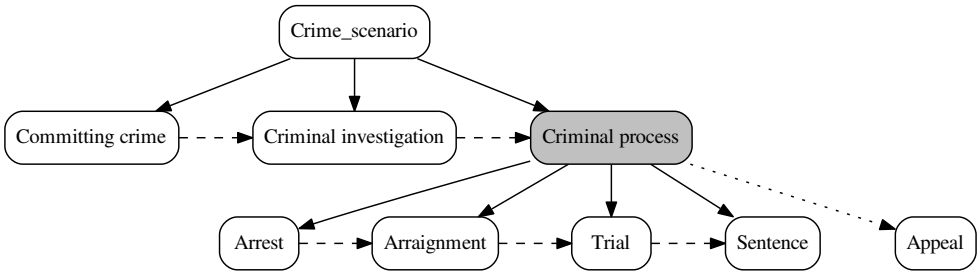

Figure 1: Example sub-graph around the CRIMINAL PROCESS frame; Solid, dashed and dotted lines respectively indicate the "SubFrame", "Precede" and "Using" relations. Only subframes of CRIMINAL PROCESS are shown.

3 Experimental Design and Features

Our goal is to provide a method to enrich FrameNet structures with new relations where supervision is given by the existing frame relations. Our experimental methodology is thus two-fold: 1) we trained a discriminative model to predict frame-to-frame relations in a supervised setting using the existing relations listed in the original FrameNet and selected counter-examples; and 2) we applied this model to predict likely frame-to-frame relations that are not already listed. We used rich features from three different sources, taking inspiration from the unsupervised relatedness measures of (Pennacchiotti and Wirth, 2009), which are based on lexical collocations, but adding more features: structural features from the existing FrameNet network, information from WordNet relations between synsets projected into semantic frames, and different additional corpus-collected lexical associations. Since we want to focus on event-denoting predicates, which have arguably richer and potentially more interesting argument structures, and are more likely to be related in common scenarios, we restricted ourselves to frames with at least one verb trigger. This restricts the existing relations to 824 frame pairs. Next we describe the different set of features used in our experiments.

3.1 WordNet Based Features

WordNet provides useful lexical and semantic relations between synonym sets. The most important among those relations are hypernymy/hyponymy and meronymy/honolymy. Hypernym and hyponym (and troponymy for verbs) are super-subordinate relations and link more general synsets to specific ones and could be relevant for Frame inheritance, and thus make the first source of information for predicting frame relations. As we are interested in relationships between pairs of frames, instead of pair of synsets, we need to transfer knowledge about relations between synsets to useful features between frames whose verbs appear in WordNet synsets. There have been attempts at matching WordNet sense inventory to FrameNet frames (Shi and Mihalcea, 2005; Tonelli and Pighin, 2009) but since both resources are incomplete, we decided to compute frame relatedness using an existing WordNet relation between synsets which include verbs from the given frames, irrespective of their senses. This certainly introduces some noise, that we hope to control with redundancies in frame-to-frame associations. For our purposes, we have divided WN-based features into two groups: (1) occurrence-based features (2) similarity-based features. Occurrence-based features are simple counts of existence of a particular relation between a pair

from all possible pairs of all senses of all lexical units of the two candidate frames. By taking the existence of a particular relation between senses and summing them up, we are projecting the knowledge about WordNet's synset relations to FrameNet's frames.

For a given pair of frames (F_i, F_j), and a given WordNet relation R (i.e. hypernym, hyponym, all meronym relations, all holonyms relations, attributes, entailments, causes, also_sees) the number of occurrence-based feature values were computed using the following formula:

$$number\_rel(F_i, F_j, R) = \sum_{(lu_i, lu_j) \in LU_{F_i} \times LU_{F_j}} \left[\sum_{(s_{lu_i}, s_{lu_j}) \in S_{lu_i} \times S_{lu_j}} R(s_{lu_i}, s_{lu_j}) = True \right]$$

LU_{F_i} and LU_{F_j} are sets of lexical units of frames F_i and F_j respectively, while S_{lu_i} and S_{lu_j} are sets of various senses of the corresponding lexical units in WordNet. The values of the semantic similarity based features were computed using a similar formula (but averaged) for a given similarity function f and two frames F_1 and F_2:

$$similarity(F_i, F_j, f) = \frac{1}{|LU_{F_i} \times LU_{F_j}|} \times \sum_{(lu_i, lu_j) \in LU_{F_i} \times LU_{F_j}} \left[\frac{\sum_{(s_{lu_i}, s_{lu_j}) \in S_{lu_i} \times S_{lu_j}} f(s_{lu_i}, s_{lu_j})}{|S_{lu_i} \times S_{lu_j}|} \right]$$

The semantic similarity measures are classical wordnet similarity measures: Path, Wu-Palmer (Wu and Palmer, 1994) and Leacock-Chodorow (Leacock and Chodorow, 1998), computed using NLTK's (Bird, 2006) Python interface. They all take into consideration the path between synsets in WordNet's hierarchy with different normalization factors. For instance Wu-Palmer is based on the depths of two synsets in the WordNet hierarchy along with the depth of the least common subsumer. The path similarity measure is a semantic association measure which is based on the shortest path that connects two synsets in the taxonomy in which the senses occurred. LCH similarity takes into consideration the depth of the taxonomy in addition to the shortest path, and is computed as $-log(p/2d)$, where p denotes the shortest path and d is the depth. For the purpose of projecting WordNet's synset knowledge to FrameNet's frames, we are summing up and averaging the corresponding semantic similarity values of all possible combinations of various senses of all lexical units of the two candidate frames.

3.2 FrameNet Based Features

FrameNet network structure can also be a useful resource to compute frame-relatedness between non explicitely related frames. (Pennacchiotti and Wirth, 2009) proposed to apply equivalents of Wu-Palmer similarity and Hirst-St.Onge's (Hirst and St-Onge, 1998) measure to FrameNet's hierarchy. They also suggested to take into account frame element overlap (the proportion of predicate roles having the same name). Here, the frame element overlap similarly is based on the number of frame-elements (role names) shared by the two candidate frames. Hirst-St.Onge measure is a semantic similarity measure which is based on the path connecting two WordNet synsets and how often one needs to change direction to reach one from the other in the network. A "change of direction" would be for instance a path along an hypernym relation then an hyponym relation (which yields a likely co-hyponym). The intuition is that two synsets are semantically closer if they are connected through a "not too long path which does not change direction too often". This can be applied similarly over FrameNet's relations, even though some of these are vaguer than WordNet relations. An example path in figure 1 would be the path (SubFrame^{-1}+Using) between SENTENCE and APPEAL.

In addition to the hierarchy-based features, frame verbal definitions can potentially provide useful information for frame relatedness, and we decided to also use a definition overlap as a feature, with a Jaccard between the sets of open-class words of each definition (open(F) being the set of open-class words in F definition):

$$def\_overlap(F_1, F_2) = \frac{\|open(F_1)\| \cup \|open(F_2)\|}{\|open(F_1)\| \cap \|open(F_2)\|}$$

3.3 Corpus-Based Features

In addition to the previous sets of features, which make use of existing resources or of the existing structure we want to expand, we derived clues from large corpora where frame lexical units can be observed in the same contexts, indicating a potentially regular relation between their corresponding frames. We collected both general ococcurences, in the spirit of (Pennacchiotti and Wirth, 2009), and targetted associations of verbs in explicit discursive contexts, inspired by (Conrath et al., 2014).

Frame Coocurrences We used statistics of frame co-occurrences from a large-scale corpus to predict frame relatedness, relying on the intuition that related frames tend to co-occur more often in the same context within a given corpus. The context could be either a document, a sentence, or a specific number of sentences. We computed the co-occurrence of frames as point-wise mutual information (PMI) within the GigaWord corpus (Graff et al., 2003). Similar information has already been used in (Pennacchiotti and Wirth, 2009), but we deal with the frame ambiguity problem differently.

Ideally, one would like to compute frame co-occurrences statistics from a frame annotated corpus which is big enough for machine learning tasks. FrameNet does provide a frame annotated corpus, but it is too small to be truly useful for making generalizations. A workaround is to use an unannotated corpus together with FN's frame-evoking lexicon to decide which frame is being triggered by a particular lexical unit. The problem is now to resolve the ambiguity in cases where a lexical unit can potentially trigger more than one frame. (Pennacchiotti and Wirth, 2009) suggested a weighted co-occurrence measure, which gave lower weights to the co-occurrence of ambiguous words. The probabilities of sense occurrences of lexical units were learned from the WordNet sense tagged corpus SemCor. Our approach is slightly different in the sense that instead of learning word-sense probabilities first and then mapping it to frames, we directly learn the probabilities of lexical units triggering particular frames from FrameNet's annotated corpus using the ratio of the number of frames triggered by a lexical unit lu in the FrameNet corpus and of the total number of occurrences of lu in the corpus. This is arguably more direct and only use FrameNet information, although both approaches need annotated data. The probabilities are then used to compute a weighted PMI between frames (the weighting function simply sums up the probabilities of a lexical unit triggering a particular frame F over the entire GigaWord).

Lexical Coocurrences We also used as features measures of semantic similarity derived from corpus-based specific associations between lexical items. If we can find valid lexical associations to match the targeted frame relations, we can obtain relevant association measures. We adapted the method of (Conrath et al., 2014), in which semantic associations between verbs are derived from cooccurrences between two verbs and certain classes of discourse markers, using mutual information measures. This shallow discourse analysis can be seen as extraction of typical semantic relations between verbs. Using the Penn Discourse Treebank (Prasad et al., 2008) list of markers, grouped into semantic classes, we computed six types of associations between verbs: (1) causal, (2) temporal, (3) continuation, (4) contrast, (5) disjunction, (6) elaboration. Each corresponds to a coherent set of markers and can provide clues to corresponding FrameNet relations: causative-of for (1), precede for (2) and (3), subframe for (6), and (4) and (5) for some form of looser relatedness that is sometimes encoded as "see-also" or "using" in FrameNet. For each class we implemented the three best measures according to (Conrath et al., 2014), which correspond to different normalizations or combinations of the verbs and discourse relation cooccurrences : normalized PMI (Evert, 2005), a specificity measure taken from (Mirroshandel et al., 2013), and a combined association measure they call w_combined. They are supposed to capture different aspects of the targeted lexical associations. Let P(V_1,V_2,R) be the probability of the association of the two verbs V_1,V_2 with the given semantic relation R:

$$\mathrm{NPMI}(V_1, V_2, R) = \mathrm{PMI}(V_1, V_2, R)/(-2\log(P(V_1, V_2, R)))$$

$$\textit{specificity}(V_1, V_2, R) = \frac{1}{3} \times \left(\frac{P(V_1, V_2, R)}{\sum_i P(V_1, V_i, R)} + \frac{P(V_1, V_2, R)}{\sum_i P(V_i, V_2, R)} + \frac{P(V_1, V_2, R)}{\sum_i P(V_1, V_2, R_i)}\right)$$

$$W_{combined}(V_1, V_2, R) = \frac{1}{3}(w_{V_1} + w_{V_2} + w_R)$$

with: $w_{V_1} = \frac{P(V_1,V_2,R)}{\max_i(P(V_i,V_2,R))}$, $w_{V_2} = \frac{P(V_1,V_2,R)}{\max_i(P(V_1,V_i,R))}$, and $w_R = \frac{P(V_1,V_2,R)}{\max_i(P(V_1,V_2,R_i))}$.

We computed the corresponding association values for frame-pairs using the same averaging scheme as for the previous features over groups of lexical units, see 3.1

4 Experiments and Results

The previous features were computed for two sets of frame-pairs: (1) All those frames-pairs which have any of the frame-relations mentioned in section 2. As mentioned previously, we restricted ourselves to frames denoting events, i.e. which have at least one verb trigger. There are 824 such instances. (2) The set of all unrelated frame-pairs. From these two sets, a balanced set of 1648 frame-pairs (824 positive, and 824 negative) was collected, 10% of which was set aside for testing the chosen model. The remaining 90% of the balanced set was used to train and evaluate different models with different feature combinations. The best combination, evaluated by cross-validation, was evaluated on the test set, and then used to train a new model on the full balanced set, which we applied to all "unrelated" frame pairs (i.e. to predict likely frame relations between frame pairs that are not already listed in the FrameNet), with a fixed *a priori* confidence threshold in order to focus first on precision of the candidate pairs[1].

4.1 Training a Supervised Model

For the first part of our method, we trained a binary classifier to decide whether a given pair of frames is related or not. To provide negative examples, we randomly sampled the set of unrelated frame pairs. Of course we don't know the real proportion of frames that should be (ideally) related, but we suspect that such a relational structure is likely to be sparse, and thus taking random pairs should yield mostly truly unrelated pairs.

Assuming the actual relational structure is sparse, we probably face an imbalanced classification problem, in which we want to identify primarily the minority class. That is why we chose to balance the number of positive and negative instances during training, since it means we are doing majority class undersampling, a classic simple way of addressing class imbalance, and it is also a simple way to evaluate the relevance of our features. This is likely to generate too many candidate pairs on the test, degrading precision while helping recall of the positive class, something we can control *a posteriori* on new instances by imposing a confidence threshold on the classifier output (see below).

We used a Random Forest classifier with 1000 estimators and a minimum of 10 instances for splitting, and the implementation provided in the scikit-learn package (Pedregosa et al., 2011). Random Forest is a robust classifier used in a variety of tasks and perform best among the classifiers evaluated on cross-validation on the training set. As baselines, we tested each separate group of features: WordNet transfer, corpus cooccurences, and FrameNet features. Note that a majority/random baseline would give a score of 50% with the balanced setting we chose. We observed that the combination of features proves very useful, as cross-validation accuracies for the three groups are much lower than the full model. Interestingly, all groups of features seem necessary, as even removing the group which performs worse by itself lowers the training accuracy by 5% (ablations of each group of features were tried by cross-validation on the train only). Final results are presented in Table 1. Not surprisingly, the most informative features come from FrameNet itself, since positively related frames are more likely to be in "denser" parts of the network, at least those parts that have been the focus of the lexicographic work, and this can be seen as a bias of the model. Note however that (1) these denser areas of the network might still be incomplete and (2) the other sources of information definitely contribute to the overall result, adding 10 points over

[1] An archive can be found at `http://www.irit.fr/~Philippe.Muller/fn_structure.zip` which contains instances and their extracted features, the manually annotated sample of frame relation instances, and various scripts to reproduce the experimental results.

FrameNet based features. We provide confidence intervals on the scores (which are proportion estimations), and we can see the different models' intervals don't overlap much, even on the small test sample.

Model	Cross-Validation / training	Test	Confidence Interval
WordNet-based	60.3	63.4	2.5/7.4
Frame information	78.1	79.3	2.1/6.2
Corpus-based	64.8	60.4	2.4/7.5
Full Model	87.3	88.4	1.7/4.9

Table 1: Accuracy of predictions with balanced dataset (in %); confidence intervals $\pm$ are given at 95% for the train/test accuracy.

4.2 Finding New Relations

We used the previous supervised model on the set of all possible pairs of frames to predict potential new relations. Since the model has been trained on a balanced set, we probably over-generate positive labels, so as a first basic step to improve the precision of the extraction, we set an arbitrary cutoff for the confidence level according to the model, at the value 0.8. This yielded over 1500 pairs, out of which we randomly selected 100 pairs for validation. We mixed the pairs with an equal number of 100 "distractors" (random pairs absent from FrameNet), to prevent annotation bias. Note that, again, we have no *a priori* way of ensuring these distractors are not actual unknown relations, but we expect true relations to be rare in this set. Two of the authors then judged if one of the FN relations could hold, based on the summary of the relations from the FrameNet book, and a description of the frames as defined in FN, i.e. a short definition, sometimes a few example sentences, a list of frame element names (arguments of the frame), and a list of lexical units that can evoke the frame. They had to label each pair as Yes/No, and were asked to indicate a tentative label from the set of FrameNet relations (there could be 0, 1, or 2 relations according to their level of confidence in their decision). We did the same procedure on the top 100 frame pairs according to the classifier, also mixed with 100 random pairs. We computed inter-annotator agreement with Cohen's Kappa which was 0.65, generally considered as an acceptable agreement above 0.6, at least for semantic tasks. Raw agreement was 0.83. To estimate agreement on the labels, we consider judgments for common Yes decisions, and we considered the intersection of proposed labels (if two labels were proposed and one was common we counted that as a positive). Keeping only pairs for which each annotator gave an answer (only half of the pairs), the Kappa was at 0.5, mainly because of agreement on inheritance pairs. Given that a Kappa of 0.5 indicates moderate agreement, even with the lenient setting we provided, the relation types need some clarification. We can still tentatively conclude that the inheritance relation can be annotated, but in the remaining, we only discuss relatedness.

Frame 1	Frame 2
Building	Manufacturing
Evidence	Reasoning
Motion_directional	Path_shape
Cause_motion	Motion
Cause_impact	Cause_motion
Intentional_traversing	Path_shape
Discussion	Statement
Make_cognitive_connection	Relating_concepts
Destroying	Killing
Cause_harm	Cause_to_fragment

Table 2: Top ten true new relations predicted, according to the probability given by the model.

Frame 1	Frame 2
Filling	Removing
Change_position_on_a_scale	Motion
Bringing	Ride_vehicle
Communication	Evidence
Change_position_on_a_scale	Path_shape
Getting_vehicle_underway	Removing
Change_direction	Path_shape
Bringing	Change_direction
Change_direction	Removing
Change_direction	Departing

Table 3: Top ten false positive new relations predicted, according to the probability given by the model.

Both authors adjudicated the differences in the relatedness question, and only pairs with both positive judgments were finally considered positive. Out of the top 100 positive candidates, 63 were labeled as positive by human annotators giving a 63% precision, and 52 out of the 100 selected above the 0.8 threshold, with respectively ± 9.3 and $\pm 9.8\%$ confidence interval. This means a large proportion of proposed frame pairs could be considered for addition, and that proportion does not decrease too quickly when the confidence of the classifier decreases. We cannot estimate recall, as we don't know how many relations there should be overall, but we observed that only 4 pairs out of the distractors were judged positive, which seems to indicate relations are indeed rare with respect to all possible pairs. Note that estimating recall among a subsample of n frames would require a number of judgments equal to $n^2 \times$ the number of relation types. Table 2 and 3 shows a list of top 10 true and false positive relations predicted by our model.

We did an error analysis on the 37 false positive in the top 100 test set, and came to the conclusion that most frame pairs were picked up as related because they involve related lexical units (and often with different senses), rather obviously, and that they involve either (1) co-hyponyms at different levels of granularity; or (2) frame describing opposite events, such as Removing and Filling, which do not correspond to any FrameNet relation. Case (2) is arguably a FrameNet problem, since a lot of frames involve antonyms, and could indicate here missing frames at a higher level up the hierarchy of inheritance, an inconsistency noted in previous work (Hasegawa et al., 2011). As an example the two adjectives *easy* and *difficult* are part of the same Frame DIFFICULTY, while the verbs *empty* and *fill* are in separate frames EMPTYING and FILLING. Case (1) is an interesting perspective for improvement: relations should not be considered between frame pairs in isolation, but with respect to all existing or predicted relations, in a global way. If a frame F_1 is already related to a frame F_2, there should not be a relation between F_1 and, e.g., subframes of F_2. Note also that most Frames that are siblings in a subframe relation also have explicit relations, usually a "Precede" relation (see figure 1), but also vaguer links such as "Using".

5 Conclusion and Future Directions

Our main contribution is to present the first supervised method to provide candidate relations between FrameNet frames, using a rich set of structural and linguistic features inspired by previous unsupervised work which did not provide evaluation with respect to FrameNet's set of relations. A secondary contribution is in showing that Frame relation annotation is possible with good agreement, based only on Frame descriptions, although labeling proves to be more difficult. This also raised the question of the completeness of relation types in FrameNet, or at least the consistency of certain decisions that are made in grouping lexical predicates. As a perspective, we plan to evaluate our model predictions at various levels of confidence, to determine the best compromise between precision and recall when providing relation instance candidates for human validation. It would also be interesting to combine this approach with work on lexical expansion of FN, such as (Pavlick et al., 2015), or use an unsupervised method to

pre-filter candidate pairs, using looser lexical association resources, such as the Moby thesaurus (Ward, 1996).

An interesting perspective given the conclusions of the error analysis would be to try to predict new relations in a global way, using principles on the well-formedness of such ontological/lexical relationships, following the ontological principles given in (Ovchinnikova et al., 2010), or work on lexical taxonomy induction, see e.g. (Navigli et al., 2011).

As mentioned previously, FrameNet does provide a list of FE-to-FE relations for each of the connected frame pairs. In this paper, we have proposed ways to predict new frame-to-frame relations, and we plan to explore the possibilities of automatically linking frame-elements of the newly proposed frame-to-frame relations.

Abstract

This paper introduces a new large-scale n-gram corpus that is created specifically from social media text. Two distinguishing characteristics of this corpus are its monthly temporal attribute and that it is created from 1.65 billion comments of user-generated text in Reddit. The usefulness of this corpus is exemplified and evaluated by a novel Topic-based Latent Semantic Analysis (TLSA) algorithm. The experimental results show that unsupervised TLSA outperforms all the state-of-the-art unsupervised and semi-supervised methods in SEMEVAL 2015: paraphrase and semantic similarity in Twitter tasks.

1 Introduction

A word n-gram is a continuous sequence of n words from a corpus of texts or speech. Word n-gram language models are widely used in Natural Language Processing (NLP), such as speech recognition, machine translation, and information retrieval. The effectiveness of a word n-gram language model is highly dependent on the size and coverage of its training corpus (Clarke et al., 2002). A simple algorithm can outperform a more complicated algorithm if it uses a larger corpus (Norvig, 2008). Many large-scale corpora (Brants and Franz, 2006; Baroni et al., 2009; Wang et al., 2010b) based on web contents have been created for this purpose. As the use of social media is increasing, Online Social Networks (OSNs) have become a norm to spreading news, rumours, and social events (Kwak et al., 2010). This growing usage of social media has created both challenges and opportunities. One major challenge is that social media data is intrinsically short and noisy. A study by (Wang et al., 2010a) revealed that different text corpora have significantly different properties and lead to varying performance in many NLP applications. More importantly, we observe that there is no existing large-scale n-gram corpus that is created specifically from social media text. This has motivated us to create an n-gram corpus that is derived from 1.65 billion comments in the Reddit corpus (Baumgartner, July 2015) and make it available to the research community. There are two main features of this corpus that do not exist in the available large-scale corpora in the literature: monthly time-varying (temporal) and purely social media text. This corpus will allow researchers to analyze and make sense of massive social network text, such as finding corresponding terms across time (Zhang et al., 2015) and improving named entity recognition in tweets (Li and Liu, 2015). Moreover, a cloud-based visualization interface is implemented to allow end users to query any n-gram from the corpus.

Although there are many applications that can be derived from this corpus, in this paper, we use the Paraphrase Identification (PI) and Semantic Similarity (SS) tasks of SEMEVAL 2015 (Xu et al., 2015) to exemplify the usefulness of this corpus. Paraphrases are words, phrases or sentences that have the same meaning, but their vocabulary may be different (Xu et al., 2015). PI and SS tasks have a strong correlation, as both focus on the underlying structural and semantic similarity between two texts (e.g., "selfie" is a paraphrase of "picture of myself"). Improving the results of PI and SS helps to increase the performance of NLP systems, such as statistical machine translation (Madnani et al., 2007) and plagiarism detection (Barrón-Cedeño et al., 2013). PI and SS have been studied intensively for formal

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3553–3564, Osaka, Japan, December 11-17 2016.

text with important results as shown in (Par, 2016). As social media text is usually very short (e.g., 140-character limit for Twitter) and noisy (flexible nature of personal communication), many NLP systems suffer from the large degree of spelling, syntactic and semantic variants, for example, "ICYMI"= "In case you missed it" or "b/c I love u" = "Because I love you". Traditional approaches have been studied intensively and proved not to work well for social media text (Zanzotto et al., 2011). A few preliminary results have shown that the shortness and noisiness of social media text have significantly decreased the performance of PI (Zanzotto et al., 2011; Xu et al., 2013) and SS tasks (Guo and Diab, 2012; Dang et al., 2015a). In this paper, we proposed a Topic-based Latent Semantic Analysis (TLSA) approach for the SS task, which assigns a semantic similarity score between two social media texts. Next, we use this similarity score to determine if two texts are a paraphrase of each other.

Latent Semantic Analysis (LSA) has been widely used for semantic text similarity tasks because of its simplicity and efficiency (Landauer et al., 1998). LSA has been used as a strong benchmark in the Microsoft Research sentence completion challenge (Zweig and Burges, 2011) and its baseline has outperformed a few state-of-the-art neural network models (Mikolov et al., 2013). However, LSA has its own drawbacks. Its models are trained on a large corpus where words in the same document have a stronger relationship. This does not consider how close two words are in a text ("apple" and "fruit" are closer in the 5-gram "apple is a fruit" instead of a whole document) (Hofmann, 1999). Another example is two topics "Barack Obama" and "Hillary Clinton" have a different meaning in two contexts "2012 US presidential race" and "2016 US presidential race". In the first one, they are opponents, while in the second one, "Barack Obama" endorsed "Hillary Clinton". In addition, LSA is usually trained on a whole corpus. This makes it not scalable with an intrinsic, dynamic, and large-scale nature of social network data. To address this issue, we proposed an approach to train an LSA model that considers the topic being discussed. This proposed LSA model is trained on word 5-grams instead of whole documents. The proposed TLSA method achieved the best result for the SS task and is more scalable compared to other LSA models. Combining TLSA with sentiment analysis, the proposed approach also achieved the best result for PI task in SEMEVAL 2015. These are the contributions of our paper:

1. We create a new word n-gram (1-5) social network corpus from 1.65 billion comments of Reddit[1]. This corpus has two distinctive characteristics that are useful for social media applications: temporal and large-scale social media text.

2. We implement a cloud-based visualization interface so that end users can query and analyze the social media n-grams in real time.

3. We propose TLSA[2], a Topic-based Latent Semantic Analysis model that is trained on word 5-grams from social media text. To the best of our knowledge, there is no similar work that employs a topic-based approach using LSA for PI and SS tasks for social media text.

4. We combine TLSA with sentiment analysis, which outperforms the state-of-the-art unsupervised and semi-supervised methods in SEMEVAL 2015: Paraphrase and Semantic Similarity in Twitter tasks.

2 Related Work

2.1 Corpus-Based algorithms

Corpus-based machine learning algorithms have an advantage over knowledge-based ones as they do not involve in human which can be expensive. The Google web 1T n-gram corpus (Brants and Franz, 2006) included all words appearing on the web in January, 2006 and is available in English and 10 European Languages (Brants and Franz, 2009). This corpus has been used for text relatedness (Islam et al., 2012) and linguistic steganography (Chang and Clark, 2010). The WaCky corpus of more than one billion

words from three languages, English, German, and Italian was introduced in 2009 by (Baroni et al., 2009). It has been used in bilingual lexicography (Ferraresi et al., 2010) and translators (Pecina et al., 2012). In 2010, Microsoft Web n-gram corpus provided all the word n-grams that are indexed by Bing search engine and provided through an XML web service (Wang et al., 2010b). Some notable usage includes textbox enriching (Agrawal et al., 2010) and social media language study (Liu et al., 2012). Google Book n-gram corpus (Michel et al., 2011), introduced in 2012, includes all word n-grams found in Google book corpus from 1505 to 2008. Due to its yearly temporal characteristics, it has been used to study the changing psychology of culture (Greenfield, 2013), concepts of happiness (Oishi et al., 2013), and mapping book to time (Islam et al., 2015). Twitter n-gram corpus (Herdağdelen and Baroni, 2011) only provides a small subset of social media n-grams in Twitter. As Twitter does not allow researchers to share full text of Tweets as a large corpus, it is not possible to collect, create and share terabyte-scale n-gram corpus for Tweets. Unlike Twitter, Reddit implements an open data policy and users can query any posted data on the website. Although OSNs have been studied intensively in recent years, there is no existing corpus that could be shared and provide insights from massive social network text. To the best of our knowledge, this new corpus is the first large-scale n-gram corpus that provides n-grams with a temporal feature (monthly) that is designed specifically for massive user-generated social media text.

2.2 Paraphrase Identification and Semantic Similarity

A summary of all the existing state-of-the-art paraphrase identification algorithms for traditional texts (e.g., newswire) using the Microsoft Research Paraphrase Corpus (MRPC) is in (Par, 2016). Although supervised approaches, such as typical machine learning classifiers using various feature sets (Das and Smith, 2009; Ji and Eisenstein, 2013) and semantic text similarity (Blacoe and Lapata, 2012; Madnani et al., 2012), achieved the best results, unsupervised methods using explicit semantic space (Hassan and Mihalcea, 2011), vector-based similarity (Milajevs et al., 2014), and WordNet similarity with matrix (Fernando and Stevenson, 2008) also attained comparable results. With the increasing popularity of OSNs, researchers started to focus on the importance of developing paraphrase identification for social media text (Zanzotto et al., 2011; Xu et al., 2013; Guo and Diab, 2012). The results and findings support the hypothesis that informal language in social media with a high degree of lexical variations has posed serious challenges to both tasks. In this paper, our focus is not the general PI or SS tasks but concentrates on the domain of social media.

The SemEval-2015 task 1 is the first competition that focuses on Paraphrase Identification and Semantic Similarity for social media text. There were 19 and 14 teams that participated in the PI and SS tasks, respectively. Most teams used supervised approach, for example, typical machine learning classifiers (Eyecioglu and Keller, 2015), neural networks (Xu et al., 2015), align and penalize architecture, semantic relatedness (van der Goot and van Noord, 2015). Two teams used unsupervised approaches (Orthogonal Matrix Factorization (Guo et al., 2014) and pre-trained word and phrase vectors on Google News dataset (Xu et al., 2015)) and one team uses semi-supervised approach that combines several word measures built from Rovereto Twitter n-gram corpus (Herdağdelen and Baroni, 2011). Our proposed approach will be compared and evaluated against these unsupervised and semi-supervised approaches.

Lately, large corpora are being used for the machine learning tasks. LSA has been widely used for paraphrase identification and semantic text analysis (Hassan and Mihalcea, 2011). (Guo and Diab, 2012) proposed Weighted Textual Matrix Factorization (WTMF), which is a novel latent model that captures the contextual meanings of words in sentences based on internal term-sentence matrix. This model uses both knowledge-based and large-scale corpus-based techniques to learn word representation. Our work uses the new corpus and introduces a novel approach to learn word representation that is dependent on the topic being discussed.

3 The New Reddit Temporal N-gram Corpus

We have created a word n-gram (1-5) corpus of 1.65 billion Reddit comments from October, 2007 until August, 2016 (Baumgartner, July 2015) using high performance distributed processing models on a cluster of 256 nodes with 16TB of shared memory. Most of the comments are in the English language.

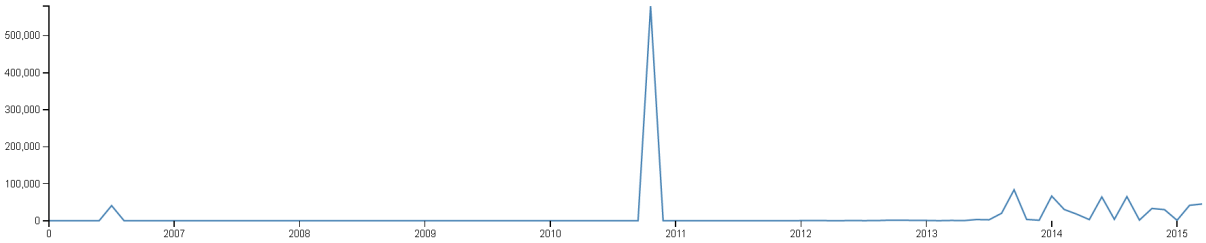

Figure 1: The frequency count of unigram "ISIS" in Reddit from 2007 to 2016. The x-axis represents the year while the y-axis shows the frequency count per month. The highest peak in the graph represents the rise of "ISIS" in October, 2010 following the outbreak of the Syrian Civil War in August, 2010.

Each comment is separated into sentences, and each sentence is tokenized using Lucence (Apache). All the comments are lowercased. The Reddit comments are close to 2TB of text containing 135 billion sentences.

Each entry in the Reddit temporal n-gram corpus is an n-gram (1-5) and its frequency, month, and year from October, 2007 to August, 2016. The size of the corpus is 2.6 TB uncompressed. We show an example of each n-gram (1-5) in Table 1. This corpus can be accessed through downloadable files and a JSON web service which will return the frequency of an n-gram for each month. In addition, we implement a cloud-based visualization interface so that end users can query and analyze the social media n-grams in real time as shown in Figure 1. As our n-gram corpus is time-dependent, we also count the total number of occurrences of each n-gram for comparison with other corpora. A detailed statistical comparison between the new corpus and some other existing corpora is shown in Table 2. Although Microsoft Web n-gram is the largest n-gram corpus, they do not provide all the data to end users. Analyzing the whole Microsoft n-grams corpus is not practical through an XML web service. The Reddit temporal n-gram corpus is much larger than the Google Web 1T n-gram corpus. One of the reasons is that Google Web 1T n-gram corpus only keeps unigrams with more than 200 frequency counts and other n-grams with more than 40 frequency counts. After analyzing the Google Web corpus, we found that although our corpus has a larger vocabulary than the Google one, the frequency count for each n-gram is lower. This confirms the noise and shortness hypothesis of social media text. We decide to keep all the raw n-grams of the new corpus to preserve these characteristics of social media text. We illustrate in Figure 2 how the Reddit temporal n-gram corpus shows the evolution of the word "ISIS".

(a) (b)

Figure 2: An example of word cloud showing the context words of "ISIS" in the 5-grams of the corpus before and after August, 2010. a) "ISIS" is mainly discussed as an Egyptian god before August, 2010, b) "ISIS" means the Islamic State in Iraq and Syria after August, 2010.

Table 1: Examples of n-grams (1-5) of the newly created corpus about the topic "Donald Trump". Each entry includes the word (n-gram), its frequency, its month, and its year from October 2007 to August 2016.

Reddit temporal n-gram corpus	word	frequency	year	month
1-gram	trump	981	2015	01
2-gram	trump apprentice	31	2015	01
3-gram	donald trump battle	16	2015	01
4-gram	donald trump ignorant tweet	8	2015	01
5-gram	take donald trump advice in	2	2015	01

Table 2: Statistical comparison between Reddit temporal n-gram corpus and its counterparts.

Corpus	1-gram	2-gram	3-gram	4-gram	5-gram
Google web 1T n-gram corpus	13.5M	314M	977M	1.3B	1.12B
Microsoft web n-gram corpus	1.2B	11.7B	60.1B	148.5B	237B
Reddit temporal n-gram corpus	170.2M	1.2B	6.7B	18.4B	30.1B

4 Topic-based Latent Semantic Analysis

We first formulate the approach for TLSA. Consider a list of topics $T = \{T_1, T_2, ..., T_l\}$ and each topic T_i has a list of pairs of Tweets $P = \{(t_{11}, t_{12}), (t_{21}, t_{22}), ..., (t_{m1}, t_{m2})\}$ where each pair is evaluated for PI and SS tasks. For each topic T_i, we construct a list of unigrams $O = \{o_1, o_2, ..., o_p\}$ from P and a list of 5-grams $F = \{f_1, f_2, ..., f_q\}$ from Reddit temporal n-gram corpus where f_i contains the topic T_i. Next, we construct the unigram/5-gram matrix X from O and F.

$$X = \begin{bmatrix} x_{11} & x_{12} & x_{13} & \dots & x_{1q} \\ x_{21} & x_{22} & x_{23} & \dots & x_{2q} \\ \dots & \dots & \dots & \dots & \dots \\ x_{p1} & x_{p2} & x_{p3} & \dots & x_{pq} \end{bmatrix}$$

where each row r_i represents the occurrence of a unigram term u_i to all 5-grams in F and x_{ij} describes the occurrence of unigram o_i in a 5-gram f_j plus the frequency of the 5-gram f_j in the Reddit temporal n-gram corpus. This matrix considers both the relation between a word with other words in a 5-gram and with the frequency of this 5-gram in the corpus. Next, we decompose matrix X using a Singular Value Decomposition (SVD):

$$X = U\Sigma V^T$$

$$= \begin{pmatrix} u_1 & \cdots & u_r & u_{r+1} & \cdots & u_p \\ | & & | & | & & | \\ | & & | & | & & | \\ \underbrace{\qquad\qquad}_{\text{col}(A)} & & & \underbrace{\qquad\qquad}_{\text{null}(A)} & & \end{pmatrix} \begin{pmatrix} \sigma_1 & & & & & \\ & \ddots & & & & \\ & & \sigma_r & & & \\ & & & 0 & & \\ & & & & \ddots & \\ & & & & & 0 \end{pmatrix} \begin{pmatrix} \text{---} & v_1^T & \text{---} \\ & \cdots & \\ \text{---} & v_r^T & \text{---} \\ \text{---} & v_{r+1}^T & \text{---} \\ & \cdots & \\ \text{---} & v_q^T & \text{---} \end{pmatrix} \begin{matrix} \\ \\ \} \text{row}(A) \\ \\ \\ \} \text{null}(A) \\ \\ \end{matrix}$$

where Σ is a diagonal matrix that contains the singular values in descending values. U and V are orthogonal matrices that contain the left and right singular vectors respectively.

Next, for each sentence s_i in topic T_i, we construct a vector $\vec{v}$ which represents the occurrence of s_i in the list of unigrams of topic T_i. This vector is translated into a sentence vector representation by the following formula:

$$\vec{v} = \vec{v} * U_k * S_k$$

where k is the chosen k singular values which show the dimensions with the greatest variance between words and documents (the value of k is explained in Section 6.3). Finally, the semantic similarity between two sentences is calculated using the cosine similarity between their vectors.

Due to the enormous size of the Reddit temporal n-gram corpus, selecting the related 5-grams for each topic is not feasible using a traditional relational database system. We tried to load our data into IBM Netezza data warehouse but the query time was not reasonable for a real-time system. We load all the corpus data to Google Bigquery. For each topic T_i, we query all the related 5-grams f_i using Google Bigquery regular expression "word like $(\%T_i\%)$" where $\%$ represents the wild card search. After constructing matrix X, we use Microsoft Azure Apache Spark for SVD decomposition. A summary of the proposed approach is shown in Figure 3.

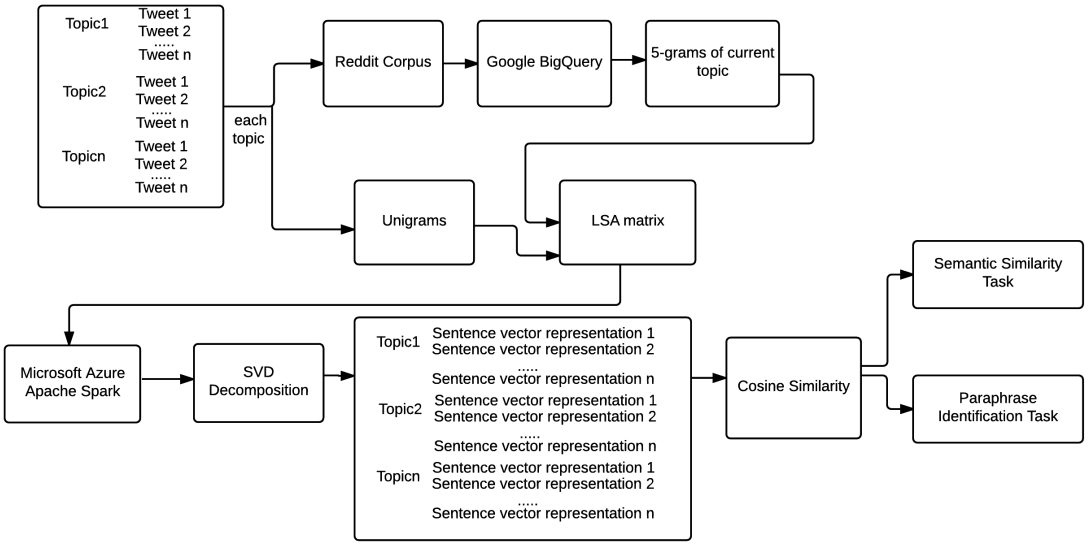

Figure 3: The proposed Topic-based Latent Semantic Analysis using distributed parallel computing, Google BigQuery, and Microsoft Azure Apache Spark. The semantic similarity between two sentences is computed with regard to a specific topic being discussed in two sentences.

5 Evaluations of Paraphrase Identification and Semantic Similarity for Social Media Text

To evaluate the performance of TLSA algorithm, we use the PIT-2015 Twitter dataset (Xu et al., 2014). Although this approach uses PIT-2015 dataset for evaluation, it can be extended to any general topic-based datasets. The PIT-2015 dataset includes 17,790 sentence pairs for training and 972 test sentence pairs which were annotated and developed by (Xu et al., 2014). The dataset was constructed from Twitter data and has intrinsic characteristics from social network data: (i) opinionated and colloquial sentences from realistic social media text; (ii) lexically diverse pairs of sentences for paraphrases; and (iii) sentences that seem lexically similar but semantically dissimilar (Xu et al., 2015). Example pairs of sentences for paraphrase, non-paraphrase, and debatable cases are shown in Table 3. The detailed statistics of this ground-truth dataset is shown in Table 4. Each sentence is processed with tokenization, part-of-speech and named entity tags and each sentence pair is annotated by experts. In the test set, there

Table 3: Examples of Paraphrase Identification and Semantic Similarity sentence pairs. All three sentence pairs are about the movie "8 Mile" which is a topic for TLSA. A sentence pair is a paraphrase if its Pearson Correlation score is above 0.6. A sentence pair is a non-paraphrase if its Pearson Correlation score is below 0.6. A sentence pair is debatable if its Pearson Correlation score is equal to 0.6.

Topic	Paraphase	Sentence 1	Sentence 2
8 mile	True	The Ending to 8 Mile is my fav part of the whole movie	Those last 3 battles in 8 Mile are THE shit
8 mile	False	All the home alones watching 8 mile	The last rap battle in 8 Mile nevr gets old ahah
8 mile	Debatable	8 mile is just a classic	After watching 8 mile I feel like such a thug

are 972 sentence pairs collected from Twitter in 20 trending topics between May 13th and June 10th, 2013. As mentioned in (Das and Smith, 2009), some algorithms may work well specifically for MRPC because of its imbalanced nature (lack of non-paraphrases). PIT-2015 Twitter dataset is more balanced as it contains 70% non-paraphrases and the 34% paraphrases.

Table 4: PIT-2015 Twitter dataset. The test data is more balanced than MRPC as it has a higher percentage of non-paraphrase sentence pairs. The unsupervised TLSA only uses the test data for evaluation.

	Sent Pairs	Paraphase	Non-paraphrase	Debatable
Train	13063	3996 (30.6%)	7534 (57.7%)	1533 (11.7%)
Test	972	175 (18.0%)	663 (68.2%)	134 (13.8%)

5.1 Task 1 - Paraphrase Identification and Evaluation Metrics

For a specific topic, given two sentences, the system has to determine if two sentences have the same or similar meaning and discuss the same topic. For two non-paraphrase sentence pairs, the sentence pair discussing the same topic has a higher score than the sentence pair discussing an unrelated topic. Precision, recall, and F1 (harmonic mean of precision and recall) are used as evaluation metrics.

5.2 Task 2 - Semantic Similarity and Evaluation Metrics

For a specific topic, given two sentences, the system has to give a score between 0 (no relation) and 1 (semantic equivalence) to represent their semantic equivalence. For two sentence pairs, the sentence pair discussing the same topic has a higher semantic similarity score than the sentence pair discussing an unrelated topic. Pearson correlation is used as an evaluation metric.

6 Evaluation

6.1 Baselines

We used first two baselines from (Xu et al., 2015) and introduced two new baselines that are more related to the proposed corpus-based and topic-based LSA.

Random: Each sentence pair is assigned a random real semantic similarity score between [0, 1]. For PI task, this baseline applies 0.5 as a cutoff (paraphrase if semantic similarity score is above 0.5).

Weighted Matrix Factorization (WTMF): This baseline uses the state-of-the-art unsupervised method of (Guo and Diab, 2012). It not only considers the semantic space of words presenting in the data but also missing words from the sentences. This feature is designed specifically for short texts in social media. Finally, the value 0.5 is used as a cutoff for the PI task.

Random 5-gram: This baseline determines whether introducing the use of topics in LSA improves the accuracy of both PI and SS tasks for SEMEVAL 2015. To construct matrix X, we select random

5-grams from the Reddit temporal n-gram corpus with the same size of the 5-grams that contain the topic.

Google Tri-gram Method (GTM): Google Tri-gram Method (Islam et al., 2012) assigns a semantic similarity score between two sentences using the unigrams and trigrams of the Google Web 1T corpus. We also use 0.5 as a cutoff for the PI task.

6.2 SEMEVAL 2015 Unsupervised and Semi-supervised Methods

Columbia: This method used Orthogonal Matrix Factorization to compute a representation vector for each sentence (Guo et al., 2014) and then computes a similarity score based on these vectors (Xu et al., 2015).

Yamraj: This method learned sentence vectors from Google News dataset (about 100 billion words) and Wikipedia articles. Cosine distance is used to compute the vector similarity scores.

MathLingBp: This method exploits the use of the align-and-penalize architecture of (Han et al., 2013) and adopts the use of several word similarity metrics using a semi-supervised approach (Xu et al., 2015).

6.3 Experimental Results

First, we compare the performance of TLSA with various parameters, such as the number of singular values and the dimensionality of the 5-grams. For SS task, we achieved the best result for SS task when the singular value k is equal to 80 with an increasing 5-gram dimensionality size as shown in Figure 4. In addition, for SS task, the Pearson correlation is not improving when the number of 5-grams is above 1M.

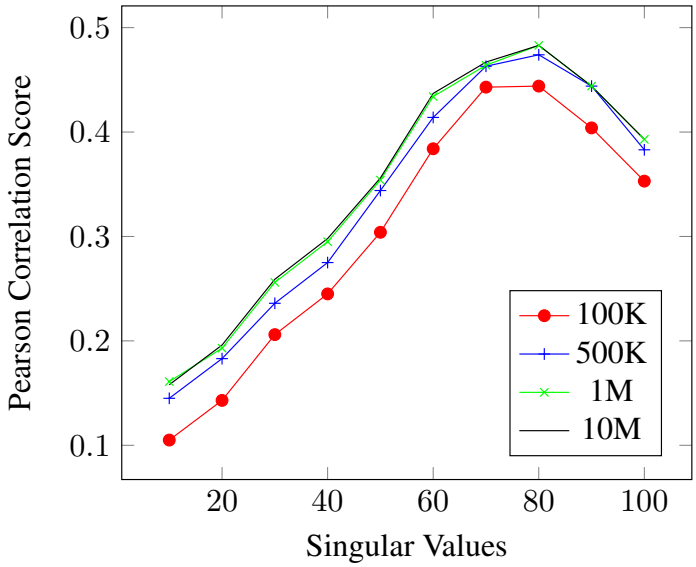

Figure 4: For SS task, Pearson correlation score with an increasing singular values and 5-gram dimensionality. TLSA achieves the best Pearson correlation score for k = 80 and the dimensionality of 5-grams = 1M.

6.3.1 Topic-based LSA versus Baselines and other Methods

This section compares the proposed approach with the baselines and SEMEVAL 2015 unsupervised and semi-supervised methods. As shown in Table 5, TLSA achieved the best result for the SS task (Pearson correlation) compared with all the baselines and compared methods. This means that training an LSA model using topic-based 5-gram helps increase the result of PI and SS tasks. For the PI task, observing that the semantic similarity scores for sentence pairs are either very high or very low, we tried two cutoffs 0.25 and 0.5 (SEMEVAL 2015 allows two runs per team) and TLSA outperforms all the baselines. With a low cutoff value, TLSA achieves a high precision and a low recall. To improve the PI results, we assumed that two sentences are paraphrases only if they have the same sentiment scores

(e.g., both are positives or negatives). Based on this assumption, each sentence is assigned a sentiment score using OpenNLP. Adding sentiment analysis to TLSA (i.e., TLSA & Sentiment) outperforms all the baselines and compared methods. Another important observation is that although our unsupervised approach achieves the best results against the baselines and compared methods, its results are still not comparable with human upperbound. This means that improving the results of PI and SS tasks for social media text using an unsupervised approach is still a challenge for researchers.

Table 5: TLSA results with other baselines and compared methods. Combining TLSA with sentiment analysis achieves the best result for both PI and SS tasks.

Methods / *Baselines*	Paraphrase Identification			Semantic Similarity			
	F1	Precision	Recall	Pearson	maxF1	maxPrec	maxRecall
Human Upperbound	0.823	0.752	0.0908	0.735	–	–	–
TLSA & Sentiment	**0.591**	0.764	0.480	**0.483**	0.582	0.761	0.472
COLUMBIA	0.588	0.593	0.583	0.425	0.599	0.623	0.577
TLSA	**0.585**	0.761	0.474	**0.483**	0.585	0.761	0.474
YAMRAJ	0.496	0.725	0.377	0.360	0.542	0.502	0.589
WTMF	0.536	0.450	0.663	0.350	0.587	0.570	0.606
Random 5-gram	0.504	0.716	0.389	0.466	0.564	0.824	0.429
GTM	0.495	0.391	0.674	0.371	0.582	0.761	0.472
Random	0.266	0.192	0.434	0.017	0.350	0.215	0.949

7 Conclusions

In this paper, we introduced Reddit temporal n-gram corpus, which is designed specifically for social media text. We create the corpus using distributed parallel computing and implement a cloud-based visualization interface so that end users can query any n-grams from the corpus. Both the corpus and the interface are publicly available in this URL - Reddit n-gram temporal corpus. This large-scale terabyte corpus includes all the word unigram to 5-gram, and their frequency per month from October, 2007 to August, 2016.

To show the usefulness of this corpus, we propose a novel Topic-based Latent Semantic Analysis approach which exploits the 5-grams of the corpus. The proposed TLSA outperforms all the state-of-the-art unsupervised and semi-supervised methods in SEMEVAL 2015 Task 1 - Semantic Similarity for the PIT-2015 dataset. Combining with sentiment analysis, the proposed approach also achieves the best result for the Paraphrase Identification of SEMEVAL 2015 Task 1. In addition, TLSA is language-independent and scalable for the large-scale nature of social media text.

For future work, we aim to use this corpus to study the linguistic patterns of social media text, for example, finding the meaning of new words in social media. In addition, we plan to integrate this proposed semantic similarity score into our existing work to improve the results of meme clustering tasks (Dang et al., 2015b) and rumour detection and visualization framework (Dang et al., 2016).

Dictionaries as Networks: Identifying the graph structure of Ogden's Basic English

Camilo Garrido and **Claudio Gutierrez**
Center for Semantic Web Research & Department of Computer Science,
Universidad de Chile
{cgarrido, cgutierr}@dcc.uchile.cl

Abstract

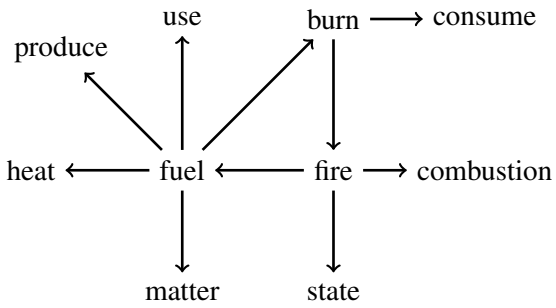
We study the network structure underlying dictionaries. We systematize the properties of such networks and show their relevance for linguistics. As case of study, we apply this technique to identify the graph structure of Ogden's Basic English. We show that it constitutes a strong core of the English language network and that classic centrality measures fail to capture this set of words.

1 Introduction

Dictionaries are rich sources to investigate the semantic structure of natural language. The purpose of dictionaries, writes Wilks et al. (1993), "is to provide definitions of senses of words and, in so doing, supply knowledge about not just language, but the world." The definition of a word involves recursively new words, and thus, new senses and meanings. In this way, a dictionary can naturally be viewed as a network where each word w is related to the set of words $w_1, \ldots, w_n$ that define it: for each word w so defined, consider the relationship $w \to w_i$ for each $i = 1, \ldots, n$, and proceed recursively with all the entries of the dictionary. The idea is not new and was already proposed by K. C. Litkowski (1978).

Clearly this basic idea must be refined. There are words that are in inflected form (e.g. verbs); that are the same but have different meanings (e.g. singer: the machine, the musician, etc.); that are in plural or singular; that are the same adjective with different gender, etc. In order to make the network conceptually coherent, one should define classes of words; for example, all the inflected forms of the verb "play" define one class whose representative is the word "play". There are several other simple processing decisions to be made. This naive version can be further refined by incorporating more elaborated linguistic features, like labeling the edges according to parts of speech to which they point, *e.g.* nouns, verbs, adjectives, adverbs, etc., or giving different nodes and weights to different meanings of a word, and so on. The surprising fact is that even using a naive approach, the network obtained gives highly relevant and interesting information about the language. See Figure 1 for a small example.

Although the idea of using mathematical and computational tools to capture the semantics information in dictionaries has been broadly explored (Amsler, 1980; Calzolari, 1984; Wilks et al., 1988), the idea



FIRE: Fuel in a state of combustion.

FUEL: Any matter used to produce heat by burning.

BURN: To consume with fire.

Figure 1: Entries in the dictionary for the words *burn*, *fire*, and *fuel*, and their corresponding subgraph built from them.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3565–3576, Osaka, Japan, December 11-17 2016.

of exploiting the inherent network structure of dictionaries has not been pursued systematically. As we mentioned, the idea was proposed several decades ago (Litkowski, 1978), but only recently, with the explosion of network studies and hardware availability, there have been some works in this direction (we discuss them in the Related Work section).

The aim of this paper is to provide evidence of the fruitfulness of studying dictionaries as networks. We show that dictionaries (in general) have similar structure from the point of view of networks, and as expected, their structural properties differ from networks obtained from other areas. We claim that dictionary networks have particular properties (strong connectivity, resilience, component analysis, etc.) that shed light on the structure of the languages and deserve to be studied in depth. We found out that classical tools for studying and analyzing networks –particularly those popularized by Social Network Analysis (Wasserman and Faust, 1994)– like centrality measures, subgroups, affiliation, etc. are not always meaningful in this new realm, and that their successful application to this linguistic setting requires to be reworked. For example, it is not evident that they help capturing notions such as "most relevant" or "non-relevant" words in a dictionary that are important, for example, for building small dictionaries, basic sets of words for beginners, etc.

In order to test these and other ideas in practice we chose as a study case *Ogden's Basic English*, a set of 850 words selected by the linguist C. K. Ogden to serve as a basic language (Ogden, 1930) . In order to study it from a network point of view, we built a network out of an English dictionary. We chose the *Online Plain Text English* (OPTED) because it is reliable, contains 94.5% of Ogden's words, and is open data, thus, allowing anyone to replicate our experiments. We then applied different graph-theoretical notions and techniques to this network, aiming to capture Ogden's set of words.

Our study shows, using *only* graph-theoretical tools, that Ogden's set of words is part of a strongly connected core of the English dictionary, a subset of words that directly use each other in their definitions. We then show that it is not formed by the "most central" words (according to classic ranking measures), but by a combination of high ranked words plus others that play the role of "covering" the rest of the network, that is, being "close" to most words in the dictionary.

The main contribution of our work is to add evidence about the value of using dictionary networks to study linguistic properties of languages.

2 Related Work

The community agrees that dictionaries are a source of lexical knowledge (Calzolari, 1984; Dolan et al., 1993). This knowledge can be used for the development of NLP techniques, establishing usage relation between words or hierarchy relations like hypernyms or "part_of". They also can be used for the creation of pocket dictionaries and many other applications.

One of the first uses of dictionaries was to develop Machine-Readable Dictionaries (Zingarelli, 1970) (MRDs). With MRDs and the concept of lexical databases, the importance of the information and knowledge that dictionaries contain began to gain attention. Amsler(1980) presents some efforts to exploit dictionaries and extract information for applications in computational linguistics. He investigates the possibility of building of taxonomies based on the structure of the definition of words. He also offers some insight on the frequency of the vocabulary and semantic ambiguity. Calzolari (1984) detects some patterns among lexical entries: hyponyms and restriction relations. Later, Calzolari et al. (1988) focused their efforts on extracting semantic information from dictionaries. They state "The dictionary is now considered as a primary source not only of lexical knowledge but also of basic general knowledge". They parse the entries and try to organize the knowledge with functions like Hypernym, Relation, Qualifier, etc. Wilks et al.(1988) discuss the importance of dictionaries for NLP tasks, in particular, the value of transforming machine readable dictionaries (MRDs) into machine tractable dictionaries (MTDs). They show three approaches for this: Obtaining and using co-occurrence statistics, producing a lexicon and extracting a Key Defining vocabulary.

At the same time MRDs began to get attention, so did modeling the dictionaries as networks. K. C. Litkowski (1978) was one of the first to state the importance of studying and exploiting dictionary networks, both as sources of material for natural language and to unravel the complexities of meaning.

He presented three models to represent a dictionary. The first model uses nodes to represent words and edges to represent the relation w_a *"is used to define"* w_b. The second model extends the first one, adding relations between words and senses. In the third and final model, nodes represent concepts and edges represent different relations between them (senses, part of sentence, etc). Definitions are broken down into subphrases. For example, "Broadcast: the act of spreading abroad" may be broken into "the act", "of", "spreading abroad", where these subphrases may be broken into smaller pieces.

After the seminal this work of Litkowski (1978), several researchers have used dictionary networks to study or extract information about the language.

Dolan el al.(1993) developed an automatic strategy to exploit dictionaries to construct a source of lexical an common sense information based on *hypernyms*, *locations*, *part_of*, and other relations. Although a network can be formed with those relations, the methods of the system to extract such relations between words is not clear. Picard et al.(2009) address the following question: "How many words do you need to know in order to be able to learn all the rest from definitions?" They approach this question representing dictionaries as networks. Levary et al.(2012) show that if we follow the definition of a word over and over, one typically finds that definitions loop back upon themselves. They also show that the loop is an essential element of the growth process of networks. They showed that words within these loops tend to be introduced into the English language at similar times. And, the evolution of these networks follow the "rich-get-richer" growth. Mihalcea(2004a) used networks derived from WordNet to test disambiguation.

There are other forms of building networks of words and using graph ideas in word analysis, *e.g.* co-occurrence of words in certain windows (bigrams, etc.) (Dorogovtsev et al., 2001; Mihalcea, 2004b).

Finally, there is a line of research that investigates the relationship between semantic networks and graph measures. Abbott et al. (2012) compare the functioning of the human mind when searching for memories with a random walk in a semantic network. They conclude results that can help clarify the possible mechanisms that could account for PageRank predicting the prominence of words in semantic memory. Yeh et al. (2009) used random walks to determine the semantic relatedness between two elements. They conclude that random walks performed with personalized PageRank is a feasible and potentially fruitful means of computing semantic relatedness for words and texts. Hughes et al. (2007) introduce a new measure of lexical relatedness based on the divergence of the stationary distributions computed from random walks over graphs extracted from WordNet. Steyvers and Tenenbaum (2005) conjecture about semantic networks stating that "these structures reflect the mechanisms by which semantic networks grow." All of these works served as sources of inspiration for our research.

3 Dictionaries as Networks

> "Ordinary dictionaries have not been given their due, either as sources of material for natural language understanding systems or as corpora that can be used to unravel the complexities of meaning and how it is represented. If either of these goals are ever to be achieved, I believe that investigators must develop methods for extracting the semantic content of dictionaries (or at least for transforming it into a more useful form). [...] A suitable framework appears to be provided by the theory of labeled directed graphs (digraphs)." (Litkowski, 1978).

If words are viewed as basic building blocks of more complex meaning structures, the network of their relationships can be considered as the skeleton that holds them together. Dictionaries are one of the primary sources to obtain such skeletons of meaning.

A network (or graph: both used synonymously) is defined by the nature of its nodes and the of relationships that connect its nodes. A dictionary viewed as a network on the lines we explained above, gives rise to different types of nodes and edges. Nodes have types of n.; n.pl.; a.; v.; v.t.;v.i.; adv.; etc. Edges also can be of different types, according the role or the place of the word in the definition. For example, consider the following three entries of the word "act", each with a different type:

Act (n.) A formal solemn writing, expressing that something has been done.

Act (v. i.) To exert power; to produce an effect; as, the stomach acts upon food.

Act (v. t.) To perform; to execute; to do.

Also, the words occurring in these definitions play different grammatical roles, can occur more than once, etc. All of these features should be included in a faithful network of a dictionary, ideally one from which one can reconstruct the dictionary (see some insights in (Litkowski, 1978)).

On the other extreme, one can build a simple (naive) network without any typing on nodes and edges, that is, just words pointing to words represented in some standard form (e.g. lemmatized). There is a compromise between these two extreme approaches: as usual, the simpler the better (for network analysis, more tools available; for comparison with other fields, particular features do not help) at the cost of losing some subtle linguistic properties. In what follows we develop the simplest possible approach, with the idea of showing the potentialities of the method, and hoping to keep enhancing this baseline with further linguistic annotations.

3.1 Building the Basic Network

For this work we implemented the following procedure to build the networks:

1. Model or Design. Consider all types of words as a single type: forget if they were nouns, verbs, adverbs, etc. Merge the entries that correspond to the same word into one definition, e.g. *Singer (n.) A machine for sewing cloth.* and *Singer (n.) One who, or that which, singes*. Forget the role and place of occurrence of a word, as well as its number of occurrences, inside a sentence (i.e. transform the defining text of a word in a set of words).

2. Clean. Remove the terms that are inflected forms, e.g *singing: from Sing*. Remove prepositions and articles. They appear too often in any text, so they would add noise to the graph. Lemmatize each word occurring in the definitions (transform nouns into singular; verbs into the infinitive; adjectives into their male singular form). Remove any word that does not appear in the dictionary, *e.g.* prefixes and suffixes like *Ex-* and *-able*.

3. Mathematical model of the dictionary. Build the graph over the previous data. At this point, the dictionary D has become a universe of words W and a set of pairs $(w, \mathrm{def}(w))$, where $w \in W$ is an entry in D and $\mathrm{def}(w) \subseteq W$ is the set of words occurring in the definition of w.

4. Build the Network. From the data in (3), construct a directed graph $G = (V, E)$, where the nodes are $V = \{w|(w, S) \in D\}$ and the edges $E = \{(w, w')|(w, S) \in D \text{ and } w' \in \mathrm{def}(w)\}$. For example, from the entry "*Eaglet (n.) A young eagle, or a diminutive eagle.*" we get the edges *(Eaglet,young), (Eaglet, eagle)* and *(Eaglet, diminutive)*.

The OPTED dictionary. We applied the above methodology to the *The Online Plain Text English Dictionary*[1] (OPTED) and the *Diccionario de la Real Academia Española*[2] (DRAE, Royal Spanish Academy Dictionary). We chose OPTED because is a public and free-access dictionary, based on Webster's Unabridged Dictionary, and an important and recognized dictionary. On the other hand, we chose DRAE because it is the most authoritative dictionary of the Spanish language. The first edition of the DRAE was published in 1780, and the current, twenty-third edition, was published in 2014.

The OPTED network has 95,095 nodes and 979,523 edges. The nodes are composed of 58,750 nouns and 12,261 verbs. The remaining 24,084 nodes correspond to adjectives and adverbs. The RAE network has 89,767 nodes and 1,152,301 edges. The nodes are composed of 54,767 nouns and 12,046 verbs. The remaining 22,954 nodes correspond to adjectives and adverbs.

To make a good description of the dictionary network, we analyzed its different features. First, we present a set of basic properties and compare them to other kinds of networks (social, information, etc.). Second, we show a component analysis. And third, we present other characteristics obtained with graph machinery.

3.2 Dictionary Networks compared to other networks

We do the comparison with other types of networks based on classic parameters used to describe networks (Newman, 2003). Table 1 shows basic parameters for three different dictionary networks, and another three networks built by humans.[3]

[1] `http://www.mso.anu.edu.au/~ralph/OPTED/`

[2] `http://www.rae.es/`

[3] We use *igraph* `http://igraph.org/` as network analysis package and Stanford CoreNLP(2014) for lemmatizing the words in the dictionary.

	n	m	z	l	α	$c1$	$c2$	r
OPTED	95 095	979 523	20.601	4.64	2.63 / 3.13	0.009	0.217	-0.0081
DRAE network	89 767	1 152 301	25.673	3.26	2.39 / 2.74	0.044	0.201	-0.0092
WordNet	84 967	1 134 957	26.715	2.99	2.84 / 2.99	0.029	0.203	-0.0157
ca-HepPh	11 204	235 268	41.997	4.67	1.76 / 1.76	0.659	0.690	0.630
cit-HepTh	27 400	352 542	25.733	4.28	2.72 /4.14	0.120	0.329	0.002
p2p-Gnutella04	10 876	39 994	7.355	4.64	- /3.55	0.005	0.008	-0.0083

Table 1: Basic measures for networks. OPTED is an English dictionary network. DRAE is a Spanish dictionary network. WordNet is a dictionary network built from WordNet. ca-HepPh is a collaboration network from the e-print arXiv. cit-HepTh is the Citation graph from the e-print arXiv. p2p-Gnutella04 is a sequence of snapshots of the Gnutella peer-to-peer file sharing network. Details for the last three networks are in (Leskovec, 2014).

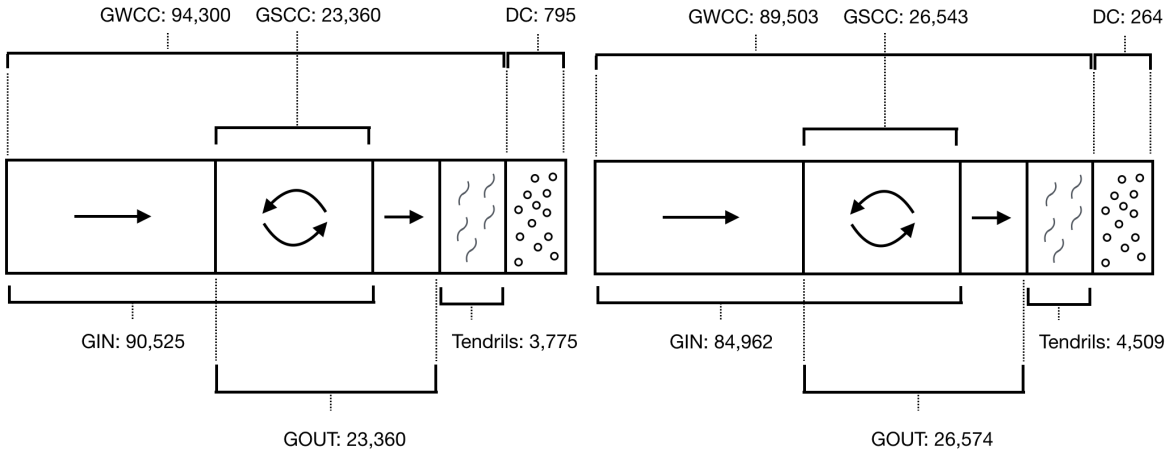
The number of nodes n tells the "size" of the network; m is the number of edges that allows for an estimation of its density, the fraction $0 \leq \frac{m}{n(n-1)} \leq 1$. Our three dictionary networks have m about 10 times n. The mean degree z gives an idea of the distribution of the edges on vertices. The mean vertex-vertex distance l tells how related/close the pairs of nodes are. The numbers in the table indicate that dictionaries have the small-world property. The parameter α refers to the exponent of the degree distribution function ($p_k \sim k^{-\alpha}$, where p_k is the fraction of the nodes that have degree k, in/out-degree) when the network (as in this case) follows this type of distribution ("power law"). It means that there are few nodes with a high degree and a large tail of low-degree nodes. The clustering coefficients $c1(= \frac{6 \times \text{number of triangles}}{\text{number of paths of length 2}})$ and $c2$ $(= \frac{1}{n}\sum_i c_i$ where $c_i = \frac{\text{number of triangles connected to vertex } i}{\text{number of triples centered on vertex } i})$ refer to the degree to which vertices tend to cluster together. In terms of network topology, the clustering coefficient refers to the presence of triangles in the network, being $c1$ a global coefficient and $c2$ a local one. In the language of social networks, the friend of your friend is likely to also be your friend. In our setting, two words having a common (non frequent) word in their definitions are likely to be related. The r coefficient indicates whether the high-degree vertices in the network associate (have links) preferentially with other high-degree vertices or not. $r = 1$ means high connectivity among them; $r = -1$ means low connectivity.

It is interesting to observe that the three dictionaries have similar parameters (as compared to other types of networks), and their properties are similar to semantic networks. Steyvers and Tenenbaum (2005) observed for the latter: "they have a small-world structure, characterized by sparse connectivity, short average path lengths between words, and strong local clustering."

Another measure is network resilience, which correlates with high connectivity. The standard measure is vertex attack tolerance VAT (Matta et al., 2014), *i.e.* behaviour of the network after removal of some nodes, defined as $\min_{S \subset V}\{\frac{|S|}{|V-S-C|+1}\}$, where C is the largest connected component in $V - S$. We determine that VAT is 0.245 for OPTED and 0.3 for DRAE. Comparing to other scale-free networks (Matta et al., 2014) (HOTNet 0.06, big barbell 0.08, star 0.11, C3 0.15, barbell 0.2, PLOD 0.25, wheel 1.0), dictionary networks are placed among the most resilient, meaning that removing some words will cause little disruption, since with high probability there will be other good relations to supply the loss.

3.3 Component Analysis

Components are classic features when describing the topology of networks. The graph is divided in two main parts: the *Giant Weakly Connected Component* (GWCC), the biggest weakly connected component present in the graph (v is connected to w if there is a undirected path from v to w), and the rest, the *Disconnected Components* (DC), that consist of separate small connected components. GWCC consists of three parts: the *Giant Strongly Connected Component* (GSCC) (strongly connected means that for each pair of nodes v, w, there is a directed path from v to w and vice versa), usually the most relevant part of the network; the *Giant in-component* (GIN), the set of nodes that have paths to GSCC (in our setting, words that in their definitions recursively use words in GSCC and are not used to define those in GSCC); and the *Giant out-component* (GOUT), the set of words that are used to define those in GSCC. Finally, the *Tendrils* are nodes which have no access to GSCC and are not reachable from it.



(a) OPTED (English, 95,095 words)

(b) DRAE (Spanish, 89,767 words)

Figure 2: Component Analysis showing similar structures for English and Spanish dictionary networks. The core part of the network (GSCC) is composed of words that are entangled –recursively use themselves in their definitions–, and amounts to approx. 25-30% of all entries in the dictionary.

3.4 Other characteristics obtained with graph machinery

One of the most basic measures to study words in text is consider their frequency of occurrence. The dictionary as network allows the use of other measures, in particular, classical centrality measures in the literature: Degree, PageRank, betweenness centrality, and closeness centrality. As shown in Figure 3, each of them captures different features as they have little correlation. To give a taste of the results, we list in Table 2 "top" words for different measures previously mentioned.

Another productive topic of application is the search for similarities among words. To illustrate it we show that big (bidirectional) cliques, which are rare in a dictionary, are formed by words with similar meanings. In OPTED there is no K_6, seven K_5 (shown in Figure 4), 174 K_4 and 2,641 K_3. In DRAE no K_5, four K_4 and 243 K_3.

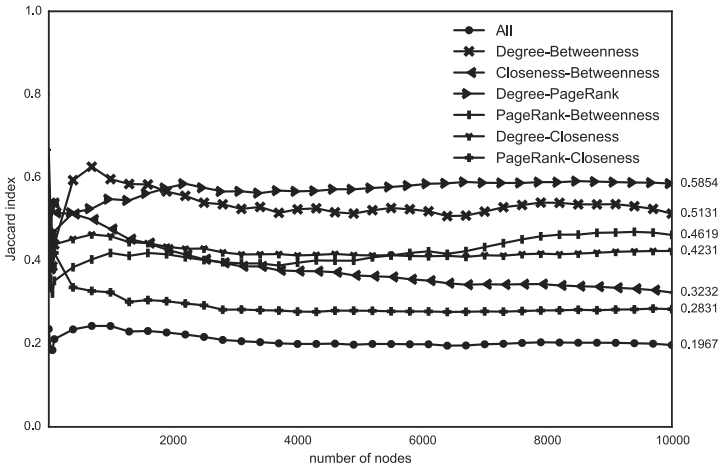


Figure 3: Common words of top rankings under different centralities, measured by Jaccard index ($\frac{|S_1 \cap S_2|}{|S_1| \cup |S_2|}$) for different number of nodes (0 to 10,000). For example the top ranked words for Degree and PageRank have 58.54% of their universe in common. All together they have 19.67% in common.

3.5 Core/Periphery Structure

Another feature that would help us understand the structure of dictionaries is the core/periphery characterization. This concept refers to the categorization of the nodes of the network. The nodes corresponding

Top Words OPTED

Table 2: Top words in OPTED and DRAE under diverse centrality measures: Degree (Deg), PageRank (Pag), Closeness (Clo), and Betweenness (Bet) Centrality. Note that there is a high degree of common notions among the top ranked words in the English and Spanish dictionaries.

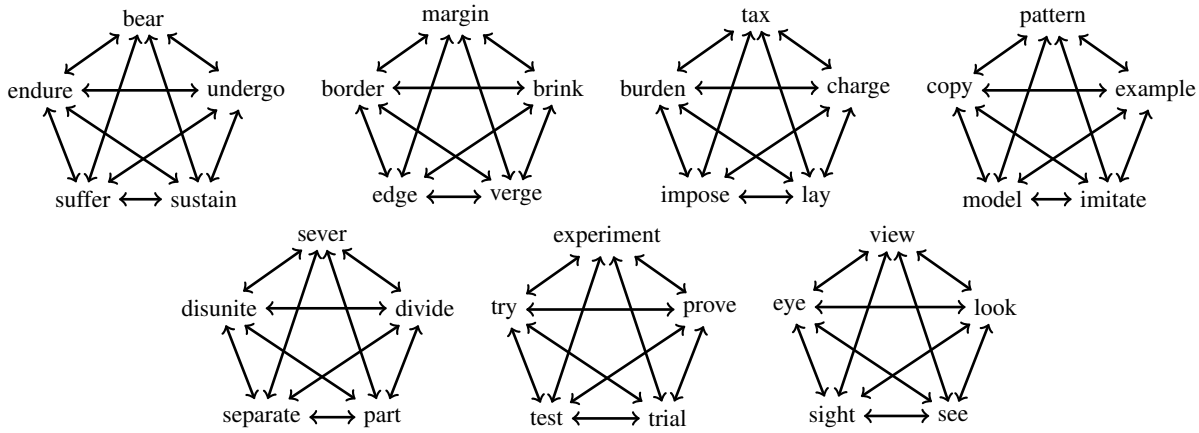

Figure 4: The only seven cliques of size 5 in OPTED (there are no bigger cliques). These words use each other in their definitions. Note their semantic closeness.

to the network core refers to a central and densely connected set. In the other hand, the periphery denotes a sparsely connected and non-central set of nodes that are linked to the core.

There are several types of core structures(Csermely et al., 2013): "traditional" core-periphery networks, rich-club networks, nested networks, bow-tie networks and onion networks. Intuitively, a dictionary network should follow one of these structures. The production of learner's dictionaries that uses a defining vocabulary to write all the definitions, or the simplification of languages through the definition of a small set of words(Ogden, 1930) supports this intuition. Unfortunately, to the best of our knowledge, there is no categorization of the core structure of dictionary networks.

4 Ogden's Basic English

Ogden's Basic English is an English-based controlled language created by Charles Kay Ogden in 1930. It is a simplified subset of the English language. According to Ogden, it is "a system in which everything may be said for all the purposes of everyday existence" (Ogden, 1930). This subset consists of 850

words[4]. The rationale of the choice of words is explained as follows (Ogden, 1930):

> The greater part of the words in use are shorthand for other words. Most common words are colored by our feelings, the words express judgment of our feelings in addition to their straight forward sense. It is generally possible to get to the factual level without much trouble.
> By putting the word to be tested in relationship with other possible words, questions can be framed in the form, "What word takes the place of the word in the middle in this connection?" Puppy is a Dog and time, young. Bitch is a Dog and sex, female. There are thirty lines for thirty sorts of questions.
> Questions of what a word will do for us has little relation to the number of times it is used in newspapers or letters.
> The number of 850 was found with 600 names of things, 150 are names of qualities, and the last 100 are the words which put the others into operation and make them do their work in statements.

Clearly the main arguments for the choice of the words are linguistic. In what follows, we will attempt to capture these words by purely graph-theoretical methods, thus shedding some light on the essential structure of Ogden's basic vocabulary in the network of the language. For our experiments we use the OPTED dictionary, that contains 803 words of the 850 of the Ogden's vocabulary.

4.1 Centrality Measures

The first naive hypothesis is that Ogden's set has good correlation with "central" nodes in the dictionary network. We investigated this with four classic centrality measures: *Degree* (most central nodes are those with higher number of adjacent nodes), *Closeness* (most central nodes are those that minimize the sum of the "distance" to other nodes in the graph), *Betweenness* (counts the number of shortest paths between all pairs of nodes passing through a given node), *PageRank* (essentially tells the number of steps taken to reach the node by a random walk starting from an arbitrary node).

We took the best k nodes for each centrality measure and every $0 < k \leq 803$, and checked how many of Ogden's words are in each of these sets. From the results (Figure 5) it follows that none of the centrality measures do a good job capturing Ogden's Basic English.

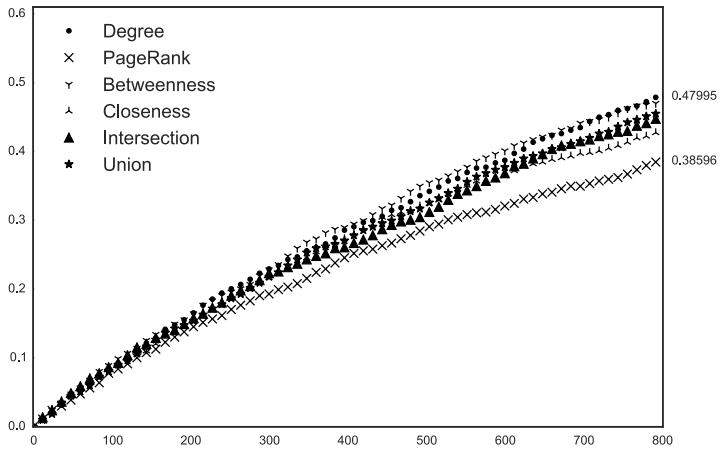

Figure 5: Ogden's Basic English words in top 800 words using different centrality measures. X-axis indicates k top-words and Y-axis, the percentage of Ogden's words in that set. Centralities by themselves are not a good method to capture the notion of importance that Ogden's Basic English represents.

The best measure in this task is degree centrality that captures almost 48% of Ogden. On the other hand, PageRank has the worst performance, capturing only 38.6%. In some sense we knew that degree centrality (which captures frequency) should perform poorly because Ogden stated explicitly that "what

[4]The list of the words can be seen in `http://ogden.basic-english.org/wordalph.html`

a word will do for us has little relation to the number of times it is used in newspapers and business letters". More surprising is the performance of PageRank, one of the most popular centrality measures today, used in multiple areas like ranking webpages, sense disambiguation (Mihalcea, 2004a), keywords and sentences from text (Mihalcea, 2004b), among others.

Group Centrality. Refining the idea, one could hypothesize that the problem is with *individual* centrality. The meaning of words is essentially a network property and not an individual one. There is an extended notion of centrality, called *group centrality* (Everett and Borgatti, 1999), that captures "centrality" of groups, not individuals. Unfortunately it is still not well developed, algorithmically.

We performed some experiments in this direction with groups of Ogden's words. We ranked Ogden's set using PageRank (seems the most promising to capture word senses (Abbott et al., 2012; Yeh et al., 2009)) and formed two groups, one with the top third and the other one with the bottom third of Ogden. As comparison and baseline, we extracted two sets of the same size from the set of words in the OPTED dictionary, one using the top nodes based on frequency, and the other one using a random selection. Results can be seen in Table 3.

	Degree	PageRank	Closeness	Betweenness
Ogden's	10 568	0.0310	0.5547	$4.06 \cdot 10^8$
Frequency	11 460	0.0314	0.5522	$4.40 \cdot 10^8$
Random	5 670	0.0129	0.5277	$2.10 \cdot 10^8$

(a) Top third set from 803 nodes (268 nodes).

	Degree	PageRank	Closeness	Betweenness
Ogden's	8 486	0.0157	0.5464	$2.95 \cdot 10^8$
Frequency	10 314	0.0199	0.5589	$3.41 \cdot 10^8$
Random	3 394	0.0097	0.5122	$1.34 \cdot 10^8$

(b) Bottom set from 803 nodes (268 nodes).

Table 3: Group Centrality for subsets of 803 words (nodes) chosen from three different sources: Ogden's set of words; selected from the OPTED dictionary by best frequency; chosen from OPTED at random.

For each of them we tested the four group centrality measures. Table 3 sheds some light on the existence of different types of roles in Ogden's set of words. The top third Ogden is rather aligned with classic centrality in the network (PageRank, many connections, in the middle of paths, etc.). On the contrary, the bottom third of Ogden behaves very much like random selection regarding PageRank and strongly diminishes its degree. This points to a role of covering an ample part of the network or being "spread" around the network. Though only slightly, this is further supported by the numbers of closeness. The closeness value of Ogden's bottom third is smaller than Ogden's top third (contrary to frequency that increases). The numbers are far from being conclusive due to the limits of the experimentation. As a baseline to compare to Ogden's top and bottom third, we had to use individual rankings, because we could not compute the actual (and ideal) group centralities due to lack of good algorithms and libraries (the problem is known to be NP complete (Garrido, 2016)).

In conclusion we state (although cannot explain well its rationale at this stage) that centrality measures inspired basically on social networks cannot be directly applied in this area. This points to the need for more sophisticated types of centrality measures for semantic networks (if the notion makes sense at all in the area), and in particular for dictionary networks.

4.2 Strong components of graphs

There are graph-theoretical notions about what the "core" (kernel) of a graph is, mainly using connectivity notions. For our dictionary network they seem promising under the hypothesis that connectivity (relationship) between and among groups of words is at the base of language.

We already saw in the component analysis (which holds for any network) that for our purposes one easily can get rid of more than 2/3 of the words in the OPTED dictionary by eliminating those words that are not used to define others (i.e. are "terminal" in some sense).

One can conduct a finer analysis as shown in Figure 6. From the whole OPTED network (which contains 803 words of Ogden) one can get the *strongly connected component* (SCC), those words that, by means of a cycle, are "used" in some sense to define themselves recursively. It has $23,360$ nodes and 802 of Ogden (99.87%). The discarded words (approx. 3/4 of the total) are those that either are terminal (not used to define other words) or n-th level terminals (and terminals after eliminating the terminals and so on).

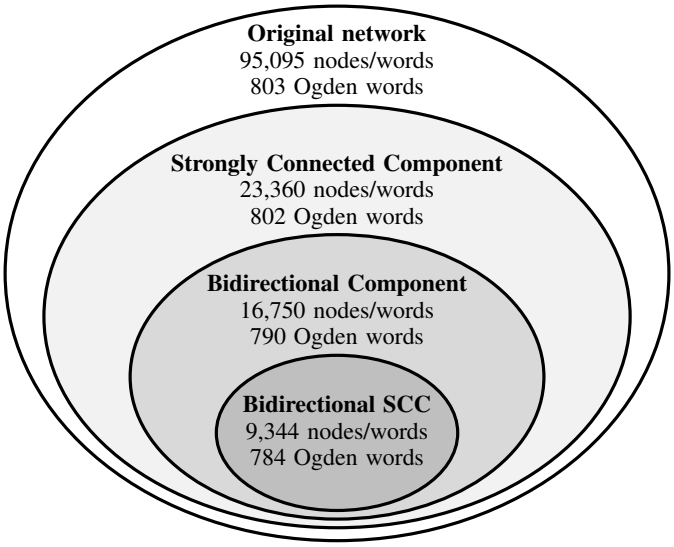

Figure 6: Connectivity analysis of components of OPTED network: The complete graph, Strongly Connected Component (words that recursively define themselves), Bidirectional Component (words that mutually need each other in order to be defined), and Bidirectional SCC. In the latter component only 3% of Ogden's words are lost), showing that Ogden's words strongly need each other.

Next, we consider a strong notion of connectivity: two words are connected if they are mutually used in the definition of the other (*e.g. fire* and *light*). Considering the subgraph induced by this relation, the Bidirectional Component (BC), one gets $16,750$ words, which contain 790 of Ogden (96.89%).

From here one can consider the biggest strongly connected component of BC (there are many small islands in BC), called BSCC in the figure, that has $9,344$ nodes and 784 words of Ogden (97.63%). This shows that Ogden is strongly correlated with these graph theoretical notions.

Picard et al.(2009) explored a notion of core (grounding kernel, which essentially recursively eliminates terminal words) and got a graph of 10% of the original graph. In size it matches our BSCC. Levary et al.(2012) used this notion in eXtended WordNet ($79,689$ nodes) and additionally collapsed synsets in one word, getting a core of $1,595$ nodes. In this core there are 314 Ogden words (52% of the part of Ogden they considered and 36.9% of total Ogden).

From these data, it seems that our BSCC is reaching the limit of the reduction of the English Dictionary (like OPTED) that can be obtained using only connectivity notions in order to capture most of Ogden's words (we are losing only 3% of all Ogden words). The challenge now is how to continue shrinking this graph while keeping most of Ogden's Basic English inside.

5 Conclusion

We provided evidence that dictionary networks share a common network structure and have a great potential to help understanding some properties of languages. We showed weaknesses and strengths of classical network notions in studying properties of dictionary/semantics networks. The results of this study highlight the need to devise more elaborated (than the classical ones) notions of centrality to understand and rank words and sets of words.

Abstract

We propose a structured generative latent variable model that integrates information from multiple contextual representations for Word Sense Induction. Our approach jointly models global lexical, local lexical and dependency syntactic context. Each context type is associated with a latent variable and the three types of variables share a hierarchical structure. We use skip-gram based word and dependency context embeddings to construct all three types of representations, reducing the total number of parameters to be estimated and enabling better generalization. We describe an EM algorithm to efficiently estimate model parameters and use the Integrated Complete Likelihood criterion to automatically estimate the number of senses. Our model achieves state-of-the-art results on the SemEval-2010 and SemEval-2013 Word Sense Induction datasets.

1 Introduction

Word Sense Induction (WSI) aims to automatically discover the different senses of polysemous words by unsupervised processing of text corpora. The related task of Word Sense Disambiguation (WSD) seeks to map the senses of word instances in a specific context to a predefined sense inventory. WSI overcomes the problem of having to define sense inventories, which may not have the appropriate granularity for all applications, and the effort of updating them for new domains or novel senses (Klapaftis and Manandhar, 2013). WSI is a challenging task that remains largely unsolved, but has important applications to a large number of tasks that require semantic processing of natural language (Navigli, 2009).

WSI is typically modelled as a clustering task, where the aim is to cluster samples of context representations of ambiguous words. Since context is the only available information to a WSI model, the choice of informative representations is a very important modelling aspect. Broad context related to topic or domain can restrict the possible senses that are applicable to an ambiguous word, but in order to make fine grained distinctions, context on the phrasal or syntactic level is usually needed. Ideally, a WSI system should incorporate different types of contexts to increase the confidence of its decisions. Combining the information present in different context representations can pose many difficulties in an unsupervised setting. Previous work has combined lexical with syntactic context (Brody and Lapata, 2009; Lau et al., 2012), and topical with local lexical context (Wang et al., 2015).

Another challenge for WSI systems is the need to apply clustering methods in high dimensional spaces of sparse features. Probabilistic latent variable models have been very successful in WSI by inducing latent representations of features that help improve generalization. While the latent variable approach has been very successful for word features, it has not provided considerable advantages when used with syntactic features (Brody and Lapata, 2009; Lau et al., 2012). A possible reason for this is that syntactic features, such as dependency contexts, exhibit much more sparsity than words.

A promising method to overcome the sparsity problem inherent in high dimensional discrete feature spaces is learning a low dimensional representation of the features. Word embeddings are an example of low dimensional vector representations for words learned in an unsupervised manner. The skip-gram

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3577–3587, Osaka, Japan, December 11-17 2016.

model (Mikolov et al., 2013) is a very popular technique for learning embeddings that scales to huge corpora and can capture important semantic and syntactic properties of words. Skip-gram embeddings exhibit compositional properties under addition, making them useful for constructing representations of phrases and larger units of text. Recently, the skip-gram model has been extended to learn embeddings of dependency context features (Levy and Goldberg, 2014; Komninos and Manandhar, 2016) that capture additional syntactic information. While word embeddings have been successfully used in many supervised NLP problems to overcome the problem of sparsity and improve generalization (Turian et al., 2010; Collobert et al., 2011), their application in WSI has been so far very limited.

In this paper, we propose a WSI model to address both the issue of multiple context representations and feature sparsity. Our model is a structured generative model that jointly models topical, phrasal and syntactic context in a hierarchical way. The probabilistic framework allows us to integrate different types of information in a principled way and also allows the application of model selection criteria to automatically determine the optimal number of senses. We address the issue of high dimensional feature spaces when dealing with syntactic features, by using word and dependency feature embeddings. In particular, we use the same skip-gram based model to create representations of all three context types.

We evaluate our model in two competitive benchmarks: SemEval-2010 Task 14: Word Sense Induction and Disambiguation (Manandhar et al., 2010), and SemEval-2013 Task 11: Word Sense Induction for graded and non-graded senses (Jurgens and Klapaftis, 2013). The two tasks provide different WSI evaluation frameworks and metrics. The proposed model achieves the state-of-the-art results in both datasets. Code is available at `https://cs.york.ac.uk/nlp/extvec`

2 Related Work

Among the most successful WSI systems are probabilistic latent variable models. Brody and Lapata (2009) extend the Latent Dirichlet Allocation (LDA) model (Blei et al., 2003) to combine evidence from different types of contexts. A limitation of this model is that the number of senses needs to be determined manually. Lau et al. (2012) propose using the non-parametric extension of LDA with a hierarchical dirichlet process (Teh et al., 2012) prior (HDP-LDA) to automatically estimate the appropriate number of senses from the data. They showed that HDP-LDA performs significantly better than LDA even when the number of senses is set to the same value. They also experimented with combined syntactic and word features. Syntactic features did not provide any advantage to either of these two LDA type models, but this could be attributed to sparsity. In addition, none of these models associate different context types with different stages of the generating process.

LDA type models assume that the topic distribution of context words correspond to different senses of the target word. Chang et al. (2014) proposed a model similar to LDA, but specifically tailored to WSI by estimating different latent variable distributions for context words and senses. In their setting, the latent topics for context words provide a method to overcome the sparsity problem related with the high dimensionality of the discrete feature space.

The sense-topic model (Wang et al., 2015) is another type of structured latent variable model related to our work. It makes a distinction between local and global context as we do, and jointly infers latent representations for both. The authors also make use of word embeddings as a method of feature weighting and for extracting additional context for ambiguous word instances. Contrary to our work, their features are discrete and syntax is ignored.

While several word embeddings models apply WSI in their training stage to create sense embeddings (Neelakantan et al., 2015; Iacobacci et al., 2015), there has been limited application of word embeddings as input representations to WSI models. The model of Huang et al. (2016) uses a recursive autoencoder to compose word embeddings to a context representation according to the structure provided by a syntactic parser. The final context representation captures both semantic and syntactic information and is used as the input to a rival penalization competitive learning clustering algorithm. While this approach uses both continuous word embeddings and syntactic information, it is fundamentally different from our work since their framework is not probabilistic. This makes difficult to incorporate additional contextual information like global context, and to define structural dependencies between context types.

A large variety of other clustering methods have been applied to WSI. A notable class of approaches is those using co-occurrence graphs and applying graph-based algorithms to identify hubs which are indicative of word senses (Klapaftis and Manandhar, 2010; Di Marco and Navigli, 2013).

3 Model Description

Target Word: operate

Local (win5) Context: from oil exploration to computer software without substantial government regulation
Syntactic Dependencies: advcl_volatile punct_, nsubj_industries nmod:without_regulation punct_.

Table 1: Global, local and syntactic context extracted for a target word.

We propose a generative model of continuous feature vectors that captures interactions between different types of contexts for a target ambiguous word. We separate context into three distinct types: global lexical, local lexical and syntactic context.

Global lexical context is indicative of the text's topic or domain, which can restrict coarse grained senses of a word. It can range between a few sentences around the target word or consider the whole document. In this work, we define global context as the words observed in the same sentence as the target word and one sentence before and after, as this is the typical context size provided by WSI evaluation datasets.

Local lexical context captures the semantics of phrases and is the most typically used context used by WSI systems. We define it as the words within a five word window before and after the target word.

Finally, we define the syntactic context of a target word as the typed dependencies with its neighbours in a dependency graph. This allows extraction of dependency context features such as $compound\_programming$, $compound^{-1}\_language$, where directionality is encoded by using an inverse dependency relation. Syntactic dependencies are a traditional word sense disambiguation feature as they capture the selectional preferences of a word.

An example of context selection can be seen in Table 1.

3.1 Continuous Context Feature Vectors

While our probabilistic model allows using the output of different models for each context type representation, e.g. a topic model for global context and a neural network for local, we use the publicly available Extended Dependency Skip-gram embeddings (Komninos and Manandhar, 2016) to construct representations for all three types. This skip-gram variant provides embeddings for both words and dependency context features trained jointly on Wikipedia text. Embeddings of dependency contexts have been used to incorporate syntactic information for sentence classification, and can be composed additively to model longer dependency relations.

Given the discrete features of the three context types, we create three continuous feature vectors by aggregating their corresponding embeddings. The operation to construct continuous context vectors is a weighted addition. We use the self information of discrete features to weight the contribution of each embedding to the overall feature vector:

$$I(x) = -log(P(x)) \tag{1}$$

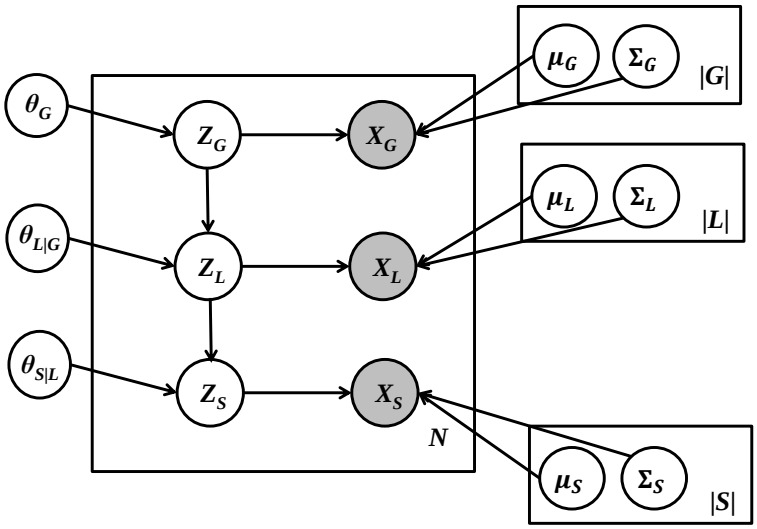

Figure 1: Graphical Representation of the model.

The three types of context feature vectors are formally defined by:

$$\boldsymbol{x_g} = \sum_{w \in G} I(w)\boldsymbol{v_w} \tag{2}$$

$$\boldsymbol{x_l} = \sum_{w \in L} I(w)\boldsymbol{v_w} \tag{3}$$

$$\boldsymbol{x_s} = \sum_{d \in S} I(d)\boldsymbol{v_d} \tag{4}$$

G,L and S are bags of discrete features corresponding to global, local and syntactic context as defined above, w and d are discrete word and dependency context features, $\boldsymbol{v_w}$ and $\boldsymbol{v_d}$ are embeddings of words and dependency contexts. We also apply L2-normalization to all feature vectors. The weighting by self-information reflects the intuition that rare words are more important for distinguishing senses than common words, and provides an automatic way of filtering the contribution of words without semantic content such as stop-words.

3.2 Probabilistic Generative Model of Context Feature Vectors

We infer the senses of an ambiguous word by combining information provided by the three context feature vectors within a structured generative model. The model assumes that there are three discrete latent variables for each target word z_g, z_l and z_s, each one generating one of the context feature vectors. The three latent variables form a hierarchical structure, where variables responsible for broader context generate a more context specific latent variable and their corresponding observed feature vector. The density of the context vectors is modelled by Mixtures of Gaussians. The full model is a structured generalization of Gaussian Mixture Models. Sampling context feature vectors follows the generative story:

For each target ambiguous word n*:*

select $z_{ng} \backsim Discrete(\boldsymbol{\theta_g})$
sample $\boldsymbol{x_{ng}} \backsim \mathcal{N}(\boldsymbol{\mu_{g=z_{ng}}}, \boldsymbol{\Sigma_{g=z_{ng}}})$
select $z_{nl} \backsim Discrete(\boldsymbol{\theta_{l|g=z_{ng}}})$
sample $\boldsymbol{x_{nl}} \backsim \mathcal{N}(\boldsymbol{\mu_{l=z_{nl}}}, \boldsymbol{\Sigma_{l=z_{nl}}})$
select $z_{ns} \backsim Discrete(\boldsymbol{\theta_{s|l=z_{nl}}})$
sample $\boldsymbol{x_{ns}} \backsim \mathcal{N}(\boldsymbol{\mu_{s=z_{ns}}}, \boldsymbol{\Sigma_{s=z_{ns}}})$

The corresponding graphical model can be seen in Figure 1. The parameters of the model are:

$$\boldsymbol{\Theta} = \{\boldsymbol{\theta_g}, \boldsymbol{\theta_{l|g}}, \boldsymbol{\theta_{s|l}}, \boldsymbol{\mu_g}, \boldsymbol{\Sigma_g}, \boldsymbol{\mu_l}, \boldsymbol{\Sigma_l}, \boldsymbol{\mu_s}, \boldsymbol{\Sigma_s}\} \tag{5}$$

We constrain the covariance matrices to be diagonal, hence having a smaller number of parameters compared to discrete mixture models for WSI.

3.3 Parameter Estimation

We estimate the parameters of the model by maximum likelihood estimation using the EM algorithm. The equations of E-step and M-step are the following:

E-step

For each sample $n \in \{1, .., N\}$ we compute:

$$\gamma(\boldsymbol{Z}) = p(\boldsymbol{Z}|\boldsymbol{X}) = \frac{p(\boldsymbol{Z}, \boldsymbol{X})}{\sum_{\boldsymbol{Z}} p(\boldsymbol{Z}, \boldsymbol{X})} \tag{6}$$

Since there are only three dependant latent variables per sample, we can easily compute this step by exact inference.

M-step

We estimate parameters that maximise:

$$\boldsymbol{\Theta^{new}} = E_{z|x}[\arg\max_{\boldsymbol{\Theta^{new}}} \log p(\boldsymbol{X}, \boldsymbol{Z}|\boldsymbol{\Theta^{old}})] \tag{7}$$

Given the factorization implied by the graphical model, each parameter can be estimated independently. The update equations are:

$$\boldsymbol{\theta_g^{new}} = \frac{1}{N} \sum_{n,l,s} \gamma(z_{ngls}) \tag{8}$$

$$\boldsymbol{\theta_{l|g}^{new}} = \frac{\sum_{n,s} \gamma(z_{ngls})}{\sum_{n,l,s} \gamma(z_{ngls})} \tag{9}$$

$$\boldsymbol{\theta_{s|l}^{new}} = \frac{\sum_{n,l} \gamma(z_{ngls})}{\sum_{n,g,s} \gamma(z_{ngls})} \tag{10}$$

Updates for means and covariances for the g context type are given by:

$$\boldsymbol{\mu_g^{new}} = \frac{\sum_{n,l,s} \gamma(z_{ngls}) \boldsymbol{x_{ng}}}{\sum_{n,l,s} \gamma(z_{ngls})} \tag{11}$$

$$\boldsymbol{\Sigma_g^{new}} = \frac{\sum_{n,l,s} \gamma(z_{ngls})(\boldsymbol{x_{ng}} - \boldsymbol{\mu_g})(\boldsymbol{x_{ng}} - \boldsymbol{\mu_g})^T}{\sum_{n,l,s} \gamma(z_{ngls})} \tag{12}$$

and similarly for the l and s types.

We initialize means with the centroids of k-means run independently for each context type, and covariance matrices with the sample covariance.

3.4 Model Selection

One of the most challenging parts of WSI is estimating the number of senses for each ambiguous word type. Since we are working with a probabilistic model we can apply model selection criteria. We use the Integrated Complete Likelihood (ICL) criterion (Biernacki et al., 2000). ICL is a model selection criterion similar to the Bayesian Information Criterion (BIC) (Schwarz, 1978) that seeks a model that provides large evidence for the observed data with a small number of parameters. Following (McLachlan and Peel, 2004) we use the approximation:

$$ICL(m, \boldsymbol{X}) = \log p(\boldsymbol{X}|\boldsymbol{\Theta}) - \frac{m_k}{2} \log(N) + \sum_{n,g,l,s} \gamma(z_{ngls}) \log \gamma(z_{ngls}) \tag{13}$$

where m_k is the total number of parameters to be estimated.

This ICL approximation is exactly equal to BIC additionally penalized by the last term, which is the mean entropy of the distribution of latent variables. The extra penalty term favours models that result in more confident assignments since the entropy of the latent variable distribution will become lower in such cases. This behaviour favours well separated clusters and avoids strongly overlapping components which may be favoured in model selection by BIC. In our experiments, we set $|z_g| = |z_l| = |z_s| = K$ and train models with K in the range of [2, 50]. We observe that given enough training instances, ICL picks models with a large numbers of components corresponding to more fine-grained senses. This is reasonable since with more data the model becomes more confident into making such fine-grained distinctions, and is also likely to encounter unusual word usages.

4 Evaluation

We evaluate our model in two SemEval WSI datasets. For both datasets we parse the data using the Stanford Neural Network dependency parser (Chen and Manning, 2014) using Universal Dependencies (De Marneffe et al., 2014), which is the same format used by the dependency based embeddings. We train a different model for every word type.

4.1 SemEval-2010 Task 14: Word Sense Induction and Disambiguation

The SemEval-2010 WSI dataset consists of 50 verbs and 50 nouns. The task organizers provide a fixed training set with 879,807 instances of the target words. The distribution of instances for each word is highly imbalanced. The test set consists of 8,915 instances. Two types of evaluation are performed: supervised and unsupervised.

The supervised evaluation is performed in two steps. In the first step, a part of the data is used to map the induced sense clusters to a fixed inventory of word senses. In the second step, the fixed sense inventory is used to evaluate the clustering of the rest of the data as a Word Sense Disambiguation system. The reported metric is F-score. Following the task procedures we report two results, one using an 80-20 split of the data for mapping and scoring, and one using a 60-40 split. For both cases, reported results are an average over a 5-fold split.

Unsupervised evaluation for the SemEval task was performed by two clustering quality metrics, V-measure and paired F-score. A problem with clustering evaluation metrics is that they are sensitive to the number of senses (Klapaftis and Manandhar, 2013), with V-measure favouring a high number of senses and F-score the opposite. This behaviour results into ranking two uninformative baselines, 1-cluster-per-instance and most-frequent-sense (or all-in-one), as the best solutions. Li and Titov (2014) argue that for the V-measure, this behaviour can be explained by biases in the estimation of entropy when there is a large number of clusters compared to the number of samples, as is the case in WSI evaluation. They propose the usage of the Best-Upper-Bound (BUB) Entropy Estimator (Paninski, 2003) instead of maximum likelihood estimation that was used by the organizers. They show that the V-measure with the BUB estimator successfully evaluates both uninformative baselines as worse solutions than actual WSI systems. Following this recommendation, we report the V-measure estimated with BUB as the unsupervised evaluation metric.

Our default approach for assigning a sense to a word instance is taking the value of $p(z_s|\boldsymbol{x})$ as the probability of a sense being applicable, since it is the variable most directly associated with the ambiguous word. It is possible however, to assign senses to joint configurations of two or all three of the latent variables, in order to better use the information provided by our model. Since the number of possible configurations grows exponentially with the number of latent variables, this approach can lead to very fine-grained partitions of the data. In practice, we observe that only a small number of all these configurations are given a high probability mass. Evaluation results for our model MultiContextContinuous (MCC) and state-of-the-art systems are reported in Table 2. We report results with both the single variable approach (MCC-S) and joint variable assignments (MCC-L,S and MCC-G,L,S).

We see that our model achieves the highest score in both metrics, however, by utilizing different information. The combined evidence provided by the three latent variables helps induce an accurate mapping

Model	80-20	60-40	VM (BUB)
MCC-G,L,S	**70.6**	**69.0**	8.1
MCC-L,S	69.3	68.1	12.4
MCC-S	68.9	67.5	**17.1**
Hidden Concept (Chang et al., 2014)	69.7	68.9	-
HDP-LDA (Lau et al., 2012)	68.0	-	-
UoY (Korkontzelos and Manandhar, 2010)	62.4	62.0	11.4

Table 2: Results on the Semeval-2010 WSI dataset. Dashes indicate that this result was not reported by the authors of the corresponding model. UoY is the best performing model participating in the SemEval-2010 WSI evaluation.

of the sense clusters to the fixed sense inventory and results in the best F-score for the supervised evaluation. The supervised evaluation benefits from this fine-grained sense distribution since splitting the senses into smaller clusters does not affect the mapping operation, as long as the induced senses are consistent subsets of the gold standard senses. The 60-40 split results into a more difficult mapping problem and can indicate how reliable is the mapping between the sense distribution and the gold standard (Klapaftis and Manandhar, 2013). We see that using the joint configuration of the latent variables again results in the highest F-score, providing evidence of the consistency of the mapping. Contrary to the supervised evaluation, the V-measure favours the clustering provided by the z_s variable alone, since it penalizes the mismatch between the more fine-grained clustering and the gold standard.

4.2 SemEval-2013 Task 13: WSI for graded and non-graded senses.

The SemEval-2013 WSI evaluation dataset consists of 50 word types: 20 verbs, 20 nouns and 10 adjectives. There are several differences compared to the SemEval-2010 setting. There are less restriction on the training set, which can be any part or all of the UkWac corpus (Ferraresi et al., 2008). In addition, the test data include instances with multiple applicable senses. There are 4664 instances in the test set, 88.5% of which are labelled with a single sense, 11% labelled with two senses and 0.5% with three. Systems are asked to provide an estimate of the applicability of each sense.

The evaluation metrics also differ from those of SemEval-2010, in order to cope with the multiple sense labelling. Clustering evaluation is performed with the Fuzzy B-cubed and Fuzzy normalized Mutual Information (NMI) criteria. Fuzzy NMI favours solutions with many clusters giving a high score to the 1-cluster-per-instance baseline, while Fuzzy B-cubed favours few clusters and favours the all-in-one baseline. Following (Wang et al., 2015), we use those two metrics but also report the geometric mean of the two, which provides a more balanced metric and also assigns a score of zero to both the uninformative baselines. We use the top 3 most probable assignments of the z_s variable with the corresponding probability as the applicability weight. Results can be seen in Table 3.

We distinguish results for the standard test data provided by the SemEval task organizers and the augmented test data used in the evaluation of the sense-topic model. The first data augmentation result, indicated as "add-actual-context", uses an extra two sentences before and after the provided test data sentences, extracted by finding the test instances in their original corpus. The second data augmentation result "add-UkWac-context", uses context extracted from UkWac by finding word instances in a similar context as the test instances. Similarities are calculated by averaging word embeddings in the test instance and calculating cosine similarities. These context augmentation techniques improve the performance of the sense-topic model since the test data provided usually consist of a single sentence as the context of the target word. Since our model also considers global context, we expect that such data augmentation techniques would also increase its performance. However, we did not apply this approach in our evaluation setting and only used the provided context found in the SemEval test data. When using the actual SemEval test data, our model achieves the highest score in all three metrics.

Model	Fuzzy-NMI	Fuzzy B-cubed	Geom. Mean
MCC-S	**7.62**	**55.6**	**20.58**
Sense-Topic (Wang et al., 2015)	6.96	53.5	19.30
Sense-Topic (sim. weighted)	7.14	55.4	19.89
AI-KU (Baskaya et al., 2013)	6.5	39.0	15.92
unimelb (Lau et al., 2013)	6.0	48.3	17.02
Sense-Topic (add-actual-context)	9.39	**59.1**	**23.56**
Sense-Topic (add-UkWac-context)	**9.74**	54.5	23.04
1cl-per-inst	7.09	0	0
all-in-one	0	62.3	0

Table 3: Results on the SemEval-2013: Task 13 dataset. All Sense-Topic model variants are reported from (Wang et al., 2015). Results with extra context (add-actual-context, add-UkWac-context) do not use the same evaluation setting and are not directly comparable to the rest. AI-KU and unimelb are systems participating in the SemEval-2013 evaluation.

5 Discussion

We attribute the good performance of the proposed model to its capacity to handle data sparsity. Both the multiple context representations and the usage of low dimensional feature embeddings contribute towards that goal. The importance of dealing with sparse inputs can be seen from the generally good performance of Bayesian latent variable models for WSI (Wang et al., 2015; Chang et al., 2014) . While these models manage to deal with the sparsity of words, they still do not manage to effectively utilize syntactic features as we do with dependency feature embeddings. By using pretrained embeddings our model has access to a very large feature set (about 220k words and 1.3m dependency context features), while having to estimate a relatively small number of parameters. In Table 4, we show some examples where clusters are formed by different but semantically related words, and the importance of syntactic features.

A weakness of the proposed model is that context representations corresponding to senses are assumed to follow Gaussian distributions. We cannot expect this assumption to hold in general, but our evaluation suggests that it is a reasonable approximation. It is possible to extend the model by using a separate Mixture of Gaussians to model each individual sense. While this extension would provide additional capacity to the model for modelling sense specific contextual representations with complex probability densities, it can lead to parametric explosion and severe overfitting.

In Figure 2, we use t-SNE (Maaten and Hinton, 2008) to visualize the syntactic context vectors of the word "operate" from the SemEval-2010 training data and their sense assignments. We see that clustered points generally form compact groups, though they are not clearly separated. In order to model senses with contexts that do not follow a Gaussian distribution, the model favours additional clusters. In practice, we observe that this behaviour does not pose a significant problem as long as these finer-grained clusters are consistent with the underlying sense distribution, which was shown by the supervised evaluation of SemEval-2010. If a coarse grained distribution is desired, methods that merge Gaussian components as a postprocessing step could be considered (Hennig, 2010).

6 Conclusion

We propose a probabilistic latent variable model for Word Sense Induction. Our model integrates information from three different context types: global lexical, local lexical and dependency syntactic context. A different latent variable is inferred for each context type and dependencies are modelled in a structured top-to-bottom way, where broader context representations directly influence only more specific representations. Our context representations are constructed by weighted addition of word and dependency context embeddings that provide a way to overcome sparsity and reduce the number of parameters needed to be estimated. The number of senses is automatically determined by applying the Integrated Likelihood

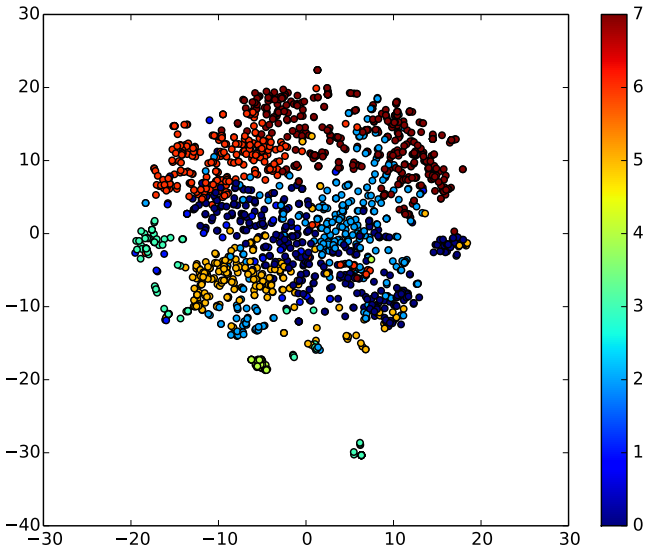

Figure 2: 2-d t-SNE of the syntactic context vectors of the word “operate”. Different colours correspond to different cluster assignments. Best viewed in colour.

Cluster 6
... energy-efficient appliances and how to *operate* them efficiently ...
... temperature rises enough for the heat pump to *operate* more efficiently than your old furnace ...
... software to enable users to *operate* their computers remotely ...
Cluster 5
... 44 of these stores *operate* as monro muffler brake & service ...
... many industries with volatile profits ranging from oil exploration to computer software *operate* without substantial government regulation ...
... bfx hospitality group , inc. owns and *operates* food services ...

Table 4: Instances of “operate” belonging into two different clusters. The contexts do not share many common words, but they are semantically related. The second instance of cluster 5 shares words with the third instance of cluster 6 (“software”, “computer”), but is assigned the correct sense because the syntactic features indicate the long range subject dependency with “industries”.

Criterion. We evaluate our model in two competitive WSI benchmarks, achieving state-of-the-art results.
