Abstract

In order to organize the large number of products listed in e-commerce sites, each product is usually assigned to one of the multi-level categories in the taxonomy tree. It is a time-consuming and difficult task for merchants to select proper categories within thousands of options for the products they sell. In this work, we propose an automatic classification tool to predict the matching category for a given product title and description. We used a combination of two different neural models, i.e., deep belief nets and deep autoencoders, for both titles and descriptions. We implemented a selective reconstruction approach for the input layer during the training of the deep neural networks, in order to scale-out for large-sized sparse feature vectors. GPUs are utilized in order to train neural networks in a reasonable time. We have trained our models for around 150 million products with a taxonomy tree with at most 5 levels that contains 28,338 leaf categories. Tests with millions of products show that our first predictions matches 81% of merchants' assignments, when "others" categories are excluded.

1 Introduction

E-commerce has grown rapidly in recent years. Giant e-commerce companies like Amazon, e-Bay, Taobao and Rakuten list millions of products on their sites sold by thousand of merchants. As of May 2016, Japan's largest e-commerce site Rakuten Ichiba[1] hosted 186 million active products sold by 43,363 different merchants. In order to organize products so that customers can navigate and search them easily, products are categorized into multi-level categories. "Women's Fashion > Tops > Sweaters > Long-sleeved knit > Crew neck" is an example for such categories. Rakuten Ichiba contains around 30 thousand categories of up to 5 levels. Merchants need to manually assign each product to one of those categories, which is a tedious task and prone to error. Moreover, merchants may not be accurate while assigning products, the cateogry assignment of the same product listed by different merchants may not be consistent. Automatic category recommendation for given product information helps to solving these problems.

Product classification is a text classification with a large hierarchical product taxonomy, and a lot of research have been conducted with various methodologies (Gupta et al., 2016; Shen et al., 2012; Kozareva, 2015; Qiu et al., 2011). Product classification includes the following challenges: 1) the products sparsely distributed in a large number of categories and data distribution is quite skewed, 2) the length of product titles and descriptions is diverse, 3) even though there are tons of product data, it is not guaranteed that pairs of current product title and assigned category are correct.

In this paper we propose a large-scale classification method for e-commerce products to classify them into thousands of multi-level categories. We use 172 million product title and description data for making predictions on products from Rakuten Ichiba. Please note that our techniques can be applied to other languages as well. Titles and descriptions are preprocessed to extract words, model numbers, sizes and

counts. Deep belief nets (DBN) and deep autoencoders (DAE) are used to build models for given data sources. Combining results from different models and different data sources, final predictions are made. Input feature vectors are very high dimensional and sparse for the deep models we train, which makes it impractical to train in usual way. We apply the selective reconstruction idea by Dauphin et al. (2011) for training DBN and DAE. DBN and DAE with selective reconstruction are implemented on GPUs in order to process a large product base within a reasonable amount of time. Conventional methods like multinomial Naive Bayes are not practical to be used in that scale. We compared our results with passive-aggressive learning, and confirmed large accuracy improvement.

We can summarize our contributions as follows:

- We propose a large-scale classification method for e-commerce products to classify them into 28,338 categories organized in 5 level.
- E-commerce-specific features, like product models, sizes, counts are extracted from a corpus which mainly contains Japanese text.
- DBN and DAE with selective input reconstruction are implemented on GPUs.
- We conducted experiments with 172 million product titles.
- Our comparisons with merchants' assignments suggest 81% match, when "others" categories are excluded. We observed that our predictions can sometimes be more accurate than human labeling.

The remainder of this paper is organized as follows. Section 2 introduces related work. Section 3 and Section 4 overview exploited deep models and explain our proposed framework. In Section 5 we explain tokenization and feature extraction from product data. Section 6 presents experimental results of product classification, with varying settings. Section 7 concludes the paper.

2 Related Work

2.1 Text classification in large taxonomies

Xue et al. (2008) worked on deep classification in large-scale text taxonomy. They proposed two stage algorithm consisting of a search stage and classification stage. A language model was trained with over 1 million web documents and 130,000 documents was classified into over 130,000 categories. Qiu et al. (2011) proposed a variant Passive-Aggressive (PA) algorithm with latent concepts and evaluated the method with LSHTC dataset[2], which include over 13,000 categories and over 100,000 documents. Kosmopoulos (2015) proposed an extended hierarchical classification to predict the correct leaf by estimating the probability of each root-to-leaf path. LSHTC dataset has also been used to evaluate the method. Ha-Thuc et al.(2011) exploited classification approach without labeled data. In their algorithm, ontological knowledge was used to define the meaning of categories instead of relying on human-labelled documents. A typology consisting of 1,131 categories was used in the evaluation.

2.2 Product classification

There are various works devoted to multi-level category predictions for e-commerce products. Chen and Warren (2013) used multi-class-SVM with cost-sensitive function. They used 1,073 categories from UNSPSC taxonomy [3], which includes over 17,000 categories, and over 1 million products. Gupta et. al (2016) used word clustering and idf values to obtain document vector from product description and showed this document representation worked well in their product classification. Kozareva (2015) has worked on product classification with Yahoo! product data. They compared several classifiers and 5 kinds of features, and showed neural network embedding representation outperformed in product classification with over 300 categories in their category taxonomy.

Shen et. al (2011; 2012) proposed hierarchical classification, which decomposes into a coarse level and a fine level task, and used graph algorithm to discover automatically groups of highly similar classes as product category instead of relying on human-defined hierarchy. The model was trained with 83 million products from eBay.

2.3 Text classification with deep learning

In the last couple of years, deep learning algorithms have been exploited to text classification.

Zhang et al. (2015) showed that character-level convolutional network is an effective method in the text classification, and compared various models, including BoW (Bag of Words), word embedding, word-based ConvNet and long-short term memory with several kinds of large-scale dataset. Lai et al. (2015) have also worked on recurrent convolutional neural network (RCNN). A recurrent structure was used to capture contextual information as far as possible when learning word representations. They compared various models with 4 kinds of datasets, including small number of classes and middle size of instances. Kim (2014) reported sentence classification with Convolutional Neural Network. A simple improvement was considered to the convolutional architecture that two input channels are used to allow the employment of task-specific and static word embeddings simultaneously. Evaluation has been conducted with 6 kinds of datasets, including a few classes and small number of instances. Wang et al. (2015) worked on semantic clustering and convolutional neural network for short text classification and used 2 kinds of datasets, which consists of small number of classes and instances.

Ha et. al (2016) used deep learning-based product classification method, which consists of multiple recurrent neural networks (RNNs). They evaluated the method with more than 94 million products with approximately 4,100 leaf categories from NAVER shopping.

3 Deep Models Exploited

Recently, neural models gained attention for classification and semantic compression tasks. Deep belief nets are multiple layer neural networks used for classification tasks. They contain all-to-all connections between layers. Top layer of a DBN represents class probabilities of a given input vector. Hinton et al. (2006) proposed greedy layer-wise pre-training for DBN. Each layer (Restricted Boltzmann Machines) is trained by constructive divergence, using 1-step Gibbs sampling. Given class labels for top layer, the network is fine-tuned after greedy layer-wise pre-training is completed.

Deep autoencoders are used for finding compressed representations, i.e., semantic hashes (Salakhutdinov and Hinton, 2009; Hinton and Salakhutdinov, 2011) of given data, so that related input items have closer hash values (Hinton and Salakhutdinov, 2006). Similar to DBN, DAE contains multiple layers of restricted Boltzmann machines (RBM) which are stacked on top of each other. Each RBM is trained one after another in a greedy way and the overall network is fine-tuned after greedy pre-training is completed. Unlike DBN, DAE does not contain any class layer on top; DAE training is fully unsupervised.

Matrix multiplication is the core operation for training deep networks. Weight for each layer corresponds to a matrix of size $v \times h$, where v is the input layer length and h is the output layer length. For large and sparse inputs, sparse operations can be used to construct output layer of an autoencoder. However, input layer should also be reconstructed from dense output vectors for which sparse operations cannot be used in the original algorithm. This is prohibitively time-consuming for large-dimensional input data. In order to train with very high dimensional and sparse inputs, Dauphin et al. (2011) applied reconstruction sampling for stacked denoising autoencoders. In this work, we apply reconstruction sampling for DBN and DAE, both for pre-training of the first layer autoencoder and during fine-tuning by stochastic gradient descent.

Let us give an example for reconstruction sampling. Let us consider a network with visible layer of size v and first hidden layer of size h. Then, size of the weight matrix W for the first autoencoder becomes $v \times h$. For the forward pass for a minibatch of 3 input vectors, $3 \times v$ matrix X is multiplied with W to generate $3 \times h$ batch output matrix Y. After Y goes some non-linear operations, during the backward pass input $\bar{X}$ is reconstructed from $\hat{Y}$ by $\bar{X} = \hat{Y} \times W^T$ (we ignore bias parameters for the sake of simplicity). Say $X[1,a] = X[1,b] = X[2,b] = X[2,c] = X[2,d] = X[3,a] = X[3,e] = 1$ and others are all 0. Then, for this minibatch, we use only rows a, b, c, d, e of W during training. This means, while reconstructing $\bar{X}$ only $h \times 5$ matrix $W[a,b,c,d,e]^T$ is multiplied with $\hat{Y}$. For each minibatch, only a portion of the weight matrix is trained. After all training batches are processed, training is completed for all rows of W.

Figure 1: 2-step classification for a given product title with trained models.

4 Classification Models

Classification is implemented in two steps. In first step, first level categories are predicted. There are 35 first level categories in Rakuten Ichiba. In the second step, leaf categories are predicted.

In each step, two classifiers, DBN and kNN (k-Nearest Neighbors) are used for each of two different data sources (titles and descriptions). Category predictions are made by averaging probability distribution scores of four different classifiers. DBN accepts 0-1 word vectors of high dimensions, and returns class probabilities as output. DAE is used to find semantic hash values for 0-1 word vectors. These semantic hashes are then used for k-nearest-neighbor classification.

For each data source, one DBN model is trained for first level classification and 35 different models are trained for sub-categories under each first level category. In total, we have $2 \times (1 + 35) = 72$ DBN models trained. However, we have only 2 DAE models for semantic hashing of titles and descriptions. In the first step, first level category IDs are used for kNN classification and in the second step, leaf level category IDs are used for kNN classification using the same semantic hashes. Two step classification using trained models is summarized in Figure 1.

kNN classification using high dimensional semantic hash values and hundreds of millions of points (training items) is not practical if all points are traversed during the neighbor search. Therefore, points are first clustered using hierarchical k-means (Böcker et al., 2004). Nearest neighbor search is implemented in the cluster whose center is the closest to the search point.

In the second step for classification, DBN classifiers return results from the same level-1 category tree. On the other hand, kNN classifiers can return any category. It is possible to build different DAE models and different kNN classifiers for each level-1 category, just like we do for DBN classification models.

However, doing so increases the number of models twice and it requires 4 kNN searches to classify a product, instead of 2. Besides decreasing run-times for training and classification, having a global model for kNN helps decreasing the error propagation ratio. If level-1 category is mispredicted in step 1, there is no way DBN classification can find the correct category. But, mixing with global kNN result may correct mispredictions made in step 1.

5 Tokenization and Feature Extraction

We use product titles and descriptions for classification, which are mainly in Japanese. Merchants in Rakuten Ichiba are free to assign their own titles and descriptions for the products they are listing. We assume no dictionary is available for meta-information, like manufacturer name. However, we extract model numbers, counts and sizes from the text. Remaining text is tokenized using Kuromoji[4] Japanese morphological analyzer to extract words.

We first normalize text by converting all Japanese characters to full-width and all non-Japanese characters to lower cases. All HTML tags are cleaned from descriptions. Products' model numbers are predicted using regular expressions, by checking alphabet/number combinations, possibly with spaces and dashes. For example, the words "iPhone 4s" is normalized to "iphone4s". Sizes are estimated by checking whether there exists quantity keywords following numbers. For example, "12.3 cm" is normalized to "12.3cm" and "12cm x 3 cm" is converted to "12cmx3cm". There may be some conflicts with model number extractor and size extractor. In this case, we keep both model numbers predictions and sizes, like "iPhone 4Gb" to be normalized as "iphone4gb 4gb". Japanese have counters for different type of objects. For example, "本" is used to count long and cylindirical objects and "枚" is used to count flat objects. Counters following numbers are not tokenized and kept together, like "3枚".

Japanese words are not split by spaces, so it is not straight-forward to split words. We use Kuromoji in search mode for tokenization of Japanese text and take the base form as word features. Stop words defined in Kuromoji plug-in for Lucene[5] and punctuation marks are excluded from the dictionary.

As a result of above feature extraction process, we have around 26 million words for titles and 47 million words for descriptions. These numbers are much bigger than dictionary sizes of natural languages, because of the nature of e-commerce data. Pre-processing for model number, size and count extraction, as well as misspelled words and failing to properly tokenize Japanese text increase the number of words. It is especially difficult to tokenize Katakana words which are used for writing imported words from other languages and prone to misspelling. We choose a frequency threshold, so that words appearing only a few times in the corpus are not selected as features to be used. Although less-frequent words are more expressive for products, by eliminating them we eliminate most of the noisy information as well. Eliminating less-frequent words also helps making the classifier practical and more robust for classification of new products. Sparse word vectors of the dictionary size after elimination of less-frequent words are accepted as input features for deep network classifiers, which we explain the details in the following sections.

6 Experimental Results

In this section, we discuss details of experiments in terms of prediction matching ratios with merchants' assignments and run-time discussions for the methods and implementations we explained in the paper.

6.1 Dataset and Model Properties

We used Rakuten product dataset, which is available under Rakuten Data Release program[6]. We processed 280 million (active and inactive) products listed by over 40,000 merchants. Products are assigned to 28,338 active categories. There are many products sharing the same title which we remove beforehand. After deduplication by titles, around 40% of products were eliminated, remaining 172 million titles. 90% of those products were randomly selected as being training data, and remaining 10% as test.

[4] http://www.atilika.org/
[5] http://lucene.apache.org/
[6] http://rit.rakuten.co.jp/opendata.html

We extracted features from training data as explained in Section 5. As a result, 26 million words were extracted for titles and 47 million words were extracted for descriptions. Words appearing more than 50 times in the training data were selected as features for training first-step DBN and DAE networks. As a result, the number of word features (dictionary size) was 968,471 for titles and 1,461,625 for descriptions. We built 4-layer step 1 DBN for titles with layer sizes $\{968471, 1000, 2000, 35\}$, and for descriptions $\{1461625, 650, 2000, 35\}$. 35 is the number of level-1 categories. For DAE, last layer size is 64, meaning we built 64-D semantic hash values for each input word vector.

Input layer is still very large for training deep networks, but the word-vectors are very sparse which makes it possible for deep networks to be trained in reasonable time using the selective reconstruction method explained in Section 3, using latest generation GPUs. Average number of words for a title is 12.9 and average number of words for a description is 98.7. Hence, for a input vector batch of size 100, at largest 1290×1000 parameters were trained for titles and at most 9870×650 for descriptions.

DBNs in step 2 for each level-1 category used different feature sets. Dictionary sizes for level-1 categories are much smaller when compared with that of whole corpus. Most frequent 500,000 words were taken as features for second step DBNs. By doing so, if there are more words than 500,000 in a level-1 category, words appearing only once or twice were eliminated. Therefore DBN models for titles and descriptions in step 2 is of size $\{\min(v, 500000), 1800, 2000, n\}$, where v is the dictionary size and n is the number of leaf categories in the corresponding level-1 category.

For kNN classification, after training DAEs (where we selected k to be 10), semantic hash values were calculated for training data. Those vectors then goes into hierarchical k-means clustering, where the set of hash vectors are clustered into 64 in each level until the number of points within a cluster falls below 10,000.

6.2 Hardware and Software Setup

We used a Ubuntu 14.04 Linux server with 4 Nvidia TitanX GPUs for our experiments. Each GPU has 12GB memory and 3072 processing cores. The server has two 12-core Intel CPUs running at 2.4GHz. The system has 96 GB main memory.

Extraction of word features was implemented on CPU, using regular expressions and Kuromoji analyzer. It took around 8 hours to extract features from 280 million titles and descriptions.

DBN and DAE were implemented using CUDA library with C++. Earlier work by Raina et al. (2009) shows that GPU implementation of deep network training can be more than two order of magnitudes faster when compared with single-core CPU implementations. In our implementation, besides the kernels we have written for original operations like selective reconstruction, we exploited CUDAMat (Mnih, 2009), cuBLAS and cuSPARSE libraries (NVIDIA, 2015) for efficient matrix operations. During training iterations, model weights were kept in GPU memory and input word vectors were stored in main memory in sparse format. For even larger models, it is possible to store model weights in main memory and communicate working parameters in each batch with GPUs, and/or stream input features from disk drive. However, these choices considerably slows down GPU training times. During greedy layer-wise pre-training, upper layers were constructed on memory using on-memory sparse input word vectors and trained lower-layer weights. This is a more practical solution than storing each layer output and streaming it for training upper layers, because intermediate layers are not sparse, requiring huge amount of storage for intermediate layers for large number of training samples.

Hierarchical k-means clustering and kNN search using hierarchical k-means tree were also implemented using GPUs, using the guidelines explained in Cevahir and Torii's work (2013). With our settings explained above, it took several days to train deep models and k-means tree using 4 GPUs.

6.3 Prediction Recalls

We compared prediction results with merchants' assignments in our test data. Merchants' assignments in Rakuten Ichiba are quite noisy, having the same products by different merchants distributed through different categories and more than 40% of products are in "Others" leaf categories (such as "Women's Fashion > Tops > Sweaters > Long-sleeved knit > Others"). However, it was not easy to eliminate noise

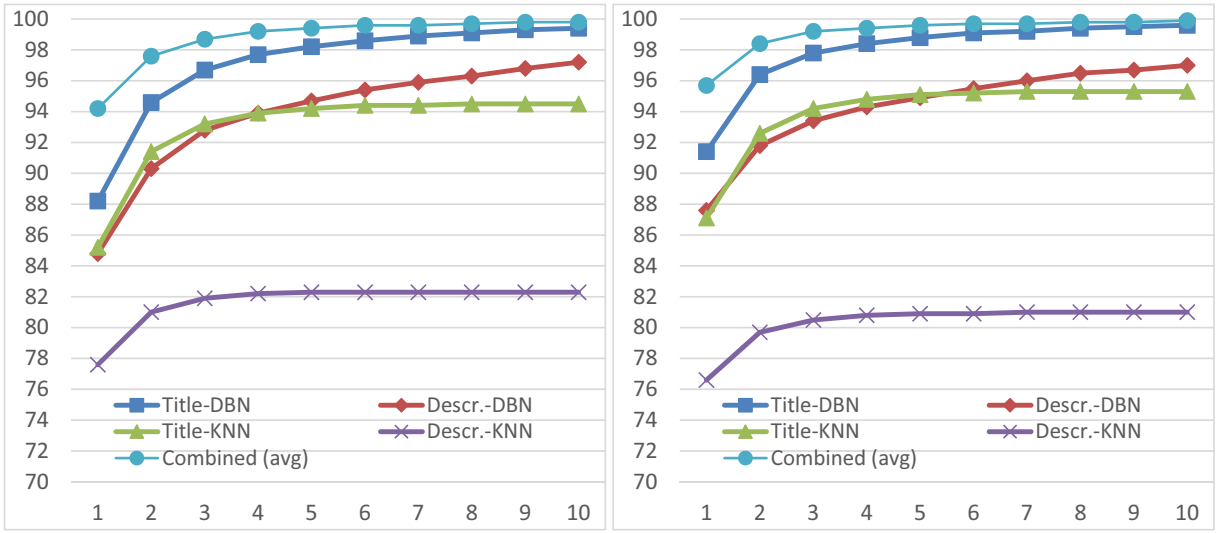

Figure 2: Top level category matching percent recalls (first step matching for 35 level-1 categories). **(a)** All categories including leaf-level categories named "Others", **(b)** excluding leaf-level categories named "Others".

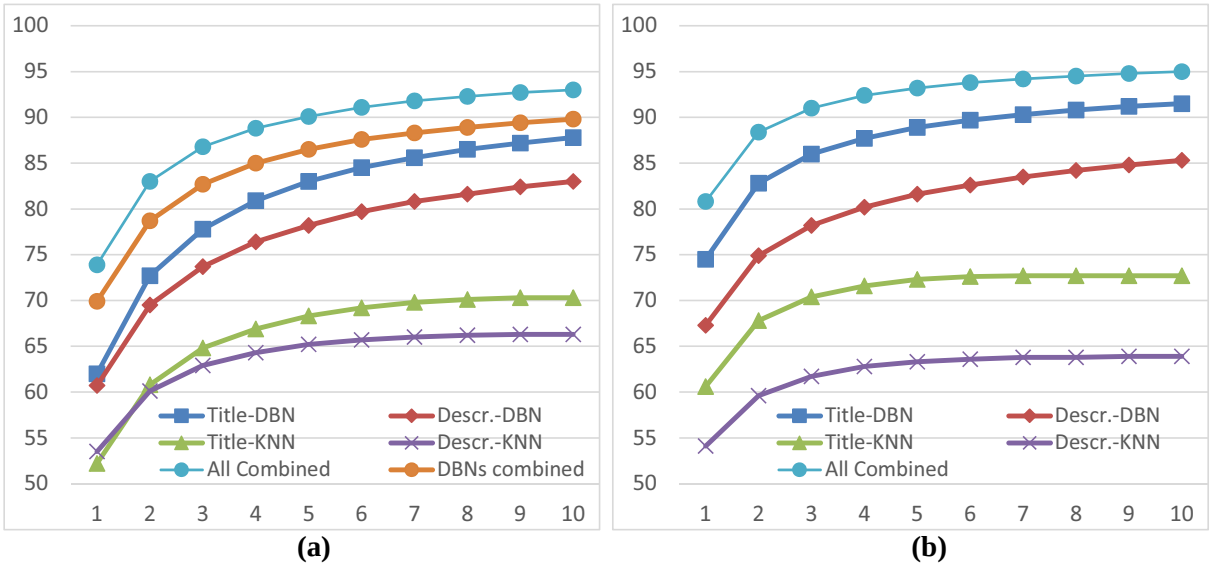

Figure 3: 2-step category matching percent recalls. **(a)** All 28,338 categories including leaf-level categories named "Others", **(b)** excluding leaf-level categories named "Others".

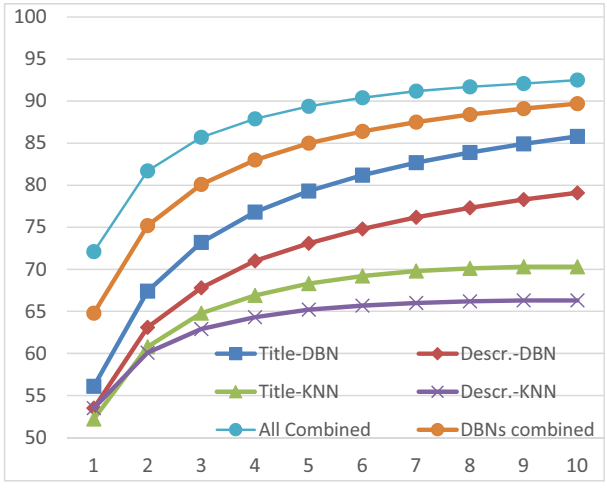

Figure 4: 1-step category matching percent recalls for all 28,338 categories including "Others".

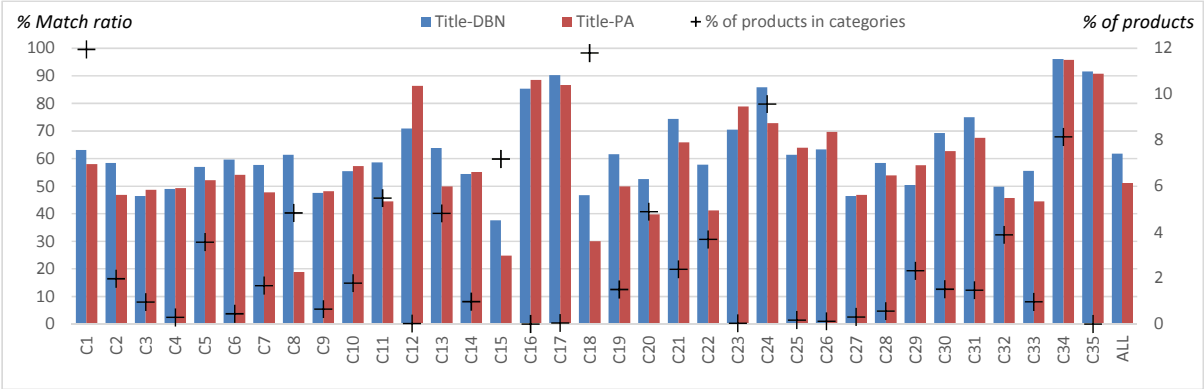

Figure 5: Comparison of category matching results grouped by first-level categories for title-DBN with a Passive-Aggressive algorithm with kernel slicing (Yoshinaga and Kitsuregawa, 2010).

for millions of test data in 28,338 categories by hand, hence we present prediction recalls considering the merchants' assignments as the basis.

Figure 2**a** depicts level-1 categorization matching percent ratios up to top-10 predictions in first step and Figure 3**a** depicts final categorization matching ratios after step 2. We excluded items from "Others" categories in evaluation results depicted in Figure 2**b** and Figure 3**b** as many products in those categories were miscategorized by merchants. Titles usually better define products, so title-based approaches yield better matching ratios than description-based approaches. DBN matching ratios were better than kNN classification, but the overall combination of methods by score averaging yielded much better matching ratios than each individual method.

Both using different data sources and different models affected the increase in matching ratios. The *DBNs combined* line in Figure 3**a** shows the matching ratios when only DBN models for titles and descriptions are combined. First prediction matches by 70% with the merchant assignments, which is better than individual model results, but combining kNN models as well increases the overall matching ratio for the first prediction 4% more.

The effect of making categorization in 2-steps, instead of using big 1-step models, can be observed by comparing results from Figure 3**a** and Figure 4. In Figure 4, categorization results are presented by using direct classification in one step with features used in the first step of 2-step approach. Although 2-step approach suffered from error propagation, number of features used in the second step is much larger, hence the overall matching ratios are better. Matching ratios of individual approaches had large gaps, but the gap reduces to 1.8% if combined models were compared for first predictions.

In order to confirm the effectiveness of deep network training for classification, we compared our results with a passive-aggressive (PA) learning algorithm (Crammer et al., 2006) with kernel slicing, using OPAL tool (Yoshinaga and Kitsuregawa, 2010). Figure 5 depicts the comparison between second step DBN classification and PA classification matching results using title data only for products grouped by level-1 categories. Please note that, we also tried one-step direct classification to 28,338 categories with PA, but it was not able to be trained on single server with 96 GB main memory, because of the memory overflow problem. It can be confirmed from the figure that DBN works better for 23 categories out of 35. Categories that PA works better were usually very small. The overall performance difference was between title-DBN and title-PA is more than 10%.

Although overall performance was worse for the passive-aggressive approach, one may think that it can still be used to increase accuracy by combining with the models which we have explained above. However, the scores given by the algorithm was not suitable for combining by score averaging.

6.4 Sample Results

Although we provide results for matching between our predictions and merchant categories, the actual correct prediction ratios are different. There are four possibilities in case of a mismatch between a prediction and the corresponding merchant: merchant correct / prediction incorrect, merchant incorrect /

	**Product title:** Sweet Mother - Isaac Andrews **Merchant Cat.:** Books, Magazines & Comics > Western Books > Books For Kids **Predicted Cat.:** Books, Magazines & Comics > Western Books > Fiction & Literature
	**Product title:** トヨトミ ［KS-67H］ 電子火式流型石油ストブ KS67H **Merchant Cat.:** Flowers, Garden & DIY/DIY & Tools > Others **Predicted Cat.:** Consumer electronics > Seasonal home appliances > Heating appliance > Oilstove > 14+ tatami (wooden) , 19+ tatami (rebar)
	**Product title:** レンタル【RG87】はかまフルセット/大学生/小学生/高校生/中学生 **Merchant Cat.:** Women's Fashion > Japanese style > Kimono > Hakama **Predicted Cat.:** Women's Fashion > Kimono > Rental
	**Product title:** 夜咄用具 スキヤろうそく 大 **Merchant Cat.:** Kitchenware, tableware & cookware > Japanese tableware > Tea utensils > Other **Predicted Cat.:** Kitchenware, tableware & cookware > Japanese tableware > Small bowl

Table 1: Sample results. Omitted description information. Images are for reference, not used for classification.

prediction correct, both correct, both incorrect. See Table 1 for sample results for those 4 cases.

In case merchant is correct and prediction is incorrect, confidence scores for predictions are lower. In the first example in Table 1, although it is predicted as a Western book, the type of the book is mispredicted. Second example is a typical mismatch case where merchant is incorrect. Products in "Others" categories, which account for 40% of all products, have high probability of being misplaced. It is possible to predict detailed correct categories for such products. In the third example, both merchant and our prediction can be considered as correct, as the product is a hakama style kimono, but it is rental. The candle in the last example is used for tea ceramonies, but it is not a tea utensil. It is predicted as small bowl because of the explanations about candle stand in the product description, but the prediction confidence score was quite low, 0.045.

7 Conclusion and Future Work

In this work, we have presented a categorization system for large scale e-commerce data using product titles and descriptions. We have trained our system with a dataset having hundreds of millions of products and tens of thousands of categories. Our tests confirm high matching ratios of predictions with merchant-assigned categories. We used different data sources and different algorithms for classification, where the final scores are calculated by averaging of scores of different models' results. Exploration and evaluation of different combination techniques of results are left as future work.

Although we have utilized all textual content about products in this work, we ignored image content as it takes a lot of time to process images. Our initial evaluations utilizing image data, which we have not discussed in this work, suggest that it is possible to increase the system performance by several percent. We leave full evaluation of the prediction system with image data as a future work.

Abstract

Product classification is the task of automatically predicting a taxonomy path for a product in a predefined taxonomy hierarchy given a textual product description or title. For efficient product classification we require a suitable representation for a document (the textual description of a product) feature vector and efficient and fast algorithms for prediction. To address the above challenges, we propose a new distributional semantics representation for document vector formation. We also develop a new two-level ensemble approach utilizing (with respect to the taxonomy tree) path-wise, node-wise and depth-wise classifiers to reduce error in the final product classification task. Our experiments show the effectiveness of the distributional representation and the ensemble approach on data sets from a leading e-commerce platform and achieve improved results on various evaluation metrics compared to earlier approaches.

1 Introduction

Existing e-commerce platforms have evolved into large B2C and/or C2C marketplaces having large inventories with millions of products. Products in ecommerce are generally organized into a hierarchical taxonomy of multilevel hierarchical categories. Product classification is an important task in catalog formation and plays a vital role in customer oriented services like search and recommendation and seller oriented services like seller utilities on a seller platform. Product classification is a hierarchical classification problem and presents the following challenges: a) a large number of categories have data that is extremely sparse with a skewed long tailed distribution, b) a hierarchical taxonomy imposes constraints on activation of labels. If a child label is active then it is necessary for a parent label to be active, c) for practical use the prediction should happen in real time - ideally within few milli-seconds.

Traditionally, documents have been represented as a weighted bag-of-words (BoW) or tf-idf feature vector, which contains weighted information about the presence or absence of words in a document by using a fixed length vector. Words that define the semantic content of a document are expected to be given higher weight. While tf-idf and BoW representations perform well for simple multi-class classification tasks, they generally do not do as well for more complex tasks because the BoW representation ignores word ordering and polysemy, is extremely sparse and high dimensional and does not encode word meaning. Such disadvantages have motivated continuous, low-dimensional, non-sparse distributional representations. A word is encoded as a vector in a low dimension vector space typically $\mathcal{R}^{100}$ to $\mathcal{R}^{300}$. The vector encodes local context and therefore is sensitive to local word order and captures word meaning to some extent. It relies on the 'Distributional Hypothesis'(Harris, 1954) i.e. *Similar words occur in similar contexts*. Similarity between two words can be calculated via cosine distance between their vector representations.

Le and Mikolov (Le and Mikolov, 2014) proposed paragraph vectors, which use global context together with local context to represent documents. But paragraph vectors suffer from the following problems: a) current techniques embed paragraph vectors in the same space (dimension) as word vectors

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 536–546, Osaka, Japan, December 11-17 2016.

although a paragraph can consist of words belonging to multiple topics (senses), b) current techniques also ignore the importance and distinctiveness of words across documents. They assume all words contribute equally both quantitatively (weight) and qualitatively (meaning).

In this paper we describe a new compositional technique for formation of document vectors from semantically enriched word vectors to address the above problems. Further, to capture importance, weight and distinctiveness of words across documents we use a graded weights approach, inspired by the work of Mukerjee et al. (Pranjal Singh, 2015), for our compositional model. We also propose a new two-level approach for product classification which uses an ensemble of classifiers for label paths, node labels and depth-wise labels (with respect to the taxonomy) to decrease classification error. Our new ensemble technique efficiently exploits the catalog hierarchy and achieves improved results in top K taxonomy path prediction. We show the effectiveness of the new representation and classification approach for product classification of two e-commerce data-sets containing book and non-book descriptions.

2 Related Work

2.1 Distributional Semantic Word Representation

The distributional word embedding method was first introduced by Bengio et al. as the Neural Probabilistic Language Model (Bengio et al., 2003). Later, Mikolov et al. (Mikolov et al., 2013) proposed a simple log-linear model which considerably reduced training time - Word2Vec Continuous Bag-of-Words (CBoW) model and Skip-Gram with Negative Sampling (SGNS) model. Figure 1 shows the architecture for CBoW (Left) and Skip-Gram (Right).

Later Glove (Jeffrey Pennington, 2014) a log-bilinear model with a weighted least-squares objective was proposed which uses the statistical ratio of global word-word co-occurrences in the corpus for training word vectors. The word vectors learned using the skip-gram model are known to encode many linear linguistic regularities and patterns (Levy and Goldberg, 2014b).

While the above methods look very different they implicitly factorize a shifted positive point-wise mutual information matrix (PPMI) with tuned hyper parameters as shown by Levy and Goldberg (Levy and Goldberg, 2014c). Some methods also describe use of non-linear dependency based context (Levy and Goldberg, 2014a). Some variants incorporate ordering information in context words to capture syntactic information by replacing summation of context word vectors with concatenation during training (Wang Ling, 2015) of CBoW and SGNS models.

2.2 Distributional Paragraph Representation

Most models for learning distributed representations for long text such as phrases, sentences or documents that try to capture semantic composition do not go beyond simple weighted average of word vectors. This approach is analogous to a bag-of-words approach and neglects word order while representing documents. Socher et al. (Socher et al., 2013) propose a recursive tensor neural network where the dependency parse-tree of the sentence is used to compose word vectors in a bottom-up approach to represent sentences or phrases. This approach considers syntactic dependencies but cannot go beyond sentences as it depends on parsing.

Mikolov proposed a distributional paragraph vector framework called paragraph vectors which are trained in a manner similar to word vectors. He proposed two types of models called *Distributed Memory Model Paragraph Vectors (PV-DM)* (Le and Mikolov, 2014) and *Distributed BoWs paragraph vectors (PV-DBoW)* (Le and Mikolov, 2014). In PV-DM the model is trained to predict the center word using context words in a small window and the paragraph vector (Le and Mikolov, 2014). Here context words to be predicted are represented by w_{t-k},....,w_{t+k} and the document vector is represented by D_i. In PV-DBoW the paragraph vector is trained to predict context words directly. Figure 2 shows the network architecture for PV-DM(Left) and PV-DBoW(Right).

The paragraph vector presumably represents the global semantic meaning of the paragraph and also incorporates properties of word vectors i.e. meanings of the words used. A paragraph vector exhibits close resemblance to an n-gram model with a large n. This property is crucial because the n-gram model preserves a lot of information in a sentence (and the paragraph) and is sensitive to word order.

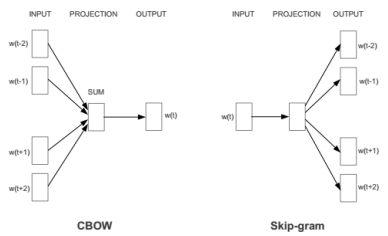

Figure 1

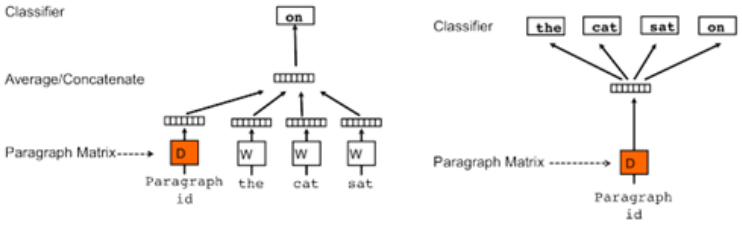

Figure 2

This model mostly performs better than the BoW models which usually create a very high-dimensional representation leading to poorer generalization.

2.3 Problem with Paragraph Vectors

Paragraph vectors obtained from PV-DM and PV-DBoW are shared across context words generated from the same paragraph but not across paragraphs. On the other hand a word is shared across paragraphs. Paragraph vectors are also represented in the same space (dimension) as word vectors though a paragraph can contain words belonging to multiple topics (senses). The formulation for paragraph vectors ignores the importance and distinctiveness of a word across documents i.e. assumes all words contribute equally both quantitatively (weight wise) and qualitatively (meaning wise). Quantitatively, only binary weights i.e. 0 weight for stop-words and non-zero weight for others are used. Intuitively, one would expect the paragraph vector to be embedded in a larger and enriched space.

2.4 Hierarchical Product Categorization

Most methods for hierarchical classification follow a *gates-and-experts* method which have a two level classifier. The high-level classifier serves as a "gate" to a lower level classifier called the "expert" (Shen et al., 2011). The basic idea is to decompose the problem into two models, the first model is simple and does coarse-grained classification while the second model is more complex and does more fine-grained classification. The coarse-grained classification deals with a huge number of examples while the fine-grained distinction is learned within a subtree under every top level category with better feature generation and classification algorithms and deals with fewer categories. Later, Xue et al. (Xue et al., 2008) suggested an interesting two stage strategy called *"deep classification"*. The first stage (search) groups documents in the training set that are similar to a given document. In the second stage (classification) a classifier is trained on these classes and used to classify the document. In this approach a specific classifier is trained for each document making the algorithm computationally inefficient.

For large scale classification Bengio et al. (Bengio et al., 2010) use the confusion matrix for estimating class similarity instead of clustering data samples. Two classes are assumed to be similar if they are often confused by a classifier. Spectral clustering, where the edges of the similarity graph are weighted by class confusion probabilities, is used to group similar classes together.

Shen and Ruvini (Shen et al., 2012) (Shen et al., 2011) extend the previous approach by using a mixture of simple and complex classifiers for separating confused classes rather then spectral clustering methods which has faster training times. They approximate the similarity of two classes by the probability that the classifier incorrectly predicts one of the categories when the correct label is the other category. Graph algorithms are used to generate connected groups from estimated confusion probabilities. They represent the relationship among classes using an undirected graph $G = (V, E)$, where the set of vertices V is the set of all classes and E is the set of all edges. Two vertices's are connected by an edge if the confusion probability $Conf(c_1, c_2)$ is greater than a given threshold α (Shen et al., 2012).

Other simple approaches like flat classification and top down classification are intractable due to the large number of classes and give poor results due to error propagation as described in (Shen et al., 2012).

3 Graded Weighted Bag of Word Vectors

We propose a new method to form a composite document vector using word vectors i.e. distributional meaning and tf-idf and call it a Graded Weighted Bag of Words Vector (gwBoWV). gwBoWV is inspired from the computer vision literature where we use a Bag of Visual words to form feature vectors. gwBoWV is calculated as follows:

1. Each document is represented in a lower dimensional space $D = K * d + K$, where K represents number of semantic clusters and d is the dimension of the word-vectors.

2. Each document is also concatenated with inverse cluster frequency(icf) values which is calculated using idf values of words present in the document.

Idf values from the training corpus are directly used for the test corpus for weighting. Word vectors are first separated into a pre-defined number of semantic clusters using a suitable clustering algorithm (e.g. k-means). For each document we add the word-vectors of each word in the document belonging to a cluster to form a cluster vector. We finally concatenate the cluster vector and the icf for each of the K clusters to obtain the document vector. Algorithm 1 describes this in more detail.

Algorithm 1: Graded Weighted Bag of Word Vectors

Data: Documents D_n, n = 1 . . . N
Result: Document vectors $gw\vec{BoWV}_{D_n}$, n = 1 . . . N

Train SGNS model to obtain word vector representation (wv_n) using all document D_n, $n = 1..N$;
Calculate idf values for all words: $idf(w_j)$, $j = 1..|V|$; `/* |V| is vocabulary size */`
Use K-means algorithm for clustering all words in V using their word-vectors into K clusters;
for $i \in (1..N)$ **do**
    Initialize cluster vector $c\vec{v}_k = \vec{0}$, $k = 1..K$;
    Initialize cluster frequency $icf_k = 0$, $k = 1..K$;
    while *not at end of document* D_i **do**
        read current word w_j and obtain wordvec $w\vec{v}_j$;
        obtain cluster index $k = idx(w\vec{v}_j)$ for wordvec $w\vec{v}_j$;
        update cluster vector $c\vec{v}_k += w\vec{v}_j$;
        update cluster frequency $icf_k += idf(w_j)$;
    end
    obtain $gw\vec{BoWV}_{D_i} = \bigoplus_{k=1}^{K} c\vec{v}_k \oplus icf_k$; `/* ⊕ is concatenation */`
end

Since semantically different vectors are in separate clusters we avoid averaging of semantically different words during Bag of Words Vector formation. Incorporation of idf values captures the weight of each cluster vector which tries to model the importance and distinctiveness of words across documents.

4 Ensemble of Multitype Predictors

We propose a two level ensemble technique to combine multiple classifiers predicting product paths, node labels and depth-wise labels respectively. We construct an ensemble of multi-type features for categorization inspired by the recent work of Zornitsa et. al. from Yahoo Labs (Kozareva, 2015). Below are the details of each classifier used at level one:

- *Path-Wise Prediction Classifier*: We take each possible *path* in the catalog taxonomy tree, from leaf node to root node, as a possible class label and train a classifier (PP) using these labels.

- *Node-Wise Prediction Classifier*: We take each possible *node* in the catalog taxonomy tree as a possible prediction class and train a classifier (NP) using these class labels.

- *Depth-Wise Node Prediction Classifiers*: We train multiple classifiers (DNP_i) one for each depth level of the taxonomy tree. Each possible *node* in the catalog taxonomy tree at that depth is a possible class label. We take all data samples which have a potential node at depth k for training. For samples of data point whose path ended before depth k we use special None Label and use 10% of such data points for training.

We use the output probabilities of these classifiers at level one (PP, NP, DNP_i) as a feature vector and train a classifier (level two) after some dimensionality reduction.

The increase in training time can be reduced by training all level one classifiers in parallel. The algorithm for training the ensemble is described in Algorithm 2. The testing algorithm is similar to training Algorithm 3

Algorithm 2: Training Two Level Boosting Approach

Data: Catalog Taxonomy Tree (T) of depth M and training data D = (d, p_d) where d is the product description and p_d is the taxonomy path label.

Result: Set of level one Classifiers C = $\{PP, NP, DNP_1, \ldots, DNP_M\}$ and level two classifier FPP.

1 Obtain $gw\vec{BoW}V_d$ features for each product description d ;

2 Train Path-Wise Prediction Classifier (PP) with possible classes as product taxonomy paths (p_d);

3 Train Node-Wise Prediction Classifier (NP) with possible classes as nodes in taxonomy path i.e. (n_d). Here each description will have multiple node labels.

4 **for** $m \in (1 \ldots M)$ **do**

5 Train Depth-Wise Node Classifier for depth m (DNP_m) with labels as nodes at depth m i.e. (n_m)

6 **end**

7 Obtain output probabilities $\vec{P}_X$ over all classes for each level one classifier X i.e. $\vec{P}_{PP}$, $\vec{P}_{NP}$ and $\vec{P}_{DNP_m}$, $m = 1..M$.;

8 Obtain feature vector $\vec{FV}_d$ for each description as:

$$\vec{FV}_d = gw\vec{BoW}V_d \oplus \vec{P}_{PP} \oplus \vec{P}_{NP} \bigoplus_{m=1}^{M} \vec{P}_{DNP_m} \quad (1)$$

/* $\bigoplus$ is the concatenation operation */

9 Reduce feature dimension ($R\vec{FV}_d$) using suitable supervised feature selection technique based on mutual information criteria;

10 Train Final Path-Wise Prediction Classifier ($F\vec{PP}_d$) using RFV_d as feature vector and possible class labels as product taxonomy paths (p_d)

5 Dataset

We use seller product descriptions and title samples from a leading e-commerce site for experimentation[1]. The data set had two product taxonomies:*non-book* and *book*. Non-book data is more discriminative with average description + title length of around 10 to 15 words, whereas book descriptions have an average length greater than 200 words. To give more importance to the title compared to the description, we repeated words in title three times (i.e. weighting trice). The distribution of items over leaf categories (verticals) exhibits high skewness and heavy tailed nature and suffers from sparseness as shown in Figure 3. We use random forest and k-nearest neighbors as base classifiers as they are less affected by data skewness.

[1]This data is proprietary to the e-commerce Company. Major part of the work was done when the first author was a research ex-tern at the E-Commerce Company Flipkart

Algorithm 3: Testing Two Level Boosting Approach

Data: Catalog Taxonomy Tree (T) of depth M and testing data D = (d,p_d) where d is product description p_d is taxonomy of paths. Set of level one Classifiers C = $\{PP$,NP,$DNP_1 \ldots DNP_M\}$ and final level two classifier FPP

Result: top 6 prediction path P_d for training description d

1 Obtain $gw\vec{BoW}V_d$ features for each product description d in test data;

2 Get Prediction Probabilities from all level one classifiers to obtain level two feature vector ($\vec{FV}_d$) using Equation 1;

3 Obtain ($\vec{RFV}_d$) reduced feature vector;

4 Output top m paths from final prediction using output probabilities from level two classifier FFP for description d.

Level	#Categories	%Data Samples
1	21	34.9%
2	278	22.64%
3	1163	25.7%
4	970	12.9%
5	425	3.85%
6	18	0.10%

Table 1: Percentage of Book Data ending at each depth level of the book taxonomy hierarchy which had a maximum depth of 6.

We have removed data samples with multiple paths to simplify the problem to single path prediction. Overall, we have 0.16 million training and 0.11 million testing samples for book data and 0.5 million training and 0.25 million testing samples for non-book data. Since the taxonomy evolved over time all category nodes are not semantically mutually exclusive. Some ambiguous leaf categories are even meta categories. We handle this by giving a unique id to every node in the category tree of book-data. Furthermore, there are also category paths with different categories at the top and similar categories at the leaf nodes i.e. reduplication of the same path with synonymous labels. Below are examples of such synonymous path labels.

1. *Household → Lights and Lamps → Bulbs → LED Bulbs*

2. *Home Decor → Lights and Lamps → Bulbs → LED Bulbs*

Another Example

1. *Home Furnishing → Living → Cushion Pillow Covers*

2. *Home Furnishing → Bed → Pillows and Pillow Covers → Pillow Covers*

The quality of the descriptions and titles also varies a lot. There are titles and descriptions that do not contain enough information to decide an unique appropriate category. There were labels like *Others* and *General* at various depths in the taxonomy tree which carry no specific semantic meaning. Also, descriptions with the special label 'wrong procurement' are removed manually for consistency.

6 Results

The classification system is evaluated using the usual precision metric defined as fraction of products from test data for which the classifier predicts correct taxonomy paths. Since there are multiple similar paths in the data set predicting a single path is not appropriate. One solution is to predict more than one path or better a ranked list of 3 to 6 paths with predicted label coverage matching labels in the true path.

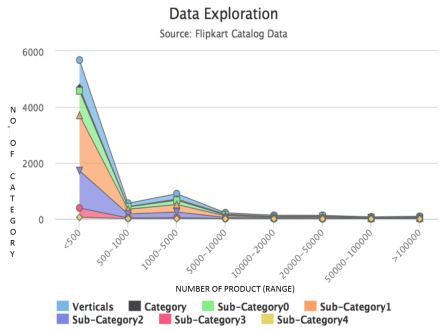

Figure: 3

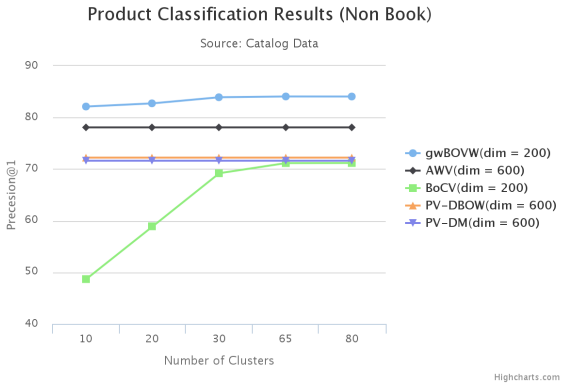

Figure: 4

The ranking is obtained using the confidence score of the predictor. We also calculate the confidence score of the correct prediction path by using the k (3 to 6) confidence scores of the individual predicted paths. For the purpose of measuring accuracy when more than one path is predicted, the classifier result is counted as correct when the correct class (i.e. path assigned by seller) is one of the returned class (paths). Thus we calculated Top 1, Top 3 and Top 6 prediction accuracy when 1, 3 and 6 paths are predicted respectively.

6.1 Non-Book Data Result

We also compare our results with document vectors formed by averaging word-vectors of words in the document i.e. Average Word Vectors (AWV), Distributed Bag of Words version of Paragraph Vector by Mikolov (PV-DBoW), Frequency Histogram of word distribution in Word-Clusters i.e. Bag of Cluster Vector (BoCV). We keep the classifier (random forest with 20 trees) common for all document vector representations. We compare performance with respect to number of clusters, word-vector dimension, document vector dimension and vocabulary dimension (tf-idf) for various models.

Figure 4 shows results for a random forest (20 trees) on various classifiers trained by various methods on 0.2 million training and 0.2 million testing samples with 3589 classes. It compares our approach gwBoWV with PV-DBoW and PV-DM models with varying word vector dimension and number of clusters. The dimension of word vector for gwBoVW and BoCV is 200. Note AWV , PV-DM and PV-DBoW are independent of cluster number and have dimension 600. Clearly gwBoWV performs much better than other methods especially PV-DBoW and PV-DM. Table 2 Shows the effect of varying cluster numbers on accuracy for Non Book Data for 0.2 million training and testing using 200 dimension word vector for Top 1 prediction using gwBoWV.

# Cluster	Precision@1
10	81.35%
20	82.29%
50	83.66%
65	83.85%
80	83.91%
100	84.40%

Table 2: *Result of classification on varying Cluster Numbers for fixed word vector size 200 for Non Book Data for Precision@1 on #Train Sample = 0.2 million , #Test Sample = 0.2 million*

We use the notation given below to define our evaluation metrics for Top K path prediction :

- τ^* represents the true path for a product description.
- τ_i represents the i^{th} predicted path by our algorithm , where $i \in \{1, 2 \dots K\}$.

#Clus, #Dim	%PP	%CP	%LR	%LC
40, 50	82.07	96.43	98.27	34.50
40, 100	**83.18**	96.67	98.39	**34.91**
100, 50	82.05	96.40	98.26	34.41
100,100	83.13	**96.75**	**98.42**	34.88

Table 3: *Result for top 6 paths predicted for multiple Bag of Word Vectors with varying dimension and number of clusters with weighting on Non-Book Data with #Training Samples = 0.50 million, #Test Samples = 0.35 million.*

#Dim	%PP	%CP	%LR	%LC
2000	81.10	94.04	96.85	35.37
4000	**82.74**	**94.78**	**97.33**	**35.61**

Table 4: *Result of top 6 paths prediction for tf-idf with varying dimension on Non Book Data #Training Samples = 0.50 million, #Test Samples = 0.35 million.*

- $\mathbb{T}^*$ represent the nodes in true path τ^*.
- $\mathbb{T}^i$ represents the nodes in i^{th} predicted path τ_i, where $i \in \{1, 2 \dots K\}$.
- p(τ^*) represents the probability predicted by our algorithm for the true path τ^*. p(τ^*) = 0 if $\tau^* \notin \{\tau_1, \tau_2 \dots \tau_K\}$
- p(τ_i) represents the probability of i^{th} predicted path by the algorithm, here $i \in \{1, 2 \dots K\}$.

We use four evaluation metrics to measure performance for the top k predictions as described below:

1. Prob Precision @ K : $PP@K$ = p(τ^*) / (p(τ_1) + p(τ_2) + . . . + p(τ_K)).
2. Count Precision @ K : $CP@k$ = 1 if $\tau^* \in \{\tau_1, \tau_2 \dots \tau_K\}$ else $CP@K$ = 0.
3. Label Recall @ K : $LR@k$ = $\|\mathbb{T}^* \cap (\cup_1^K \mathbb{T}^i)\| / \|\mathbb{T}^*\|$. Here $\|$S$\|$ represent number of elements in set S.
4. Label Correlation @ K : $LC@k$ = $\| \cap_1^K \mathbb{T}^i \| / \| \cup_1^K \mathbb{T}^i \|$. Here $\|$S$\|$ represent number of elements in set S.

Table 3 shows the results on all evaluation metrics with varying word-vec dimension and clusters on Non Book Data. Table 4 shows results of top 6 paths prediction for tf-idf baseline with varying dimension for Non Book Data.

6.2 Book Data Result

Book data is harder to classify as it has larger text ($>$ 200 words) with more common words. There are more cases of improper paths and labels in the taxonomy and hence we had to do a lot of pre-processing. Around 51% of the books did not have labels at all and 15% books were given extremely ambiguous labels like 'general' and 'others'. To maintain consistency we prune the above 66% data samples and work with the remaining 44% i.e. 0.37 million samples.

To handle improper labels and ambiguity in the taxonomy we use multiple classifiers one predicting path (or leaf) label, another predicting node labels and multiple classifiers, one at each depth level of the taxonomy tree, that predict node labels at that level. In depth-wise node classification we also introduce the 'none' label to denote missing labels at a particular level i.e. for paths that end at earlier levels. However we only take a random strata sample for this 'none' label.

Ensemble	Dim_n	Feature	%PP	%CP	%LR	%LC

Yes	8000	gwBoWV	45.64	**77.26**	**88.86**	24.57
Yes	6000	gwBoWV	**46.68**	75.74	87.67	**25.08**

Table 5: *Results from various approaches for Top 6 predictions for Book Data*

Accuracy	Precision	Recall	F-score
81.6%	81.1%	81.1%	80.9%

Table 6: *Preliminary Result of gwBoWV with 60 clusters on word-vector dimension of 200 (min word count 20, context window 10), 83% features selection with Anova reduction, C is 2.1 with Linear SVM (one vs rest) on 20newsGroup using weighted averaging for Precision, F-Score and Recall.*

6.3 Ensemble Classification

We use the ensemble of multi-type predictors as described in Section 4 for final classification on Book Data. Results on Non-Book data was already very good and as discussed earlier books were harder to classify. For dimensionality reduction we use feature selection methods based on mutual information criteria (ANOVA F-value i.e. analysis of variance). We obtain improved results for all four evaluation metrics with the new ensemble technique as shown in Table 5 for Book Data for Top 6 Prediction.

6.4 Real Examples from Book Data

Description : *harpercollins continues with its commitment to reissue maurice sendaks most beloved works in hardcover by making available again this 1964 reprinting of an original fairytale by frank r stockton as illustrated by the incomparable maurice sendak in the ancient country of orn there lived an old man who was called the beeman because his whole time was spent in the company of bees one day a junior sorcerer stopped at the hut of the beeman the junior sorcerer told the beeman that he has been transformed if you will find out what you have been transformed from i will see that you are made all right again said the sorcerer could it have been a giant or a powerful prince or some gorgeous being whom the magicians or the fairies wish to punish the beeman sets out to discover his original form. the beeman of orn. the beeman of orn. the beeman of orn.*

6.5 Quality of WordVec Clusters

Below are examples of words contained in some clusters formed by clustering of word vectors and their possible cluster topic meaning for book data.

1. Cluster #0 basically talks about crime and punishment related terms like *accused, arrest, assault, attempted, beaten, attorney,brutal,confessions, convicted cops, corrupt, custody, dealer, gang, investigative, gangster, guns, hated, jails, judge, mob, undercover, trail, police, prison, lawyer, torture, witness etc*

2. Cluster #10 talks about scientific experiments and related terms like *yield, valid, variance, alternatives, analyses, calculating, comparing, assumptions, criteria, determining, descriptive, evaluation, formulation, experiments, measures model, parameters, inference, hypothesis etc*

Similarly, Cluster #13 is talking about dating and marriage, Cluster #11 about tools and tutorials and Cluster #15 about persons. Similarity of words within a cluster leads to an efficient distributional semantic representation of word vectors.

7 Conclusions

We presented a novel compositional technique using embedded word vectors to form appropriate document vectors. Further, to capture importance, weight and distinctiveness of words across documents we used a graded weighting approach. Our document vectors are embedded in a vector space that is different from and has higher dimension than the word embedding vector space. This higher dimensional document vector space tries to encode the intuition that a document has more topics than a word.

We also developed a new technique which uses an ensemble of multiple classifiers that predicts label paths, node labels and depth-wise labels to decrease classification error. We tested our method on data sets from a leading e-commerce platform We gain nearly 4% PP@K , 2% CP@K , 2% LR@K and 3% LC@K using gwBoWV with the ensemble classifier compared to other competing methods without the ensemble classifier - see top 6 path prediction on Book Data in Table 5. On Non Book Data we gain nearly 2% in CP@K using gwBoWV without ensemble refer Table 3 and Table 4.

8 Future Work

The number of clusters K is a hyper-parameter we would like to learn this from the data set. We intend to extend the gwBOVW approach to incorporate the path class label in some fashion during the embedding. However, most results are shown on proprietary e-commerce datsets. We experimented gwBoWV with the 20newsgroup data-set and obtain state of art results(Liu et al., 2015) refer Table 6. We are currently applying the approach on large a scale public hierarchy like DMOZ and Wikipedia.

Abstract

Query relevance ranking and sentence saliency ranking are the two main tasks in extractive query-focused summarization. Previous supervised summarization systems often perform the two tasks in isolation. However, since reference summaries are the trade-off between relevance and saliency, using them as supervision, neither of the two rankers could be trained well. This paper proposes a novel summarization system called AttSum, which tackles the two tasks jointly. It automatically learns distributed representations for sentences as well as the document cluster. Meanwhile, it applies the attention mechanism to simulate the attentive reading of human behavior when a query is given. Extensive experiments are conducted on DUC query-focused summarization benchmark datasets. Without using any hand-crafted features, AttSum achieves competitive performance. We also observe that the sentences recognized to focus on the query indeed meet the query need.

1 Introduction

Query-focused summarization (Dang, 2005) aims to create a brief, well-organized and fluent summary that answers the need of the query. It is useful in many scenarios like news services and search engines, etc. Nowadays, most summarization systems are under the extractive framework which directly selects existing sentences to form the summary. Basically, there are two major tasks in extractive query-focused summarization, i.e., to measure the saliency of a sentence and its relevance to a user's query.

After a long period of research, learning-based models like Logistic Regression (Li et al., 2013) etc. have become growingly popular in this area. However, most current supervised summarization systems often perform the two tasks in isolation. Usually, they design query-dependent features (e.g., query word overlap) to learn the relevance ranking, and query-independent features (e.g., term frequency) to learn the saliency ranking. Then, the two types of features are combined to train an overall ranking model. Note that the only supervision available is the reference summaries. Humans write summaries with the trade-off between relevance and saliency. Some salient content may not appear in reference summaries if it fails to respond to the query. Likewise, the content relevant to the query but not representative of documents will be excluded either. As a result, in an isolated model, weights for neither query-dependent nor query-independent features could be learned well from reference summaries.

In addition, when measuring the query relevance, most summarization systems merely make use of surface features like the TF-IDF cosine similarity between a sentence and the query (Wan and Xiao, 2009). However, relevance is not similarity. Take the document cluster "d360f" in DUC[1] 2005 as an example. It has the following query: *What are the benefits of drug legalization?* Here, "Drug legalization" are the key words with high TF-IDF scores. And yet the main intent of the query is to look for "benefit", which is a very general word and does not present in the source text at all. It is not surprising that when measured by the TF-IDF cosine similarity, the sentences with top scores all contain the words "drug" or "legalization". Nevertheless, none of them provides advantages of drug legalization. See Section 4.6

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 547–556, Osaka, Japan, December 11-17 2016.

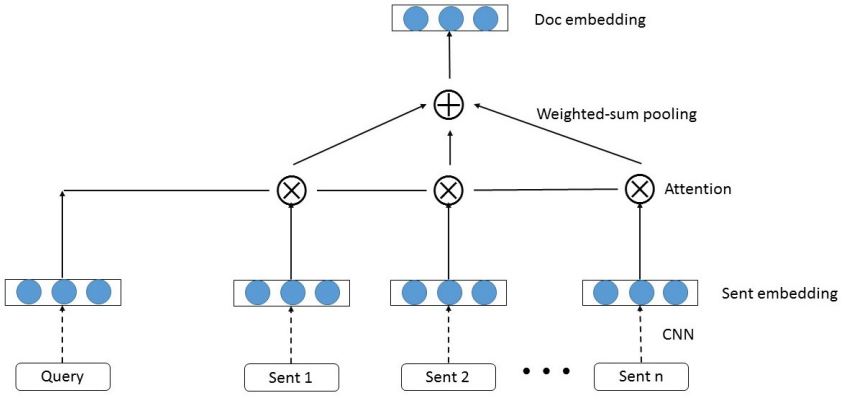

Figure 1: Generation of sentence and document cluster embeddings. "⊕" stands for a pooling operation, while "⊗" represents a relevance measurement function.

for reference. Apparently, even if a sentence is exactly the same as the query, it is still totally useless in the summary because it is unable to answer the query need. Therefore, the surface features are inadequate to measure the query relevance, which further augments the error of the whole summarization system. This drawback partially explains why it might achieve acceptable performance to adopt generic summarization models in the query-focused summarization task (e.g., (Gillick and Favre, 2009)).

Intuitively, the isolation problem can be solved with a joint model. Meanwhile, neural networks have shown to generate better representations than surface features in the summarization task (Cao et al., 2015b; Yin and Pei, 2015). Thus, a joint neural network model should be a nice solution to extractive query-focused summarization. To this end, we propose a novel summarization system called AttSum, which joints query relevance ranking and sentence saliency ranking with a neural attention model. The attention mechanism has been successfully applied to learn alignment between various modalities (Chorowski et al., 2014; Xu et al., 2015; Bahdanau et al., 2014). In addition, the work of (Kobayashi et al., 2015) demonstrates that it is reasonably good to use the similarity between the sentence embedding and document embedding for saliency measurement, where the document embedding is derived from the sum pooling of sentence embeddings. In order to consider the relevance and saliency simultaneously, we introduce the weighted-sum pooling over sentence embeddings to represent the document, where the weight is the automatically learned query relevance of a sentence. In this way, the document representation will be biased to the sentence embeddings which match the meaning of both query and documents. The working mechanism of AttSum is consistent with the way how humans read when having a particular query in their minds. Naturally, they pay more attention to the sentences that meet the query need. It is noted that, unlike most previous summarization systems, our model is totally data-driven, i.e., all the features are learned automatically.

We verify AttSum on the widely-used DUC 2005 $\sim$ 2007 query-focused summarization benchmark datasets. AttSum outperforms widely-used summarization systems which rely on rich hand-crafted features. We also conduct qualitative analysis for those sentences with large relevance scores to the query. The result reveals that AttSum indeed focuses on highly query relevant content.

The contributions of our work are as follows:

- We apply the attention mechanism that tries to simulate human attentive reading behavior for query-focused summarization;
- We propose a joint neural network model to learn query relevance ranking and sentence saliency ranking simultaneously.

2 Query-Focused Sentence Ranking

For generic summarization, people read the text with almost equal attention. However, given a query, people will naturally pay more attention to the query relevant sentences and summarize the main ideas

from them. Similar to human attentive reading behavior, AttSum, the system to be illustrated in this section, ranks the sentences with its focus on the query. The overall framework is shown in Fig. 1. From the bottom to up, AttSum is composed of three major layers.

CNN Layer Use Convolutional Neural Networks to project the sentences and queries onto the embeddings.

Pooling Layer With the attention mechanism, combine the sentence embeddings to form the document embedding in the same latent space.

Ranking Layer Rank a sentence according to the similarity between its embedding and the embedding of the document cluster.

The rest of this section describes the details of the three layers.

2.1 CNN Layer

Convolutional Neural Networks (CNNs) have been widely used in various Natural Language Processing (NLP) areas including summarization (Cao et al., 2015b; Yin and Pei, 2015). They are able to learn the compressed representations of n-grams effectively and tackle the sentences with variable lengths naturally. We use CNNs to project both sentences and the query onto distributed representations, i.e.,

$$\mathbf{v}(s) = \text{CNN}(s)$$
$$\mathbf{v}(q) = \text{CNN}(q)$$

A basic CNN contains a convolution operation on the top of word embeddings, which is followed by a pooling operation. Let $\mathbf{v}(w_i) \in \mathbb{R}^k$ refer to the k-dimensional word embedding corresponding to the i_{th} word in the sentence. Assume $\mathbf{v}(w_i : w_{i+j})$ to be the concatenation of word embeddings $[\mathbf{v}(w_i), \cdots, \mathbf{v}(w_{i+j})]$. A convolution operation involves a filter $\mathbf{W}_t^h \in \mathbb{R}^{l \times hk}$, which is applied to a window of h words to produce the abstract features $\mathbf{c}_i^h \in \mathbb{R}^l$:

$$\mathbf{c}_i^h = f(\mathbf{W}_t^h \times \mathbf{v}(w_i : w_{i+j})), \tag{1}$$

where $f(\cdot)$ is a non-linear function and the use of $tanh$ is the common practice. To simplify, the bias term is left out. This filter is applied to each possible window of words in the sentence to produce a feature map. Subsequently, a pooling operation is applied over the feature map to obtain the final features $\hat{\mathbf{c}}^h \in \mathbb{R}^l$ of the filter. Here we use the max-over-time pooling (Collobert et al., 2011).

$$\hat{\mathbf{c}}^h = \max\{\mathbf{c}_1^h, \mathbf{c}_2^h, \cdots\} \tag{2}$$

The idea behind it is to capture the most important features in a feature map. $\hat{\mathbf{c}}^h$ is the output of CNN Layer, i.e., the embeddings of sentences and queries.

2.2 Pooling Layer

With the attention mechanism, AttSum uses the weighted-sum pooling over the sentence embeddings to represent the document cluster. To achieve this aim, AttSum firstly learns the query relevance of a sentence automatically:

$$r(s, q) = \sigma(\mathbf{v}(s)\mathbf{M}\mathbf{v}(q)^T), \tag{3}$$

where $\mathbf{v}(s)\mathbf{M}\mathbf{v}(q)^T, \mathbf{M} \in \mathbb{R}^{l \times l}$ is a tensor function, and σ stands for the sigmoid function. The tensor function has the power to measure the interaction between any two elements of sentence and query embeddings. Therefore, two identical embeddings will have a low score. This characteristic is exactly what we need. To reiterate, relevance is not equivalent to similarity. Then with $r(s, q)$ as weights, we introduce the weighted-sum pooling to calculate the document embedding $\mathbf{v}(d|q)$:

$$\mathbf{v}(d|q) = \sum\nolimits_{s \in d} r(s, q)\mathbf{v}(s) \tag{4}$$

Notably, a sentence embedding plays two roles, both the pooling item and the pooling weight. On the one hand, if a sentence is highly related to the query, its pooling weight is large. On the other hand, if a sentence is salient in the document cluster, its embedding should be representative. As a result, the weighted-sum pooling generates the document representation which is automatically biased to embeddings of sentences match both documents and the query.

AttSum simulates human attentive reading behavior, and the attention mechanism in it has actual meaning. The experiments to be presented in Section 4.6 will demonstrate its strong ability to catch query relevant sentences. Actually, the attention mechanism has been applied in one-sentence summary generation before (Rush et al., 2015; Hu et al., 2015). The success of these works, however, heavily depends on the hand-crafted features. We believe that the attention mechanism may not be able to play its anticipated role if it is not used appropriately.

2.3 Ranking Layer

Since the semantics directly lies in sentence and document embeddings, we rank a sentence according to its embedding similarity to the document cluster, following the work of (Kobayashi et al., 2015). Here we adopt cosine similarity:

$$\cos(d, s|q) = \frac{\mathbf{v}(s) \bullet \mathbf{v}(d|q)^T}{||\mathbf{v}(s)|| \bullet ||\mathbf{v}(d|q)||} \tag{5}$$

Compared with Euclidean distance, one advantage of cosine similarity is that it is automatically scaled. According to (Kågebäck et al., 2014), cosine similarity is the best metrics to measure the embedding similarity for summarization.

In the training process, we apply the pairwise ranking strategy (Collobert et al., 2011) to tune model parameters. Specifically, we calculate the ROUGE-2 scores (Lin, 2004) of all the sentences in the training dataset. Those sentences with high ROUGE-2 scores are regarded as positive samples, and the rest as negative samples. Afterwards, we randomly choose a pair of positive and negative sentences which are denoted as s^+ and s^-, respectively. Through the CNN Layer and Pooling Layer, we generate the embeddings of $\mathbf{v}(s^+)$, $\mathbf{v}(s^-)$ and $\mathbf{v}(d|q)$. We can then obtain the ranking scores of s^+ and s^- according to Eq. 5. With the pairwise ranking criterion, AttSum should give a positive sample a higher score in comparison with a negative sample. The cost function is defined as follows:

$$\begin{aligned} &\epsilon(d, s^+, s^-|q) \\ &= \max(0, \Omega - \cos(d, s^+|q) + \cos(d, s^-|q)), \end{aligned} \tag{6}$$

where Ω is a margin threshold. With this cost function, we can use the gradient descent algorithm to update model parameters. In this paper, we apply the diagonal variant of AdaGrad with mini-batches (Duchi et al., 2011). AdaGrad adapts the learning rate for different parameters at different steps. Thus it is less sensitive to initial parameters than the stochastic gradient descent.

3 Sentence Selection

A summary is obliged to offer both informative and non-redundant content. While AttSum focuses on sentence ranking, it employs a simple greedy algorithm, similar to the MMR strategy (Carbonell and Goldstein, 1998), to select summary sentences. At first, we discard sentences less than 8 words like the work of (Erkan and Radev, 2004). Then we sort the rest in descending order according to the derived ranking scores. Finally, we iteratively dequeue the top-ranked sentence, and append it to the current summary if it is non-redundant. A sentence is considered non-redundant if it contains significantly new bi-grams compared with the current summary content. We empirically set the cut-off of the new bi-gram ratio to 0.5.

4 Experiments

4.1 Dataset

In this work, we focus on the query-focused multi-document summarization task. The experiments are conducted on the DUC 2005 $\sim$ 2007 datasets. All the documents are from news websites and grouped

into various thematic clusters. In each cluster, there are four reference summaries created by NIST assessors. We use Stanford CoreNLP[2] to process the datasets, including sentence splitting and tokenization. Our summarization model compiles the documents in a cluster into a single document. Table 1 shows the basic information of the three datasets. We can find that the data sizes of DUC are quite different. The sentence number of DUC 2007 is only about a half of DUC 2005's. For each cluster, a summarization system is requested to generate a summary with the length limit of 250 words. We conduct a 3-fold cross-validation on DUC datasets, with two years of data as the training set and one year of data as the test set.

Year	Clusters	Sentences	Data Source
2005	50	45931	TREC
2006	59	34560	AQUAINT
2007	30	24282	AQUAINT

Table 1: Statistics of the DUC datasets.

4.2 Model Setting

For the CNN layer, we introduce a word embedding set which is trained on a large English news corpus (10^{10} tokens) with the word2vec model (Mikolov et al., 2013). The dimension of word embeddings is set to 50, like many previous work (e.g., (Collobert et al., 2011)). Since the summarization dataset is quite limited, we do not update these word embeddings in the training process, which greatly reduces the model parameters to be learned. There are two hyper-parameters in our model, i.e., the word window size h and the CNN layer dimension l. We set $h = 2$, which is consistent with the ROUGE-2 evaluation. As for l, we explore the change of model performance with $l \in [5, 100]$. Finally, we choose $l = 50$ for all the rest experiments. It is the same dimension as the word embeddings. During the training of pairwise ranking, we set the margin $\Omega = 0.5$. The initial learning rate is 0.1 and batch size is 100.

4.3 Evaluation Metric

For evaluation, we adopt the widely-used automatic evaluation metric ROUGE (Lin, 2004) [3]. It measures the summary quality by counting the overlapping units such as the n-grams, word sequences and word pairs between the peer summary and reference summaries. We take ROUGE-2 as the main measures due to its high capability of evaluating automatic summarization systems (Owczarzak et al., 2012). During the training data of pairwise ranking, we also rank the sentences according to ROUGE-2 scores.

4.4 Baselines

To evaluate the summarization performance of AttSum, we implement rich extractive summarization methods. Above all, we introduce two common baselines. The first one just selects the leading sentences to form a summary. It is often used as an official baseline of DUC, and we name it "LEAD". The other system is called "QUERY_SIM", which directly ranks sentences according to its TF-IDF cosine similarity to the query. In addition, we implement two popular extractive query-focused summarization methods, called MultiMR (Wan and Xiao, 2009) and SVR (Ouyang et al., 2011). MultiMR is a graph-based manifold ranking method which makes uniform use of the sentence-to-sentence relationships and the sentence-to-query relationships. SVR extracts both query-dependent and query-independent features and applies Support Vector Regression to learn feature weights. Note that MultiMR is unsupervised while SVR is supervised. Since our model is totally data-driven, we introduce a recent summarization system DocEmb (Kobayashi et al., 2015) that also just use deep neural network features to rank sentences. It initially works for generic summarization and we supplement the query information to compute the document representation.

[2] `http://stanfordnlp.github.io/CoreNLP/`

[3] ROUGE-1.5.5 with options: -n 2 -m -u -c 95 -l 250 -x -r 1000 -f A -p 0.5 -t 0

To verify the effectiveness of the joint model, we design a baseline called ISOLATION, which performs saliency ranking and relevance ranking in isolation. Specifically, it directly uses the sum pooling over sentence embeddings to represent the document cluster. Therefore, the embedding similarity between a sentence and the document cluster could only measure the sentence saliency. To include the query information, we supplement the common hand-crafted feature TF-IDF cosine similarity to the query. This query-dependent feature, together with the embedding similarity, are used in sentence ranking. ISOLATION removes the attention mechanism, and mixtures hand-crafted and automatically learned features. All these methods adopt the same sentence selection process illustrated in Section 3 for a fair comparison.

4.5 Summarization Performance

The ROUGE scores of the different summarization methods are presented in Table 2. We consider ROUGE-2 as the main evaluation metrics, and also provide the ROUGE-1 results as the common practice. As can be seen, AttSum always enjoys a reasonable increase over ISOLATION, indicating that the joint model indeed takes effects. With respect to other methods, AttSum largely outperforms two baselines (LEAD and QUERY_SIM) and the unsupervised neural network model DocEmb. Although AttSum is totally data-driven, its performance is better than the widely-used summarization systems MultiMR and SVR. It is noted that SVR heavily depends on hand-crafted features. Nevertheless, AttSum almost outperforms SVR all the time. The only exception is DUC 2005 where AttSum is slightly inferior to SVR in terms of ROUGE-2. Over-fitting is a possible reason. Table 1 demonstrates the data size of DUC 2005 is highly larger than the other two. As a result, when using the 3-fold cross-validation, the number of training data for DUC 2005 is the smallest among the three years. The lack of training data impedes the learning of sentence and document embeddings.

It is interesting that ISOLATION achieves competitive performance but DocEmb works terribly. The pre-trained word embeddings seem not to be able to measure the sentence saliency directly. In comparison, our model can learn the sentence saliency well.

Year	Model	ROUGE-1	ROUGE-2
2005	LEAD	29.71	4.69
	QUERY_SIM	32.95	5.91
	SVR	36.91	**7.04**
	MultiMR	35.58	6.81
	DocEmb	30.59	4.69

2007	LEAD	36.14	8.12
	QUERY_SIM	36.32	7.94
	SVR	43.42	11.10
	MultiMR	41.59	9.34
	DocEmb	33.88	6.46
	ISOLATION	42.76	10.79
	AttSum	**43.92**	**11.55**

Table 2: ROUGE scores (%) of different models. We draw a line to distinguish models with or without hand-crafted features.

4.6 Query Relevance Performance

We check the feature weights in SVR and find the query-dependent features hold extremely small weights. Without these features, the performance of SVR only drops 1%. Therefore, SVR fails to learn query relevance well. The comparison of AttSum and ISOLATION has shown that our method

AttSum	It acknowledges that illegal drugs cannot be kept out of the country by tougher border control and interdiction measures.
	Much greater resources, derived from taxation of the drugs that are now illegal and untaxed and from the billions saved by not wasting money on more criminal- justice measures, must be devoted to drug treatment and drug prevention.
	As is the case with tobacco, legalizing marijuana, cocaine and heroin would not signify an endorsement of their use.
	The consumption and production of marijuana in the United States is on the decrease, and that criminalization costs society more in terms of increased law-enforcement-related costs and deprived revenues from taxes on pot than legalization would.
TF-IDF	Drug prices have soared.
	Drug addicts are not welcome.
	How refreshing to have so much discourse on drugs and legalization.
	The only solution now is a controlled policy of drug legalization.
Query	What are the benefits of drug legalization?
AttSum	Boparai also said that wetlands in many developing countries were vital to the sustenance of human beings, not just flora and fauna.
	EPA says that all water conservation projects, and agriculture and forestry development along China's major rivers must be assessed in accordance with environmental protection standards, and that no projects will be allowed if they pose a threat to the environment.
	Finland has agreed to help central China's Hunan Province improve biodiversity protection, environmental education, subtropical forestry and wetlands protection, according to provincial officials.
	The EPA had sought as early 1993 to subject all development on wetlands to strict environmental review, but that approach was rejected by the courts, which ruled in favor of arguments made by developers and by the National Mining Association.
TF-IDF	Statistics on wetlands loss vary widely.
	Mitigation of any impact on wetlands by creating or enhancing other wetlands.
	The new regulations would cover about one-fourth of all wetlands.
	Now more and more people have recognized wetlands' great ecological and economic potential and the conservation and utilization of wetlands has become an urgent task.
Query	Why are wetlands important? Where are they threatened? What steps are being taken to preserve them? What frustrations and setbacks have there been?

Table 3: Sentences recognized to focus on the query.

can learn better query relevance than hand-crafted features. In this section, we perform the qualitative analysis to inspect what AttSum actually catches according to the learned query relevance. We randomly choose some queries in the test datasets and calculate the relevance scores of sentences according to Eq. 3. We then extract the top ranked sentences and check whether they are able to meet the query need. Examples for both one-sentence queries and multiple-sentence queries are shown in Table 3. We also give the sentences with top TF-IDF cosine similarity to the query for comparison.

With manual inspection, we find that most query-focused sentences in AttSum can answer the query to a large extent. For instance, when asked to tell the advantages of drug legalization, AttSum catches the sentences about drug trafficking prevention, the control of marijuana use, and the economic effectiveness, etc. All these aspects are mentioned in reference summaries. The sentences with the high TF-IDF similarity, however, are usually short and simply repeat the key words in the query. The advantage of AttSum over TF-IDF similarity is apparent in query relevance ranking.

When there are multiple sentences in a query, AttSum may only focus on a part of them. Take the second query in Table 3 as an example. Although the responses to all the four query sentences are involved more or less, we can see that AttSum tends to describe the steps of wetland preservation more. Actually, by inspection, the reference summaries do not treat the query sentences equally either. For this query, they only tell a little about frustrations during wetland preservation. Since AttSum projects a query onto a single embedding, it may augment the bias in reference summaries. It seems to be hard even for humans to read attentively when there are a number of needs in a query. Because only a small part of DUC datasets contains such a kind of complex queries, we do not purposely design a special model to handle them in our current work.

5 Related Work

5.1 Extractive Summarization

Work on extractive summarization spans a large range of approaches. Starting with unsupervised methods, one of the widely known approaches is Maximum Marginal Relevance (MMR) (Carbonell and Goldstein, 1998). It used a greedy approach to select sentences and considered the trade-off between saliency and redundancy. Good results could be achieved by reformulating this as an Integer Linear Programming (ILP) problem which was able to find the optimal solution (McDonald, 2007; Gillick and Favre, 2009). Graph-based models played a leading role in the extractive summarization area, due to its ability to reflect various sentence relationships. For example, (Wan and Xiao, 2009) adopted manifold ranking to make use of the within-document sentence relationships, the cross-document sentence relationships and the sentence-to-query relationships. In contrast to these unsupervised approaches, there are also various learning-based summarization systems. Different classifiers have been explored, e.g., conditional random field (CRF) (Galley, 2006), Support Vector Regression (SVR) (Ouyang et al., 2011), and Logistic Regression (Li et al., 2013), etc.

Many query-focused summarizers are heuristic extensions of generic summarization methods by incorporating the information of the given query. A variety of query-dependent features were defined to measure the relevance, including TF-IDF cosine similarity (Wan and Xiao, 2009), WordNet similarity (Ouyang et al., 2011), and word co-occurrence (Prasad Pingali and Varma, 2007), etc. However, these features usually reward sentences similar to the query, which fail to meet the query need.

5.2 Deep Learning in Summarization

In the summarization area, the application of deep learning techniques has attracted more and more interest. (Genest et al., 2011) used unsupervised auto-encoders to represent both manual and system summaries for the task of summary evaluation. Their method, however, did not surpass ROUGE. Recently, some works (Cao et al., 2015a; Cao et al., 2015b) have tried to use neural networks to complement sentence ranking features. Although these models achieved the state-of-the-art performance, they still heavily relied on hand-crafted features. A few researches explored to directly measure similarity based on distributed representations. (Yin and Pei, 2015) trained a language model based on convolutional neural networks to project sentences onto distributed representations. (Cheng and Lapata, 2016) treated single document summarization as a sequence labeling task and modeled it by the recurrent neural networks. Others like (Kobayashi et al., 2015; Kågebäck et al., 2014) just used the sum of trained word embeddings to represent sentences or documents.

In addition to extractive summarization, deep learning technologies have also been applied to compressive and abstractive summarization. (Filippova et al., 2015) used word embeddings and Long Short Term Memory models (LSTMs) to output readable and informative sentence compressions. (Rush et al., 2015; Hu et al., 2015) leveraged the neural attention model (Bahdanau et al., 2014) in the machine translation area to generate one-sentence summaries. We have described these methods in Section 2.2.

6 Conclusion and Future Work

This paper proposes a novel query-focused summarization system called AttSum which jointly handles saliency ranking and relevance ranking. It automatically generates distributed representations for sentences as well as the document cluster. Meanwhile, it applies the attention mechanism that tries to simulate human attentive reading behavior when a query is given. We conduct extensive experiments on DUC query-focused summarization datasets. Using no hand-crafted features, AttSum achieves competitive performance. It is also observed that the sentences recognized to focus on the query indeed meet the query need.

Since we have obtained the semantic representations for the document cluster, we believe our system can be easily extended into abstractive summarization. The only additional step is to integrate a neural language model after document embeddings. We leave this as our future work.

Abstract

A news article summary usually consists of 2-3 key sentences that reflect the gist of that news article. In this paper we explore using public posts following a new article to improve automatic summary generation for the news article. We propose different approaches to incorporate information from public posts, including using frequency information from the posts to re-estimate bigram weights in the ILP-based summarization model and to re-weight a dependency tree edge's importance for sentence compression, directly selecting sentences from posts as the final summary, and finally a strategy to combine the summarization results generated from news articles and posts. Our experiments on data collected from Facebook show that relevant public posts provide useful information and can be effectively leveraged to improve news article summarization results.

1 Introduction

Nowadays people are often overwhelmed by their daily exposure to large amount of online information. To make information easier to digest, news press like CNN, USAToday or news disseminator like Yahoo often provide 'summaries' for their news articles, so that readers can get the gist of a story quickly. Typically this kind of short summaries is manually generated. Obviously, it is very time consuming to manually produce high quality summaries for many popular topics. Therefore, automatic summarization for related news articles is essential to alleviate the manual work. With the popularity of social media, online news providers or disseminators are moving towards offering more interactions with news readers, for example, via comments on the news provide sites or post service like Twitter or Facebook public posts. When a news is published, we have access to not only the related news articles, but also the related public comments and posts. Our task in this paper is thus to explore how to use relevant public posts to improve summarization of a single news article. In particular, we use Facebook public posts related to a news article to help summarize a popular topic. This work is also motivated by the following observations of the data (see Sec 3 for the data we use). First, the posts under a news article are closely related to and very indicative for the topic of that news story. Second, the sentences from some posts whose accounts are maintained by news agencies are well written, so they may be directly used as the units of extractive summarization. In addition, the sentences in posts are often shorter than those from the news, thus again they may be more suitable to be used as summary sentences in sentence-based extractive summarization.

Our contributions in this paper are as follows: (1) We propose an integer linear programming (ILP) based news summarization approach using relevant Facebook public posts. It involves generating extractive and abstractive summaries. (2) We explore various ways of using post information to boost summarization performance. There are three general strategies: one is to leverage the lexical frequency information in the post to help estimate a word's importance in the news article and thus choose better summary sentences; another one is to extract sentences from the posts to form the summary; and the last one is to combine summarization results generated from the news articles and the posts. (3) To evaluate our method, we collect 190 popular news topics from Facebook. Each one has a news article, a human

generated summary and hundreds to thousands of related public posts. To our knowledge, this is the first data set of this kind.

2 Related Work

Our work is closely related to the following aspects: ILP based summarization method, dependency tree based sentence compression by considering extra information, and mining social media for document summarization.

Recently optimization methods have been widely used in extractive summarization. McDonald (2007) first introduced sentence level ILP for summarization. Later Gillick et al. (2009) revised it to concept-based ILP, which is similar to the Budgeted Maximal Coverage problem in (Khuller et al., 1999). Then other optimization methods have been used in summarization (Lin and Bilmes, 2010; Davis et al., 2012; Li et al., 2015b; Li et al., 2015a). In the concept-based ILP summarization methods, how to determine the concepts and measure their weights are the two key factors impacting the system performance. Woodsend and Lapata (2012) utilized ILP to jointly optimize different aspects including content selection, surface realization, and rewrite rules in summarization. Galanis et al. (2012) used ILP to jointly maximize the importance of the sentences and their diversity in the summary. In this work, we leverage the unsupervised ILP framework from Gillick et al. (2009) as our summarization system and incorporate post information to help boost summarization performance.

Sentence compression techniques are widely used in summarization in order to generate abstractive summaries. Previous research has shown the effectiveness of sentence compression for automatic document summarization (Knight and Marcu, 2000; Zajic et al., 2007; Chali and Hasan, 2012; Wang et al., 2013). The compressed summaries can be generated through a pipeline approach that combines a generic sentence compression model with a summary sentence pre-selection or post-selection step. In addition, joint summarization and sentence compression method attracts lots of attention these years. (Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011; Li et al., 2014) are typical work in this area. Their focus is to leverage the ILP technique to jointly select and compress sentences for multi-document summarization. In our work, we consider posts as summary related information and then use them for joint sentence compression and summarization.

Although there is little work about generating summaries by considering extra information on Facebook data, there is some similar work done on Twitter or other resources. Unsupervised method was tried for summarization by (Wong et al., 2008). (Phelan et al., 2011) used tweets to recommend news articles based on user preferences. (Gao et al., 2012) produced cross-media news summaries by capturing the complementary information from both sides. Kothari et al. (2013) and Štajner et al. (2013) investigated detecting news comments from Twitter for extending news information provided. Wei and Gao (2014) derived external features based on a collection of relevant tweets to assist the ranking of the original sentences for highlight generation. In addition to tweets, Svore et al. (2007) leveraged Wikipedia and query log of search engines to help document summarization. Tsukamoto et al. (2015) proposed a method for efficiently collecting posts that are only implicitly related to an announcement post, taking into account retweets on Twitter in particular. Our work involves the two aspects when using post information: one is that we utilize post information to help choose sentences from new articles and compress them to form a summary, and the other is that we directly use sentences from the posts as the summary.

3 Corpus Construction

For our work, we manually collected popular news stories and related data from a personal Facebook account during the period of Oct 20, 2015 to Nov 10, 2015. During that time, we collected the top 10 popular news stories every day (each story includes a human generated summary, a related news article and all the following public posts). The topics of these stories may come from politics, science and sport categories. An example of such a news summary and corresponding posts is shown in Fig1.

Due to the space limit, we only show one public post following the new story on the right side of the picture. In order to better evaluate the impact of the relevant posts, we ignore the popular news stories

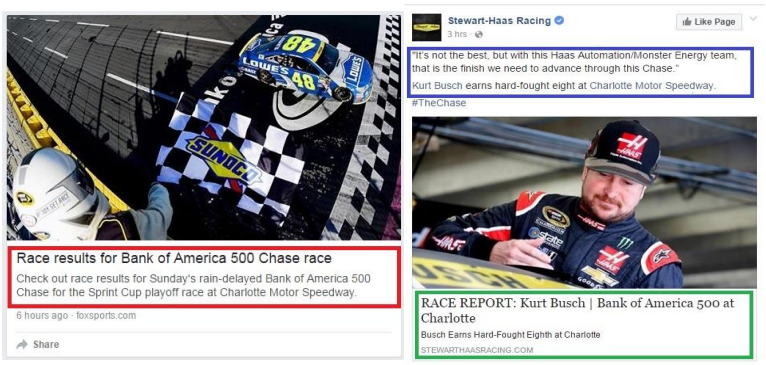

Figure 1: An example of a news story in our data set. The short manual summary is marked in red rectangle. The blue rectangle shows a post from a user. In the green rectangle, it is a link of a related news story. Some posts may only include comments, reactions, etc. without the link to the related news stories.

with less than 50 public posts. In total, we collected 190 popular news topics and their public posts[1].

The statistics of this corpus are given in Table 1. As shown in the table, the number of relevant posts for a popular topic varies a lot, with a mean of about 217 and standard deviation of 188. The high variance is because some of the topics are much more popular than others. We expect that the large number of relevant posts to a news story can provide useful information to guide the summary generation model. We can see from the table that the average sentence length from posts (12.85 tokens) is much shorten than that from the news (21.67 tokens). The average summary length for each topic is 43 words. This means that a summary can only contain on average two sentences from the news, or sometime just one long sentence. But usually such one or two sentences can not represent all the important information in the summary, therefore we may need to compress the long sentences in the news, or extract shorter sentences from the posts that contain similar information as the long sentences in the news.

	All	Politics	Science	Sports

4 Extractive Summarization Methods and Results

4.1 Background: ILP-based Document Summarization

The core idea of using ILP for summarization is to select the summary sentences by maximizing the sum of the weights of the language concepts that appear in the summary. Gillick et al. (2009) showed that using bigrams as concepts gave consistently better performance than unigrams or trigrams for a

[1]The data is available at http://www.hlt.utdallas.edu/∼chenli/summarization

variety of ROUGE measures. The association between the language concepts and sentences serves as the constraints. This ILP method is formally represented as below:

$$
\begin{aligned}
max \quad & \textstyle\sum_i w_i b_i && (1)\\
s.t. \quad & s_j Occ_{ij} \leq b_i && (2)\\
& \textstyle\sum_j s_j Occ_{ij} \geq b_i && (3)\\
& \textstyle\sum_j l_j s_j \leq L && (4)\\
& b_i \in \{0,1\}\ \forall i,\ \ s_j \in \{0,1\}\ \forall j && (5)
\end{aligned}
$$

b_i and s_j are binary variables that indicate the presence of a bigram and a sentence respectively. l_j is the sentence length and L is maximum length of the generated summary. w_i is a bigram's weight and Occ_{ij} means the occurrence of concept i in sentence j. Inequalities (2) and (3) associate the sentences and concepts. They ensure that selecting a sentence leads to the selection of all the concepts it contains, and selecting a concept only happens when it is present in at least one of the selected sentences.

4.2 Our Extractive Summarization Methods

The following describes all the extractive methods we use.

4.2.1 Generating summaries from news article

In this setup we extract sentences from news articles using the ILP based summarization framework. Our main goal is to investigate if we can use the relevant posts to better determine the bigrams and their weights in the ILP model described above. We compare the following three ways for the selection and weight of bigrams.

- **Bigram and Weight from News Article**: we use the bigram in the news article and its augmented term frequency as its weight: $w_i = 0.5 + \frac{f_{i,d}}{max\{f_{i,d}:i \in d\}}$ ($f_{i,d}$ is the raw frequency of bigram i in document d).

- **Bigram from News and Posts**: among the bigram candidates extracted from the news article, we use the subset that also appear in the posts, and the same weight as above (that is, the weight information is just based on the news article).

- **Bigram and Weight both from News and Post**: using the common bigrams from both the news article and posts (same as the previous setup), we further update the bigram weight by adding a bigram's post frequency in the relevant posts. In the following equation , pf_i is the number of posts that contain bigram i: $w_i^{'} = 0.5 + \frac{f_{i,d}}{max\{f_{i,d}:i \in d\}} + pf_i$.

4.2.2 Generating summary from posts only

In this setup, we evaluate whether sentences from posts are good candidates for a summary. Here each post can be seen as an individual document and we can treat this as a 'multi-document' summarization task and easily apply the ILP module on all the posts to choose a set of sentences as the final summary. In this process, the input sentences and bigrams are only from the posts, and the bigram weight is post frequency: $w_i^{''} = pf_i$ (Number of posts in which the bigram has appeared.).

4.2.3 Generating summary from news and posts

Here we use all the sentences from the news and posts as the input for summarization. This is again a multi-document summarization task, where we consider each post and the new article as a document. The bigram weight is document frequency. This method combines the news article and posts together to form a document collection for summarization. In the following we call it document level combination.

4.2.4 Combination of summarization results from news article and posts

In contrast to the above combination method, we can also build summarization systems using the news article and the relevant posts separately, and then combine the generated summaries. This kind of summary result level combination allows us to develop individual models tailored for different input sources, and may produce better combined final results. In this combination method, we have two summarization results, generated from the sentences in the news article and the posts respectively. Our aim is to decide which of the two summaries is better and use that as the final result. Since we do not have enough data to train supervised models, we propose to use heuristic rules to select which summary to use. The combination rules are based on the following parameters.

- **Sentence number**: $n_{sentNum}$. This represents how many sentences a summary result consists of. We observe that often when a summary contains just one sentence, that sentence is the news highlight and contains the most important information.

- **Bigram weight**: w_i in Section 4.1. Sentences containing bigrams with high weights are often good summary sentence candidates. We further define $w_{maxInTopic}$ as the maximum weight of the bigram in a topic, and $w_{maxInRes}$ as the maximum weight of the bigram in the summary result.

- **Bigram exist ratio**: R_{Bigram}, which represents the percentage of bigrams in a sentence that are used as variables in the ILP formula.We define this ratio since we prefer sentences that contain more bigrams that are used in the ILP model.

Then our rule-based classifier works by going through the following rules one by one. If a decision can be made at any point, the procedure will stop.

- **Rule 1**: If $n_{sentNum}$ from a summary result equals to one and the length of that sentence is longer than 40 words, choose that result. If both or neither equals to one, go to Rule 2.

- **Rule 2**: If $w_{maxInRes}$ from the post summary equals to $w_{maxInTopic}$, but if it is not true for the summary from news, choose the result from posts as the final summary. Otherwise, go to Rule3.

- **Rule 3**: If the maximum R_{Bigram} from a sentence in post result is larger than a threshold value[2], use the post result as the final summary; otherwise use the news result as the final summary. If the maximum R_{Bigram} from post and news results are the same, go to Rule 4.

- **Rule 4**: Choose the result with higher average R_{Bigram}. If the average R_{Bigram} is the same, go to Rule 5.

- **Rule 5**: Choose news result as the final result.

4.3 Experimental Setup and Results

The summary length is set as 45 words maximum (because the average length of human summary is 43 words in each topic). Note that a sentence in the post may be exactly the same as a sentence in the reference summary. One possible reason for this is that a user may simply copy the summary and then post it. In order to minimize this effect, in our data set we only consider the posts whose cosine similarity with the corresponding reference summary is less than 65%. We use the ROUGE evaluation metrics (Lin, 2004), with R-1 and R-2 measuring the unigram and bigram overlap between the system and reference summaries, and R-SU4 measuring the skip-bigram with the maximum gap length of 4.

We compare the following summarization methods:

(a) Summary sentences from news article I: bigrams are from news, and weight is their augmented term frequency from news.

[2]This value is empirically set as 0.85 in our experiments.

(b) Summary sentences from news article II: bigrams are from both news and posts, and weight is their augmented term frequency from news.

(c) Summary sentences from news article III: bigrams are from news, and weight is the combination of their augmented term frequency from news and their raw post frequency.

(d) Summary sentences from news article IV: bigrams are from news and posts, and weight is the combination of their augmented term frequency from news and their raw post frequency.

(e) Summary sentences from posts: bigrams are from posts, and weight is their post frequency.

(f) Document level combination: sentences are from news or posts, and bigram weight is 'document' frequency.

(g) Summary result level combination: given two summaries with sentences extracted from either news or posts, decide which one to use as the final result.

Table 2 presents the recall performance of these systems in ROUGE-1, ROUGE-2 and ROUGE-SU4 along with the corresponding 95% confidence intervals. We determine the statistical significance by comparing the 95% confidence intervals, that is, significant differences are those where the confidence intervals for the estimates of the means for the two systems either do not overlap, or where the two intervals overlap but neither contains the best estimate for the mean of the other.

From the results we find that systems using only information from the news (e.g., 'a') performs the worst. This also shows that this kind of single document summarization is not a trivial task. After adding information from posts, such as requiring the bigrams to also appear in posts (system 'b') or computing bigram weights using post related frequency (system 'd'), the results (system 'd' compared with 'a' and 'b') improved significantly. It is consistent with our expectation that post information can help enhance summarization of news topics.

System	ROUGE-1	ROUGE-2	ROUGE-SU4

Table 2: ROUGE-N recall results for different extractive summarization systems.

One important finding from Table 2 is that system 'e' (using post sentences in extraction) performs even better than that from news article sentences. To better understand this, we conducted an oracle experiment when extracting sentences from the news article and posts respectively: we use the bigrams from the reference summary as the bigram concepts in the ILP method, and the weight is the bigram's term frequency in the reference summary. This oracle experiment can reflect the possible best result of the ILP extractive summarization system when extracting sentences from news or posts. The results are also included in Table 2. We can see that the possible best summaries from posts are also significantly better than that from news. By analyzing the results of this oracle experiment, we find that the average length of the generated summary is 38.15 tokens when using news, and is 41.25 when using posts. This means that the summary generated from posts may contain more information. Looking at this from another aspect, the news-based summary contains 2.1 sentences on average, in contrast to 2.5 sentences for the post-based summary. As mentioned earlier, the sentences from posts are often shorter than those from news. Therefore when the target summary has a short length limit (for example 45 tokens, usually

fewer than 3 sentences), one informative long sentence could use up all the length budget, while shorter sentences have more flexibility, allowing different information to be incorporated (sentence compression will be discussed in Section 5). Similar patterns are also found in the results of system d and e. The average length of the summary from system d is 41.8, and there are 2.3 sentences on average, comparing to the length of 43.4 words and 2.7 sentences for the summary from system e.

Even though overall system 'e' has the best performance, our analysis of results shows that only for 110 topics, the summary results from the posts are better than that from the news article, and for the remaining 80 topics, the results based on the news sentences are better. This also justifies why we expect combining results from the news and the posts based summaries may improve system performance. From the results in Table 2, we find that document level combination (system 'f') is not very effective. It is similar to the results using just the posts. A better bigram selection and weighting strategy may be needed when combining the posts and news at the input level. However, summary result level combination (system 'g') significantly outperforms each individual system, suggesting we can build each individual system, and then effectively choose one as the final output. The oracle result combination (i.e., comparing to the reference summary and picking the one with better scores as the system prediction) has a ROUGE-2 Recall score of 0.1922 (0.18085 - 0.20394). Our rule based combination method is quite close to the oracle combination result, indicating our rules can measure the goodness of a system generated summary.

5 Abstractive Summarization Method and Results

5.1 Dependency Tree Based Compression

We have mentioned that sentences from the news are generally long. Intuitively compressing the sentences in the news will give us room to incorporate more information. In fact, as discussed above, the summaries generated from the news sentences are on average shorter than that from the posts. This is due to the long sentences and the summary length constraint. Therefore next we investigate abstractive summarization by applying sentence compression when extracting sentences from news to improve summarization performance. Again the core idea of our proposed compression method is using the information from relevant posts to guide compression. Our compression framework is inspired by the work in (Filippova and Strube, 2008), where they use extra resources to guide the unsupervised dependency tree based sentence compression module.

The sentence compression task can be defined as follows: given a sentence s, consisting of words $w_1, w_2, ..., w_m$, identify a subset of the words of s, such that it is grammatical and preserves essential information of s. In the framework of (Filippova and Strube, 2008), a dependency graph for the original sentence is first generated and then compression is done by deleting edges of the dependency graph. The goal is to find a subtree with the highest score:

$$max \sum_{e_i \in E} a_{e_i} * w_{info}(e_i) * w_{syn}(e_i) \tag{6}$$

where a_{e_i} is a binary variable, indicating whether a directed dependency edge e_i is kept (a_{e_i} is 1) or removed (a_{e_i} is 0), and E is the set of edges in the dependency graph. The weighting of edge e considers both its syntactic importance ($w_{syn}(e_i)$) and the informativeness ($w_{info}(e_i)$). Suppose edge e_i is pointed from head h to node n with dependency label l, we use two methods to calculate the two weights in Formula 6.

The first one uses a bigram news corpus with the corresponding summaries: $w_{info}(e_i) = \frac{P_{summary}(n)}{P_{news}(n)}$ and $w_{syn}(e_i) = P(l|h)$, $P_{summary}(n)$ and $P_{news}(n)$ are the unigram probabilities of word n in the language models trained on human generated summaries and the original news articles respectively. $P(l|h)$ is the conditional probability of label l given head h. We used the New York Times Annotated Corpus (LDC Catalog No: LDC2008T19) as the extra background corpus. It has both the original news articles and human generated summaries.

In the second method, we explore using relevant posts as background information for compression. Here, $w_{info}(e_i) = \frac{pf(n)}{\#Post}$ and $w_{syn}(e_i) = \frac{pf(h,n)}{\#Post}$, $pf(n)$ is the number of posts including word n and

$pf(h, n)$ is the number of posts where n and head h appear together. If h and n appear together in two sentences in one post, it is counted as one. #Post represents the total number of posts in a topic.

5.2 Joint model for summarization and sentence compression

We propose a joint model for sentence selection and compression at the same time under the ILP framework, in order to avoid the problem with pre-compression (error propagation due to imperfect compression, important information may be missing) or post-compression (after compression it is hard to add new sentences to use the new available space). In the joint model, we combine the objectives in Section 4.1 and Formula 6, and thus the goal is to find a set of sentences with the highest score:

$$max \sum_{e_{jk} \in E} \lambda * a_{e_{jk}} * w_{info}(e_{jk}) * w_{syn}(e_{jk}) + \sum_i w_i b_i, \quad \forall i, j, k \tag{7}$$

e_{jk} means the k^{th} edge in the j^{th} sentence in this news article. λ is used to balance the contribution from the edge importance and bigram weights. After we add edges into our ILP-based summarization model, we need to adjust the previous constraints and also design more constraints to represent relationships between sentences and edges, and bigrams and edges in order to produce valid results.

First, the length constraint in Section 4.1 should be expressed in the form of edges rather than sentences.

$$\sum_{j,k} a_{e_{jk}} \leq L - 1, \ \forall j, k \tag{8}$$

Second, we want to avoid picking just a few words from many sentences as the summary, which typically leads to ungrammatical summaries. Hence it is more desirable to obtain a solution with only a few sentences extracted and compressed. To do so, we create the relationship between edges and sentences like following: if sentence j is selected, there are at least $\rho * L_j$ words extracted. L_j is the length of sentence j. This constraint is shown in the first inequality in Formula 9. Together with the second inequality there, they make sure that if sentence j is selected, at least $\rho * L_j$ words will be chosen; if sentence j is not selected, none of the edges from this sentence will be selected.

$$\sum_{j,k} a_{e_{jk}} \geq \rho * L_j * s_j, \quad a_{e_{jk}} \leq s_j, \ \forall j, k \tag{9}$$

Third, one bigram has two tokens, meaning it involves at least one edge and at most two edges. Therefore we build the relationship between bigrams and edges as follows:

$$b_i \geq a_{e_{jk}}, \qquad b_i \leq \sum a_{e_{jk}} \tag{10}$$

where e_{jk} represents all the edges whose head h or node n is one element of bigram i.

Forth, in the dependency tree, if an edge $e_{j,k}$ is removed, all the edges whose head node is $e_{j,k}$'s node n need to be removed as well.

$$a_{e^l_{jk}} \geq a_{e^{l+1}_{jk'}} \tag{11}$$

in which edge $e^{l+1}_{jk'}$ is at level $l+1$ and its head node is the node n of e^l_{jk} at level l. Please note we do not include the vice verse constraints. This means even if all the edge $e^{l+1}_{jk'}$ are removed, we can still keep edge e^l_{jk}.

In addition to all the constraints from Formula 7 to 11, we require that b_i, s_j and $a_{e_{jk}}$ are all binary variables. This gives the ILP setup for the joint summarization and sentence compression model.

5.3 Results

The abstractive summarization experiments are based on the setup of System 'd', that is, we extract sentences from the news articles, but the bigrams and their weight information come from both the news and the posts. We use the joint summarization and compression method described above, with extra background information to help guide compression. λ in Formula 7 and ρ in Formula 9 are empirically set as 20 and 0.85 respectively in our experiment.

Results are shown in Table 3. For System 'd', we present results using two different resources for compression: the generic NY Times Corpus and the relevant posts for each topic. We find adding compression improves summarization performance over the extractive summarization baseline. Using posts as extra information outperforms that using the general news. This improvement is also statistically significant. In the table we also include the result using the System 'g' configuration. For this method, once the combination rules determine to use the extractive summary from the news as the final system output, we apply abstractive summarization (i.e., joint compression and summarization) to this topic to regenerate the summary. We can see applying compression on these topics gave additional improvement over the original combination result.

Compression System		ROUGE-1	ROUGE-2	ROUGE-SU4
Based on	Extra Resource			
Sys d	NYT corpus	0.40437 (0.39326 - 0.41586)	0.15059 (0.14095 - 0.15985)	0.16311 (0.15484 - 0.17167)
	Post	0.41111 (0.40025 - 0.42282)	0.15567 (0.14561 - 0.16637)	0.17100 (0.16231 - 0.18051)

Table 3: Recall of ROUGE-N results on abstractive summary.

6 Conclusion and Future Work

In this paper we explore utilizing relevant Facebook public posts in addition to news articles to generate a summary of popular news. We adopt the ILP based summarization method and propose different ways using information from posts, including weighting the bigrams using frequency information from the posts, compressing news sentences by estimating importance of dependence tree edges based on occurrence information in the posts, selecting sentences from posts as final summary, and finally combining the results generated from news articles and posts. Our experiments show that post information is useful for improving the performance.

We plan to pursue a number of directions in our future work. First, we plan to use a statistical classifier to choose a better summary for system combination. Second, we will perform more fine grained combination by choosing individual sentences from different results. Third, we will conduct human evaluation for our system results. Finally, it is worthwhile to investigate multi-document summarization once we can collect multiple news articles for a popular topic.

Abstract

Abstractive summarisation is not yet common amongst today's deployed and research systems. Most existing systems either extract sentences or compress individual sentences. In this paper, we present a summariser that works by a different paradigm. It is a further development of an existing summariser that has an incremental, proposition-based content selection process but lacks a natural language (NL) generator for the final output. Using an NL generator, we can now produce the summary text to directly reflect the selected propositions. Our evaluation compares textual quality of our system to the earlier preliminary output method, and also uses ROUGE to compare to various summarisers that use the traditional method of sentence extraction, followed by compression. Our results suggest that cutting out the middle-man of sentence extraction can lead to better abstractive summaries.

1 Introduction

Abstraction, rather than extraction, is generally seen as the more desirable method of performing automatic summarisation. It implies generating an entirely new text from the information contained in the input text. Amongst its advantages is the promise of better information packaging: conveying more information using less output text. But end-to-end abstractive summarisation is still uncommon in current systems, mostly due to the problems with NLP text analysis and knowledge representation that would plague any "deeper" method. Current research into abstractive summarisation therefore mainly concerns compressing individual sentences or merging sentences of similar content. Sentence compression using machine learning and/or constraint-solving methods is an active area of research. Common methods use syntactic, lexical and discourse-based features to determine which words should be dropped or paraphrased (Knight and Marcu, 2000; McDonald, 2006; Clarke and Lapata, 2008; Cohn and Lapata, 2007, 2008; Yoshikawa et al., 2012). More recently, neural language model has also been applied to the problem (Rush et al., 2015). For multi-document summarisation, sentence fusion (Barzilay and McKeown, 2005) allows the synthesis of common information across documents in one sentence, using grammatical dependencies as a substitute for a semantic representation. These methods have the ability to produce high-quality output, but their sentence generation is a local step in the summarisation pipeline, i.e. isolated from the content selection, which is essentially global. The only exceptions we know are Martins and Smith's (2009) system, and Nishikawa's (2014) system for Japanese text, both of which optimise sentence selection jointly with sentence compression.

A different paradigm for abstractive summarisation would be to avoid the "middle man" of sentence extraction altogether, and to operate over propositions instead. Such a system would first transform the text into sub-sentential semantic units, then perform summarisation operations over these (possibly performing inference and creating new semantic units), and finally use NL generation techniques to verbalise the semantic units that make up the final summary. Kintsch and van Dijk (1978, henceforth KvD) present one such summarisation technique. They use a tree of connected propositions to simulate the human memory. While the text is processed incrementally, new propositions are attached to the tree

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers,
pages 567–578, Osaka, Japan, December 11-17 2016.

by argument overlap, and old propositions are pruned according to simulated memory limitations. The final summary is based on the best-connected propositions. We have presented in previous work (Fang and Teufel, 2016) an implementation of KvD's core ideas. However, it did not have the ability to generate new text from the propositions, and we were thus forced to use sentence extraction for the creation of a compromise summary output. We were nevertheless able to show that the content selection of our summariser outperforms state-of-the-art extractive summarisers.

The contribution in the current paper is the combination of our summariser with an existing NL generator that can verbalise the summary propositions. The propositions we use are created by aggregating grammatical dependencies gained from a syntactic parse with the Stanford Parser (Klein and Manning, 2003), in an attempt to create more meaningful semantic units similar to KvD's original concept. This close-to-surface representation allowed us ease of operation and robustness, but the grammatical relations do not contain enough semantic information to regenerate from them. During our research, we decided to experiment with the ACE processor[1], allowing parsing and generation from Minimal Recursion Semantics (MRS) representations (Copestake et al., 2005) and related formalisms such as Dependency Minimal Recursion Semantics (DMRS) (Copestake, 2009). For sentences containing summary propositions, our generation module aligns Stanford grammatical dependencies with their corresponding DMRS components (called Elementary Predicates or EPs). New text is then generated by selecting the minimal set of EPs such that it fulfils two conditions: 1. it covers all the information in the desired proposition from our summariser and 2. it contains all the EPs necessary for successful generation with ACE. The second condition ensures grammaticality.

How should one assess the quality of a summary sentence that minimally expresses the information in a proposition? Our first evaluation aims at measuring the grammaticality and truth preservation of the generated sentences using a human experiment. It is clear that producing grammatical, semantically and pragmatically interpretable text is a necessary goal for any abstractive technology. Truth-preservation is a property that also needs to be evaluated carefully whenever sentential material is manipulated. It is easy to accidentally introduce effects that would distort the meaning of the new sentence, be it by inappropriate referring expressions, by dropping restrictive relative clauses and thus changing the truth-conditional conditions of the sentence, or by many other subtle unintentional changes. In our evaluation, we ask humans to interpret the shortened sentence together with its original context in order to detect possible truth distortions.

Our second evaluation uses the ROUGE metric (Lin, 2004) to evaluate the overall content selection of our abstractive end-to-end method. We cannot directly compare our output to that of an isolated sentence compressor; we first need to select the sentences. We therefore build a pipeline system that uses our summariser as the sentence extractor, and then compresses the summary sentences with two competitive sentence compression methods (Clarke and Lapata, 2008; Cohn and Lapata, 2007). This gives the extraction–compression route a fair chance because our system as a sentence extractor was found to be the best system evaluated in our previous work (Fang and Teufel, 2016). As a further comparison system, we additionally use the next best "generation" algorithm that can express the information in a proposition: one that simply extracts all words that gave rise to the proposition (cf. section 4.2). This is the output mechanism we used in (Fang and Teufel, 2014).

Our results show that our system produces sentences of a good textual quality, and that the overall content selection (as measured in ROUGE) rivals current sentence-selection, while achieving much stronger compression than traditional sentence compressors do. We see two possible reasons why leaving out the middle-man of sentence selection is advantageous in abstractive summarisation. General sentence compression systems are trained to recognise material that tends to be dropped in a "general case". But without information about global discourse effects in the overall text, such a compressor cannot choose particular information selectively inside the sentence. The sentence extractor, which is run independently of it, would typically have selected sentences based on different criteria. In contrast, our system has access to global information about what connects the best propositions, which, as we would argue, enables it to perform better content selection. Secondly, the fact that our system works on propositions, i.e.,

[1]The Answer Constraint Engine, `http://sweaglesw.org/linguistics/ace/`

smaller semantic units, also affords it better information packaging abilities. This is shown by the fact that our abstractive summariser compresses sentences more heavily than traditional systems, because it uses an input sentence only as "raw material" to realise the small piece of information which it has determined to be essential.

In what follows, we will review previous work including the operation of the underlying proposition-based summariser and the NL generator we use (section 2). We will then explain our generation algorithm (section 3), describe our evaluations (section 4), and conclude with a discussion of our results.

2 Background

We now introduce the two modules we use: the summariser that chooses the summary propositions, and the grammar on which the generation operates.

2.1 Proposition-based summarisation

Our proposition-based summariser was introduced in Fang and Teufel (2014) and improved in Fang and Teufel (2016). The summariser maintains a coherence tree, which simulates human working memory. It processes the text sentence by sentence, incrementally adds new propositions to the tree, and prunes old propositions off the tree. Propositions are attached to existing propositions in the tree with which they share arguments (semantic participants). They are "forgotten" if the summariser predicts that no new propositions are likely to be attached to them, using a "leading-edge strategy" that prefers keeping recent nodes that are high-level (i.e. of small depth) on the tree. The idea of applying a graph algorithm on a semantic representation is not new to unsupervised summarisation (Vanderwende et al., 2004), but we have shown that the incremental processing of our model is superior to computing centrality on a single graph that represents the full text (Fang and Teufel, 2016).

The summariser is inspired by KvD's theory of text comprehension. The computational model we present is a simplification of the theory in two ways: 1. It does not generalise propositions or create meta-statements (macro-propositions) for specific domains. (These operations could in principle be performed if NLP technologies such as robust inference and entailment recognition were in place.) Instead it defines the summary-worthiness of a proposition in the simplest possible way, as the number of cycles during which it is retained in memory. 2. Rather than using "concepts" as arguments in the propositions (which would require human intelligence), we create propositions based only on a syntactic parse, and only containing textual tokens, not intelligent "concepts". Our propositions are comparable to the subject-verb-object triples in Genest and Lapalme (2011), but we allow more kinds of predication such as adjectival and prepositional modifications to be propositions in their own right, which means these pieces of information can be selected independently. For example, "*The discovery of the element revolutionised fire-lighting*" gives rise to the propositions *revolutionised (the discovery, fire-lighting)* and *of (the discovery, the element)*. We use coreference resolution and models of semantic relatedness (such as lexical chains and cosine similarity in a vector space) to determine the overlap between these arguments.

Starting from a list of summary propositions found to be important by the summariser, how should we generate a textual summary from it? Doing so is not only important for the usability of the summariser, but also for automated evaluation – ROUGE evaluates the quality of summaries by comparing them to human-written gold standard summaries. It cannot evaluate abstract propositions without surface forms. To solve this problem, we previously made our summariser extract full sentences that contain the summary propositions. However, this does not fully demonstrate the fine granularity of the content selection of our proposition-based summariser, and the advantages this granularity brings. We also ideally want grammatical sentences that *only* realise the information from the propositions selected by the summariser. We do not want the summary to be diluted by any other content that happened to co-occur with it in the same input sentence. In this paper we present a solution, namely NL generation from propositions.

2.2 ACE and The English Resource Grammar

ACE is one of the processors designed to work with DELPH-IN HPSG wide-coverage, linguistically motivated grammars such as the English Resource Grammar (ERG) (Flickinger, 2000; Flickinger et al.,

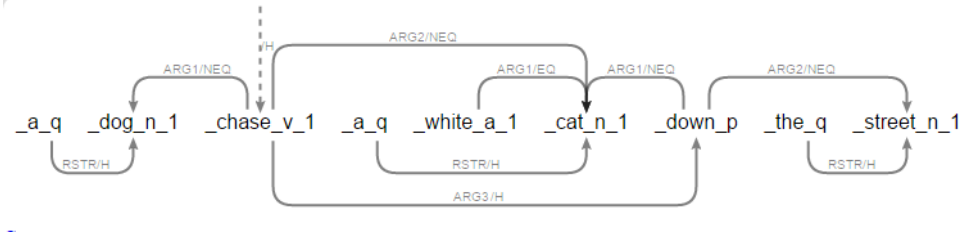

Figure 1: A DMRS graph for the sentence "*A dog chased a white cat down the street.*"

2014), a broad-coverage, symbolic, bidirectional grammar of English. It was developed as part of the DELPH-IN initiative[2] and LinGO[3] project. The ERG uses Minimal Recursion Semantics (MRS) (Copestake et al., 2005) as its semantic representation. In contrast to this, the kind of generation that is traditionally used in summarisation to realise proposition-like units is much shallower, e.g. SimpleNLG as used by Genest and Lapalme (2011, 2013). The MRS format can be transformed into a more readable Dependency Minimal Recursion Semantics (DMRS) graph (Copestake, 2009), which represents its dependency structure. An example of a DMRS graph is shown in Figure 1. The nodes correspond to predicates (EPs); edges (links), represent relations between them.

DMRS graphs can be manipulated using two existing Python libraries. The `pyDelphin` library[4] is a more general MRS-dedicated library. It allows conversions between MRS and DMRS representations but internally performs operations on MRS objects. The `pydmrs` library[5] (Copestake et al., 2016) is dedicated solely to DMRS manipulations.

3 NL generation from propositions

To generate, a deep semantic representation for generation is needed – as well as the propositions, which represent the content we want to include in the summary. But for historic reasons, the front-end of our summariser is the Stanford parser. At the time, propositions based on dependency relations seemed to provide the best fit to KvD's notion of propositions. After realising the shortcomings of shallow generation by extraction, and after the ACE generator became available, we started experimenting with deep generation of summaries using DMRS, as described in this paper. As a downside of this development, we now have to run two parsers on each sentence that is involved in the final summary.

We iteratively generate summary text for each proposition in the ranked list of propositions output by our summariser described in section 2.1, until the summary length limit is reached. For each proposition to be verbalised, we use the original sentence that contains it as the source, parse it using ACE, and then manipulate its DMRS representation so as to generate a (much shortened and) grammatical summary sentence, which should then express the meaning of the proposition in a human-digestible form.

Because propositions from a sentence are ranked independently, as we go down the ranked list, it is possible that we encounter a proposition that shares the source sentence with one or more propositions that were verbalised a few iterations ago. In this case, we restart the generation on that source sentence, and require the new formulation to include the information of both the new and the old propositions. The previously generated summary sentence is then replaced by the new formulation.

3.1 Initial nodes selection

The first step of generating a sentence is to select the initial set of nodes (EPs) in the DMRS representation of the source sentence. This initial set corresponds to the one or more propositions we want to verbalise from the source sentence. A proposition contains information of the index of the source sentence, as well as the textual tokens of its functor and arguments. The character offset of a token is useful because a token in the dependency parse (and therefore in the proposition) may not necessarily align with an EP of

[2]Deep Linguistic Processing with HPSG, `www.delph-in.net`
[3]Linguistic Grammars Online, `lingo.stanford.edu`
[4]`https://github.com/delph-in/pydelphin`
[5]`https://github.com/delph-in/pydmrs`

ERG. For example, the Stanford parser analyses "*didn't*" as two tokens `did` and `n't`, while ERG treats it as one grammar predicate called `neg`. Referring to the character span of `neg`, we are able to select it if the propositions contain either token.

We also need a strategy for unknown words, as ACE does not allow generation from a DMRS if any of its EPs contains an unknown word. We handle this by a temporary replacement mechanism where dummy words stand in for unknown words in the input text.

3.2 Node set expansion for grammaticality

After obtaining the initial node set, our algorithm appends additional nodes and removes existing nodes, based on syntactic information from the ERG parse. The most essential general rule is to always add EPs which are syntactic arguments of already selected EPs. These arguments are indicated by NEQ and HEQ links in the ERG. The ERG has more sophisticated mechanisms than shallower parsers for dealing with subcategorisation in general, which should improve the grammaticality of our results. Our rules include adding compulsory prepositional complements of verbs, adding quantifiers, and dismantling sentence coordination.

We have devised specialised rules for cases when the syntactic parse is more superficial than the ERG's analysis. For instance, the ERG can handle complicated cases of quantification, e.g. "*most of the students*", by using additional meaning-bearing EPs which express semantic relationships such as a part-of relationship or a quantity relationship. In the Stanford dependencies, however, the quantifier "*most*" is the head of the noun phrase, modified by a prepositional phrase "*of the students*". We therefore prevent the undesirable outcome where "*most*" is selected on its own for the summary, by including the semantic head "*the students*", which is connected to the predicate `part_of` via an NEQ link.

As an example, consider a source sentence encountered in our evaluation:

> *In Britain, for example, the dull weather of winter drastically cuts down the amount of sunlight that is experienced which strongly affects some people.*

Extracting the textual tokens that gave rise to the selected summary propositions produces an uninformative and ungrammatical sentence for the summary:

> *In Britain, for example, the weather cuts down the amount strongly affects.*

But our ERG-based generation preserves the semantic head of the quantity relationship, and the obligatory object of the transitive verb:[6]

> *In Britain, the weather cuts down the amount of sunlight, which affects some people, strongly.*

We have also written rules for abstract DMRS predicates such as compound, implicit conjunction, and apposition. We use about ten specialised rules to treat certain constructions, such as "*in order to*", and phrasal verbs such as "*keep from*". The system could be strengthened in the future by the systematic addition of more such rules.

3.3 Node set expansion for graph connectivity

Generation with ACE requires a connected DMRS graph. In this step we ensure connectivity of the subgraph using an undirected graph algorithm. But the subgraph consisting of the EPs selected so far (henceforth "the subgraph"), which we will use for generation, may or may not be connected: If the initial set of EPs was already connected, the expanded set created by the algorithm in section 3.2 will certainly remain connected. If the initial set of EPs was not connected, however, the algorithm for grammaticality can sometimes make the set connected, but there is no guarantee.

Making a disconnected subgraph connected by including the minimum set of additional nodes corresponds to the NP-hard Steiner tree problem (Hwang et al., 1992). Our greedy approach to this problem is to iteratively grow the largest connected component. An iteration starts with the largest connected

[6]Please note that the adverbial modifier "*strongly*" appears in a different place from the source sentence, but is still grammatical. This is an effect of the generator's degree of freedom when verbalising a semantic representation, discussed in section 3.5.

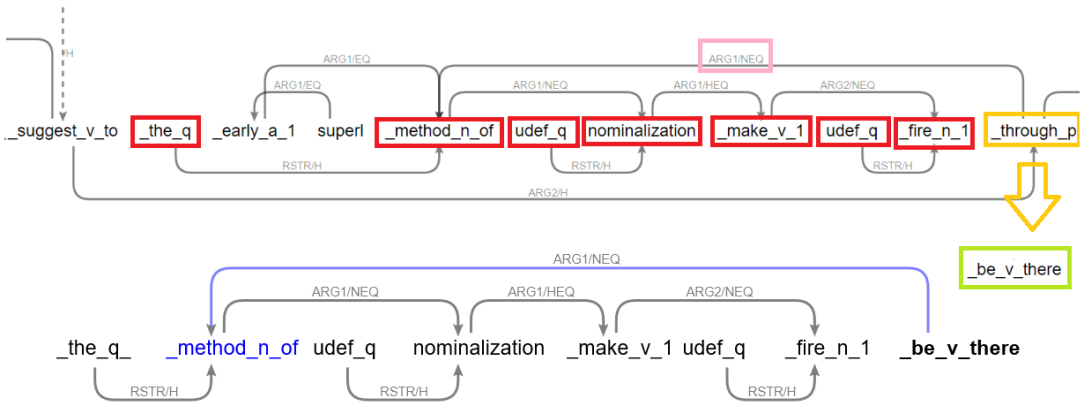

Figure 2: A "*there be*" generation.

component in the subgraph. We want to include one additional node into the subgraph in each iteration, and we select such a node among the non-selected nodes that are adjacent to this connected component. First, we prefer including a node if that node can join the maximum number of other connected components to this component. Second, in case of a tie, we prefer a node that is positioned in the EP sequence (i.e. in textual order) between this connected component and an other connected component. This serves as a heuristic that guides us towards the nodes that are adjacent to the other components. Third, as an additional tiebreaker, we prefer a node that is connected to this connected component via an NEQ link over one connected via an EQ link. After adding the additional node to the subgraph, the next iteration starts with the currently largest connected component in the subgraph. The process continues until there is only one connected component in the subgraph, i.e. the subgraph is connected.

3.4 Node modification

We always want to generate full, grammatical sentences. For propositions that are expressed as noun phrases in the original text, the best solution would be to reformulate the phrase in a verbal predicate. But this is hard, so instead we devised a graph-based procedure that generates "*there be*" sentences for them. This algorithm works by finding the local top node for the set of selected nodes (called `s_n`), and changing this local top node to `_be_v_there_`.

Figure 2 shows a part of the subgraph of the DMRS representation of the sentence

> *Studies of primitive societies suggest that the earliest method of making fire was through friction.*

After expanding the node set from the initial set indicated by our selected proposition, we arrive at the selected node set as shown in the red boxes, namely {`_the_q`, `_method_n_of`, `udef_q`, `nominalization`, `_make_v_1`, `udef_q`, `_fire_n_1`}. The local top node for the node set is `_through_p` (shown in the yellow box); it is connected to the noun predicate `_method_n_of` with an outgoing NEQ link (shown in the pink box), and it is the only link connected with the set. Therefore, we replace the local top with the predicate `_be_v_there_`, and pass the resulting DMRS subgraph to the generator, resulting in the summary sentence

> *There is the method of making fire.*

While this sentence is not perfectly natural, it verbalises the information about fire-making methods reasonably fluently, without introducing unnecessary information from the source sentence that was not selected for the summary.

3.5 Selection among generations

The final step of our method concerns the selection of the best surface sentence generated by ACE. Given a DMRS, ACE generates a list of sentence variants covering the DMRS's semantics, which can

differ by active vs. passive tense, verb alternations, order variations and various other effects. ACE ranks the variants using a statistical model according to naturalness. If a sentence is parsed into EPs, the regenerated sentence from these EPs may therefore be different from the original (e.g. "*Kim gave a book to Sandy*" can turn into "*Kim gave Sandy a book*"). But sentence reformulation is undesirable for us, because we want the shortest sentence that is also closest in meaning and external form to the original sentence – and not necessarily the "most likely" sentence. We therefore select, from the top five generated sentences, the one that shares the longest common subsequence (LCS) with the original sentence.[7]

Of course, Stanford and ACE do not always give the same sentence an equivalent analysis, and not all ACE parses and generations succeed. ACE parsing could fail for different reasons, mostly in our case due to very complex and long sentences, unforeseen syntactic constructions and unusual punctuation. We used our corpus of 108 documents described below to measure its coverage, which is 86.5%.[8] Our backoff strategy in case of parsing or generation failure is to produce the sequence of all tokens which are involved in the proposition, as we did in Fang and Teufel (2014). This primitive generation technique, also a baseline system we use in the following section, is quite likely to produce ungrammatical output, but it is generally applicable to any proposition.

4 Evaluation

For both evaluations we perform, we use the IELTS summary corpus, which we introduced in Fang and Teufel (2016). The IELTS is a standardised test of English proficiency for non-native speakers. The texts we use are taken from the academic reading sections of the official practice tests. We use all 108 such documents available in *Cambridge IELTS 1–9*,[9] of which we randomly sampled 31. For each of the 31 texts, we commissioned four 100-word summaries by 15 native, near-native, or highly proficient speakers of English. We chose this corpus over the commonly-used news corpora for evaluation, because the IELTS texts are not in the journalistic genre, where the lead sentences are usually abstract-like, yet they are naturally occurring, generally understandable and of high editorial standard. They have the additional advantage that they do not need specialised world knowledge in the areas of politics or economics, as news articles (and particularly the frequently used Wall Street Journal) often do. This is beneficial if one wants to study text understanding-based forms of summarisation.

We use human judgement to evaluate the textual quality of individual generated sentences, and use the automatic ROUGE metric to evaluate the content selection ability on entire summaries.

4.1 Systems

We test four kinds of generation mechanisms for summarisation here (Figure 3): 1. OurAbs, our KvD-based summariser with NL generation, which realises the summary propositions directly as new text; 2. various sentence extraction systems (without sentence compression); 3. various combinations of sentence extraction systems followed by sentence compression systems; and 4. OurTok, our KvD summariser with the primitive generation technique, which only outputs the word tokens involved in summary propositions in textual order, without any attempt at generating fully grammatical sentences.

Both OurAbs (category 1) and OurTok (category 4) are based on first deriving a ranked list of summary propositions, where the importance (weight) of a proposition is determined by the KvD-style simulation of text understanding (cf. section 2.1). In principle, a summariser in categories 2 and 3 could also use the same information to extract sentences (followed by a compression stage for category 3). For instance, an extractor can choose sentences such that the sum of the weights of the propositions from these sentences is maximised. We have in fact implemented such a sentence extractor and formally

[7] If there is a tie, we choose the sentence with fewer words. If candidates of the maximum LCS are equally long, we choose the top-ranked generation.

[8] We also implemented a simple sentence simplification method that splits unparsed sentences at top-level S coordination nodes, which increased coverage to 90%. But we do not further report on this method here because its ROUGE results suffered slightly.

[9] For example, *Cambridge IELTS 9: authentic examination papers from Cambridge ESOL*, Cambridge University Press, ISBN: 9781107615502.

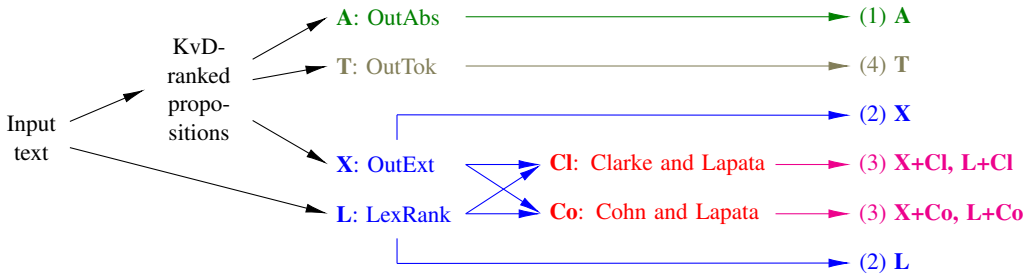

Figure 3: The 8 summarisation systems in 4 categories.

	Grammatical			Truthful		
	OurAbs	OurTok	Tie	OurAbs	OurTok	Tie
Average	20	5	15	25.3	5.3	9.3
Total	120	30	90	152	32	56

Table 1: Text quality evaluation: number of "higher" judgements given.

evaluated its performance in Fang and Teufel (2016); we call it OurExt here.

Alternatively, the sentence extraction module could be a shallower summariser that is not based on propositions. For instance, LexRank (Erkan and Radev, 2004) is a summariser that internally represents the input document as a graph of sentences. The inter-sentential similarity dictates the edges and their weights, and the centrality algorithm computes the value of a sentence by the probability of a random walk arriving at it. It does not build the graph incrementally, and it only measures the importance of sentences but not meaning units.

We use two sentence compression methods in combination with OurExt and LexRank. Clarke and Lapata (2008) use integer linear programming (ILP) to find the optimal compression per sentence within linguistic constraints. We choose its unsupervised version,[10] which requires a language model. We trained a trigram language model on the 100M-word British National Corpus (BNC) with interpolated Kneser-Ney smoothing and the "unknown word" token. Cohn and Lapata (2007) present a supervised tree-to-tree transduction method for sentence compression.[11] It is a variation of the Noisy Channel model for sentence compression first introduced by Knight and Marcu (2000). Instead of the Broadcast News Corpus they used, we trained the tree rewriting model on the full Written News Corpus, which only became available later (Clarke and Lapata, 2008). Following them, we aligned the words between the original and the compressed sentences using GIZA++ (Och et al., 1999), with additional pairs added where each word in the lexicon is aligned with itself, and symmetrised the alignment using the intersection heuristic (Koehn et al., 2003). We used the Stanford PCFG Parser (Klein and Manning, 2003) to obtain the sentence parses, and the above-mentioned BNC language model for training and decoding.

Both compressors were run on all input sentences.[12] The sentence extractor (OurExt or LexRank) computes the summary-worthiness of the uncompressed sentences, and then the corresponding compressed sentences are output.

4.2 Textual quality evaluation

We performed a human experiment to evaluate the textual quality of the sentences generated by our new system OurAbs, in comparison to OurTok. This evaluation is performed on individual sentences. We only tested sentences where OurAbs's generation succeeded, as OurAbs's fall-back strategy is identical to OurTok's normal operation.

We recruited six participants for this study. They were provided with 40 sentence triples, each consisting of a sentence from the input document, and both outputs by OurTok and OurAbs based on the same

[10] We used the implementation from `https://github.com/cnap/sentence-compression`

[11] We obtained the implementation from the authors.

[12] The Cohn and Lapata compressor failed to process 8 sentences. If any of them is chosen for summary, the uncompressed sentence is used instead.

	R-1	R-2	R-L	R-SU4
Abstract generation from propositions				
OurAbs (A)	0.364	0.088	0.340	0.131
Sentence extraction with compression				
X + Cl	0.361	0.090	0.335	0.132
X + Co	0.340	0.074	0.321	0.113
L + Cl	0.356	0.077	0.325	0.126
L + Co	0.336	0.067	0.314	0.110
Sentence extraction				
OurExt (X)	0.376	0.122	0.345	0.154
LexRank (L)	0.349	0.087	0.316	0.129
Token extraction for propositions				
OurTok (T)	0.356	0.088	0.336	0.130

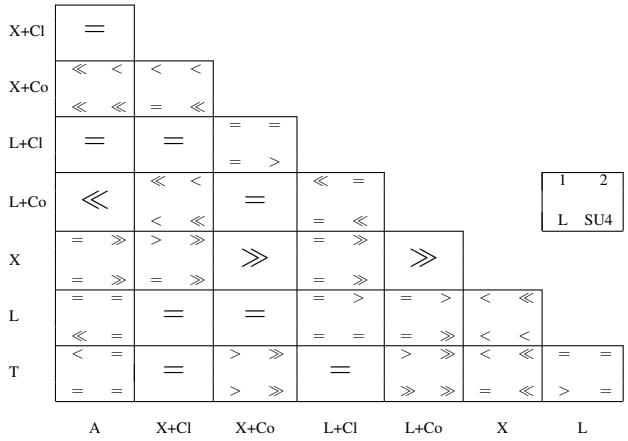

Table 2: ROUGE F-scores and statistical significance of the differences. The four positions in the significance table correspond to ROUGE-1, 2, L and SU4, respectively. "$\gg$" means row statistically outperforms column at $p < 0.01$ significance level; "$>$" at $p < 0.05$ significance level, and "$=$" means no statistical difference detected.

underlying summary proposition(s), in randomised order across triples. They were asked to rank the two summaries for two properties: 1. Which sentence is more grammatical? 2. Which sentence is more truthful to the meaning of the original sentence? They were allowed to judge two summaries as equally good (i.e. tie). The total number of judgements in this evaluation is 240 (40×6) for each question.

The results are given in Table 1. In 50% of cases (120/240), OurAbs was judged as strictly more grammatical than OurTok; as opposed to 12% of cases where OurTok was judged as strictly more grammatical. In terms of truth preservation, OurAbs was judged as distorting the truth less in 63% of cases (152 out of 240), whereas OurTok was seen as more truth-preserving in 13% of cases (32 out of 240). All differences are statistically significant as determined with the sign test at $p = 0.05$. Seeing that the new system improved or did not decrease grammaticality in 87% of cases where generation was successful, and improved or did not decrease truth-preservation in 86% of cases, we believe that the new generation technique has increased text quality overall considerably over our previous primitive method, while achieving a very strong compression of 33%.

4.3 Content selection evaluation

We evaluate the quality of content selection using four ROUGE metrics (ROUGE-1, 2, L, and SU4) on the IELTS corpus, and compute the statistical significance using the paired Wilcoxon test (Table 2). Although OurExt is the best system in all metrics, OurAbs performs comparably to it on ROUGE-1 and ROUGE-L. It performs at least as well as the four pipeline systems. This is an achievement because the goal of OurAbs is to generate only the summary propositions, and is therefore only directly comparable to OurTok. It is an improvement over OurTok, which is significantly worse than OurExt in all metrics except ROUGE-L.

To a limited degree, we can compare OurAbs to the pipeline systems that combine sentence extraction with compression, as long as we bear in mind that OurAbs faces a more challenging generation task: it is required to capture specific information with a sentence, instead of what is generally important in that sentence. It performs this task very well, which is shown by a very low compression rate (length of generation divided by length of original, in words) of 33%, and easily beats either sentence extractor combined with Cohn and Lapata's compressor, which compresses to 43%. Under ROUGE, when the compression rate decreases, the shorter sentences give rise to much fewer n-grams, so that the generation imperfections become disproportionately penalised by ROUGE's numerical scores. We see the extreme case in OurExt, which has the highest ROUGE scores but does not compress at all. Even under these adverse conditions, OurAbs still performs indistinguishably from any sentence extractor with Clarke and Lapata's compressor, which, at a compression rate of 67%, benefits under ROUGE from being closer to full-sentence extractions.

5 Conclusions

What we have presented here are the first steps in abstractive summarisation via propositions. What we hope we have shown is that there is promise in using propositions as a functional semantic representation, which works for both content selection and verbalisation of the output. Relying only on text coherence for the memory operations, this content selection process has the flexibility to work across domains.

Our new KvD-based abstractive summariser uses propositions not only for content selection, but also for generation. For this we use a deep generator based on the DMRS formalism. Others have used proposition-like units for selection and generation, but they use a much shallower NL generator and they limit the units either to certain syntactic constructions (Genest and Lapalme, 2011) or to certain domains (Genest and Lapalme, 2013). The addition of the NL generator is of course an important step forward for the usability of our summariser, but it is also an improvement for evaluation, because it allows us to measure the effect of granularity in content selection, without being tied to sentence extraction as our generation method, as we were before. In the future, we also plan to concentrate our efforts on developing a fully automatic proposition-based evaluation.

Our current system produces summary output of a higher quality than our previous primitive output method. For a more extensive comparison, we have constructed the combinations of sentence extractors (both ours and LexRank) with two well-cited sentence compressors. Sentence compression presupposes a prior step of sentence extraction; it is the only other way how abstractive summaries can be constructed. However, this previous step is rarely talked about in the literature. In this work, we have implemented four versions of this extraction–compression model, and found that our system performs at least as well as these systems. But its biggest advantage is that it has better information packaging abilities, as demonstrated by the lower compression rate. This is arguably an effect of our use of propositions.

There are also many ways how the generation component could be made more robust. Despite ERG's high quality, parsing and generation sometimes still produces ungrammatical or awkward text, or fails altogether, in which case our system has to fall back to the crude token-based output method. The main reasons for this is that our system is still not very deep, as there are many cases when neither the KvD step nor the generation step has enough information to select the correct information.

We see the fact that our summariser is not based on sentence extraction for content selection as one of its advantages. However, the generation step itself currently has the limitation that the textual output representing a proposition can only come from a single sentence. This leads to an abundance of bullet point-like short sentences in our automatic summaries, which also makes our abstractive summaries disadvantaged in the ROUGE-based evaluation. Removing this limitation would allow a truly flexible summariser. This could be achieved by knowing the identity of concepts in a document, and aggregating attributes of an entity (i.e. propositions about an entity). As a subproblem of this, we would need to generate appropriate referring expressions, or create discourse-new elements as needed.

The KvD summariser itself is also constantly being developed further. For instance, keeping a distinction between identity and bridging links between arguments is important to the above-mentioned task. On top of this, the recognition of identical propositions and generalised propositions that already exist in text can also be achieved, which will be an initial step towards inference.

Cross-lingual Learning of an Open-domain Semantic Parser

Abstract

We propose a method for learning semantic CCG parsers by projecting annotations via a parallel corpus. The method opens an avenue towards cheaply creating multilingual semantic parsers mapping open-domain text to formal meaning representations. A first cross-lingually learned Dutch (from English) semantic parser obtains f-scores ranging from 42.99% to 69.22% depending on the level of label informativity taken into account, compared to 58.40% to 78.88% for the underlying source-language system. These are promising numbers compared to state-of-the-art semantic parsing in open domains.

1 Introduction

Scarceness of manually annotated corpora for training dependency parsers has led researchers to explore more indirect forms of supervision, such as cross-lingual learning, where annotations in one language are used in training a system for another language. Semantic parsers, which map sentences directly to logically interpretable meaning representations, equally suffer from a lack of annotated training corpora, despite recent efforts like the Groningen Meaning Bank (Basile et al., 2012) or AMR Bank (Banarescu et al., 2013). The lack is especially pronounced for languages other than English.

This paper aims to show that cross-lingual learning can help create semantic parsers for new languages with little knowledge about those languages and minimal human intervention. We present a method that takes an existing (source-language) semantic parser and parallel data and learns a semantic parser for the target language. Our method is in principle applicable to all parsers producing interpreted derivations (i.e., parse trees) of Combinatory Categorial Grammar (CCG; Steedman 2001) . It is independent of the concrete meaning representation formalism used, as long as meaning representations are assembled in the standard CCG way using the lambda calculus. We evaluate our method by applying it to English as source language, Dutch as target language and Discourse Representation Theory (DRT; Kamp and Reyle 1993) as meaning representation formalism, and measuring the performance of the obtained Dutch semantic parser.

2 Related Work

Semantic parsing has been tackled from a wide variety of angles. Systems that add a semantic interpretation component to an existing supervised syntactic parser (Curran et al., 2007; Le and Zuidema, 2012; Lewis and Steedman, 2013) have wide coverage but require much syntactically annotated training data. Other approaches are restricted to relatively narrow linguistic domains but manage to do without strong syntactic supervision. Forms of supervision used include sentence/meaning representation pairs (Wong and Mooney, 2007; Zettlemoyer and Collins, 2007) and even weaker forms of supervision (Clarke et al., 2010; Liang et al., 2011; Kwiatkowski et al., 2013; Goldwasser and Roth, 2011; Chen and Mooney, 2011; Krishnamurthy and Mitchell, 2012; Reddy et al., 2014; Artzi and Zettlemoyer, 2011; Poon, 2013). Only recently have approaches not relying on explicit syntactic supervision successfully been applied to

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 579–588, Osaka, Japan, December 11-17 2016.

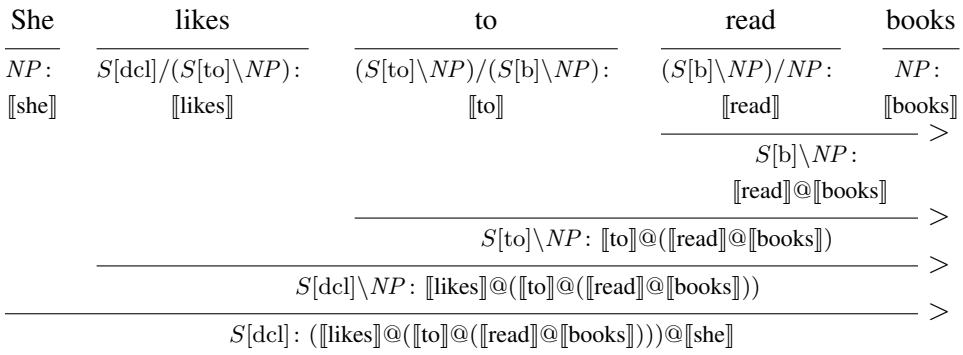

Figure 1: Example CCG derivation.

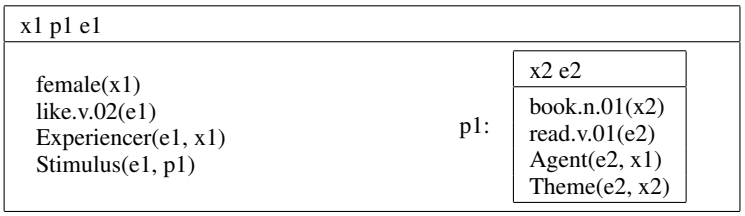

Figure 2: Example DRS for the sentence in Figure 1.

more open-domain sentences (Vanderwende et al., 2015; Artzi et al., 2015). Ours is, to the best of our knowledge, the first such work using cross-lingual learning.

Cross-lingual learning has previously been applied to different NLP tasks, notably part-of-speech tagging and dependency parsing. For dependency parsing, the task most similar to ours, three families of approaches can be distinguished. In **annotation projection**, existing annotations of source-language text are automatically projected to target-language translations in a parallel corpus; the result is used to train a target-language system (Hwa et al., 2005; Tiedemann, 2014; Rasooli and Collins, 2015; Johannsen et al., 2016; Agić et al., 2016). In **model transfer**, parsers for different languages share some of their model parameters, thereby using information from annotations in multiple languages at the same time. (Zeman and Resnik, 2008; Ganchev et al., 2009; McDonald et al., 2011; Naseem et al., 2012; Täckström et al., 2013). The **translation approach** pioneered by Tiedemann et al. (2014) is similar to annotation projection, but instead of relying on existing translations, it automatically translates the data and synchronously projects annotations to the translation result. Our approach falls within the annotation projection family, with the new challenge that entire CCG derivations with logical interpretations need to be transferred.

3 Combinatory Categorial Grammar

Combinatory Categorial Grammar (Steedman, 2001) is a grammar formalism widely used for semantic parsing due to its suitability to statistical parsing (Clark and Curran, 2007) and its transparent syntax-semantics interface. Every constituent has a *category*—either a basic one (S for sentence, N for noun, NP for noun phrase, PP for prepositional argument) or a functional one such as $S\backslash NP$ for verb phrase, indicating that a constituent can combine with a noun phrase to its left to yield a sentence. Smaller constituents are combined into larger ones according to a handful of combinatorial rules such as application and composition. Every constituent also has a semantics, its *interpretation*, which is a term of the lambda calculus. Crucially, the combinatorial rules specify precisely how the interpretation of each non-lexical constituent is computed from the interpretations of the constituents that combine to form it. An example derivation (CCG parse tree) for an English sentence is shown in Figure 1.

The lambda calculus and thus CCG is applicable to any kind of meaning representation, as long as it can be constructed compositionally. In this paper, we use a flavor of Discourse Representation Theory (DRT; Kamp and Reyle 1993) and a corresponding semantic lexicon introduced by Bos (2009) which

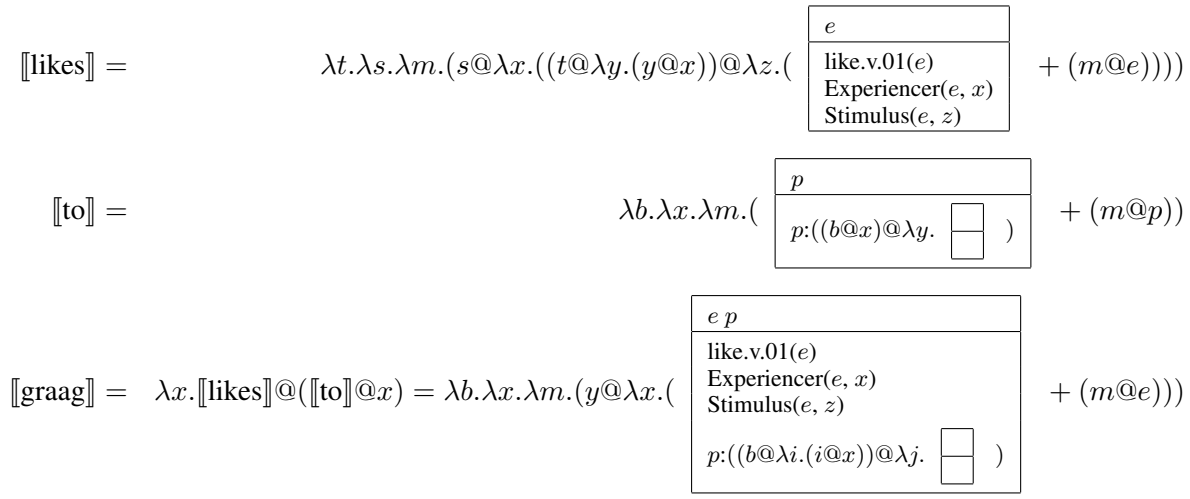

Figure 3: Examples of some lexical interpretations (two English, one Dutch).

uses a neo-Davidsonian event semantics with VerbNet/LIRICS semantic roles (Bonial et al., 2011) and WordNet 3.0 senses (Fellbaum, 1998). The meaning representation (discourse representation structure; DRS) for our example sentence is shown in Figure 2. Lexical interpretations of some words are shown in Figure 3.

4 Method

We start with a parallel corpus of sentence pairs whose source-language part has been annotated with semantic CCG derivations as in Figure 1 by the source-language system. We use this annotation in two ways: first, to induce a target-language lexicon in a first step called **category projection**. Secondly, we use it as a form of indirect supervision: we assume that the source-language system works mostly correctly, and that if two sentences are translations of each other, they should have the same interpretation—thus we can train the target-language parser to produce the same interpretations as the source-language parser. To this end, we try to find target-language derivations resulting in the same interpretations as the source-language ones, based on the target-language candidate lexical items found in category projection. We call this second step **derivation projection**. The derivations thus found are used to train a statistical parsing model for the target language. We call this third step **parser learning**.

All three steps make use of a shift-reduce CCG parser similar to that of Zhang and Clark (2011). Parse actions are SHIFT-C-I, COMBINE-C, UNARY-C (where C is the category placed on top of the stack by shifting or applying a binary/unary rule and I is the interpretation of the (multi)word placed on top of the stack by shifting), SKIP for skipping words as semantically empty, FINISH for marking a parse as complete and IDLE for keeping complete parses on the agenda while others are still incomplete (Zhu et al., 2013).

We now describe the three steps in more detail.

4.1 Step 1: Category Projection

Category projection assigns candidate categories and interpretations to target-language (multi)words in the training data. It thereby also induces the target-language lexicon that we use in subsequent steps. It serves as a cross-lingual alternative to the two traditional main strategies of inducing CCG lexicons for semantic parsing, namely hand-written, language-specific lexical templates (Zettlemoyer and Collins, 2005) and higher-order unification constrained by search heuristics (Kwiatkowksi et al., 2010).

Category projection first word-aligns the training corpus—we use the n best alignments found by GIZA++ (Och and Ney, 2003) with default settings. The result is a large, noisy set of translation units. From each contiguous translation unit, we try to induce a candidate lexical item. Figure 4 shows an

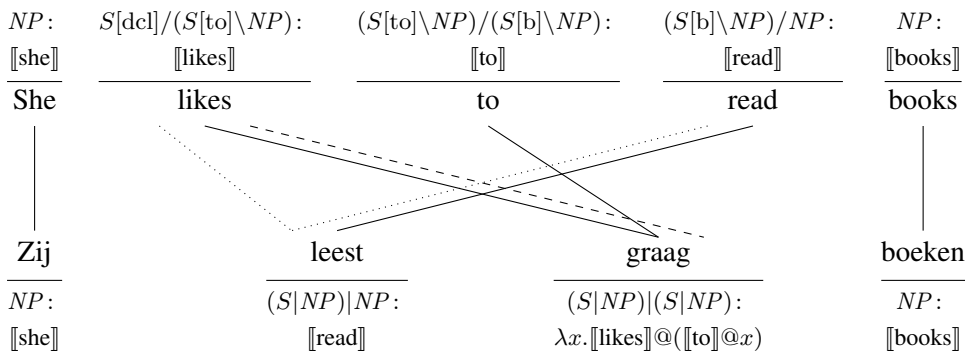

Figure 4: Category projection: word alignments induce candidate categories and interpretations for target-language words.

example sentence pair: at the top there are the lexical items from the English derivation in Figure 1, each with a CCG category and interpretation. The interpretations are here represented using the $[\![\cdot]\!]$ notation but are actually a complex λ-terms with DRT-based meaning representations (for short: a λ-DRS) as exemplified in Figure 3. The lines in the center represent possible word alignments, with correct translation units drawn as solid lines and incorrect ones as dashed or dotted ones. At the bottom there is the Dutch sentence with induced candidate lexical items. For the sake of the example, we only show one candidate lexical item per word, those induced from the correct translation units.

Inducing a candidate lexical item from a translation unit works as follows: if the translation unit contains only one source-language word, it provides the category and interpretation for the (multi)word on the target side, as is the case for *She*/*Zij*, *read*/*leest* and *books*/*boeken*. Since slash directions are language-specific, we change all categories to have vertical slashes, which can apply in either direction. We also remove English-specific category features such as $[b]$ and $[dcl]$, distinguishing bare and declarative verb phrases. For example, $(S[\mathrm{b}]\backslash NP)/NP$ becomes $(S|NP)|NP$.

If the translation unit contains more than one source-language word, this string is parsed using CCG combinatory rules, and if successful, the resulting category and interpretation are used as a lexical item for the word on the target side. For example, the verb *likes* and the particle *to* combine via forward composition into one category and interpretation for the Dutch adverb *graag*, which expresses the same meaning in a syntactically different way. The full resulting λ-DRS for *graag* is shown in Figure 3.

Unaligned target words get a special category $skip$.

The final target-language lexicon $\mathcal{L}$ contains the lexical items thus induced, but only those that are at least a cutoff factor c times as frequent as the most frequent candidate for this target-language word/part-of-speech combination.

4.2 Step 2: Derivation Projection

The lexical items assigned to target-language words in category projection give rise to a space of possible CCG derivations. The space is large and noisy, partly because of the pervasive syntactic ambiguity of natural language, partly because we use more than one word alignment in category projection. In derivation projection, the task is to filter out only the "correct" derivations so we can then train on these. We regard as "correct" any derivation that results in the same interpretation for the whole sentence as the source-language derivation.

For finding the "correct" derivations, we use the method of Zhao and Huang (2015) of running the parser in forced decoding mode: we use a beam of unlimited width but prune away parse items where, based on their interpretations, we can rule out that they could lead to a "correct" derivation. For instance, in our example, an item with interpretation ⟦read⟧@⟦she⟧ would be pruned because it cannot be part of (⟦likes⟧@(⟦to⟧@(⟦read⟧@⟦books⟧)))@⟦she⟧. To make this check tractable, we treat English lexical interpretations such as ⟦read⟧ as atomic.

The forced decoding uses a local lexicon, using only lexical items induced from the same sentence pair.

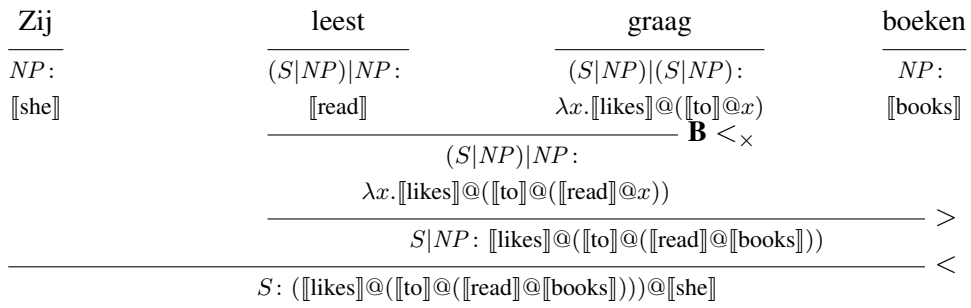

Figure 5: Derivation projection: combinatory rules are applied to find a derivation with the same interpretation as the source-language sentence.

The combinatory rule instances used are extracted from all English training derivations, but to allow for different word orders, we verticalize all slashes and for binary rule instances add mirror-image versions, e.g., the backward application instance $NP\ S\backslash NP \Rightarrow S$ generates $NP\ S|NP \Rightarrow S$ and $S|NP\ NP \Rightarrow S$.

If we cannot find any "correct" derivation, this means we did not get the word alignments inducing the lexical items needed to find one. This can be due to translations being idiomatic, loose or informative (Bos, 2014). In such cases, our assumption that the interpretation for source and target sentence should be the same breaks down, and we would not want to use this training example anyway. In this sense, derivation projection also has the function of cleaning the training set.

Despite the pruning, for some sentences the search space is prohibitively large, so we restrict the size of the parser agenda to 256, a number that still allows us to run this step in reasonable time. If this limit is exceeded or if we do not find a complete derivation with the target interpretation, we discard the sentence. If we do find one or more—such as the one in Figure 5—the sentence becomes part of the training data for the following step.

4.3 Step 3: Parser Learning

For statistical parsing, we use an averaged perceptron with a hash kernel (Bohnet, 2010) and the same feature templates as Zhang and Clark (2011), plus, for shift actions, a feature uniquely identifying a lexical item including the (multi)word, its part(s) of speech and the chosen category and interpretation. The parser uses the full global lexicon $\mathcal{L}$. The same grammar as in derivation projection is used.

The parser uses beam search. If at some point during training on one example there is no item on the beam anymore that could lead to one of the "correct" derivations found in derivation projection, the parser aborts training on this example and performs an early perceptron update (Collins and Roark, 2004).

5 Experimental Setup

To ensure that derivation projection can find a large number of high-quality derivations, we need training data with a large proportion of "literally" translated sentences. By this we do not mean that the translation has to be syntactically isomorphic—our projection approach can actually deal with a wide range of such syntactic divergences (cf. Dorr, 1993), such as the *likes to*/*graag* example. But translations should not be informative or loose, as this changes their meaning. More literal translations than in freely occurring text can be found in resources aimed at human language learners (who are faced with a similar task as our system: learning to understand an unknown language, helped by example sentences translated into a familiar one). One such resource is `tatoeba.org`, based on the Tanaka corpus (Tanaka, 2001). We used 13,122 English-Dutch sentence pairs from Tatoeba as training data, 1,639 for development and 1,641 as final test set, of which a random sample of 150 sentences was manually annotated to serve as a gold standard.

In preliminary experiments, we tried out different values for n where we use the n-best alignments per direction to extract candidate lexical item from. Too low and derivation projection may not find a derivation for many target-language sentences for lack of needed candidate lexical entries. Too high and the agenda gets polluted with spurious parse items, and derivation projection aborts due to the agenda limit. We found that for our training set, the percentage of examples for which we find at least one target-language derivation peaked at $n = 3$ with 57.7%.

The source language system whose output we use for supervision is the C&C/Boxer system (Curran et al., 2007), which takes English sentences and produces discourse representation structures. We use SVN repository version 2444, giving the options `--modal true --nn true --roles verbnet` to Boxer and making some minor modifications to its code to better match our annotation scheme for adjectives, adverbs, semantic roles and modals.

For statistical parsing, we initialize all model weights to 0 and use a beam width of 16. The Dutch sentences are POS-tagged using TreeTagger (Schmid, 1995). For decoding, the input is only POS-tagged Dutch development/test sentences. We use the same lexicon as for training, but to deal with unseen content words, an abstract version of each lexical entry is created where the synset ID in its λ-DRS is replaced by the $\_\_UNKNOWN\_\_$ symbol. The parser then selects between all categories occurring with the POS tag, with the most common abstract interpretation for each category. The output is a CCG derivation—or, since the parser can fall back to fragmentary output, a sequence thereof—each of which has a DRS interpretation.

6 Evaluation Setup

For evaluation, we follow the approach proposed by Allen et al. (2008): meaning representations are converted to graphs and an alignment between system output and gold graph vertices is found that maximizes the number of labeled edges in a maximum common subgraph. An instantiation of this evaluation metric for Abstract Meaning Representations, SMATCH (Cai and Knight, 2013), is now commonly used. We use the instantiation for DRSs that was first introduced by Le and Zuidema (2012).

We first measure how closely the output of our system for Dutch resembles that of C&C/Boxer for English on the development/testing portion of our parallel corpus. This gives an idea of how well our system has learned to imitate the existing system, but has two problems: first, it does not say much about the quality of the output because that of C&C/Boxer is not free from errors, it is not a gold standard. Secondly, the data contains idiomatic, informative and loose translations, in which case we *want* the outputs of both systems to differ.

Therefore, we also measure how closely the outputs of C&C/Boxer and our system resemble a gold standard of 150 sentence/DRS pairs from the testing portion, for their respective input languages. Since DRSs are complex structures not easily created in completely manual annotation, we resorted to hand-correcting automatically produced ones to obtain the gold standard. This was done as follows: Two annotators independently corrected 50 DRSs produced by C&C/Boxer so that the DRSs represented the meaning of the Dutch annotations. Inter-annotator agreement at this point as measured by the evaluation metric was 67%. Instances of disagreement were identified, with 29% related to WordNet senses, 22% to semantic roles, 16% to other relations such as prepositional ones, 13% to the rendering of Dutch idioms using English WordNet senses, 9% to modal and logical operators such as implication and negation, and 11% to other structural issues such as nested DRSs. In an adjudication phase, both annotators resolved the differences together and agreed on a common gold standard. A single annotator then corrected another 100 Boxer DRSs, which were then checked by the other annotator, and differences were again resolved through discussion. One annotator finally created an adapted version of all 150 DRSs where in case of non-literal translations, the annotation matches the English rather than Dutch sentence.

No comparable systems for Dutch as input language and DRS as meaning representation language exist yet. To demonstrate the effect of learning the parsing model, we picked a simple baseline that assigns each target-language word the semantic representation most frequently associated with aligned English words and outputs the resulting, very fragmented graph.

Table 1: Development set (non-gold-standard) f-score depending on lexical cutoff factor c and training iterations T (i.e., number of passes over the entire training data).

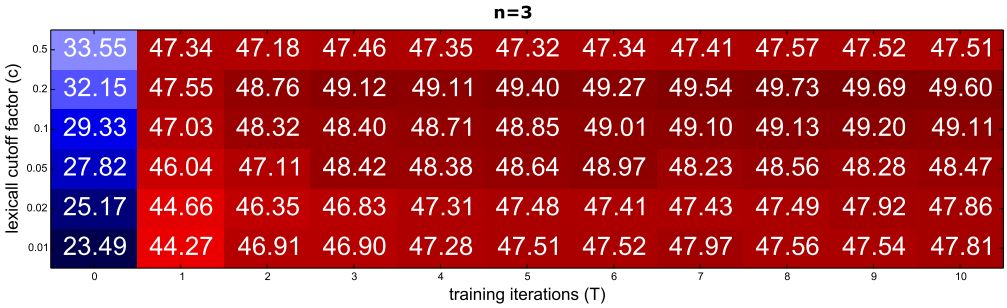

Table 2: Gold-standard match f-score for Boxer, our baseline and our best cross-lingually trained model.

Language	English	Dutch	
System	C&C/Boxer	Baseline	Our system
Full	58.40	26.71	42.99
Ignoring WordNet senses	69.06	36.67	60.23
Ignoring VerbNet/LIRICS roles	64.51	27.57	47.82
Ignoring other relation labels	59.18	27.57	43.39
Ignoring all	78.88	39.04	69.22

7 Results and Discussion

Table 1 shows how the f-score of our system on the (non-gold-stard because automatically annotated) development corpus varies as a function of the lexical cutoff factor c and number of training iterations T. We used the model with the highest score ($c = 0.1$, $T = 10$) for final testing. Table 2 shows the results, comparing the performance of our cross-lingually learned system on Dutch against the baseline and against C&C/Boxer's performance on the English versions of the same sentences.

C&C/Boxer obtains an f-score of 58.40% on the gold standard. Although the data and the formalism are not directly comparable, we note that this f-score is close to those of current state-of-the-art open-domain semantic parsers for English, e.g. those that participated in the recent Abstract Meaning Representation shared task (May, 2016). A large part of the errors comes from misidentifying word senses and semantic roles. "Sloppy" evaluations in which we treat all word senses, all roles and/or other (e.g. prepositional) relation labels as equal give markedly higher f-scores of up to 78.88%.

Our system for Dutch scores around 15% lower than the source-language system under the strict evaluation, at 42.99%. The gap narrows to around 10% under the sloppy evaluation, scoring 69.22%. The gap is expected for a number of reasons. For one, the English system has the advantage of a strong syntactic parser which was trained on a far larger number of sentences, which also had explicit syntactic annotation. The especially large gap under the strict evaluation can partially be explained by many unseen words in the test data, with the training data insufficiently large to learn a wide-coverage lexicon, while the system for English has access to the full WordNet lexicon.

For languages like Dutch, available resources could be exploited to address these problems. For example, one could improve a cross-lingually bootstrapped CCG parser by training it to recover the dependencies in a dependency treebank, e.g. Universal Dependencies (Nivre et al., 2016). Multilingual lexical databases like Open Multilingual Wordnet (Bond and Foster, 2013) could be exploited to attack unseen words. For truly low-resource languages where such resources are not available, parallel data could be mined in order to extend the target-language lexicon. This could work even with data that is currently too loosely translated or too syntactically complex to work well with our projection approach.

Although we optimized the hyperparameter $n = 3$ for the number of successfully projected derivations, Dutch derivations were found for only 58.35% of our training sentences, considerably reducing the amount of training data that is available for parser learning. To what extent this is due to non-literal translations being weeded out (cf. Section **??**), and to what extent failing derivation projections could be avoided (e.g. by considering other combinatory rules than those extracted from the English data) is an important question for future work.

8 Conclusions

Semantic parsing for open domains is a young and very dynamic research area that may shortly enable computers to make use of natural language on a new and significantly deeper level. With a field notoriously focused on English, how can other languages keep up with the developments?

In this paper, we have shown a possible avenue. We draw upon CCG's flexible notion of constituency and the language-independent nature of its combinatory rules to develop a lexicon induction technique that overcomes certain translation divergences between languages. We have then used cross-lingual supervision to train a semantic parser for Dutch at a far lower cost than the original English one, considering the cost of manually creating explicit syntactic annotation and a semantic lexicon.

Bridging the gap between source and target language does come at an additional cost in performance. However, there are a number of possible ways to attack this gap in future work, including using target-language lexical resources if available, unsupervised mining of large amounts of parallel data for lexical entries, and also improving the parsing model itself with recent advances in CCG semantic parsing.

Dutch and English are relatively close cousins; in ongoing work we are investigating the applicability of our method to a number of Germanic and Romance languages (e.g., German and Italian) and so far have found no theoretical obstacles. To what extent applying it to less closely related language pairs than English/Dutch is harder empirically remains to be investigated. In any case, we are confident that the techniques presented in this paper can help develop multilingual semantic parsers without starting from scratch, software-wise and data-wise, for every new language.

Acknowledgments

We would like to thank Phong Le for sharing his evaluation code, Johannes Bjerva, Hessel Haagsma, Dieke Oele and Rob van der Goot for feedback on earlier version of this paper, and the three anonymous reviewers for helpful comments. This work was partially funded by the NWO-VICI grant "Lost in Translation—Found in Meaning" (288-89-003).

Abstract

We propose a dependency parsing pipeline, in which the parsing of long-distance projections and localized dependencies are explicitly decomposed at the input level. A chosen baseline dependency parsing model performs only on 'carved' sequences at the second stage, which are transformed from coarse constituent parsing outputs at the first stage. When k-best constituent parsing outputs are kept, a third-stage is required to search for an optimal combination of the overlapped dependency subtrees. In this sense, our dependency model is subtree-factored. We explore alternative approaches for scoring subtrees, including feature-based models as well as continuous representations. The search for optimal subset to combine is formulated as an ILP problem. This framework especially benefits the models poor on long sentences, generally improving baselines by 0.75-1.28 (UAS) on English, achieving comparable performance with high-order models but faster. For Chinese, the most notable increase is as high as 3.63 (UAS) when the proposed framework is applied to first-order parsing models.

1 Introduction

Incorporating 'non-local' features into syntactic parsing has been well-studied in literature. For exact parsing, we have seen cubic-time decoders for first and second-order models (Eisner, 1996; McDonald and Pereira, 2006), quadratic-time decoders for third-order models (Koo and Collins, 2010) and etc. In transition-based parsers, e.g. (Nivre et al., 2006), so-called non-local features can be easily extracted from parsing history. With a global inference framework, e.g. approximate Linear Programming (Martins et al., 2011; Koo et al., 2010), arbitrary structural constraints can be imposed. There are two main research goals underlying these works, one is to localize long-distance dependencies, which can be achieved by assuming the optimal substructure property or introducing parsing actions like reductions. The other goal is to appropriately factor tree score, over parts like arcs as well as over parsing actions.

In this work, we propose a dependency parsing pipeline, so that long-distance dependencies are explicitly localized at the input level. With the proposed factorization, dependency tree score sums over its subtrees. More specifically, we address a distinction between long-distance projections and localized dependencies, which can be characterized by word categories of their lexical heads. The long-distance projections can be captured by a coarse constituent parser, which only sees peripheral and head words of such long-distance projections. So as to reduce error propagation, we transform k-best constituent parsing outputs to 'carved' sequences for the following dependency parsing, which could be overlapped. Therefore, a third stage is required to search for the optimal subset of all candidate subtrees to combine.

Given previous work on parsing, e.g. (Charniak and Johnson, 2005),(McDonald et al., 2005),(Martins et al., 2013) and so on, reliable constituent-based parsers and dependency parsers are available. Our main implementation challenge is to select an subset of those subtrees over overlapped carved sequences of the original input to cover the original sentence. We propose to formulate this as an Integer Linear Programming (ILP) problem, which is similar to a set cover problem. Note that, since the search space at this stage is highly constrained by the input of the previous stages, an exact decoding is efficient enough.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 589–598, Osaka, Japan, December 11-17 2016.

Example 2.2. :

"The SEC will probably vote"
"vote on early next year"
"on the proposal"
"will , he said ."

Example 2.3. :

(VBDC (MDC (DT The) (NNP SEC)
(MD will) (RB probably)
(VBC (VB vote)
(INC (IN on) (DT the) (NN proposal))
(RB early) (JJ next) (NN year)))
(, ,) (PRP he) (VBD said) (. .))

Figure 1: Example 2.2 demonstrates 'carved sequences'. Example 2.3 demonstrates the coarse constituent parsing.

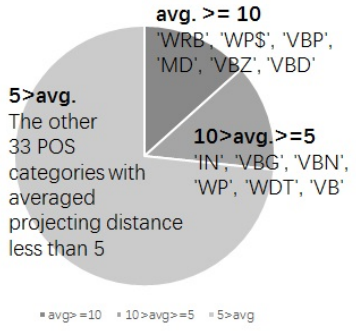

Figure 2: The averaged length of projections headed by each POS category, as computed from Penn WSJ treebank.

We experiment with two alternative approaches for scoring subtrees. A feature-based perceptron classifier, and Dependency-based Convolutional Neural Networks (DCNN) (Ma et al., 2015). Previous use of continuous representation in parsing mainly models parsing actions, phrases, words, or features. When dependency chains are modeled, they were only used for reranking of k-best lists of whole dependency trees, e.g. (Le and Zuidema, 2014; Zhu et al., 2015). Since transition-based parsers are known to act worse on long-distance dependencies, they benefit from this pipeline the most. With no algorithmic change to transition-based or first-order models, an increase of 1.28/1.21 (UAS) can be achieved solely due to the proposed factorization of input, thus achieving comparable performance with high-order models but faster. For Chinese, the most notable increase is as high as 3.63 (UAS), when the proposed framework is applied to first-order parsing models.

2 System Design

2.1 Motivation

Consider a sentence as follows:

Example 2.1. *The SEC will probably vote on the proposal early next year , he said .*

Suppose, magically, we could determine oracle 'carved' sequences of this input, such that all words in a sequence are dependent of some word in the same sequence, except for one head word, e.g. Example 2.2 in Figure 1. Further dependency parsing over these short sequences could be much easier than parsing the original input. This kind of localization is implicitly realized during a dynamic programming parsing process, assuming the optimal substructure property. We propose to explicitly capture this kind of localization by decomposing input space, especially motivated by the following two observations:

- There is a notable distinction in word categories with respect to their averaged projection scope.
- The input to a first-stage constituent-based parsing for long projections can be pruned to contain relevant peripheral and head words only (otherwise, the pipeline is of no practical interest at all.)

First of all, we acquire the distinction in word categories and define long-distance projecting POS categories according to statistics of the training corpus. Based on this statistically verifiable distinction we propose the following parsing pipeline:

(1) Constituent-based parsing for phrases headed by long-distance projecting word categories.
(2) Dependency parsing over carved sequences of input, which are transformed from the coarse constituent parsing outputs of the first stage.
(3) When k-best constituent-based parsing is employed at the first stage, search for an optimal subset of subtrees to combine into a whole dependency tree over the original input.

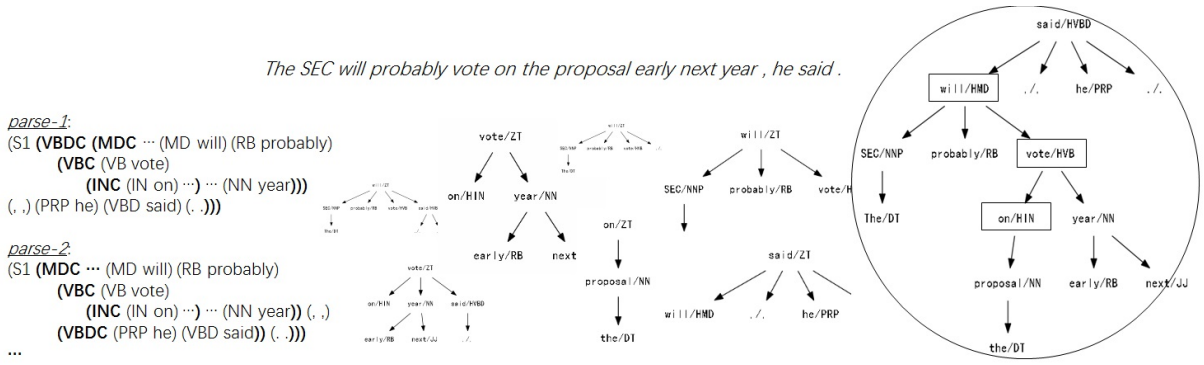

Figure a. First stage: K-best outputs of the coarse constituent-based parsing.

Figure b. Second stage: parse carved sequences into dependency trees. Those vague treelets at background demonstrate redundant subtrees that are not selected to the optimal subset for combination

Figure c. Third stage: combine subtrees by substitution.

Figure 3: A parsing framework of three stages.

Given previous work on parsing, e.g. (Charniak and Johnson, 2005),(McDonald et al., 2005),(Martins et al., 2013) and so on, reliable constituent-based parsers and dependency parsers are available. In other words, other than selecting the set of POS tags that are considered as long-distance projecting categories, there are few implementation details for the first and second stages. Our main implementation challenge seems lies in the third stage. However, since the search space at this stage is highly constrained by the input of the previous stages, we propose to straightforwardly model this search as an ILP problem, which can be efficiently solved by a general ILP decoder, e.g. cplex.

2.2 The first constituent parsing stage

In a projective dependency tree, we consider the projection of a head as the range of input covering all of its descendants. As shown in Figure 2, the POS categories that project longer distance in average is in accordance with our 'linguistic instinct'. Nominal categories, adverbs, adjectives and most closed-class categories, except for subordinating conjunction words and *wh-* holders, tend to project over local words only. And for other categories, we do not stipulate, but leave it as a variant in our experiments.

Given a projective tree, projections of heads can be expressed in brackets, e.g. Example 2.3 in Figure 1. At this stage, we are only interested in projections that are headed by words that fall in long-distance projecting POS categories. Given such a head word of tag 'X', for the sake of expressive convenience, we tag the corresponding bracket covering all its descendants as 'XC'. This simple rule could transform a dependency treebank to brackets of long-distance projections with no ambiguities. Any constituent-based parser that doesn't impose fixed head rules, can be trained over this type of structures, instead of a conventional Treebank. However, if this stage is as slow as a full constituent parsing process, the whole pipeline is of no practical use. As will be shown in Section 5.3, with pruned input and coarse grammar, the constituent parsing stage is no longer a painful bottleneck for parsing speed.

2.3 The second dependency parsing stage

For a bracket, e.g. *(VBC (VB vote) (INC (IN on) (DT the) (NN proposal))(RB early) (JJ next) (NN year))* in Example 2.3 of Figure 1 , we carve all its embedded brackets out, but leaving head words to hold the space. This transformation gives 'carved' sequences such as *"vote on early next year"*. As long as long-distance dependencies do not cross, this simple rule can transform long-distance constituent parsing outputs to 'carved' sequences of the original input without ambiguities. For each oracle sequence, all of its words are guaranteed to be dependant of some word in the same range except for one head word. For example, in Figure 1 brackets in Example 2.3 are transformed to sequences in Example 2.2 by this rule.

Dependency parsing over these carved sequences is much easier, in the sense that both performance and efficiency are dramatically improved. If the first-stage constituent parsing offers reliable 1-best output, we can combine subtrees over these sequences by substituting each word, r, with the subtree rooted at r, if any. For example, in Figure 3-c, a squared node indicates that a subtree is substituted here. We borrow the term 'substitution' from TAG formalism (Joshi and Schabes, 1997). However, when k-

best constituent parsing outputs are kept for reducing error propagation, further search strategy for an optimal subset of these redundant subtrees will be discussed in Section 3.

3 Combination of subtrees

At the first k-best constituent parsing stage, we generate "carved" sequences to be parsed at the second dependency parsing stage. At the third stage, dependency parsing is reduced to the search of an optimal subset to form a legal tree over the original whole input. In this section, we show how to formulate this search as an Integer linear Programming problem, and alternative approaches for scoring subtrees.

3.1 Formulated as an ILP problem

Given a set of subtrees, searching for its optimal subset over the original input can be straightforwardly formulated as an Integer Linear Programming (ILP) problem, which is similar to a set cover problem. The only practical concern is whether it can be solved efficiently by a general ILP decoder. As will be shown with experiments in Section 5.3, the search space of this stage is well-constrained by outputs from the previous stages, therefore this succinct idea nicely works out in the proposed pipeline.

Because subtree outputs from the second stage already satisfy tree requirements, we only need to impose the globally single-root and single-headed constraints on a compatible subset, but not to worry about the non-cyclic requirement. We introduce a designated root \$ for the final dependency tree. For each candidate subtree, add a dummy subtree that includes only a single arc from the designated root \$ to the subtree's root node. Suppose there are n words in the original input sentence, $N = 1...n$, not including the designated root node. Let $\mathbf{T}$ be a set of subtrees, $\mathbf{T} = t_1...t_s$. Our goal is to find an optimal solution $\mathbf{x} = x_1...x_s$ that maximizes $\sum_{i=1}^{s} score(t_i) \cdot x_i$, and subjects to

$$(1) \sum_{i:n \in t_i \text{as non-root node}} x_i = 1,\ \forall n \in N; \qquad (2)\ x_i \in \{0,1\}, 1 \leq i \leq s$$

The boolean value of x_i, as guaranteed by constraint (2), indicates whether t_i is selected in the combination solution or not. Constraint (1) requires every node has one and only one head, and the introduction of the dummy root trees guarantees single-root.

3.2 Scoring of subtrees

A dependency tree y is commonly factored into smaller *parts*, which can be scored in isolation. At the third stage of our parsing pipeline, an overall dependency tree is computed by the combination of a compatible set of subtrees, thus tree score sums over subtree scores. In this sense, our parsing model is *subtree-factored*. We consider two alternatives for scoring subtrees:

(1) further factor subtrees into smaller parts; or

(2) Dependency-based Convolutional Neural Networks to model dependency chains in trees.

3.3 Factor subtrees to smaller parts

A 'first-order' parser decomposes dependency trees into arcs; and for second-order and third-order factorizations, parts of consecutive siblings, grandchild, grand-sibling and tri-sibling, have been widely studied in literature, e.g. (Eisner, 2000; McDonald and Pereira, 2006; Koo and Collins, 2010). Since our parsing model is subtree-factored, there is no limitation on high-order features for us to consider. However, in practice, we follow the second-order and third-order notations.

3.4 DCNN for scoring subtrees

Dependency-based Convolutional Neural Networks were originally proposed for sentence embedding (Ma et al., 2015) and evaluated for sentiment analysis and question classification tasks. We adopt this model for scoring subtrees since it captures dependency chains in trees including ancestor paths and siblings. Given parsed subtrees from the second stage, an oracle combination computes subtree scores as the number of gold arcs it contains. For any input sentence, if a subtree is selected into the oracle

combination, it is considered as a 'legal' subtree otherwise 'illegal'. A subtree classifier, e.g. DCNN, is trained to tell legal subtrees apart from illegal subtrees. This is not a structured learning schema as we are familiar with for parsing tasks, since DCNN is not designed to capture specific structural factorization of dependency trees, such as arcs or RCNN units as defined in (Zhu et al., 2015).

4 Related work

Klein and Manning (2003) proposed to factor parsing model into a phrase-structure tree and a dependency tree, even before dependency parsing was well-studied later in literature. The idea of combining the merits of constituents and dependency parsing is not new, but our proposed factorization is novel.

Since k-best constituent parsing outputs are used, this work resembles the re-ranking works. However, we do not perform k-best list re-ranking, e.g. (Charniak and Johnson, 2005; Hall, 2007; Qian and Liu, 2015). Neither forest reranking (cube pruning), e.g. (Huang, 2008; Zhang and McDonald, 2012; Hayashi et al., 2011). Our search space is factored into pieces of subtrees, thus represents more combinatory candidates than a k-best list of whole dependency trees. This decomposition distinguishes our work from (Le and Zuidema, 2014) and (Zhu et al., 2015) which use NN-based models to re-rank whole dependency trees. These models could also be evaluated in our parsing pipeline. Furthermore, our work concerns very different aspects with (Ren et al., 2013), which uses dependency model for forest reranking of constituent-based parsing. Our dependency parsing process deals with local dependencies only, a complementary task to the constituent parsing process. The third combination stage performs a global search, neither as a simple reranking. It is more accurate to describe our pipeline as imposing constituent-based structural constraints to dependency parsing. Even though imposing constraints practically performs similarly as pruning, it provokes interesting work, e.g. recent work on approximate Linear Programming decoders for parsing, (Koo et al., 2010; Martins et al., 2011). In this work, we also formulate the search of optimal combination of subtrees as an ILP problem, and due to our efforts on constraining the search space in previous stages, it can be efficiently solved by exact decoding.

Furthermore, works on Vine parsing, e.g. (Dreyer et al., 2006; Rush and Petrov, 2012), especially relate to ours. This line of work pays special attention to lengths of arcs and consider it as an import factor to constrain the search. Instead of pruning arcs by distance like Vine parsing, we decompose parsing of long-distance projections and localized dependencies, which is characterized by pattern in word categories but not absolute distance. There is also a more recent related work, (Fernandez-Gonzalez et al., 2016), that also pays attention to length of arcs. In their work, they use simple criteria based on the length and position of dependency arcs to determine how to combine the outputs of an left-to right transition-based parser and its "mirrored" version.

5 Experiments

Our main experiments are performed on dependency trees extracted from English WSJ Treebank (Marcus et al., 1993). We use Yamada and Matsumoto (2003)'s head rules to convert phrase structures to dependency structures, considering the productivity assumption. Following the conventional split, we use sections 02-21 for training, section 22 for development and section 23 for testing. Dependency parsing is evaluated by unlabeled attachment score (UAS), which is the percentage of words that correctly identified their heads. Chinese experiments are performed on CTB5 with the conventional splits described in (Zhu et al., 2015).

For both English and Chinese experiments, the BLLIP parser (Charniak and Johnson, 2005) is used for the first-stage constituent parsing. Because the BLLIP parser doesn't require POS tag input, we do not impose gold POS tags or use an automatic POS tagger. We use 10-fold cross-validation training data at the third combination stage, since the subtree classifier needs to cope with noisy input from the previous stages. More specifically, we divide training corpus into 10 folds and train a coarse constituent-based parser for each divide, then combine all parsing outputs from each divide into a whole training corpus containing k-best constituent parsing outputs.

Oracle parsing is performed by the oracle combination of oracle-parsed subtrees transformed from k-best constituent parsing outputs. We have defined oracle combination in Section 3.4. Given a carved

	constituents recall 200-best	dependency UAS gold subtrees	oracle combination
avg.>= 5	**98.34**	**96.21**	**95.24**
avg.>= 10	97.97	92.19	91.75

Table 1: The threshold of averaged length for long-distance projecting POS categories affects constituent parsing and dependency parsing.

avg. >= 5	constituents k-best recall	avg. number of subtrees	oracle parsing
k= 200	98.34%	59.7	99.46
k= 500	98.41%	72.75	99.51
k= 1000	98.43%	80.75	99.52

Table 2: The choice of k in k-best constituent parsing.

sequence of input, each word's oracle head is either its gold head, or the root of this sequence when the word's gold head is not seen in the same sequence. Oracle-parsed subtrees are not used for training, but only for tuning parameters on development sets.

5.1 The first-stage constituent parsing

As discussed in section 2.2, there are two distinct jumps in the distribution over averaged lengths of projections headed by each POS category. We select the set of POS tags that are considered as long-distance projecting by tuning a threshold on the development set. As shown in Table 1, a proper setting of this threshold matters for all parsing stages. For following experiments on English (also Chinese and German), we consider a POS category as long-distance projecting, if the averaged distance of its projections is more than or equal to 5. For English, this setting gives us all verbal categories, *wh*-holders, and prepositions. For Chinese, it gives long-distance projecting categories of 'VA', 'DEC', 'P', 'CS', 'SP', 'VV', 'VE', 'LB', 'BA' and 'VC', whose meanings are referred to (Xia et al., 2000).

The choice of k defines k-best constituent parsing outputs that will be transformed to carved sequences in the following dependency parsing stage. As shown in Table 2, a larger k doesn't introduces sharply more subtrees per sentence, because most brackets in the top k-best constituent parsing outputs are the same. This observation shows a great advantage of our factorization and distinguishes our pipeline from k-best list reranking of whole trees. We can make use of a relatively large k to achieve higher recall, which is set to be 500 in the following experiments on English and Chinese.

5.2 Dependency Parsing Results

baseline parsing models	directly parse whole trees to compare	parsing subtrees in pipeline	oracle combination of parsed subtrees	combination by subtree scores of order-1 ptron	combination by subtree scores of order-2 ptron	combination by subtree scores of DCNN
NNDep	91.59	97.05	96.13	92.52	92.87(**+1.28**)	92.79
Mst-1	91.39	96.93	95.90	92.38	92.60 (+1.21)	92.45
Mst-2	92.13	97.05	96.05	92.51	92.88 (+0.75)	92.57
Turbo-standard	93.11	97.34	96.31	92.85	93.17 (+0.06)	92.88
Turbo-full	93.43	97.35	96.36	92.91	93.24 (-0.19)	92.93
merged	N/A	N/A	97.31	93.25	**93.57**	93.26

Table 3: Performance (UAS) of parsing by the combination of subtrees. The order-1/2 perceptron-based subtree classifier and DCNN are three alternative combination strategies. The highest increase of UAS for each baseline model is given in parentheses. A merge of the subtrees from all baseline models can be used to improve the second dependency parsing stage.

We could pick any dependency model for subtree dependency parsing, especially the following:

- An NN-based transition-based model, NNDep, (Chen and Manning, 2014).
- A first- (second-) order graph-based model, MST-1(2), (McDonald and Pereira, 2006).
- A third-order(and beyond) approximate model, Turbo-standard(full), (Martins et al., 2011).

For scoring subtrees, we experiment with a feature-based perceptron classifier of first/second- order MST features, as well as the DCNN model described in Section 3.4. Given the well-known over-fitting problem for re-ranking models, we adopt the same mixture strategies as both (Le and Zuidema, 2014)

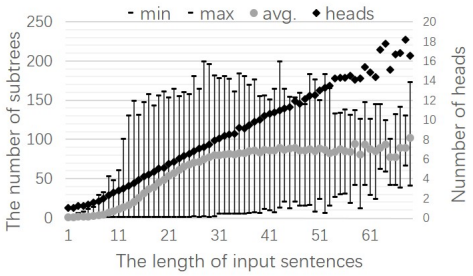

Figure 4: The range (min, max, average) of the number of subtrees (primary y-axis) and the averaged number of long-distance projecting heads (secondary y-axis) with respect to the length of input sentences as computed from 500-best constituent parsing outputs.

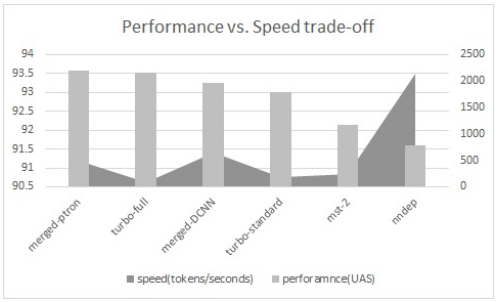

Figure 5: The trade-off between performance (UAS on the promary y-axis) and speed (tokens/seconds on the secondary y-axis).

and (Zhu et al., 2015) with arc scores by a standard Turbo parser. The classifiers are trained with merged dependency parsing outputs, since to do 10-fold cross-validation training for every baseline model is overloading. For a given set of carved sequences transformed from constituent parsing outputs, the merged dependency parsing model covers the subtrees from all baseline models, thus increasing the oracle-combination score by 0.95 even compared to Turbo-full, the best baseline model. More specifically, the feature-based classifiers are trained with online perceptron-based learning (Collins, 2002). DCNN is trained off-line with the same settings as (Ma et al., 2015). And oracle combination as described in Section 3.4 is used to guide training.

As shown in Table 3, with the merged dependency parsing model, our parsing system performs better than Turbo-full, by 0.14 (UAS). However, this is not what we push for in this work. We are more encouraged by the results that, with no algorithmic change to transition-based or first-order models, an increase of 1.28/1.21 (UAS) can be achieved solely due to a factorization of input. It is worth to notice that, on full dependency parsing, Turbo-full performs better than the transition-based and first-order models by nearly 2 (UAS). However, all baseline models achieve the same level of performance for subtree dependency parsing, no bigger difference than 0.5 (UAS). This is enough to show that the proposed factorization works. The use of DCNN doesn't introduce special gain in performance, however, we observe the same advantage as described in (Chen and Manning, 2014), i.e. the NN-based model is nearly 40 times faster than the feature-based discriminative classifier.

5.3 Efficiency

The efficiency of solving the ILP problem at the third combination stage depends on the number of possible subtrees generated at the second stage. As shown in Figure 4, the averaged number of long-distance projecting heads is linearly dependent on the input length, which suggests that the number of subtrees increases at most linearly. Furthermore, since we only keep k-best constituent parsing outputs, the averaged number of subtrees stays below a constant. When k is set as large as 500, the averaged number of subtrees still stays below 100, as shown in Figure 4. Therefore a general ILP decoder, e.g. cplex, is efficient enough. This efficient combination clearly shows the strength of the proposed factorization.

As shown in Table 3, all baseline models achieve comparable performance for subtree dependency parsing. In this sense, we can now make use of the fastest dependency parsing model for subtree parsing, without concerns in performance loss.

It turns out that the k-best constituent parsing stage is the efficiency bottleneck. Therefore, we propose to prune the input to this stage. As a first try, we tag all head words with 'H', any beginning or end words of some bracket with 'B', and other words with 'I'. Then those words of tag 'I' can be pruned for constituent parsing. However, this classification pattern cannot be acquired. This failure is worth special notice, it reminds us that the success of a classification task not only depends on powerful machine learning techniques but also crucially on appropriate representations. We then keep all punctuations, all words before head words and all words before punctuational bracket endings , i.e. tag them with label 'B'. This tagging task can be performed with a precision above 93%, with a perceptron tagger. However,

	grammar size	input avg./max	words per sec.	oracle parsing
full	69630	24/99	681	99.51
pruned	57256	18/76	912	99.50

Table 4: Compare full and pruned input to constituent parsing. Grammar size is the number of unlexicalized rewrite rules.

(UAS)	baseline	subtree	oracle combination	order-2 ptron
MST-1	80.48	96.61	88.54	84.11 (**+3.63**)
Turbo-full	84.74	97.08	89.07	84.35 (-0.39)

Table 5: Results on CTB5, the same terms of Table 3.

high recall of 'B' and 'H' is more crucial for our task, i.e. relevant input are not wrongly pruned. For decoding, we set $b = 20$ for tag 'B' and 'H', and 0 for tag 'I', achieving 98.4% recall of tag 'B' and 'H', still pruning 27.5% of the original input. As shown in Table 4, by feeding pruned input to the coarse constituent parsing, we can process about 25% words more per second at this stage.

In Figure 5, we show that the proposed pipeline provides a better trade-off between parsing performance and parsing efficiency. Merged-ptron achieves comparable performance (93.57 UAS) with Turbo-full (93.24 UAS) but 5 times faster. Even though NNDep (92.87 UAS) is about 6 times faster than merged-ptron, there is a loss of 1.3 (UAS) in performance.

6 Experiments on Chinese

It is well-known that, Chinese parsing performance is much lower than English, for example, with MST-1 and Turbo-full, it is only 80.48 and 84.74 (UAS) respectively for full dependency parsing. Thus it is a surprise for us to see in Table 5 that, for subtree dependency parsing, MST-1 and Turbo-full achieve the same level of parsing performance on Chinese as on English, 96.61 and 97.08 (UAS) respectively. It is the first constituent parsing stage that reveals the difficulty in parsing Chinese. With 500-best c-parsing over full input, the recall is merely 88.63%, and even with the proposed pruned input, the recall is improved by 1% only. However, if we prune the input for constituent parsing with oracle 'H', 'B', 'I' tags, a recall as high as 97% can be achieved. This big gap in results leaves a huge space for future work to explore. The proposed factorization intriguingly discovers the bottleneck in Chinese parsing.

For non-projective parsing, we take the German case as an example. There are about 3 percent of arcs are crossing in the TIGER corpus (Brants et al., 2002). Recall that the projective assumption is only essential to the first constituent parsing stage. If these crossing arcs are local, our pipeline still works. However, 98% of the crossing arcs involve long-distance projecting heads. We can employ techniques such as super-tagging instead of constituent parsing to deal with non-projective long-distance dependencies .

7 Conclusion and Discussion

We propose a novel factorization of parsing task that explicitly utilizes the distinction between long-distance projections and localized dependencies. This intuitive idea works out given that this factorization can be characterized by POS categories of each projection's head word. The first and second stages, which cope with long-distance projections and localized dependencies separately, are fed with complementary input instead of full input, thus taking great advantage of the constrained search space to perform better and faster.

In this work, the proposed factorization is realized in a parsing pipeline of three stages. At the second stage, any dependency parsing model can be used for subtree parsing, so 'baseline' models in our work are not only used for comparison, but to show how much increase in parsing performance can be introduced solely by the proposed factorization, with no change in parsing algorithms or learning strategies to baseline models. On the final stage, dependency parsing is subtree-factored, thus any high-order feature-based model and even continuous representation of dependency chains can be used for subtree scoring. Moreover, dependency parsing over carved sequences of the original input especially suits for parallel computing. Therefore, the proposed factorization provides a better trade-off in parsing speed and performance. In future work, we would like to experiment with end-to-end learning framework for future reducing error propagation.

Abstract

Semantic role labeling (SRL) is the task of identifying and labeling predicate-argument structures in sentences with semantic frame and role labels. A known challenge in SRL is the large number of low-frequency exceptions in training data, which are highly context-specific and difficult to generalize. To overcome this challenge, we propose the use of *instance-based learning* that performs no explicit generalization, but rather extrapolates predictions from the most similar instances in the training data. We present a variant of *k-nearest neighbors* (kNN) classification with composite features to identify nearest neighbors for SRL. We show that high-quality predictions can be derived from a very small number of similar instances. In a comparative evaluation we experimentally demonstrate that our instance-based learning approach significantly outperforms current state-of-the-art systems on both in-domain and out-of-domain data, reaching F_1-scores of 89,28% and 79.91% respectively.

1 Introduction

Semantic role labeling (SRL) is the task of annotating predicate-argument structures in sentences with shallow semantic information. One prominent labeling scheme for the English language is the Proposition Bank (Palmer et al., 2005), which annotates predicates with *frame* labels and arguments with *role* labels (see Figure 1 for examples). Frame labels disambiguate the predicate meaning in the context of the sentence. Role labels roughly correspond to simple questions (*who, when, how, why, with whom*) with regards to the disambiguated predicate. SRL has been found useful for a wide range of applications such as information extraction (Fader et al., 2011), question answering (Shen and Lapata, 2007; Maqsud et al., 2014) and machine translation (Lo et al., 2013).

Current state-of-the-art SRL approaches train classifiers with bags of features (Johansson and Nugues, 2008; Björkelund et al., 2009; Choi and Palmer, 2011) to predict semantic labels for each constituent in a sentence. These approaches typically employ classifiers such as logistic regression or SVM that learn for each feature a measure of impact on the classification decision and abstract away from local contexts in specific training examples.

Local bias. We argue that such approaches are not ideal for SRL due to a strong local bias of features within specific contexts. Low-frequency examples in SRL are often not noise to be abstracted away, but rather correspond to exceptions that require explicit handling.

For example, consider the task of argument labeling: Arguments that are syntactically realized as passive subjects are typically labeled **A1**[1]. However, there exist numerous low-frequency exceptions to this rule. For instance, passive subjects of certain frames (such as the frame TELL.01) are most commonly labeled **A2**. See Figure 1 for an example. Other examples of local bias include different types of diathesis alternation which affect specific frames and argument types (Kipper et al., 2008), the syntactic realization of higher order roles (A2 to A5) which is highly irregular among frames (Palmer et al., 2005), and the realization of roles in non-agentive frames. These phenomena are observed only in specific and often low-frequency contexts of composite features, but are highly relevant to SRL.

[1]This corresponds to the linguistic intuition that active subjects are commonly thematic *agents*, while direct objects and passive subjects are most commonly the thematic *patient* or *theme* of a frame (van der Plas et al., 2014)

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 599–608, Osaka, Japan, December 11-17 2016.

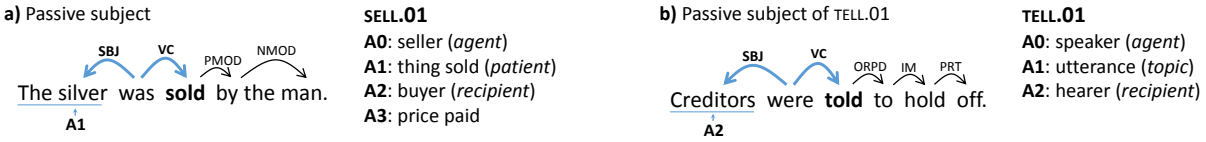

Figure 1: Example sentences with a passive subject (underlined). Passive subjects are typically labeled **A1** (e.g. Sentence a), but there are exceptions to this rule (e.g. frame TELL.01 in Sentence b).

	STATEMENT	COMPOSITE	SUPPORT
(1)	57% of all subjects are labeled **A0**	**P**	17,788 instances
(2)	33% of all subjects are labeled **A1**	**P**	17,788 instances
(3)	74% of *active* subjects are labeled **A0**	**P+V**	13,737 instances
(4)	86% of *passive* subjects are labeled **A1**	**P+V**	4,051 instances
(5)	100% of passive subjects of SELL.01 are labeled **A1**	**P+V+F**	137 instances
(6)	88% of passive subjects of TELL.01 are labeled **A2**	**P+V+F**	53 instances

Table 1: Observations based on CoNLL09 training data: The more atomic features we include in a composite, the more discriminative (and descriptive) it becomes, but generally with lower support.

Feature contexts. We propose to explicitly capture local bias with feature contexts by constructing composites of standard SRL features. Refer to Table 1 for a list of observations over the CoNLL09 shared task gold data (Hajič et al., 2009) for different numbers of features combined into composites: Statements 1 and 2 involve only the syntactic path feature P that models the syntactic function of an argument. Statements 3 and 4 use a composite feature of P and V, the predicate voice feature (either *active* or *passive*). Finally, statements 5 and 6 use a composite feature of P, V and F, the specific frame context.

We make three observations in Table 1: First, the more atomic features we include in a composite feature, the more discriminative it becomes and the more explicitly it captures local bias. For instance, statement 6 is a composite of three atomic features and explicitly captures the exception for passive subjects of TELL.01 discussed earlier. Second, higher order composite features tend to have lower support (i.e. number of training examples that share this combination of atomic features). The use of composite features can therefore aggravate sparsity issues in training data. Finally, since composite features make the interplay of features explicit, they can be rendered as human readable statements. Classification decisions using such features can be easily interpretable for error analysis and extension.

Instance-based Learning for SRL Based on these observations, we propose to use *instance-based learning* (Aha et al., 1991; Daelemans and Van den Bosch, 2005) for SRL. Such learning does not abstract away from specific feature contexts, but rather considers the overall similarity of a test instance to instances in the training data. It has been shown to be applicable to a range of NLP tasks such as PoS tagging (Daelemans et al., 1999), dependency parsing (Nivre et al., 2004) and word sense disambiguation (Veenstra et al., 2000). The arguably most well-known approach of this kind is *k-nearest neighbors* classification (kNN) in which the class label is determined as the majority label of the k most similar training examples (Cover and Hart, 1967).

We propose to identify nearest neighbors using composite features, i.e. instances that share the most similar combination of atomic features. We use a function to assign to each composite of atomic features a discrete distance value, effectively rendering the search for nearest neighbors as a search within a *Parzen* window (Parzen, 1962). The variable k represents the minimum support within this window that we require.

Figure 2 illustrates our proposed approach: To classify the underlined argument in the sample sentence, we search for nearest neighbors using composite features. A distance 1 composite feature consists of P+V+F and AL, the lemma of the argument head. Nearest neighbors at this distance are therefore all training instances in which "creditor" is a passive subject of TELL.01. As the diagram on the right hand side in Figure 2 shows, this finds only one match, labeled **A2**, which is below the minimum support k that we require. We therefore increase the window to distance 2, which relaxes the argument head lemma

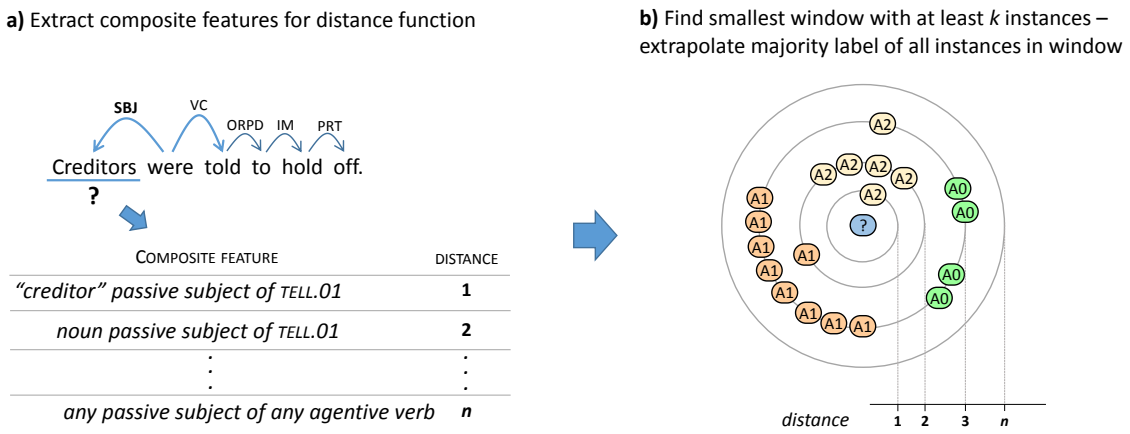

Figure 2: Example of argument labeling with nearest neighbor classification and a composite feature distance function.

restriction on composites features. Nearest neighbors at this distance are all passive subjects of TELL.01 in the training data. As the diagram shows, there are six nearest neighbors within a distance 2 window. From this neighborhood, we extrapolate the label **A2** as prediction.

Contributions We propose a simple and highly effective instance-based learning model for semantic role labeling[2]. We develop a *nearest k-window* variant of kNN in which we use a composite feature distance function to explicitly capture local contexts in sparse data. We give a full description of our SRL system, dubbed K-SRL, motivate and illustrate the atomic and composite features we use, and describe an easy-first algorithm for modeling global argument labeling constraints (Section 2). We present a detailed experimental evaluation that shows that our proposed approach significantly outperforms existing state-of-the-art systems (Section 3).

2 Instance-based Learning for SRL

We use instance-based learning for SRL as a sequence of two classification tasks: First, joint predicate identification and classification (referred to as *predicate labeling*), followed by joint argument identification and classification (referred to as *argument labeling*). See Figure 3 for an illustration. In this section, we describe the proposed nearest *k*-window classifier (Section 2.1) and discuss the specific features used (Sections 2.3 and 2.2), before presenting how we include global constraints into argument labeling (Section 2.4).

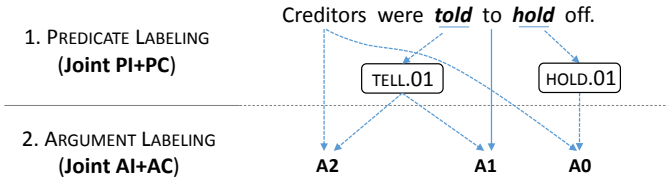

Figure 3: K-SRL system outline.

2.1 Nearest *k*-Window Classification

Algorithm 1 outlines our nearest *k*-window classification algorithm. It takes as input unlabeled instances and performs feature extraction. A distance function assigns each feature an integer distance value, with 1 as the closest distance. The search for nearest neighbors begins with a window of distance 1. The algorithm retrieves for each unlabeled sample all training examples whose distance from the current sample lie within this window. If the window contains fewer than *k* training instances, we increase the window size until it passes a threshold. Among the instances in the window, the algorithm determines

[2]In this work, we focus on verbal predicates since they are comprehensively and consistently labeled in available PropBank releases. We aim to revisit SRL for other types of predicates once current efforts to consistently annotate noun predicates, light verb constructions and adjectives (Bonial et al., 2014) are completed.

the relative frequencies of each label. For instance, if the window contains 10 similar instances of which 9 are labeled **A0** and one is labeled **A1**, the relative frequencies of **A0** and **A1** are 90% and 10% respectively. We interpret this relative frequency as a measure of *confidence*. The label with the highest relative frequency is returned as the most confident prediction. A label is returned only if its associated confidence is higher than a threshold (denoted by θ). If either insufficient examples in the nearest neighborhood are found, or the associated confidence is below the threshold, we return a fallback label. For the subtask of predicate labeling, the fallback label is the most common sense of a verb. For argument labeling, the fallback is to not label the word as an argument.

Algorithm 1 Nearest k-Window Classification

```
ws ← 1
if ws ≤ maximal distance then
  for each x ∈ Unknown Sample do
    Add to I all y ∈ Training Set, where distance(x, y) ≤ ws
    if |I| ≥ k then
      Determine majority class label I
      if the relative frequency of the label for x ≥ θ then
        Return I, the label and its relative frequency for x
      end if
    else
      ws = ws + 1
    end if
  end for
end if
```

2.2 Features for Instance-based Predicate Labeling

Atomic Features The Proposition Bank distinguishes different frame options for a verb based on syntactic subcategorization and coarse-grained polysemy (Palmer et al., 2005). For instance, the verb *return* may evoke the frames RETURN.01 (*return to a place*, as in *John returned to Boulder*) and RETURN.02 (*return an item to someone*, as in *John returned the stapler to Mary*). The key difference of the two in subcategorization is that RETURN.02 may take a syntactic object while RETURN.01 may not. Besides objects, other differentiators in subcategorization involve particles, complements and prepositional objects mediated by different prepositions.

We use each component of a subcategorization frame as one feature: The subject lemma S, the verb lemma VB, the verb particle VP, the object lemma O and the prepositional object PP . Each of these features may also be empty if unobserved. In addition to such lexical features, we define a set of binary features that indicate whether a subcategorization frame component is observed or not: S? for subjects, O? for objects and PP? for prepositional objects. Finally, we use the verb voice V since some frames are more commonly observed in passive voice.

Composite Feature The set of atomic features described above constructs one single composite feature, denoted as F_x for a given instance x. The distance between x_{test} (test instance) and x_{train} (training instance) corresponds to the total number of non-empty features that the two instances do not share, defined as $d(x, y) = |F_{x_{test}} \cup F_{x_{train}}| - |F_{x_{test}} \cap F_{x_{train}}|$. This distance function in essence corresponds to Jaccard distance, without normalizing to a value between 0 and 1.

2.3 Features for Instance-based Argument Labeling

Atomic Features Table 2 includes a list of atomic features. Besides four well-established features from previous work (i.e. the predicate frame F, the predicate voice V, the argument head lemma AL and the argument head PoS tag AP), we define the following two novel atomic features:
(1) *Syntactic-Semantic Path* P: A variant of the syntactic path that, instead of traversing only the syntactic tree, traverses semantic arcs from preceding classifications whenever possible. It is designed for the

FEATURE	SHORTHAND
Predicate frame	F
Predicate frame class	FC
Predicate voice	V
Syntactic-semantic path	P
Argument head lemma	AL
Argument head pos	AP

Table 2: Argument labeling features, with novel features in bold.

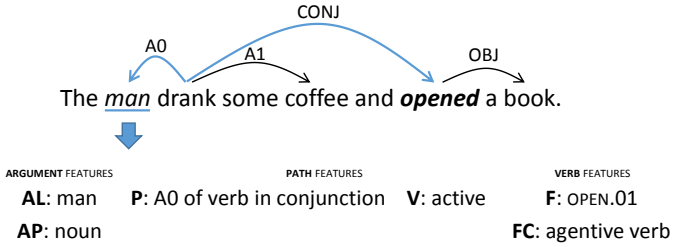

Figure 4: Features extracted for the underlined word (*man*) with regards to the predicate OPEN.01.

COMPOSITE	DISTANCE	EXAMPLE
AL+V+P+F	1	"man" ∧ A0 of verb in conjunction ∧ active ∧ OPEN.01
AP+V+P+F	2	any noun ∧ A0 of verb in conjunction ∧ active ∧ OPEN.01
V+P+F	3	any word ∧ A0 of verb in conjunction ∧ active ∧ OPEN.01
AL+V+P+FC	4	"man" ∧ A0 of verb in conjunction ∧ active ∧ agentive verb
AL+V+P+FC	5	any noun ∧ A0 of verb in conjunction ∧ active ∧ agentive verb
V+P+FC	6	any word ∧ A0 of verb in conjunction ∧ active ∧ agentive verb

Table 3: Distance value assigned to each composite feature, with an example for features extracted in Figure 4.

phenomenon of *raised* arguments, defined as syntactic constituents of a preceding verb. For instance, in Figure 4, *man* is a constituent of the verb *drank* as well as a raised argument for the verb *open*. In this example, we build the path from *man* to *open* by first traversing the semantic arc (A0) from *man* to *drank* and then the syntactic arc (CONJ) from *drank* to *open*. The resulting syntactic-semantic path is verbalized as "A0 of verb in conjunction".

(2) *Frame Class* FC: This feature categorizes frames based on whether they may take a thematic *agent* as argument. Some frames, such as FESTER.01 and HOVER.01, cannot and are therefore considered non-agentive. Non-agentive frames define no **A0** and therefore realize semantic roles differently[3].

Composite Features Table 3 lists all composite features along with their associated distances, including features extracted for the sample sentence in Figure 4. As described in Section 1, the relevant context for argument labeling includes: 1) The syntactic-semantic relationship between predicate and argument (P+V), 2) The frame-specific context of this syntactic-semantic relationship (F or FC), and 3) The argument-specific context (AL or AP). We require each of the three components to be represented in each composite feature in order to capture argument contexts. We define a distance function that assigns the closest distance 1 to the most discriminative of these composite features (i.e. AL+P+V+F). The function assigns higher distances to composites with fewer or less specific features (AP is a less specific representation of the argument context than Al).

This approach draws inspiration from *backoff* modeling, a well known method for addressing sparsity in language modeling with n-grams (Katz, 1987): If insufficient training data exists, such models commonly backoff to lower histories (for instance, a 3-gram model may back off to a 2-gram language model). The six distance values assigned to composite features in Table 3 may be interpreted in a similar spirit since our approach broadens the search to nearest neighbors with less specific composite features if insufficient training data exists.

2.4 Easy-First Argument Labeling

While argument labeling decisions are made locally, each core semantic role (labels **A0** through **A5**) may only be assigned once per predicate (Che et al., 2009). To include this global constraint, we use a greedy approach in which already assigned core labels are removed from consideration for the remaining predictions. Our approach follows an easy-first philosophy (Goldberg and Elhadad, 2010) where clas-

[3]For example, while active subjects are most commonly labeled **A0** (agent) of a verb ("the dog ate", "the bird sang"), they are typically the **A1** (theme) of non-agentive frames ("the wound festered").

Algorithm 2 Easy-First Argument Labeling

```
for each predicate p ∈ Unknown Sample do
  A ← ∅
  C ← Candidate arguments of p, their labels and confidence value in sorted order by confidence
  for c ∈ C with the highest confidence value in C do
    Remove c from C
    if Label of c ∉ Set of labels in A then
      Add c to A
    end if
  end for
end for
```

sifications for all predicate arguments are ordered by confidence and highest confidence predictions are made first. Algorithm 2 outlines this approach.

3 Experiments

In this section we evaluate K-SRL, our proposed instance-based labeling approach for SRL. We conduct a comparison study to evaluate its performance against previously published state-of-the-art systems. We also examine how different parameters of K-SRL impact its performance, including the minimum support variable *k*, different components in composite features, and our interpretation of relative label frequencies in the nearest neighborhood as an indication of confidence for assigning labels.

3.1 Experimental Setup

We use the benchmark data sets from the CoNLL-2009 shared task (Hajič et al., 2009) and compare our results against the top two scoring systems of the CoNLL-2009 shared task as well as two recent state-of-the-art systems: 1) CHEN (Zhao et al., 2009), which uses maximum entropy classifiers. 2) CHE (Che et al., 2009), which uses SVM classifiers. 3) MATEPLUS (Roth and Woodsend, 2014a), a state-of-the-art extension of a previous system (Björkelund et al., 2009) that uses logistic regression classifiers and word embeddings. 4) PATHLSTM (Roth and Lapata, 2016), the current state-of-the-art which uses logistic regression classifiers for predicates and neural network models with word embeddings for arguments. Our default settings for K-SRL are $k = 3$ and confidence threshold $\theta = 0$, both determined through experimentation. For both settings, we present parameter sweep experiments.

We compute the precision, recall and F_1 to measure the quality of the systems. In our study, we focus on verbal predicates and their roles, which we evaluate using the scoring metric of the CoNLL-2009 shared task. We recomputed the measures for the previous state-of-art systems using their published results to focus on verbal predicates and their roles[4].

3.2 Evaluation Results

Tables 4 and 5 summarize the results for our comparison study on in-domain and out-of-domain data respectively. As can be seen, K-SRL outperforms all previous approaches by a significant margin on both data sets. In the in-domain setting, K-SRL achieves 89.28% F_1-score, outperforming PATHLSTM, the currently published state-of-the-art approach, by 1.1 percentage points. In the out-domain setting, K-SRL achieves 79.91% F_1-score, outperforming MATEPLUS, the best previous system on out-of-domain data in our evaluation, by over 3 percentage points, and PATHLSTM by an even larger margin.

3.3 Additional Experiments

We conduct a detailed empirical examination to evaluate different aspects of our approach and make the following observations:

[4] As a result, the numbers for previous work reported here are slightly different from the published numbers.

SYSTEM	PRECISION	RECALL	F_1
CHE	87.43	83.92	85.64
CHEN	88.45	84.22	86.28
MATEPLUS	89.59	86.07	87.79
PATHLSTM	90.24	86.24	88.19
K-SRL	**91.21**	**87.42**	**89.28**
K-SRL$_{local}$	90.19	87.15	88.64
K-SRL$_{(-AL)}$	90.33	86.55	88.4
K-SRL$_{(-F)}$	88.74	85.11	86.89
K-SRL$_{(-FC)}$	91.17	87.53	89.31

Table 4: Evaluation results on in-domain data.

SYSTEM	PRECISION	RECALL	F_1
CHE	76.25	71.24	73.66
CHEN	78.1	71.64	74.73
MATEPLUS	79.46	74.21	76.74
PATHLSTM	79.92	73.31	76.47
K-SRL	**82.09**	**77.84**	**79.91**
K-SRL$_{local}$	80.38	77.78	79.06
K-SRL$_{(-AL)}$	81.69	77.28	79.42
K-SRL$_{(-F)}$	80.96	76.88	78.86
K-SRL$_{(-FC)}$	81.69	77.71	79.65

Table 5: Evaluation results on out-of-domain data.

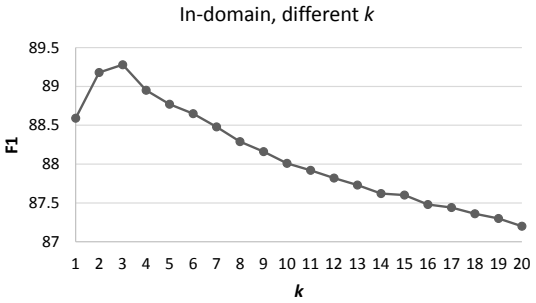

Figure 5: Parameter sweep over k on in-domain data.

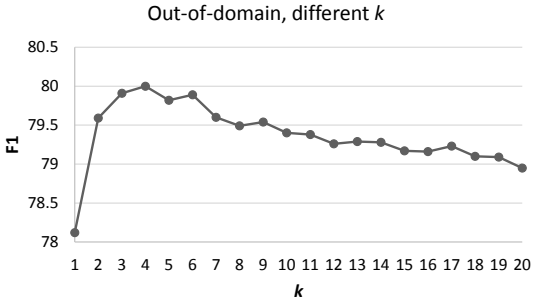

Figure 6: Parameter sweep over k on out-of-domain data.

Highest quality predictions from small neighborhoods. To determine the best setting for *k*, we conduct a parameter sweep experiment. Figures 5 and 6 summarize results of SRL for *k* from 1 to 20 on both in-domain and out-domain data. The results show that the best F_1 scores are achieved at relatively low settings for *k*, with best results obtained with $k = 3$ for in-domain and $k = 4$ for out-of-domain data. At higher *k*, F_1-score drops gradually, indicating that this approach loses its ability to capture local bias. At lower *k*, the approach overfits, decreasing F_1-score especially in the out-of-domain scenario (↓1.8 pp). These observations confirm our initial conjecture that SRL is affected by a strong local bias and that a small nearest neighborhood suffices to make high quality predictions.

Global constraints improve argument labeling. We run an ablation test in which we make only local predictions without modeling global constraints as described in Section 2.4, which reduces the F_1-score by .6 and .8 percentage points respectively on in-domain and out-of-domain data (see K-SRL$_{local}$ in Tables 4 and 5). These results are in line with previous evaluations on the impact of modeling global argument constraints (Toutanova et al., 2008; Roth and Lapata, 2016).

Frame and argument contexts are important. To assess the importance of individual features in their contexts, we run ablation tests in which we remove individual atomic features from composites, as summarized in Tables 4 and 5. Specifically, removing the frame feature F from argument labeling (K-SRL$_{(-F)}$)), which causes all argument labeling predictions to be made without frame-specific contests, leads to the most significant decrease on F_1 scores (↓2.5 pp and ↓1 pp) in our ablation tests. Omitting argument head lemma feature AL (K-SRL$_{(-AL)}$), the only feature capturing argument-level selectional preference (Resnik, 1997) in our approach, results in evident reduction on F_1 scores (↓0.8 pp and ↓0.5 pp). Meanwhile, the removal of frame class feature (K-SRL$-FC$) impacts only the out-of-domain scenario slightly (↓0.3 pp). This observation indicates that small neighborhoods with the frame feature often suffice to capture exceptions for non-agentive verbs.

Relative frequencies measures confidence. We assess our interpretation of relative frequencies in the nearest neighborhood as a measure of confidence by running a parameter sweep over θ. The results are depicted in Figures 7 and 8. As can be seen, precision improves at higher θ, while recall decreases, indicating that the quality of label prediction positively correlates with the associated confidence. We measure the best F_1-scores at $\theta = 0.5$ and $\theta = 0.6$ respectively, but F_1-score remains relatively stable between $\theta = 0.0$ and $\theta = 0.7$, indicating a balanced trade-off within these parameters. These observa-

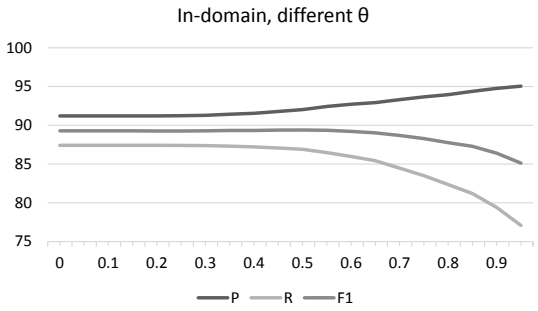

Figure 7: Parameter sweep over θ on in-domain data.

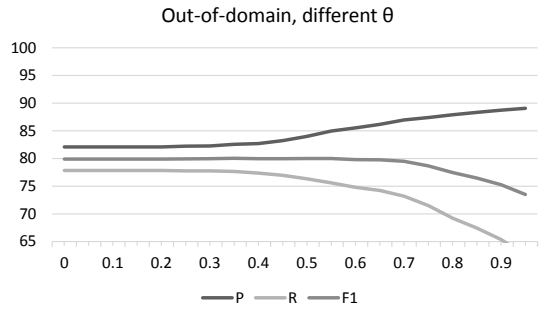

Figure 8: Parameter sweep over θ on out-of-domain data.

tions indicate that relative frequencies can serve as a good measure of confidence and be used to influence the precision-recall trade-off.

3.4 Discussion

Our instance-based learning approach is designed to capture the strong local bias of SRL. We note that even in out-of-domain evaluation scenarios, a very small nearest neighborhood suffices to make high quality predictions. Our experimental results demonstrate the effectiveness of this approach compared to previous state-of-the-arts for both in-domain and out-of-domain scenarios.

The state-of-the-art results are also remarkable in light of the relatively simple feature set we used. While previous work has investigated the use of word clusters (Choi and Palmer, 2011), word embeddings (Roth and Woodsend, 2014b; Roth and Lapata, 2016) and explicit learning of selectional preference (Zapirain et al., 2013) for better generalization across the training data, such features are absent in our current approach. Instead, for predicate labeling we use only the subcategorization frame and for argument labeling a simple set of 6 basic atomic features. This is in stark contrast to previous works that often employ dozens of different features classes (Johansson and Nugues, 2008; Björkelund et al., 2009; Choi and Palmer, 2011).

Interpretability of classification decisions. Our approach has the advantage of interpretability since each classification is determined through a specific composite feature that can be translated into a human readable statement (as illustrated in Table 3). This enables us to easily understand classification results and debug misclassifications, and thus facilitates the process of defining atomic features and composites for SRL. At the same time, we note that explicitly modeling composites does add another layer of complexity in feature engineering to this task. We plan to further investigate this in future work.

4 Conclusion and Outlook

We introduced an instance-based learning approach for semantic role labeling that is designed to address the large number of low-frequency exceptions in training data. We proposed to construct composites based on a few existing well-known features to identify similar instances. Our experimental results indicates that our model built on top of this approach significantly outperform existing systems, leading to new state-of-the-art results in SRL for verbal predicates and their roles.

We intend to focus more specifically on feature engineering for instance-based SRL. In particular, we plan to explore automatic feature selection methods especially in the context of composite features. We also plan to evaluate generalization features such as word clusters or word embeddings in the context of instance-based SRL.

Finally, we plan to extend our system to different types of predicates including nouns and complex predicates (Bonial et al., 2014), as well as evaluate its applicability to SRL in different languages (Xue and Palmer, 2005).

Keystroke dynamics as signal for shallow syntactic parsing

Barbara Plank
University of Groningen
The Netherlands
b.plank@rug.nl

Abstract

Keystroke dynamics have been extensively used in psycholinguistic and writing research to gain insights into cognitive processing. But do keystroke logs contain actual *signal* that can be used to *learn* better natural language processing models?

We postulate that keystroke dynamics contain information about syntactic structure that can inform shallow syntactic parsing. To test this hypothesis, we explore labels derived from keystroke logs as auxiliary task in a multi-task bidirectional Long Short-Term Memory (bi-LSTM). Our results show promising results on two shallow syntactic parsing tasks, chunking and CCG supertagging. Our model is simple, has the advantage that data can come from distinct sources, and produces models that are significantly better than models trained on the text annotations alone.

1 Introduction

As people produce text, they unconsciously produce loads of cognitive side benefit such as keystroke logs, brain activations or gaze patterns. However, natural language processing (NLP) hitherto almost exclusively relied on the written text itself. We argue that cognitive processing data contains potentially useful information beyond the linguistic signal and propose a novel source of information for shallow syntactic parsing, keystroke logs.

Keystroke dynamics concerns a user's typing pattern. When a person types, the latencies between successive keystrokes and their duration reflect the unique typing behavior of a person. Keystroke logs, the recordings of a user's typing dynamics, are studied mostly in cognitive writing and translation process research to gain insights into the cognitive load involved in the writing process. However, until now this source has not yet been explored to inform NLP models.

Very recent work has shown that cognitive processing data carries valuable signal for NLP. For instance, eye tracking data can inform sentence compression (Klerke et al., 2016) and gaze is predictive for part-of-speech (Barrett and Søgaard, 2015; Barrett et al., 2016).

Keystroke logs have the distinct advantage over other cognitive modalities like eye tracking or brain scanning, that they are readily available and can be harvested easily, because they do not rely on any special equipment beyond a keyboard. Moreover, they are non-intrusive, inexpensive, and have the potential to offer continuous adaptation to specific users. Imagine integrating keystroke logging into (online) text processing tools.

We hypothesize that keystroke logs carry syntactic signal. Writing time between words can be seen as proxy of the planning process involved in writing, and thus represent structural information between words. To test our hypothesis, we evaluate a multi-task bidirectional Long-Short Term Memory (bi-LSTM) model that is—to the best of our knowledge—the first to exploit keystroke logs to improve NLP models. We test our model on two shallow syntactic tasks, chunking and CCG supertagging. The choice of tasks is motivated by the fact that writing research analyzes so-called *bursts* of writing (i.e., consecutive spans of text, cf. Section 2.2), which are related to shallow syntactic annotation.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 609–619, Osaka, Japan, December 11-17 2016.

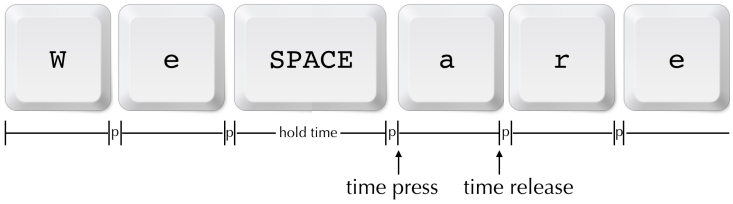

Figure 1: Keystroke logging. p are pauses between keystrokes.

To exploit the keystroke log information we model it as auxiliary task in a multi-task setup (cf. Section 3). This setup has the advantage that the syntactic data and keystroke information can come from *distinct* sources, thus we are not restricted to the requirement of jointly labeled data (a corpus with both annotations). Our exploratory evaluation shows that little keystroke data suffices to improve a syntactic chunker on out-of-domain data, and that keystrokes also aid CCG tagging.

Contributions We are the first to use keystroke logs as signal to improve NLP models. In particular, the contributions of this paper are the following: i) we present a novel bi-LSTM model that exploits keystroke logs as auxiliary task for syntactic sequence prediction tasks; ii) we show that our model works well for two tasks, syntactic chunking and CCG supertagging, and iii) we make the code available at: `https://github.com/bplank/coling2016ks`.

2 Keystroke dynamics

We see keystroke dynamics as providing a complementary view on the data beyond the linguistic signal, which can be harvested easily and is particularly attractive to build robust models for out-of-domain setups. Keystroke logging data can be seen as an instance of *fortuitous data* (Plank, 2016); it is side benefit of behavior that we want to exploit here. However, keystroke log is raw data, thus first needs to be *refined* before it can be used. Our idea is to treat the duration of pauses before words as a simple sequence labeling problem.

We first describe the process of obtaining auto-labeled data from raw keystroke logs, and then provide background and motivation for this choice. Section 3 then describes our model, i.e., by solving the keystroke sequence labeling problem jointly with shallow syntactic parsing tasks (chunking and CCG supertagging) we want to aid shallow parsing.

2.1 From keystroke logs to auxiliary labels

While keystroke dynamics considers a number of timing metrics, such as *holding time* and *time press* and *time release* between every keystroke (p in Figure 1), in this study we are only concerned with the pause preceding a word (i.e., the third p in Figure 1).[1] We here use a simple tokenization scheme. Whitespace delimits tokens, punctuation delimits sentence boundaries.

An example of pre-word pauses (in the remainder simply called *pauses*) calculated from our actual keylog data is shown in Table 1. If we take an arbitrary threshold of 500ms, the chunks indicated by the brackets are derived. This affirms that pre-word pauses carry constituency-like information.

However, typing behavior of users differs, as illustrated in Figure 2. Hence, rather than finding a global metric we rely on per-user calculated aggregate statistics and discretize them to obtain auto-derived labels, as explained next.

We calculate p, the pause duration before a token, and bin it into the following categories, using BIO encoding, where $median$ is the per-user median and mad the median absolute deviation. In this way, we automatically gather labels from keystrokes representing pause durations.

In particular, we use the following discretization, i.e., a label for a token is calculated by:

[1] Figure inspired by the figure in (Goodkind and Rosenberg, 2015).

Token:	[Coefficient	of	determination]	[is	a]	[measure	used	in]	[statisitcal	model]	[analysis]
Pause (ms):	0	96	496	30769	96	2144	96	80	2975	240	680

Table 1: Example keystroke log for user 33 (including typo). If we segment the data using an arbitrary 500ms pre-word pause the chunks indicated by the brackets are obtained. To normalize over idiosyncrasies of users we use per-user average statistics to obtain segments with auto-derived labels, see Section 2.1.

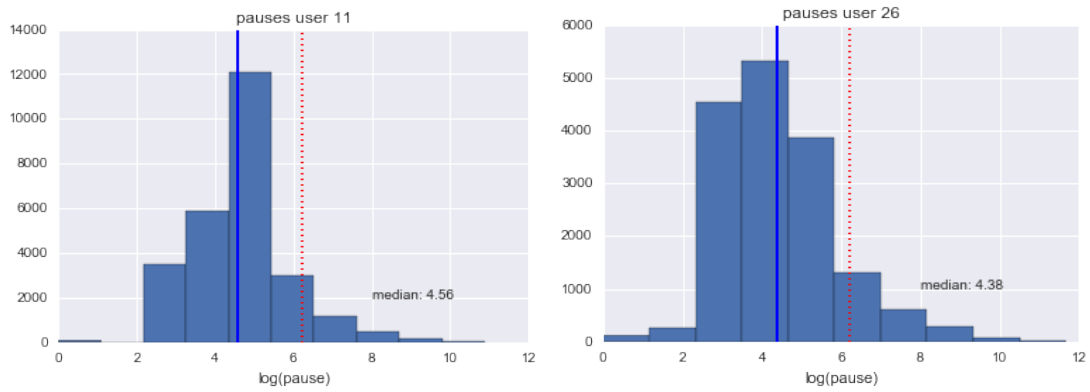

Figure 2: Distribution of pauses for two users (plotted in log space). Red solid line: per-user median pause. Dotted line: arbitrary 500ms threshold. As can be seen from the plots, the users' typing dynamics differs.

$$
\begin{array}{lll}
label = & \texttt{<m} & \text{if } p < median; \\
& \texttt{<m+.5} & \text{if } p < median + 0.5 * mad; \\
& \texttt{<m+1} & \text{if } p < median + mad; \\
& \texttt{>m1} & \text{else;} \\
& \texttt{O} & \text{for punctuation symbols.}
\end{array}
$$

The label is further enriched with a prefix in BIO encoding style, motivated by the fact that we want to model spans of information. Punctuation symbols are treated as `O`, because due to their location at boundary positions the pause information varies highly. We leave treating punctuation separately as future work. Klerke et al. (2016) use a related encoding scheme to discretize fixation durations obtained from eye tracking data, however, in contrast to them we here use median-based measures which are better suited for such highly skewed data (Leys et al., 2013). An actual example of automatically labeled keystroke data is given in Table 2.

B-<m	B-<m+1	B-<m	I-<m	B-<m+.5	I-<m+.5	B->m+1
the	closer	the	number	is	to	1

Table 2: Example auto-derived keystroke annotation.

2.2 Background

The major scientific interest in keystroke dynamics is that it provides a non-intrusive method for studying cognitive processes involved in writing. Keystroke logging has developed to a promising tool in writing research (Sullivan et al., 2006; Nottbusch et al., 2007; Wengelin, 2006; Van Waes et al., 2009; Baaijen et al., 2012), where time measurements—pauses, bursts and revisions (described below)—are studied as traces of the recursive nature of the writing process.

In its raw form, keystroke logs contain information on which key was pressed for how long (key, time press, time release). This data is then used to calculate between keystroke pause durations, such as pre-word pauses. It has been shown that pauses reflect the planning of the unit of text itself (Baaijen

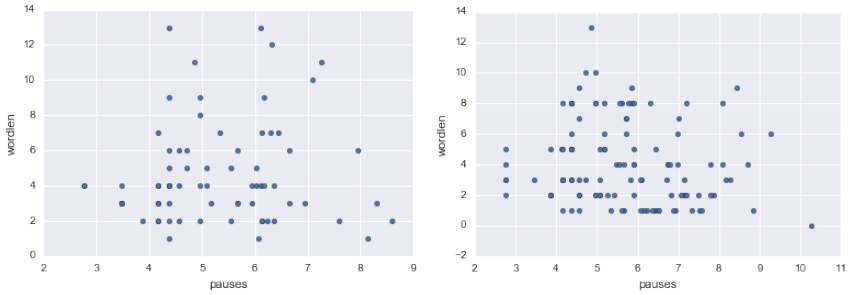

Figure 3: left: Word pauses length vs word length (left: user 7, right: user 3; Pearson $\rho = 0.08$, and $\rho = -0.12$)

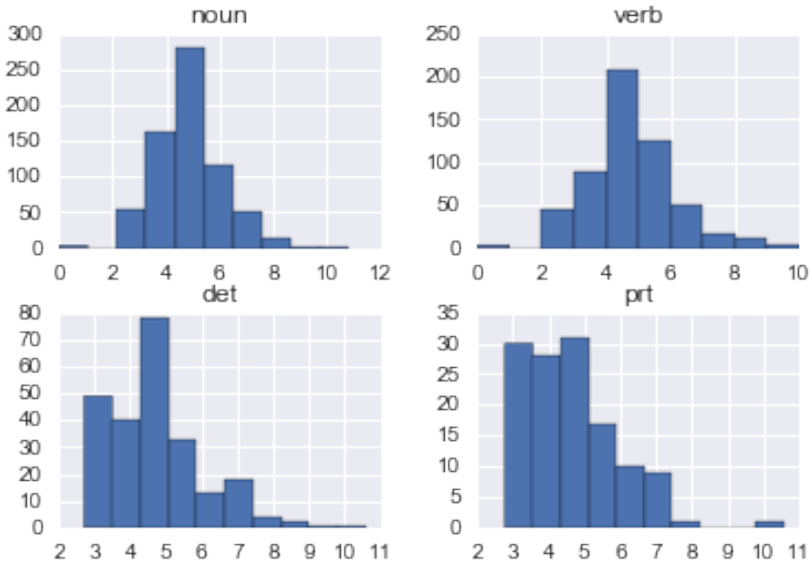

Figure 4: Word pause length distribution per part-of-speech (user 5).

et al., 2012) and that they correlate with clause and sentence boundaries (Spelman Miller and Sullivan, 2006). Writing research is interested in *bursts* of writing, defined as consecutive chunks of text produced and defined by a 2000ms time of inactivity (Wengelin, 2006), or revisions. Such a cutoff is rather arbitrary (Baaijen et al., 2012), and from our own experience results in long chunks. Taking writing research as a starting point, we postulate that keystrokes contain further fine-grained information that help identify syntactic chunks. We aim at a finer-grained representation, and transform user-based average statistics into automatically derived labels (cf. above).

We notice that the literature defines different ways to define a pause. Goodkind and Rosenberg (2015), coming from a stylometry background, use the difference between release time of the previous key and the timepress of the current key to calculate pre-word pause duration.[2] In contrast, writing research (Wengelin, 2006; Van Waes et al., 2009; Baaijen et al., 2012) defines pauses as the start time of a keystroke until the start time of the next keystroke. We experimented with both types of pause definitions, and found the former slightly more robust, hence we use that to calculate pauses throughout this paper.

In order to get a better feel of word pause durations, we examine various properties of them. First, do we need to normalize pauses for word length? Goodkind and Rosenberg (2015) found a linear relationship between pre-word pauses and word length in their dataset. We calculated the correlation between word length and pauses in our dataset, but could not observe such a relation in our data (cf.

[2]Goodkind sets negative pause durations (which can arise in this setup) to 0 (personal communication).

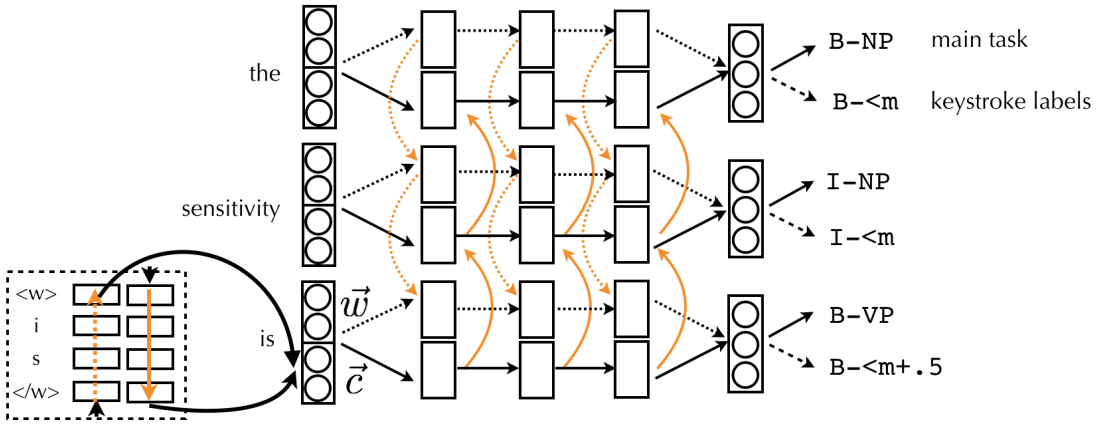

Figure 5: Hierarchical Bi-LSTM with 3 stacked layers using word $\vec{w}$ and characters $\vec{c}$ embeddings.

Figure 3; plots for the other participants looks similar). Even if we break the data down by POS and calculate per-POS wise correlations we found no relation between pause duration and word length.[3] Hence we do not normalize word pause durations. In addition, Figure 4 plots pauses for various part-of-speech, showing that function POS (determiner, particles) are preceded by shorter pauses than content POS (we obtain similar plots for other participants).

Second, keystroke logs are presumably idiosyncratic, can we still use it? In fact, user keystroke biometrics are successfully used for author stylometry and verification in computer security research (Stewart et al., 2011; Monaco et al., 2013; Locklear et al., 2014). However, also eye tracking data like scanpaths (the resulting series of fixations and saccades in eye tracking) are known to be idiosyncratic (Kanan et al., 2015). Nevertheless it has been shown that gaze patterns help to inform NLP (Barrett and Søgaard, 2015; Klerke et al., 2016). We believe this is also the case for biometric keystroke logging data.

3 Tagging with bi-LSTMs

We draw on the recent success of bi-directional recurrent neural network (bi-RNNs) (Graves and Schmidhuber, 2005), in particular Long Short-Term Memory (LSTM) models (Hochreiter and Schmidhuber, 1997). They read the input sequences twice, in both directions. Bi-LSTM have recently successfully been used for a variety of tasks (Collobert et al., 2011; Ling et al., 2015; Wang et al., 2015; Huang et al., 2015; Dyer et al., 2015; Ballesteros et al., 2015; Kiperwasser and Goldberg, 2016; Liu et al., 2015). For further details, see Goldberg (2015) and Cho (2015).

3.1 Bidirectional Long-Short Term Memory Models

Our model is a a hierarchical bi-LSTM as illustrated in Figure 5. It takes as input word embeddings $\vec{w}$ concatenated with character embeddings obtained from the last two states (forward, backward) of running a lower-level bi-LSTM on the characters. Adding character representations as additional information has been shown to be effective for a number of tasks, including parsing and tagging (Ballesteros et al., 2015; Gillick et al., 2015; Plank et al., 2016).

In more detail, our model is a context bi-LSTM taking as input word embeddings $\vec{w}$. Character embeddings $\vec{c}$ are incorporated via a hierarchical bi-LSTM using a sequence bi-LSTM at the lower level (Ballesteros et al., 2015; Plank et al., 2016). The character representation is concatenated with the (learned) word embeddings $\vec{w}$ to form the input to the context bi-LSTM at the upper layers.

For the hidden layers, we use stacked LSTMs with h=3 layers. The 3-layer bi-LSTM and lower-level character bi-LSTM represents the shared structure between tasks. From the topmost (h=3) layer labels for the different tasks (e.g., chunking, pauses) are predicted using a softmax. In Figure 5, the main

[3]POS annotations were obtained by looking up the possible tag of a token in English wiktionary (Li et al., 2012).

task (chunking or CCG tagging) is represented by the solid arrow, the auxiliary task (keystroke logs) is indicated by the dashed arrow.

During training, we randomly sample a task and instance, and backpropagate the loss of the current instance through the shared deep network. In this way, we learn a joint model from distinct sources. Note that we also experimented with predicting the pause durations at lower levels (h=1), motivated by having lower-level tasks at lower layers in the network (Søgaard and Goldberg, 2016), however, we found the setup with both tasks at the outer layer more robust. Predicting all tasks at the outermost layer is the most commonly used form of multi-task learning in neural networks (Caruana, 1998; Collobert et al., 2011).

4 Experiments

We implement our model in `CNN/pycnn`.[4] For all experiments, we use the same hyperparameters, set on a held-out portion of the CoNLL 2000 data, i.e., SGD with cross-entropy loss, no mini-batches, 30 epochs, default learning rate (0.1), 64 dimensions for word embeddings, 100 for character embeddings, random initialization for all embeddings, 100 hidden states, $h = 3$ stacked layers, Gaussian noise with σ=0.2. As training is stochastic, we use a fixed seed throughout (chosen and fixed upfront). No further unlabeled data is considered.

Datasets An overview of the syntactic datasets considered in this paper is given in Table 3. For chunking, we use the original CoNLL data (Tjong Kim Sang and Buchholz, 2000) from WSJ (WSJ sections 15-18 as training data and section 20 as test data, containing 8936 and 2012 sentences, respectively).[5] For testing we take out-of-domain data whenever available, to test the adaptability of the method to noisy out-of-domain data. For chunking we use Twitter data from Ritter (2011) (all, 2364 tweets) and Foster et al. (2011) (250 sentences), converted to chunks (Plank et al., 2014).

The CCG supertagging data also comes from WSJ (39604 training and 2407 test sentences). We unfortunately do not have access to out-of-domain test data, hence use the CCG tagging test set.

sentences	TRAIN	DEV	TEST
CONLL 2000	8936	–	2012
FOSTER	–	269	250
RITTER	–	–	2364
CCG	39604	1913	2407

Table 3: Statistics on the data sets

The keystroke logging data stems from students taking an actual test on spreadsheet modeling in a university course (Stewart et al., 2011; Monaco et al., 2013). The advantage of this dataset is that it contains free-text input.[6] We used data from 38 users,[7] which produced on average 250 sentences. The data totals to 7699 sentences.

To evaluate our models we use standard evaluation measures computed with `conlleval.pl` with default parameters, i.e., we report F1 on chunks and accuracy on CCG tags. Statistical significance is computed using the approximate randomization test (Noreen, 1989) using $i = 1000$ iterations and p-values are reported (Søgaard et al., 2014).

4.1 Results

Baseline model Both or baseline models are comparable to prior work, while being simpler. The results are summarized in Table 4. Our chunking baseline achieves an $F1$ of 93.21 on CoNLL, compared to the $F1$ of 93.88 of Suzuki and Isozaki (2008), who use a CRF and gold POS tags. We do not use any POS information. A similar bi-LSTM achieves 93.64 (Huang et al., 2015), however, additionally uses

[4] `https://github.com/clab/cnn`

[5] `http://www.cnts.ua.ac.be/conll2000/chunking/`

[6] In contrast to `http://www.casmacat.eu/` data that logs revisions from MT post-editing.

[7] Disregarding users due to issues with logging (Stewart et al., 2011).

Chunking	F1	CCG tagging	Accuracy
Our model	93.21	Our model	92.41
Suzuki and Isozaki (2008)	93.88	Xu et al. (2015)	93.00

Table 4: Baseline model, comparison to existing systems

POS embeddings. Our baseline CCG supertagging model achieves 92.41, compared to the more complex model by Xu et al. (2015) achieving an accuracy of 93.00. Very recently even higher accuracies were reported, e.g. (Vaswani et al., 2016), however, in this exploratory paper we are interested in examining whether we find signal in keystroke data, and are not interested in beating the latest state-of-the-art.

	FOSTER.DEV	FOSTER.TEST	RITTER	CCG

p-values	$<$0.01	$<$0.01	$<$0.01	$<$0.048

Table 5: Chunking results (F1, +Pause is average over 38 participants) and CCG accuracy (using all pause data at once). Results marked with † are significantly better than the corresponding baseline using a randomization test with $i = 1000$ iterations; p-values provided in row below.

Keystroke pauses The aim of our experiments is to gauge whether through joint learning of shallow syntax and pause duration the system learns to generalize over the pause information and thus aids the syntactic signal.

The results in Table 5 support our hypothesis that keystroke dynamics contains useful information for chunking. We here report the average over models trained on a per-user basis, i.e., 38 participants. The results show that overall F1 chunking score improves over all datasets. For instance on the Ritter data, for 25/38 participants using their keystroke information as auxiliary task helps to improve overall chunking performance. However, if we combine all data and train a single model, performance degrades on chunking. We attribute this effect to the fact that the chunking data is relatively small, and higher amounts of keystroke data show signs of overfitting. In fact, similar effects have been shown in a multi-task machine translation and parsing setup (Luong et al., 2016), where mixing coefficients were used to downplay the importance of the auxiliary parsing data that otherwise swamped the main task data. We leave examining task-specific weights for the loss for future work.

In contrast in CCG tagging, where we have more training data, we see a positive effect of using keystroke data when training a model that uses all keystroke data at once (concatenation of all keystroke data from all users), see last column in Table 5. Note that all results in Table 5 are significant.

5 Discussion

To gain better insights into what the model has learned, Table 6 provides the per-label breakdown for chunking, Table 7 for CCG tagging. Most of the improvements come from noun phrases (NP) chunks. From manual inspection we determine that the model improves particularly on non-conventional spelling and fragmented noun phrases typical for Twitter, see examples given in Table 8.

As Table 6 shows, keystroke data also helps for verb phrases on one dataset. The current encoding is not so beneficial for PPs. Pauses before prepositions are short, as illustrated in Figure 4, and pauses often fall within segments in the auxiliary annotation, while prepositions constitute separate tokens in chunking. Hence, it is unsurprising that the model fares worse on PPs.

We believe that our pause encoding mainly captures structural information between words, less morphosyntactic information itself, i.e., that pauses are more informative of syntactic structure than of part-of-speech. This intuition is in fact confirmed by initial experiments on POS tagging (UD English), which are less promising. We observe small improvements for low amounts of auxiliary data, however, they are not significant. Thus keystrokes seem to capture mostly structural shallow syntactic information, as confirmed in our experimental evaluation. However, this is only a first exploration, with one way of using keystroke logging data, but given our promising results, further experiments are warranted.

6 Related Work

Keystroke logging has developed into a promising tool for research into writing (Wengelin, 2006; Van Waes et al., 2009; Baaijen et al., 2012), as time measurements can give insights into cognitive processes involved in writing (Nottbusch et al., 2007) or translation studies. In fact, most prior work that uses keystroke logs focuses on experimental research. For example, Hanoulle et al. (2015) study whether a bilingual glossary reduces the working time of professional translators. They consider pause

durations before terms extracted from keystroke logs and find that a bilingual glossary in the translation process of documentaries reduces the translators' workload. Other translation research has combined eye-tracking data with keystroke logs to study the translation process (Carl et al., 2016). An analysis of users' typing behavior was studied by Baba and Suzuki (2012). They collect keystroke logs of online users describing images to measure spelling difficulty. They analyzed corrected and uncorrected spelling mistakes in Japanese and English and found that spelling errors related to phonetic problems remain mostly unnoticed.

Goodkind and Rosenberg (2015) is the only study prior to us that use keystroke loggings in NLP. In particular, they investigate the relationship between pre-word pauses and multi-word expressions and found within MWE pauses vary depending on cognitive task. We take a novel approach and *learn* keystroke patterns and use them to inform shallow syntactic parsing.

A recent related line of work explores eye tracking data to inform sentence compression (Klerke et al., 2016) and induce part-of-speech (Barrett and Søgaard, 2015). Similarly, there are recent studies that predict fMRI activation from reading (Wehbe et al., 2014) or use fMRI data for POS induction (Bingel et al., 2016). The distinct advantage of keystroke dynamics is that it is easy to get, non-expensive and non-intrusive.

7 Conclusions

Keystroke dynamics contain useful information for shallow syntactic parsing. Our model, a bi-LSTM, integrates keystroke data as auxiliary task, and outperforms models trained on the linguistic signal alone. We obtain promising results for two syntactic tasks, chunking and CCG supertagging. This warrants many directions for future research, e.g., using information from the non-linear writing process, which we here disregarded (e.g., revisions), evaluating on other languages and going to the full parsing task.

A Bayesian model for joint word alignment and part-of-speech transfer

Robert Östling
Department of Modern Languages, University of Helsinki
Department of Linguistics, Stockholm University
robert.ostling@helsinki.fi, robert@ling.su.se

Abstract

Current methods for word alignment require considerable amounts of parallel text to deliver accurate results, a requirement which is met only for a small minority of the world's approximately 7,000 languages. We show that by jointly performing word alignment and annotation transfer in a novel Bayesian model, alignment accuracy can be improved for language pairs where annotations are available for only one of the languages—a finding which could facilitate the study and processing of a vast number of low-resource languages. We also present an evaluation where our method is used to perform single-source and multi-source part-of-speech transfer with 22 translations of the same text in four different languages. This allows us to quantify the considerable variation in accuracy depending on the specific source text(s) used, even with different translations into the same language.

1 Introduction

Word alignment is the problem of identifying translationally equivalent words across the languages of a parallel text. It has found widespread use for enabling applications such as statistical machine translation (Brown et al., 1993; Koehn et al., 2003), annotation transfer (Yarowsky et al., 2001), word sense disambiguation (Diab and Resnik, 2002) and lexicon extraction (Wu and Xia, 1994).

Although many types of algorithms have been explored, the main line of research through the last couple of decades has been based on the generative IBM models introduced by Brown et al. (1993). What these models have in common is that they are unsupervised, asymmetric models, assuming one of the languages in a bitext (the *source language*) generates the corresponding text in the other language (the *target language*), word by word.

Most often, a variant of the Expectation-Maximization algorithm (Dempster et al., 1977) has been used for inference in these models, but recently there has been some work using Bayesian alignment models using Gibbs sampling for inference (DeNero et al., 2008; Mermer and Saraçlar, 2011; Gal and Blunsom, 2013). The incorporation of Bayesian priors into these models has been shown to improve accuracy, since they provide a flexible way of biasing the model towards empirical observations about language, most importantly that a given word type tends to have a very limited number of translations.

While the basic word alignment models use only lexical co-occurrence and word order, lexical data tends to be sparse and a number of authors have explored the usefulness of other information sources. Toutanova et al. (2002) showed that Part of Speech (PoS) tags can be integrated into the IBM models to improve word alignment accuracy, and others have reported similar results for dependency (Cherry and Lin, 2003; Wang and Zong, 2013) and phrase-structure (Yamada and Knight, 2001) parse trees, and for lemmatized texts (Bojar and Prokopov, 2006).

In addition to the studies just mentioned that showed how various types of linguistic annotation can be used to guide word alignment, there has been research showing that the reverse also holds: word-aligned parallel texts can be used to transfer annotations and models from languages where those resources exist to languages where they do not. Pioneering work by Yarowsky et al. (2001) explored tasks such as PoS

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 620–629, Osaka, Japan, December 11-17 2016.

tagging, shallow parsing and lemmatization, which was followed by e.g. dependency parsing (Hwa et al., 2005).

The present work combines these previous lines of work by exploring joint models of word alignment and annotation transfer (of PoS tags), within a Bayesian framework. The source code of our implementation is available at `http://www.ling.su.se/spacos`.

2 Methods

This section first discusses Bayesian word alignment using IBM-based models along with extensions to these, and finally describes our model of joint PoS transfer and word alignment.

2.1 Bayesian IBM models

The IBM 1 alignment model can be extended with sparse Dirichlet priors, and efficient inference is possible using Gibbs sampling (Mermer and Saraçlar, 2011; Mermer et al., 2013; Gal and Blunsom, 2013) or Variational Bayesian techniques (Riley and Gildea, 2012).

IBM model 1 assumes each target word $t_j = f$ of a sentence is generated by one source word $s_{a_j} = e$ through the alignment variable a_j, and that all words are generated independently and do not depend on the sentence positions i and j. The probability of a target sentence $\boldsymbol{t}$ (of length J) and an alignment $\boldsymbol{a}$ given a source sentence $\boldsymbol{s}$ (of length I) then becomes

$$P(\boldsymbol{t}, \boldsymbol{a}|\boldsymbol{s}) \propto p(J|I) \prod_{j=1}^{J} P(t_j|s_{a_j}) \tag{1}$$

One drawback of this model (apart from the extreme independence assumptions addressed by later IBM models) is that there is no penalty for having very flat distributions $P(f|e)$ for target words conditioned on a source word, a fact that causes the so-called *garbage collection effect* where rare source words are incorrectly linked to a large number of target words. By using priors on the translation distributions that discourage such solutions, it is possible to improve alignment accuracy. Mermer and Saraçlar (2011) introduced the use of Dirichlet priors for this task. If the Dirichlet parameter α is 1, this reduces to the uniform distribution, but it turns out that by using much smaller values of α, below about 10^{-2} (Riley and Gildea, 2012, Figure 1), the model better reflects the empirical observation that words tend to have very few possible translations.

2.2 Inference

For the standard IBM models, the EM algorithm is normally used for inference. In the Bayesian version with Dirichlet priors, we mentioned above that two main options have been investigated: Variational Bayes and Gibbs sampling. While both methods have been shown to improve word alignment accuracy for IBM model 1, the computational complexity of Gibbs sampling is lower with more complex models (Östling and Tiedemann, 2016, Section 3.2). For this reason, Gibbs sampling is used in the present work and will be discussed in further detail.

Gibbs sampling (Gelfand and Smith, 1991) is a specific instance of the more general Markov Chain Monte Carlo algorithm, which is used to draw samples from a model M which defines a probability function $p_M(\boldsymbol{x})$ over the variable space $\boldsymbol{x}$. This is done by constructing a Markov chain with p_M as its stationary distribution and performing a sufficiently long random walk in it. A Gibbs sampler achieves this by specifying for each variable x_i in $\boldsymbol{x}$ a sampling distribution $P(x_i = a|\boldsymbol{x}_{-i})$ for x_i conditioned on $\boldsymbol{x}_{-i}$, which denotes all variables in $\boldsymbol{x}$ except x_i. For IBM model 1, this gives the following sampling equation, which we also use, and for more complex models extend with additional factors given Equation (4):

$$P(a_j = i) = \frac{n_{\boldsymbol{a}_{-j}, s_i, t_j} + \alpha_{t_j}}{\sum_f (n_{\boldsymbol{a}_{-j}, s_i, f} + \alpha_f)} \tag{2}$$

Here, $n_{\boldsymbol{a}_{-j}, e, f}$ is a count vector representing the number of times each source type e is aligned to each target type f under the alignment $\boldsymbol{a}$, not counting the alignment at position j. In the end, we are interested

in computing the expectations $\mathbb{E}\left[\delta_{a_j,i}\right]$ under the alignment model, where δ is the Kronecker delta. Given a series of samples of $\boldsymbol{a}^{(t)}$ for $t \in 1 \ldots T$, we approximate this using

$$\mathbb{E}\left[\delta_{a_j,i}\right] \approx \frac{1}{T} \sum_{t=1}^{T} P(a_j = i | \boldsymbol{a}_{-j}^{(t)}, \boldsymbol{s}, \boldsymbol{t}) \tag{3}$$

The initial alignments $\boldsymbol{a}^{(0)}$ are sampled from a uniform distribution, and in order to reduce initialization bias we average the marginals from eight independently initialized samplers. For details on the tradeoffs involved in choosing the number of samplers and sampling iterations, we refer to Table 2 of Östling and Tiedemann (2016).

2.3 Word order and fertility

Even with good prior parameters, IBM model 1 is a poor model of word alignment because it ignores two important characteristics of parallel text: word order and morpheme counts. While different distortion models have been used to model word order, we use the HMM-based model of Vogel et al. (1996), which has been demonstrated to deliver better performance than either no distortion model (like IBM model 1) or models based on absolute sentence positions (IBM models 2 and 3). This introduces a distribution $P(a_j - a_{j-1}|I)$ of the "jump" $a_j - a_{j-1}$ in the source sentence when moving one step in the target sentence.

As a way of modeling the relative number of morphemes in a word for a pair of languages, the *fertility* of a source word e is defined as the number of target words it is aligned to in a particular context. This is modeled using a distribution $P(\phi_i = k|s_i = e)$, where the fertility ϕ_i at position i is conditioned on the word e at that position. This is particularly important when the languages have large differences in word formation strategies and the general level of morphological complexity.

Zhao and Gildea (2010) explored a model with a word order and fertility model as described above, but based their work on the EM algorithm, using Gibbs sampling only for approximating the expectations. An important conclusion from their work is that a simple HMM with fertility model is competitive with the more complex IBM model 4, and we follow them in using this model as our baseline. Our full baseline model is given by

$$\begin{aligned} &P\big(\boldsymbol{s}, \boldsymbol{t}, \boldsymbol{a}, \boldsymbol{\theta}, \boldsymbol{\psi}, \boldsymbol{\pi}, \boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\gamma}\big) \\ &\quad \propto \left(\prod_{k=1}^{K} \prod_{j=1}^{J^{(k)}} \theta_{s_{a_j^{(k)}}^{(k)}, t_j^{(k)}} \right) \cdot \left(\prod_{e=1}^{E} \prod_{f=1}^{F} \theta_{e,f}^{\alpha_f - 1} \right) \\ &\quad \cdot \left(\prod_{k=1}^{K} \prod_{j=1}^{J^{(k)}+1} \psi_{a_j^{(k)} - a_{j-1}^{(k)}} \right) \cdot \left(\prod_{I=I_{min}}^{I_{max}} \prod_{m=m_{min}}^{m_{max}} \psi_m^{\beta_{I,m}-1} \right) \\ &\quad \cdot \left(\prod_{k=1}^{K} \prod_{i=1}^{I^{(k)}} \pi_{s_i^{(k)}, \phi_i} \right) \cdot \left(\prod_{e=1}^{E} \prod_{n=0}^{n_{max}} \pi_{e,n}^{\gamma_n - 1} \right) \end{aligned} \tag{4}$$

where K is the number of parallel sentences, $\boldsymbol{\theta} \sim \mathrm{Dir}\big(\boldsymbol{\alpha}\big)$ are the lexical translation parameters, $\boldsymbol{\psi} \sim \mathrm{Dir}\big(\boldsymbol{\beta}\big)$ are the categorical distribution parameters for the word order model $P\big(a_j - a_{j-1} = m|I\big)$, and $\boldsymbol{\pi}_e \sim \mathrm{Dir}\big(\boldsymbol{\gamma}\big)$ for the fertility model $P(\phi_i = k|s_i = e)$.

2.4 PoS-guided word alignment

This work follows Toutanova et al. (2002) in adding another factor to the model, akin to the lexical translation probability $P(f|e)$ but using the PoS tags of the respective words, $P(\boldsymbol{T}_f^t|\boldsymbol{T}_e^s)$. The main difference is that in their work PoS tags for both source and target languages were assumed, whereas here only one of the languages is assumed to be PoS-annotated. For the other language, the PoS tags are sampled using the method described below.

Algorithm 1 Alternating alignment-annotation.

▷ Align a single sentence pair $\boldsymbol{s}, \boldsymbol{t}$. The extension to multiple sentences is straightforward.
function AAA($\boldsymbol{s}, \boldsymbol{t}$)
  ▷ initialize alignments using the baseline HMM + fertility model
  ▷ the forward direction uses alignment vector $\boldsymbol{a}$
  $\boldsymbol{a} \leftarrow$ Baseline($\boldsymbol{s}, \boldsymbol{t}$)
  ▷ the backward direction uses alignment vector $\boldsymbol{b}$
  $\boldsymbol{b} \leftarrow$ Baseline($\boldsymbol{t}, \boldsymbol{s}$)
  while sampling **do**
    $M \leftarrow$ estimate bigram HMM model using $\boldsymbol{a}, \boldsymbol{b}, \boldsymbol{s}, \boldsymbol{t}, \boldsymbol{T}^s$
    ▷ set the target sentence tags $\boldsymbol{T}^t$ using the Viterbi algorithm
    $\boldsymbol{T}^t \leftarrow \arg\max_T P(T|M)$
    ▷ sample alignment variables $\boldsymbol{a}$, $\boldsymbol{b}$
    for all $j \leftarrow 1 \ldots J$ **do**
      $a_j \sim P(a_j = i|\boldsymbol{a}_{-j}, \boldsymbol{s}, \boldsymbol{t}, \boldsymbol{T}^s, \boldsymbol{T}^t)$
    end for
    for all $i \leftarrow 1 \ldots I$ **do**
      $b_i \sim P(b_i = j|\boldsymbol{b}_{-i}, \boldsymbol{s}, \boldsymbol{t}, \boldsymbol{T}^s, \boldsymbol{T}^t)$
    end for
  end while
  ▷ return expected values for PoS tags alignments, as in Equation (3)
  return $\mathbb{E}[\boldsymbol{a}], \mathbb{E}[\boldsymbol{b}], \mathbb{E}[\boldsymbol{T}^t]$
end function

2.5 PoS transfer

We focus on applying PoS transfer as a way of obtaining better word alignment accuracy, rather than improving PoS transfer as such. These are largely complementary goals, as our evaluation in Section 3 shows that small changes in PoS tagging accuracy do not seem to influence alignment accuracy. For this reason, and because of our focus on low-resource languages precludes using data-intensive approaches like that of Das and Petrov (2011), we choose the simple method of Yarowsky and Ngai (2001) as a starting point for the PoS transfer part of our model. The basis of this method is to use heuristics to estimate a robust first-order HMM tagger from (noisy) projected tags, and to re-tag the data using this tagger. Furthermore we extended the tagger using the affix-tree method of Schmid (1994) for rare words, in order to be able to handle morphologically complex languages better.

While it would have been preferable for reasons of theoretical elegance to use a simpler PoS transfer model, matching the alignment model, such attempts by Östling et al. (2015) resulted in very modest improvements for their sign language data set, and their model gave no improvement at all for our data sets.

2.6 Alternating alignment-annotation (AAA)

Algorithm 1 summarizes our method, which can be viewed as a modified Gibbs sampler of the latent alignment variables $\boldsymbol{a}$ and $\boldsymbol{b}$ (in the forward and backward alignment direction) as well as the target-side PoS tags $\boldsymbol{T}^t$. While the PoS transfer part is not stochastic,[1] it operates on samples of the alignment variables $\boldsymbol{a}$ and $\boldsymbol{b}$ and can be seamlessly integrated into the sampler.

3 Evaluation

The empirical evaluation aims at investigating whether the alternating alignment-annotation (AAA) algorithm improves word alignment and/or PoS transfer accuracy, compared to the corresponding PoS-

[1] We also tried sampling $\boldsymbol{T}^t$ using marginal distributions computed by the forward-backward algorithm, but found no effect on the accuracy of the algorithm.

Corpus	Sentences	$\|S\|$	$\|P\|$
English-French	1 130 588	4 038	17 438
Romanian-English	48 641	5 034	5 034
English-Inuktitut	333 185	293	1 972
English-Hindi	3 556	1 409	1 409
English-Swedish	692 662	3 340	4 577

Table 1: Total corpus sizes (in sentences) and number of (S)ure and (P)ossible alignment links in their respective evaluation sets.

unaware Bayesian IBM model with an HMM word order model and fertility.

3.1 Data

In order to assess the general usefulness of the method presented, a number of parallel corpora representing a diverse set of languages and genres are used: the English-French Hansards corpus in the version presented by Mihalcea and Pedersen (2003), the Romanian-English, English-Inuktitut and English-Hindi corpora from Martin et al. (2005), as well as parts of the Swedish-English Europarl corpus (Koehn, 2005) with the evaluation set of Holmqvist and Ahrenberg (2011). In addition, a set of translations of the New Testament will be used to investigate the quality of the transfered PoS tags. Some properties of these corpora are summarized in Table 1.

Silver-standard PoS annotations were provided for English, French and German by the Stanford Tagger (Toutanova et al., 2003) and for Swedish by Stagger (Östling, 2013). The native tagsets were mapped to the Universal PoS Tagset of Petrov et al. (2012).

3.2 Experimental setup

The main intended use case is a fairly short parallel text, with two very different languages of which only one has an accurate PoS tagger available. This excludes the possibility of extensive per-language tuning (unlike some of the previous results cited), and in this evaluation the different language pairs use identical parameters to the largest possible extent.[2] We fixed the hyperparameters in Equation (4) to $\alpha = 10^{-5}$, $\beta = \gamma = 1$.

The experiments use eight individually initialized samplers, each of which used a pipelined approach where initially a lexical-only model equivalent to that of Mermer and Saraçlar (2011) was used, then a word order term using the HMM model was added, then the fertility term, and finally (when applicable) the PoS translation probability. No burn-in period was used during sampling, since the initial value of the last pipeline step is already quite good.

Since the model is asymmetric, the alignments are run in both directions and symmetrized. A soft variant of the intersection heuristic is used, where the final set of links L is defined as $L = \{(i, j) \mid P(a_j = i)P(b_i = j) > t\}$. for a threshold value t, in these evaluations fixed to 0.25. This gives a fairly conservative set of links, favoring precision before recall. Note however that the model does not use NULL words, so this conservatism is not as severe as in models with NULL words.[3] Heuristics based on the union on the contrary tend to over-generate links under these conditions.

3.3 Results

The systems used as baselines in the evaluation are mainly from the Workshop on Parallel Text shared tasks (Mihalcea and Pedersen, 2003; Martin et al., 2005), where most of the data sets used were intro-

[2]The main exception is that some of the language pairs (Romanian-English and English-Hindi), following previous work, use a poor man's stemming trick where only the first four letters of each token is used. The only other exception is that the English-French evaluation did not use the fertility parameter, since it showed no further improvement beyond the plain HMM model.

[3]Later experiments with a related model (Östling and Tiedemann, 2016, compare their Table 2 with our Table 2) show that for some language pairs in particular, using NULL with standard symmetrization heuristics gives considerably worse AER scores.

duced: ISI2 (Fraser and Marcu, 2005), JHU (Schafer and Drábek, 2005), UMIACS2 (Lopez and Resnik, 2005) and XRCE (Dejean et al., 2003). The Swedish-English figures, LIU, are from Holmqvist and Ahrenberg (2011). Finally, we have run GIZA++ (Och and Ney, 2003) on the corpora as an additional baseline.[4] Results from previous work using more data than a bitext plus PoS tags for one of the languages are not included, although some such systems have obtained better results on some of the corpora used, using e.g. semi-supervised discriminative training (Liu et al., 2010).

Table 2 summarizes the main results of the evaluation. In all cases, the alternating alignment-annotation method surpasses the baseline model that does not use PoS tags. The model is generally competitive compared to previous work, in particular for the smaller corpora and where the languages are substantially different. The improvement compared to the non-Bayesian baselines is particularly good for the English-Inuktitut corpus, which could be due to the fact that the morpheme/word ratio of Inuktitut is very high, resulting in very many low-frequency words that tend to function as garbage collectors in non-Bayesian models. The situation is similar for the English-Hindi corpus, although in this case the cause for the many rare words is rather the short bitext than the languages themselves.

It is interesting to compare the corresponding **AAA** and **Supervised** figures in Table 2, where the only difference is that **AAA** uses a supervised PoS tag on one language (English) and annotation transfer to the other, whereas **Supervised** uses supervised PoS tags on both languages. The overall accuracy figures are nearly identical, even though the accuracy of the transfered tags is lower. This indicates that the word alignment algorithm is not very sensitive to PoS tagging accuracy, so that the relatively simple PoS transfer method used is sufficient for the purpose of increasing word alignment accuracy.

There are multiple translations of the New Testament into each of English, French, German and Swedish, which can be exploited for multi-source transfer. In our model, multi-source transfer can be done trivially by averaging the expectations returned by Algorithm 1. Table 3 shows that this overall has a large positive effect on PoS accuracy, with an average error reduction of one fourth compared to the median single-source result, and one tenth compared to the best (out of 22) single-source result. Using many translations in each language allows us to see how widely the accuracy varies, even when using the same source (or target) language. This is due to many factors, including the large time span (hundreds of years) between the different translations. In contrast, the multi-source results are, as could be expected, much more robust. This is an encouraging result, given that the New Testament is perhaps the most widely translated text of significant length, and offers a great possibility to transfer linguistic annotations to languages where little other data is available.

4 Conclusions and future work

We have presented a model for joint word alignment and PoS annotation transfer, and shown empirically that it leads to improved word alignment accuracy, in particular for low-resource languages. Using automatically transfered PoS tags led to improvements that were as big as the improvements seen when using PoS tags from supervised taggers on both sides of a bitext.

In addition, we took the opportunity to perform an evaluation investigating what kind of variation can be expected depending on which translation(s) are used as source texts in PoS annotation transfer, and found that this variation can be great, even among translations into the same language. Using multi-source transfer reduces this variation considerably and typically gives better accuracy than even the best single-source transfer among many.

In this study, only PoS annotations were considered, but there are other types of annotation such as parse trees, named entities and word senses which potentially could be transfered jointly with word alignment. This is left to future work, as are improvements to the baseline alignment model.

Acknowledgments

Thanks to the anonymous reviewers, Mats Wirén, Jörg Tiedemann and Joakim Nivre for advice.

[4] In order to provide a competitive but fair baseline, the same general approach was used with GIZA++ as with the new system presented, using default parameters and no language-specific tuning. The specific alignment pipeline used was $1^3h^53^34^{10}$, and the symmetrization that provides the best alignment on the test set is chosen. This gives GIZA++ some advantage, but ensures that any claimed improvements by our algorithm over GIZA++ are not simply due to symmetrization.

Splitting compounds with ngrams

Abstract

Compound words with unmarked word boundaries are problematic for many tasks in NLP and computational linguistics, including information extraction, machine translation, and syllabification. This paper introduces a simple, proof-of-concept language modeling approach to automatic compound segmentation, demonstrated with Finnish. The approach utilizes an off-the-shelf morphological analyzer to split training words into their constituent morphemes. A language model is subsequently trained on ngrams composed of morphemes, morpheme boundaries, and word boundaries. Finally, linguistic constraints are used to weed out phonotactically ill-formed segmentations, thereby allowing the language model to select the best grammatical segmentation. This approach achieves an accuracy of ∼97%.

1 Introduction

Compound segmentation—the automatic splitting of compounds into their constituent words—is essential to many language processing tasks, including machine translation, information extraction, semantic parsing, spell checking, and syllabification. To that end, we propose a simple, supervised approach to compound segmentation that integrates existing morphological analysis software with language modeling and optional linguistic constraints.

Specifically, the proposed segmenter seeks to identify word boundaries in *closed compounds*, compounds in which word boundaries go undelimited by spaces, hyphens, or other markers (e.g., *bookworm*). These are distinct from *open compounds*, where word boundaries are clearly indicated (e.g., *rain gutter*) and thus less of an issue for applications that require their whereabouts. (Note that all compounds are considered *complex*, while words that are not compounds are considered *simplex*—e.g., *book*, *rain*).

In contrast to previous approaches, which have primarily sought to identify the dictionary forms of compound constituents, this approach aims to identify the exact location of word boundaries in compounds. This sort of identification is highly relevant to the domain of computational phonology.

For instance, the location of word boundaries is crucial for syllabification. Closed compounds pose a problem for automatic syllabification because word boundaries form a proper subset of syllable boundaries; a syllable break will always fall on a word boundary (or, so common phonological theory tells us). Without insight into the location of these boundaries, a rule-based syllabifier might fail to recognize compound-internal word boundaries. For example, if *bookworm* is mistaken for a simplex word, English phonotactics would syllabify it as **boo.kworm*. Instead, we expect the syllabification *book.worm*, where the syllable break falls on the unmarked word boundary between *book* and *worm*.

Hence, we have developed an approach to compound segmentation that specifically identifies word *boundaries* in compounds, versus lemmatized constituents. In Section 2, we describe previous approaches to compound segmentation in the areas of machine translation and information extraction. We then give a broad sketch of our approach in Section 3, introducing morpheme-based language modeling. Finally, in Section 4, we describe and evaluate an implementation of our approach on Finnish data. This

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 630–640, Osaka, Japan, December 11-17 2016.

implementation uses the morphological analyzer Morfessor 2.0 (Virpioja et al., 2013) and a trigram language model with Stupid Backoff smoothing (Brants et al., 2007). We also compare our approach to the popular frequency-based method by Koehn and Knight (2003).

2 Related work

Research in compound segmentation has varied in its motivations. While some has focused on improving information retrieval (e.g., Alfonseca et al., 2008) and spell checking (e.g., Huyssteen and Zaanen, 2004) systems, the majority of this work has been tailored to machine translation (e.g., Brown, 2002; Koehn and Knight, 2003; Macherey et al., 2011).

Motivated by a need for translatable constituents, many of these approaches involve multiple lexica and corpora. For instance, Brown (2002) utilizes parallel corpora and a translation lexicon to establish cognates between source and target languages. This allows decompounding into cognate constituents. Brown also proposes an extension to this approach that does not rely on cognate relationships.

Perhaps best known is Koehn and Knight's (2003) benchmark work on compound segmentation. Though the paper proposes several splitting methods, it is most cited for its frequency-driven approach, which scores candidate segmentations according to the geometric means of their constituents' corpus frequencies:

$$\hat{c} = \arg\max_{c \in C} \left(\prod_{p \in C} \text{count}(p)\right)^{\frac{1}{n}} \quad (1)$$

Above, $\hat{c}$ is the highest-scoring candidate in candidate set C, where each candidate c is composed of n number of constituent parts p. Candidate sets include all splits into known words, according to a training corpus. Splitting options are further confined to constituents of a minimum length three, and can assume hand-specified letters either inserted or dropped between constituent words, mirroring morphological operations at word joints. This monolingual approach is considered state-of-the-art and serves as a comparison in subsequent work (e.g., Alfonseca et al., 2008; Clouet and Daille, 2014), as well as in Section 4 of this paper.

Also in the domain of machine translation, Macherey et al. (2011) pitch an unsupervised, language-independent approach to compound segmentation. The approach uses phrase translation tables to learn the morphological operations that facilitate compounding, such as the insertion of linking morphemes. It then references a monolingual corpus to assess candidate segmentations. These elements are brought together in a complex dynamic programming algorithm.

Tackling compound segmentation from an information retrieval perspective, Alfonseca et al. (2008) leverage 900 million web documents to determine whether proposed compound constituents exist in anchor texts pointing to the same document. This approach builds on the semantic relationship between compound constituents: "If two words can create a compound word in a language, we can assume that there is some kind of semantic relationships [sic] between them and therefore we would expect to be able to find them near each other in other situations" (134). Alfonseca et al. combine this mutual information feature with lexical, frequency, and probability-based features in a Support Vector Machine classifier.

Efforts in compound segmentation vary widely in terms of the resources they require to get off the ground: monolingual and bilingual corpora, hand-written linguistic rules, web documents, and POS and frequency information. In addition, they have focused largely on the identification of lemmatized constituent words, and not on the identification of compound-medial word boundaries.

The segmenter presented in this paper is a supervised, monolingual approach that uses existing software and incorporates hand-written linguistic constraints. Instead of using multiple corpora, it draws from a single word list annotated for word boundaries. In addition, its linguistic rules are to ensure grammatical constituents, and do not mirror morphological operations to restore constituents to their pre-compound or lemmatized form (as in Koehn and Knight, 2003; Clouet and Daille, 2014; Owczarzak et al., 2014).

3 Compound splitting method

The method of compound segmentation introduced here begins with annotated training data, a set of word forms, both simplex and complex, hand-annotated with any unseen word boundaries. For instance, an annotator would likely mark up the Finnish closed compound *Suomenmaassa* 'in the Finnish country' as *Suomen=maassa* (*suomen* 'Finland-NOM', *maassa*-INE 'country'). Affix boundaries are not annotated unless they also constitute word boundaries.

An off-the-shelf morphological analyzer is trained on the annotated data and used to segment words into their constituent morphemes (e.g., one might split *Suomenmaassa* into the morphemes *suome*, *n*, *maa*, *ssa*). This morphological analyzer is then used to generate candidate compound segmentations and to train a language model.

3.1 Candidate generation

For every morpheme m asserted by the morphological analyzer, there are the four possible bigrams below, where # denotes a word boundary and X denotes a boundary between two morphemes, or $\neg$#.

$$\begin{array}{c} \# \; m \\ \mathrm{X} \; m \\ m \; \# \\ m \; \mathrm{X} \end{array}$$

Using this decomposition, candidate segmentations are generated for a word by proposing a word boundary along each of its alleged morpheme boundaries. Suppose that the morphological analyzer takes in the input w_i and outputs the morphemes $\{m_1,\ m_2,\ m_3\}$. The list of candidate segmentations for w_i would then be every possible combination of internal morpheme boundaries, as shown below. (A word assigned n morphemes will have 2^{n-1} candidate segmentations.)

$$\begin{array}{ll} \# \; m_1 \; \# \; m_2 \; \# \; m_3 \; \# & \text{(the most segmented)} \\ \# \; m_1 \; \# \; m_2 \; \mathrm{X} \; m_3 \; \# & \\ \# \; m_1 \; \mathrm{X} \; m_2 \; \# \; m_3 \; \# & \\ \# \; m_1 \; \mathrm{X} \; m_2 \; \mathrm{X} \; m_3 \; \# & \text{(the least segmented)} \end{array}$$

To give a real world example, if *Suomenmaassa* is split into the constituents {*suomen*, *maa*, *ssa*},[1] it would yield the following four candidate segmentations:

$$\begin{array}{ll} \# \; suomen \; \# \; maa \; \# \; ssa \; \# & (\textit{suomen=maa=ssa}) \\ \# \; suomen \; \# \; maa \; \mathrm{X} \; ssa \; \# & (\textit{suomen=maassa}) \\ \# \; suomen \; \mathrm{X} \; maa \; \# \; ssa \; \# & (\textit{suomenmaa=ssa}) \\ \# \; suomen \; \mathrm{X} \; maa \; \mathrm{X} \; ssa \; \# & (\textit{suomenmaassa}) \end{array}$$

One benefit of this approach to candidate generation is that it takes advantage of the linguistic insight that a word boundary will only occur where there is also a morpheme boundary. This reduces the size of the candidate set, compared to approaches that generate candidates by proposing a word boundary in between each letter of a word (e.g., Macherey, 2011), or by recursively proposing all two-part segmentations of some minimum length (e.g., Clouet and Daille, 2014).

Yet, a drawback of this approach is that candidate generation is at the mercy of the performance of the morphological analyzer. If the analyzer fails to identify a morpheme boundary between two morphemes, that boundary will not be considered as a potential word boundary site during compound segmentation.

3.2 Language modeling with morphemes

The intuition behind this segmenter is that the left and right edges of a morpheme each have a certain likelihood of appearing with a word boundary: For some morpheme m_i, the bigram '# m_i' might be more likely than the bigram 'X m_i' (or vice versa), and likewise for 'm_i #' and 'm_i X'.

Consider the English simplex word *lighting*, composed of the root *light* and affix *-ing* ('# $light$ X ing #'). English speakers know the bigram 'X ing' to be extremely common, or, at least, far more common than its counterpart '# ing'. This intuition can be captured with language modeling.

[1] The correct morphological analysis for *Suomenmaassa* is *Suome-n=maa-ssa* 'Finland-NOM=country-INE'.

Language models are used to assign probabilities to sequences of natural language tokens, typically words and punctuation. A language model sets out to determine the conditional probability of some token w_i given its history h (i.e., all of the tokens that precede w_i in a training corpus). We approximate the posterior $P(w|h)$ using the Markov assumption that w_i's history can be estimated through the few tokens that precede w_i:

$$P(w_i|h) \approx P(w_i|w_{i-n+1}^{i-1}) \tag{2}$$

Above, w_i^j is a string of tokens $w_i, ..., w_j$ and n is the order of ngram (i.e., $n = 2$ for bigrams, $n = 3$ for trigrams, etc.). We can calculate $P(w_i|w_{i-n+1}^{i-1})$ by dividing the frequency of w_{i-n+1}^{i} by the frequency of w_{i-n+1}^{i-1} in a training corpus. This gives us a *maximum likelihood estimate* (MLE) of $P(w_i|h)$:

$$P(w_i|w_{i-n+1}^{i-1}) = \frac{\text{count}(w_{i-n+1}^{i})}{\text{count}(w_{i-n+1}^{i-1})} \tag{3}$$

The probability of some sequence of tokens w_1^L is then estimated by taking the product of the MLE for each ngram that appears in the sequence:

$$P(w_1^L) = \prod_{i=1}^{L} \frac{\text{count}(w_{i-n+1}^{i})}{\text{count}(w_{i-n+1}^{i-1})} \tag{4}$$

Just as language modeling is used to estimate the likelihood of a sentence, it can be used to predict the likelihood of a proposed compound. Instead of training ngram probabilities on sentences (i.e., sequences of words), we can train them on words, wherein each word is a sequence of *morphemes* and *morpheme boundaries*.

Thus, to continue with the English example *lighting*, the bigram-MLE of the candidate segmentation **light=ing* would be calculated as follows:

$$P(\#light\#ing\#) = P(light|\#) \times P(\#|light) \times P(ing|\#) \times (\#|ing) \tag{5}$$

Since the bigram 'X ing' is far more frequent than '# ing', $P(\#light\text{X}ing\#)$ will receive a higher MLE than $P(\#light\#ing\#)$. Simply put, $P(lighting) > P(light{=}ing)$.

As the core component of this segmenter is a language model trained with morphemes, we consider this a *morpheme-driven* approach to compound segmentation. This is in contrast to word-driven approaches, such as the approaches outlined in the previous section. Word-driven approaches can struggle with accounting for compounds composed of constituent words that were unseen in their training lexicon (see Owczarzak et al., 2014, which addresses this issue). Our segmenter faces this same challenge, but attempts to overcome it by exploiting how, for any set of words, there is generally more information about the distribution of morphemes in the language than the distribution of its words.

3.3 Phonotactic constraints

Using morpheme-based language modeling alone, this approach is vulnerable to predications that are phonotactically ungrammatical, in that it can assert impossible word-internal sequences of sounds. For example, analyzing *bookworm* as **bookw=orm* produces the unpronounceable constituent **bookw*.

To compensate for these ungrammaticalities, linguistic constraints can be posited to prune unsound candidates from the candidate sets. Imagine that we imposed the constraint that all constituent words have at least one vowel. This would discard the candidate compound **boobwo=rm* because its constituent **rm* violates the constraint.

With a whittled-down candidate set, the segmenter selects the remaining candidate with the highest language model score.

4 Experiment

We trained and evaluated this approach on an annotated subset of the Aamulehti-1999 Finnish daily newspaper corpus (Aamulehti, 1999).

Data set	*Total*	*Simplex*	*Complex*		
			Total	*Open*	*Closed*
training set	18,079	14,489	3,590	312	3,278
test set	2,001	1,606	395	41	354

Table 1: Training-test set split.

4.1 The data

Aamulehti-1999 contains 16,608,843 words across 61,529 news articles. We extracted a subset composed of 20,080 unique word types, including any word that appears one hundred or more times in the corpus.

A single annotator hand-annotated unmarked word boundaries in this subset. The annotator identified 3,632 closed compounds among the 20,080 word types, giving the data the distribution in Table 1. This gold standard underwent a 90-10 train-test split: We used 90% of the annotated data to train both a morphological analyzer and morpheme-based language model. We then evaluated the segmenter on the held-out 10%.

4.2 The segmenter

Morphological analyzer

We used a baseline Morfessor 2.0 model (Virpioja et al., 2013) to segment words into morphemes. The Morfessor model was trained on raw text consisting of space-delimited data, in which all marked and unmarked word boundaries were indicated with spaces. (E.g., '`...runoja raaka-aineen suomen=maassa...`' would have been represented as '`...runoja raaka aineen suomen maassa...`'.) As needed for candidate generation and the language model, the model's `viterbi_segment` method was used to segment words along their predicted morpheme boundaries.

Language model

To avoid zero-probabilities (i.e., where $P(sequence) = 0$), we used a simple trigram language model with Stupid Backoff smoothing (Brants et al., 2007). The model ultimately backed off to a Laplace-smoothed unigram count, assigning a score S to a morpheme/boundary m_i accordingly:[2]

$$S(m_i|m_{i-2}^i) = \begin{cases} \dfrac{\text{count}(m_{i-2}^i)}{\text{count}(m_{i-2}^{i-1})}, & \text{if count}(m_{i-2}^i) > 0 \\ \alpha \times \dfrac{\text{count}(m_{i-1}^i)}{\text{count}(m_{i-1})}, & \text{if count}(m_{i-1}^i) > 0 \\ \alpha^2 \times \dfrac{\text{count}(m_i) + \delta}{N + \delta|V|}, & \text{otherwise} \end{cases} \tag{6}$$

Above, N is the total number of unigrams seen during training, V is the vocabulary size (i.e., the number of unique morphemes and boundaries), and the Laplace discount δ is 1.0. As in Brants et al. (2007), the Stupid Backoff discounting parameter α is 0.4 — it was not tuned to the corpus.

The language model score (S_{LM}) for a candidate c_i is the product of the score for each morpheme and boundary that appeared in c_i; this sequence is defined as m_1^L:

$$S_{LM}(c_i) = S_{LM}(m_1^L) = \prod_{i=1}^{L} S(m_i|m_{i-2}^i) \tag{7}$$

[2]Stupid Backoff dispenses with real probabilities, assigning a score $S(x)$ instead of a probability $P(x)$. Some, however, attribute this S to stand for $Stupid$.

To predict the best segmentation $\hat{c}$ for a word given its candidate set C, the segmenter selected the candidate with the highest language model score:

$$\hat{c} = \arg\max_{c \in C} S_{LM}(c) \tag{8}$$

Phonotactic constraints

We formulated four phonotactic constraints that are, in effect, unviolable in Finnish:

- *Minimal Word* (MINWRD): A candidate incurs a MINWRD violation for each constituent word that contains fewer than two vowels. (Cf. Suomi et al., 2008). E.g., *a=*asian* ∼ *aasian*, *jun=*tunen* ∼ *juntunen*, *kä=*väisi* ∼ *käväisi*, *n=*uotio* ∼ *nuotio*, *mat=*ala=vaahtoisen* ∼ *matala=vaahtoisen*, and *ta=*lutus=nuorasta* ∼ *talutus=nuorasta*.

- *Sonority Sequencing* (SONSEQ): A candidate incurs a SONSEQ violation for each constituent word that begins in a consonant cluster not in */pl*, *pr*, *tr*, *kl*, *kr*, *sp*, *st*, *sk*, *spr*, *str*/ or that ends in any consonant cluster. (Cf. Sulkala and Karjalainen, 1992; Suomi et al., 2008). E.g., *luonn=*ehti* ∼ *luonnehti*, *ehtoisa=mpaa* ∼ *ehtoisampaa*, and *jukola=ntupien* ∼ *jukolan=tupien*.

- *Vowel Harmony* (V-HARMONY): A candidate incurs a V-HARMONY violation for each constituent word that contains both front vowels */ä*, *ö*, *y*/ and back vowels */a*, *o*, *u*/. (Cf. Sulkala and Karjalainen, 1992; Suomi et al., 2008; Ringen and Heinamaki, 1999; Karlsson, 2015). E.g., *kesäillan* ∼ *kesä=illan*, *taaksepäin* ∼ *taakse=päin*, and *muutostöitä* ∼ *muutos=töitä*.

- *Word-Final Consonants* (WRDFINAL): A candidate incurs a WRDFINAL violation for each constituent word that ends in a consonant that is not */t*, *s*, *n*, *l*, *r*/. (Cf. Sulkala and Karjalainen, 1992; Suomi et al., 2008). E.g., *pitem=pään* ∼ *pitempään*, *sulok=kuutta* ∼ *sulokkuutta*, and *hyp=pää* ∼ *hyp=pää*.

Since these constraints are largely unviolable in Finnish, we designed the segmenter to discard candidates that violate the constraints. Given a set of candidates for an input, for each phonotactic constraint, the segmenter discarded any candidates that violated the constraint, unless it was the case that *every* candidate violated the constraint. If every candidate violated it, the number of shared violations was subtracted from the number of violations incurred by each candidate. Any candidates that still violated the constraint were then discarded. This is the notion of wiping out shared violations found in Optimality Theory (Prince and Smolensky, 1993/2004).

After using the constraints to pare down the candidate set, the segmenter selected the remaining candidate with the highest language model score. If no candidates remained, it defaulted to the simplex candidate;[3] this meant that all of the candidates violated *some* phonotactic constraint, but not the same constraint equally.

4.3 Evaluation

We evaluated our approach by comparing the segmentations produced by the segmenter to the held-out gold standard. This was done by tallying true and false positives and negatives according to the definitions below. These metrics mirror those used by Koehn and Knight (2003), Alfonseca et al. (2008), Aussems et al. (2013), and Clouet and Daille (2014).

- **True positives** (TP): Closed compounds that are correctly segmented.

- **False positives** (FP): Simplex words that are mistakenly segmented.

[3]Motivations to default to the simplex candidate were twofold. First, the dataset's high simplex rate renders a word more likely to be simplex than complex. (However, it is important to recall that the dataset is skewed towards more frequent words, and that compound frequency likely has an inverse correlation with word frequency.) In addition, as we learned from a development set, it is generally only with loanwords that *every* candidate violates a constraint. Since the language model is trained predominantly on core Finnish, it stands to reason that it will make poorer predictions with loanwords, resulting in a greater number of false positives with loanwords. Hence, in these cases, we had the segmenter default to the simplex candidate.

- **True negatives** (TN): Simplex words or open compounds that are appropriately left unsegmented.
- **False negatives** (FN): Closed compounds that the segmenter fails to segment altogether.
- **Bad segmentations** (Bad): Closed compounds that the segmenter segments, but improperly so.

Using these classifications, precision, recall, and accuracy were calculated, with both precision and recall penalized for bad segmentations:

- **Precision** = $\frac{TP}{TP + FP + Bad}$
- **Recall** = $\frac{TP}{TP + FN + Bad}$
- **Accuracy** = $\frac{TP + TN}{TP + TN + FP + FN + Bad}$

As a probabilistic morphological analyzer, Morfessor predicts slightly different segmentations for the same set of data each time a model is trained. These segmentations consequently impact the ngrams stored in the language model, as well as the constraint interactions further down the pipeline. Due to this variation, we trained a Morfessor model and subsequent language model 50 times on the training set. This was done to ascertain the average performance of each segmenter given the training set and variation from Morfessor. Table 2 portrays the mean precision, recall, and accuracy for using language modeling alone and language modeling with constraints to segment compounds.

Segmenter	*P*	*R*	*Acc.*
Baseline (no segmentation)	-	0.0	0.8230
Language model	0.7493	0.8970	0.9373
Language model + constraints	0.8855	0.9201	0.9690

Table 2: Mean performance from training the Morfessor and language models for 50 iterations.

On average, language modeling alone achieved an accuracy of ∼94%. In contrast, a language model coupled with linguistic constraints achieved a much higher accuracy, hovering around 97%. Both methods substantially surpassed a baseline of leaving all inputs unsegmented.

Error analysis

To examine specific errors from a representative iteration, we found the iteration that produced accuracies most similar to the mean accuracies depicted in Table 2. The results from this average iteration are shown in Table 3.

Segmenter	*TP*	*TN*	*FP*	*FN*	*Bad*	*P*	*R*	*Acc.*
Baseline (no segmentation)	0	1,647	0	354	0	-	0.0	0.8230
Language model	322	1,553	92	16	18	0.7454	0.9045	0.9370
Language model + constraints	328	1,611	36	18	8	0.8817	0.9266	0.9690

Table 3: Performance from the average iteration.

The 62 errors made by the constraint-based (i.e., "language model + constraints") segmenter fell under one of three types: constraint errors, Morfessor errors, and language modeling errors. The distribution of these errors is summarized in Table 4.

Constraint errors. A constraint error occurred when one of the phonotactic constraints was the cause of the correct segmentation losing. The constraint-based segmenter encountered only three such errors (4.8%), the false negatives **mäkicup* 'ski jump cup' and **bruttokansantuote* 'gross domestic product', and the false positive **yksin=omaan* 'only'.

Error type	*FP*	*FN*	*Bad*	*Total*
Constraint errors	1	2	0	3 (4.8%)
Morfessor errors	0	4	3	7 (11.3%)
Language modeling errors	35	12	5	52 (83.9%)
All errors	36	18	8	62

Table 4: Distribution of errors from the "language model + constraints" segmenter.

The correct segmentation *mäki=cup* was ruled out due to the loanword *cup* violating MINWRD. And, *brutto=kansan=tuote* was eliminated because the */br/* onset of the Swedish stem *brutto* 'gross' violated SONSEQ. In these two cases, all of the candidates violated some constraint and the segmenter consequently defaulted to the simplex candidate. Had the correct segmentation not violated a phonotactic constraint, it would have been uniquely identified as the winner.

In the third case, the simplex candidate *yksinomaan* violated V-HARMONY, as it contains the front vowel */y/* and back vowels */o*, *a/*.[4] This led **yksin=omaan* to be selected, as it violated none of the phonotactic constraints.

The presence of constraint errors cautions us that a segmentation approach that uses phonotactic constraints is sensitive to loanwords. However, it was only with loanwords where each candidate violated a constraint. This, to some extent, offers loanword detection that falls naturally out of the architecture of the segmenter. This might render it possible to make special considerations for core-periphery structure in the future.

Morfessor errors. The most serious error this segmenter faced was one that stemmed from the morphological analyzer. If the morphological analyzer failed to segment a word into its correct constituent morphemes and, in doing so, did not insert a morpheme boundary that also constituted a true word boundary, that word's candidate set did not include the correct segmentation. 11.3% (7/62) of the errors made were Morfessor errors. For example, the segmenter was unable to predict the compound *oheis=kräsän* 'extraneous junk', since Morfessor split the input *oheiskräsän* into the constituents {*o*, *hei*, *sk*, *rä*, *ä*, *sä*, *n*}. Here, the constituent *sk* subsumes the compound break.

The non-trivial frequency of these errors emphasizes the importance of having a well-trained morphological analyzer.[5] One way to possibly minimize these errors would be to train the analyzer on words annotated for morpheme boundaries instead of word boundaries. (However, morpheme annotation would require more specialized knowledge than compound annotation.) As always, training the morphological analyzer on more data would also likely lead to some improvement.

Language modeling errors. By far the most rampant errors were language modeling errors, totaling 83.9% of the errors (52/62). Language modeling errors arose when, given a refined set of grammatical candidates, the language model favored the incorrect segmentation. Their prevalence is telling about the compound segmentation problem: It highlights the difference between predicting possible *nonword* compounds and predicting *actual* compounds. It also indicates that the language model is the paramount site for improvement with this approach.

Comparison to frequency-based approaches

We also implemented two versions of Koehn and Knight's (2003) frequency-based segmenter. Both implementations scored candidates solely according to the geometric means of their constituents' frequencies, as in (1). Frequency information and part-of-speech (POS) tags were provided by Aamulehti-1999.

[4] Although *yksinomaan* is left simplex in the gold standard, *yksin=omaan* is quite arguably the correct segmentation. *Yksinomaan* is composed of the stems *yksin* 'alone' and *oma-an* 'own-ILL'. While the word is semantically noncompositional, evidence from syllabification suggests that it is a compound. Were *yksinomaan* truly simplex, its syllabification would be **yk.si.no.maan*. However, it syllabifies as if it were a compound, with a syllable boundary falling in between the two stems: *yk.sin.o.maan*.

[5] As an aside, we used Morfessor's own built-in evaluation suite to evaluate this iteration's Morfessor model. Like Virpioja et al. (2013), we used the morpheme-annotated Finnish gold standard from Morpho Challenge 2010 (Kurimo et al., 2010). Our Morfessor model received 0.548 and 0.614 on precision and recall, respectively. We find it promising that language modeling alone achieved a 0.937 accuracy, despite our Morfessor model's performance.

Segmenter	*TP*	*TN*	*FP*	*FN*	*Bad*	*P*	*R*	*Acc.*
Baseline (no segmentation)	0	1,647	0	354	0	-	0.0	0.8230
Frequency-based	252	1.389	251	34	75	0.4360	0.6981	0.8201
Frequency-based + POS	287	1,554	92	46	22	0.7157	0.8085	0.9200
Language model	322	1,553	92	16	18	0.7454	0.9045	0.9370
Language model + constraints	328	1,611	36	18	8	0.8817	0.9266	0.9690

Table 5: Performance of the frequency-based and language model segmenters.

The two implementations differed with respect to their candidate sets. The first implementation allowed splits into *any* words found in the corpus; the second implementation employed POS-filtering, only permitting splits into *content* words (but not proper nouns). Candidate sets for both implementations were restricted to constituents of at least three characters in length.

Table 5 displays the results from evaluating the frequency-based segmenters on the test set; the language modeling results from the average iteration are repeated for easy comparison. As the table shows, the pure frequency-based approached received 43.60% on precision and 69.81% on recall, culminating in an accuracy comparable to the baseline's accuracy (∼82%). Both the baseline and frequency-based segmenters were surpassed by the POS-filtered approach, which achieved an accuracy of 92.00%. The language modeling approach achieved a slightly higher accuracy of 93.70%. And, overall, the constraint-based approach achieved the highest precision (88.17%), recall (92.66%), and accuracy (96.95%).

Most notably, the language modeling segmenters earned far fewer false negatives (i.e., higher recall) than the frequency-based segmenters. This returns us to the issue mentioned in Section 3.2. As word-driven segmenters, the frequency-based approaches struggled with capturing compounds whose constituents did not appear on their own in the corpus. Out of the 46 false negatives produced by the POS-filtered segmenter, 32 occurred because, in each case, one or more of the correct segmentation's constituents did not appear in Aamulehti-1999 (or did not appear as a content word), precluding it from the candidate set.

On the other hand, as morpheme-driven approaches, the language modeling segmenters largely avoided these errors. (They produced only 3 of the aforementioned 32 errors.) For instance, the frequency-based approaches failed to segment the compound *yli=määräistä* 'extra' (i.e., *yli=määrä-is-tä* 'over=amount-Adj.-PAR'), since the corpus did not contain *määräistä* as a standalone word. In contrast, the language modeling approaches were able to insert a word boundary in between *yli* and *määräistä*, since the bigram 'yli #' surfaced 58 times in the training set, and 'yli X' only 17 times.

5 Conclusion

We have proposed a language modeling and constraint-based approach to compound segmentation. This approach was demonstrated with Finnish, a highly agglutinative language. We showed that, by using a morphological analyzer to split words annotated for compound-medial word boundaries into constituent morphemes, we can train a language model that scores different configurations of morphemes, morpheme boundaries, and word boundaries.

Our implementation of this approach used the off-the-shelf morphological analyzer Morfessor 2.0 (Virpioja et al., 2013) and a simple trigram language model with Stupid Backoff smoothing (Brants et al., 2007). This achieved a segmentation accuracy of ∼94%. Then, by layering linguistic constraints on top of the language model, we rooted out phonotactically ill-formed segmentations, allowing the language model to select only grammatical segmentations. This boosted the segmentation accuracy to ∼97%.

In sum, using imperfect morphological analysis with language modeling can achieve impressive results in compound segmentation. This suggests that using a better trained morphological analyzer in conjunction with a more sophisticated language model will lead to further traction in the compound segmentation problem. Furthermore, the better the language model performs, the more the need for phonotactic constraints is obviated.

Lastly, while this approach was specifically designed to identify word boundary sites in the realm of computational phonology, perhaps it can be adapted for machine translation and information retrieval. For instance, a LEMMA constraint could be added: A candidate segmentation could incur a LEMMA violation for each constituent whose lemmatized form cannot be found in a dictionary or translation lexicon.

Acknowledgements

I am grateful to Arto Anttila for his mentorship throughout this project and to Christopher Manning and the anonymous reviewers for their constructive feedback. In addition, many thanks to Kati Kiiskinen for providing swift and thoughtful annotations of Finnish compounds.

Abstract

Knowledge embedding, which projects triples in a given knowledge base to d-dimensional vectors, has attracted considerable research efforts recently. Most existing approaches treat the given knowledge base as a set of triplets, each of whose representation is then learned separately. However, as a fact, triples are connected and depend on each other. In this paper, we propose a graph aware knowledge embedding method (GAKE), which formulates knowledge base as a directed graph, and learns representations for any vertices or edges by leveraging the graph's structural information. We introduce three types of graph context for embedding: neighbor context, path context, and edge context, each reflects properties of knowledge from different perspectives. We also design an attention mechanism to learn representative power of different vertices or edges. To validate our method, we conduct several experiments on two tasks. Experimental results suggest that our method outperforms several state-of-art knowledge embedding models.

1 Introduction

Knowledge bases, such as DBpedia, YAGO, and Freebase, are important resources to store complex structured facts about the real world in the form of triplets as (*head entity*, *relation*, *tail entity*). These knowledge bases have benefited many applications, such as web search and question answer. In the meanwhile, knowledge base embedding, which aims to learn a D-dimensional vector for each *subject* (i.e., an entity or a relation) in a given knowledge base, has attracted considerable research efforts recently (Bordes et al., 2013; Wang et al., 2014; Lin et al., 2015b; Ji et al., 2015). For instance, TransE method (Bordes et al., 2013) regards the relation in a triplet as a translation between the embedding of the two entities. In other words, TransE learns a preference of $\mathbf{h} + \mathbf{r} = \mathbf{t}$ for each triple, where $\mathbf{h}$, $\mathbf{r}$, and $\mathbf{t}$ are the representation vector of head entity, relation, and tail entity respectively. Similar ideas are also proposed in TransH (Wang et al., 2014), TransR (Lin et al., 2015b), TransSparse (Ji et al., 2016), etc.

Despite the success of above methods in learning knowledge representations, most of them mainly consider knowledge base as a set of triples and models each triple separately and independently. However, in reality, triples are connected to each other and the whole knowledge base could be regarded as a directed *graph* consisting of vertices (i.e., entities) and directed edges (i.e., relations). In this way, we see that most of existing methods only consider "one hop" information about directed linked entities while miss more global information, such as multiple-steps paths, K-degree neighbors of a given vertex, etc. We call these different structural information as *graph context* inspired by *textural context* utilized in learning a given word's representation (Tomas Mikolov, 2013).

In this paper, we present a novel method to learn the representations of knowledge by utilizing graph context. Figure 1 gives an example to further explain the motivation of our work. In Figure 1(a), we are given a knowledge base organized as a directed graph which shores the facts about the singer Taylor Swift and president Barack Obama. We then demonstrate three kinds of graph context utilized to encode "Taylor_Swift" and "Barack_Obama".

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 641–651, Osaka, Japan, December 11-17 2016.

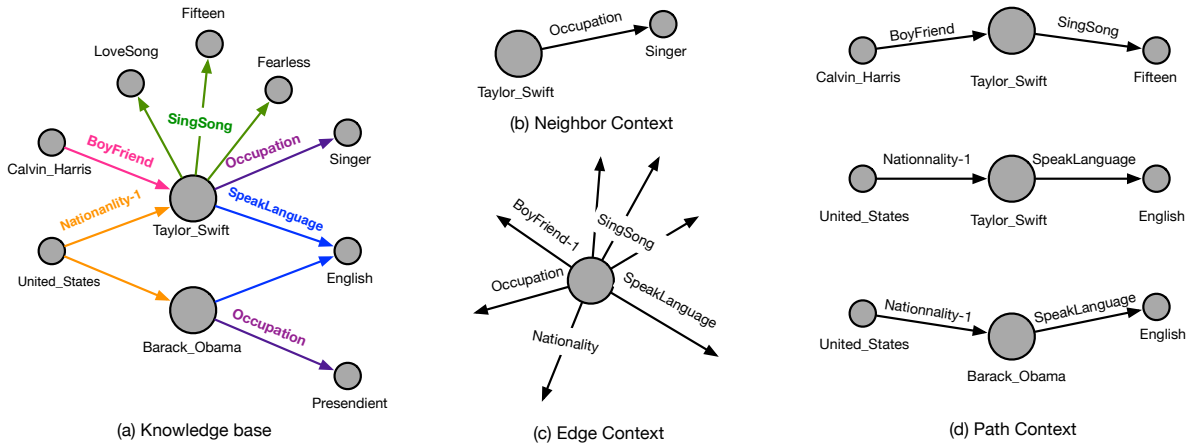

Figure 1: An illustration of three types of graph context, given by a knowledge base.

Neighbor context, as shown in Figure 1(b), consists of the target entity (e.g., "Taylor_Swift") and its directed linked entities (e.g., "Singer") along with their relations (e.g., "Occupation"). It is the most common context and is used in all knowledge base embedding methods.

Edge context, which is shown in Figure 1(c), indicates all kinds of relations relevant to the target entity, such as "SingSong", "BoyFriend^{-1}"(a reverse relation of 'BoyFriend"), "Nationality", and "Occupation" relations of "Taylor_Swift". The relations together would be helpful identify the target entity. For example, "SingSong" and several "BoyFriend^{-1}" relations represent the fact that Taylor, as a singer, has quite a few boy friends in reality. Please notice that different relations has different representation power. For instance, "SingSong" is a very unique relation and is very helpful to identify a singer. Meanwhile, "Nationality" occurs with every human being, so that gains less value. We will introduce how to handle this issue by utilizing an *attention mechanism* in our proposed method later.

Path context is defined as paths in the given graph containing the target entity. Figure 1(d) gives an example of several 3-step paths containing "Taylor_Swift" or "Barack_Obama". The two paths $United\_States \xrightarrow{Nationality^{-1}} Taylor\_Swift/Barack\_Obama \xrightarrow{SpeakLanguage} English$ represent that the two target entities are similar in terms of nationality and language and suggests their embedding vectors should be somehow similar from this perspective.

There are several challenges when learning knowledge representation by graph context. First, there are quite a few different types of graph context while each has unique structural properties. How to propose a general framework that is able to handle all kinds of graph context is one of the challenges in this work. Second, as we have mentioned previously, in the same type of graph context, different entities/relations have different representation power. For example, in edge context, the "SingSong" relation is more powerful than the "occupation" relation as the former one is less frequent and more unique for singers. How to learn the representation power of each entity/relation is the second challenge we meet. Third, how to estimate model parameters by utilizing real data is also a challenge.

Our contributions in this work include: (1) We treat a given knowledge base as a directed graph instead of a set of independent triples, and extract different types of graph context to study the representation of knowledge. (2) We propose a novel and general representation learning approach, GAKE (Graph Aware Knowledge Embedding), which can be easily extended to consider any type of graph context. (3) We propose an attention mechanism in our approach to learn representation power of different entities and relations.

The rest of this paper are organized as follows. In Section 2, we introduce some related works. In Section 3, we detail the proposed method of graph aware knowledge embedding. Section 4 describes the data and presents experimental results to validate our method. Section 5 concludes the paper.

2 Related Work

In this section, we review some existing work relevant to our paper. Generally, our work is closely related to the following two topics: (1) knowledge base embedding (2) Graph embedding.

2.1 Knowledge Base Embedding

A variety of approaches have been explored for knowledge base embedding, such as general linear based models, such as SE (Bordes et al., 2011), bilinear based models, like LFM (Jenatton et al., 2012; Sutskever et al., 2009), neural network based models, like SLM (Socher et al., 2013), NTN (Socher et al., 2013), and translation based models (Bordes et al., 2013; Wang et al., 2014; Xiao et al., 2015). The mainstream models for knowledge base embedding are translation based models including TransE (Bordes et al., 2013) and its variant models.

Translation-based models all share quite similar principle $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$, where $\mathbf{h}, \mathbf{r}$ and $\mathbf{t}$ are the embedding vectors of a triple (h, r, t), though these models differ in score functions. The score function of the translation based models is designed as: $f_r(h, t) = \mathbf{h}_r + \mathbf{r} - \mathbf{t}_r$, where $\mathbf{h}_r$ and $\mathbf{t}_r$ are the embedding vectors of head and tail entities which projected into the relation-specific space.

In TransE (Bordes et al., 2013), the entity and relation embedding vectors are in the same space, say $\mathbf{h}_r = \mathbf{h}, \mathbf{t}_r = \mathbf{t}$. In TransH (Wang et al., 2014), entity embedding vectors are projected into a relation-specific hyperplane $\mathbf{w}_r$, say $\mathbf{h}_r = \mathbf{h} - \mathbf{w}_r^\top \mathbf{h}\mathbf{w}_r, \mathbf{t}_r = \mathbf{t} - \mathbf{w}_r^\top \mathbf{t}\mathbf{w}_r$. In TransR (Lin et al., 2015b), $\mathbf{h}_r = \mathbf{h}\mathbf{M}_r, \mathbf{t}_r = \mathbf{t}\mathbf{M}_r$, where entities are projected from the entity space to the relation space by $\mathbf{M}_r$. In TransD (Ji et al., 2015), $\mathbf{h}_r = \mathbf{M}_{rh}\mathbf{h}$, $\mathbf{t}_r = \mathbf{M}_{rt}t$, where the mapping matrices $\mathbf{M}_{rh}$ and $\mathbf{M}_{rt}$ are both related to the entity and relation. In TransSparse (Ji et al., 2016), $\mathbf{h}_r = \mathbf{M}_r(\theta_r)\mathbf{h}$, $\mathbf{t}_r = \mathbf{M}_r(\theta_r)\mathbf{t}$, where $\mathbf{M}_r$ is an adaptive sparse matrix, whose sparse degrees are determined by the number of entities linked by the relations.

In addition, there are still some works(Xiao et al., 2016b; Xiao et al., 2016a) follow the principle $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$, although they do not share the same form of score function. Particularly, (Xiao et al., 2016b) proposes to use a generative model to deal with multiple semantic meanings of a relation. To accommondate more flexible knowledge embedding, (Xiao et al., 2016a) proposes a manifold principle instead of a point-wise estimation of entity and relation embeddings. There are some other works incorporate additional information, such as text(Toutanova and Chen, 2015; Toutanova et al., 2015) and entity types(Guo et al., 2015).

Above knowledge base embedding models all treat the knowledge base as a set of triples. However, in fact, knowledge base is a graph with its graph structure which can be used to better embed the entities and relations in knowledge base. Although (Gu et al., 2015) and PTransE(Lin et al., 2015a) introduce the relation path instead of only considering the direct relations between entities, they just treat the relation path as a new relation and the path length is limited to the model complexity.

However, (Feng et al., 2016) claims the principle $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$ is too strict to model the complex and diverse entities and relations and propose a novel principle Flexible Translation to address these issues without increasing the model complexity.

Table 1 compares different knowledge representation learning methods by types of information each method considers. In the table, *Triple* means using each fact as the context when embedding an entity

(or a relation); *Path* stands for treating multiple steps of (undirected) linked entities as the context; *Edge* indicates using all relations that connect to the target entity as the context.

2.2 Graph Embedding

A growing literature has been studying the embedding of graph structure. For example, DeepWalk (Perozzi et al., 2014) uses local information obtained from truncated random walks to learn latent representations by treating walks as the equivalent of sentences. Line (Tang et al., 2015) is a network embedding method that preserves both the local and global network structures.

Although the graph embedding models use the network structures to learn the latent representations, the proposed models are still not suit for us to learn the embeddings of knowledge base. The first reason is that, the knowledge base embedding should learn the representations of both entities(vertices) and relations(edges), but network embedding models only learn the representations for vertices. Second, the assumptions which is the foundation of their models do not hold in knowledge base. For instance, in Line (Tang et al., 2015), it assumes that two vertices which are connected through a strong tie should be similar and be placed closely. But, in knowledge base the head entity and tail entity of a triple may be totally different, such as in triple *(Barack_Obama, Gender,Male)*, entity "Barack_Obama" and "Male" are not the same at all.

In this paper, we propose a novel approach to learn the representations of entities and relations by formulating a given knowledge base as a directed graph and leveraging the graph's structural information.

3 Our Approach

In the following, we present our approach, GAKE (Graph Aware Knowledge Embedding), for learning representations of a given knowledge graph. We describe our approach in steps, adding complexity, and start with necessary notations and definitions.

3.1 Preliminaries

A traditional knowledge graph is a set of triples, each describes a fact, as (*Barack_Obama*, *SpeakLanguage*, *English*). In this work, we use a directed graph to represent these facts by treating head/tail entities as vertices and relations as directed edges. More formally, we have

Definition 1 (Knowledge Graph) *A knowledge graph $G = (V, E)$ is a directed graph, where V is the set of vertices (i.e., entities), and E is the set of edges, where each directed edge $e = (v_i, v_j)$ represents the relation from the entity v_i to the entity v_j $(v_i, v_j \in V)$.*

The way to build a knowledge graph as we defined from given facts (or triples) is as follows: for each fact (h, t, r), where h and t are two terms to represent head entity and tail entity respectively, we first create two corresponding vertices v_i and v_j in the graph G, where i and j are unique index of h and t respectively. After that, we create a directed edge e, which represents the relation r, from v_i to v_j, along with a reverse relation r^{-1} from v_j to v_i. This is a common trick, which is similar to "back translation" in machine translation, to allow us to fully utilize the structural information of knowledge graph and improve the performance. The above process keeps running until all facts are included in the graph G.

Moreover, we use $s = (t, k)$ to represent a *subject* (i.e., a vertex or an edge) of the knowledge graph G, where t indicates subject type, and k is the index of the corresponding vertex or edge. Specifically, we let $t = 0$ to denote a vertex and let $t = 1$ to denote an edge. We use a set $S = \{s_i\}$ to represent all subjects in G.

Given a subject s_i, we define its *context* as a set of other subjects to indicates vertices or edges relevant to s_i:

Definition 2 (Graph Context) *Given a subject s_i, its graph context $c(s_i)$ is a set of other subjects relevant to s_i: $\{s_w | s_w \in S, s_w$ relevant to $s_i\}$.*

Different types of graph context defines the "relevance" between subjects differently. In this work, we use three types of graph context as examples, which will be introduced in detail later.

The objective of GAKE is to learn the representation of each subject in a given knowledge graph G according to its graph context. More formally, we target the problem of *Knowledge Graph Embedding* as

Problem 1 (Knowledge Graph Embedding) *Given a knowledge graph $G = (V, E)$, the problem of knowledge graph embedding aims to represent each vertex $v \in V$ and each edge $r \in E$ by a d-dimensional vector with real numbers.*

Then, we introduce te notations used in GAKE. In detail, s is a subject (i.e., a vertex or an edge); $C(s)$ means graph context of the subject s; $\phi(s)$ is embedding vector of the subject s; $\pi(C(s))$ is translation of subject s's context; $a(s)$ means attention model of a given subject s; θ is parameters used in the attention model.

3.2 Framework

We then introduce our approach in detail. Generally, the learning objective of GAKE is to predict missing subjects given by their context. (e.g., given two vertices, predicting whether there is a missing link from one to another). More formally, we define the probability of s_i given one of its contexts $c(s_i)$:

$$P(s_i|c(s_i)) = \frac{exp(\phi(s_i)^\top \pi(c(s_i))}{\sum_{j=1}^{|S|} exp(\phi(s_j)^\top \pi(c(s_i)))} \tag{1}$$

where $\phi : s_i \in S \longmapsto \mathbb{R}^{|S| \times D}$ is the embedding vector of a given subject s_i, and $\pi(\cdot)$ is a function that represents the translation of a graph context. In this work, we define $\pi(\cdot)$ as follows:

$$\pi(c(s_i)) = \frac{1}{|c(s_i)|} \sum_{s_j \in c(s_i)} \phi(s_j) \tag{2}$$

We then introduce how to construct different types of graph context. Specifically, to take advantage of the graph structure, given a subject s_i, we consider three types of context: *neighbor context* $C_N(s_i)$, *path context* $C_P(s_i)$, and *edge context* $C_E(s_i)$. Please notice that we take these context as examples while our approach is flexible and could easily be extended to other types of graph context.

Neighbor context. Given a subject s_i, taking an entity as an example, we regard each of its out-neighbors, along with their relations, as the *neighbor context*. Formally, when s_i is an entity, its neighbor context $c_N(s_i)$ is a pair of subjects (e, v), where v is an another vertex in G and e is a directed edge links s_i and v. One thing worth to notice is that neighbor context is equivalent to using triplets relevant to the given subject s_i.

The objective function of taking neighbor context into consideration is to maximize the log-likelihood of all subjects given by their neighbor contexts. Based on Eq. 1, we have

$$O_N = \sum_{s_i \in S} \sum_{c_N(s_i) \in C_N(s_i)} \log p(s_i|c_N(s_i)) \tag{3}$$

where $C_N(s_i)$ is the set of neighbor context of subject s_i.

Path context. A path in a given knowledge graph reflects both direct and indirect relations between entities. For example, the path $v_1 \xrightarrow{BornInCity} v_2 \xrightarrow{CityInState} v_3 \xrightarrow{StateInCountry} v_4$ indicates the relation "Nationality" between v_1 and v_4.

In this work, given a subject s_i, we use *random walk* to collect several paths starting from s_i. For more details, we first sample a integer L uniformly to indicates the length of the path (i.e., number of edges) we aim to generate. After that, at each step, the random walk will choose a neighbor randomly and will terminate once L edges have been collected. We define the path context $c_P(s_i)$ as a set of vertices and edges that are contained in a generated path. Similar methods are also used in (Spielman and Teng, 2004) and (Perozzi et al., 2014).

We then aim to maximize the probability of a subject s_i given by all paths starting from s_i:

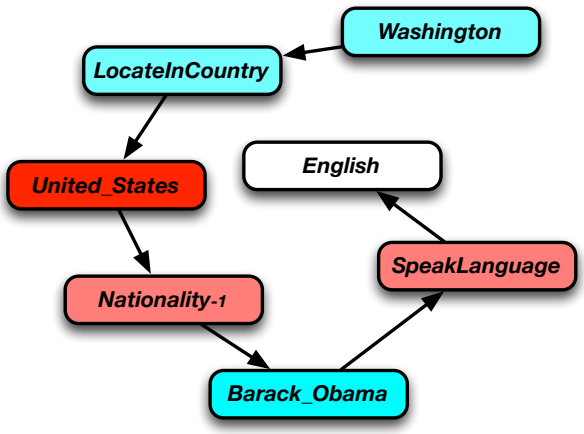

Figure 2: Illustration of the attention for a path context when predicting the entity "English". Darker cells indicate greater attentions.

$$O_P = \sum_{s_i \in S} \sum_{c_P(s_i) \in C_P(s_i)} \log p(s_i | c_P(s_i)) \tag{4}$$

Edge context. All relations connecting a given entity are representative to that entity. For example, the entity connected with "SpeakLanguage" are most likely to be a kind of languages. We define the edge context $c_E(s_i)$ of a subject s_i as all other subjects directly linked with s_i. When s_i is a vertex, $c_E(s_i)$ is a set of edges of s_i. Similar with other two types of graph context, we define the objective function of learning knowledge representation when considering edge context as follows:

$$O_E = \sum_{s_i \in S} \log p(s_i | c_E(s_i)) \tag{5}$$

Context extension. To utilize other types of graph context, one could first define $c(s_i)$ and the algorithm used to extract the context from the given knowledge graph G. After that, the remaining steps for knowledge representation learning would be exactly the same with other types of graph context. Thus, our framework is general and flexible to extend different types of graph context easily.

3.3 Attention Mechanism

So far, the translation of a graph context, $\pi(\cdot)$, takes the embedding results of each subject contained in the context equally. However, in reality, different subjects may have different power of influence to represent the target subject. As an example shown in Figure 1, in edge context, "SingSong" relation is more unique and preventative than "Nationality" as only few people like singers will connect with this "SingSong" while everyone has "Nationality". In this work, we model representative powers of different subjects in graph context by an *attention mechanism* (Ling et al., 2015; Hermann et al., 2015).

The basic idea of the attention mechanism is using an *attention model* $a(s_i)$ to represent how subject s_i selectively focuses on representing another subject s_j when s_i is a part of s_j's context (Kelvin Xu, 2015). In this work, we define the attention model $a(s_i)$ as

$$a(s_i) = \frac{\exp(\theta_i)}{\sum_{s_j \in C(s_i)} \exp(\theta_j)} \tag{6}$$

where θ is the parameters we aim to estimate. Figure 2 illustrates the attention for a path context when predicting the entity "English", where darker color indicates a greater attention. We see that entities like "Washington" and relations like "LocateInCountry" have less attentions, while the entity "UnitedStates" and the relation "SpeakLanguage" have greater attentions on representing "English".

We then re-define the translation of a given graph context, taking the embedding vector of each subject with different weights by further considering attention mechanism. Specifically, we have

$$\pi(c(s_i)) = \sum_{s_j \in c(s_i)} a(s_j)\phi(s_j) \tag{7}$$

3.4 Model Learning

To utilize these three types of context, we combine them by jointly maximizing the objective functions:

$$O = \lambda_N O_N + \lambda_P O_P + \lambda_E O_E \tag{8}$$

We define λ_T, λ_P and λ_N to represent the prestige of neighbor context, path context and edge context separately. We then use a Stochastic gradient descent (SGD) algorithm to estimate model parameters by optimizing Eq. 8. The derivatives are calculated using the back-propagation algorithm. The learning rate for SGD is initially set to 0.1 at first and decreased linearly with the number of training instances. Furthermore, to speed up the training process, we use Hierarchical Softmax (Bengio et al., 2006; Mikolov et al., 2013) to reduce the time complexity of normalization.

4 Experiments

We evaluate our proposed approach with two experiments: (1) triple classification (Bordes et al., 2013; Wang et al., 2014; Lin et al., 2015b), which determines whether a given triple is correct or not, and (2) link prediction (Wang et al., 2014; Xiao et al., 2016b), which aims to predict missing entities. For the data, we adopt dataset from Freebase (Bollacker et al., 2008): FB15K (Bordes et al., 2013). We then demonstrate the effectiveness of GAKE in the two tasks respectively. In all experiments, we set the dimension of embedding vectors to 100, $\lambda_T = 1$, , $\lambda_P = 0.1$ and $\lambda_E = 0.1$. The code and data used in this work are publicly available[1].

4.1 Triple classification.

Setup. In this task, given a knowledge base and a triple (h, r, t), we aim to determine whether it is correct (i.e., existing in the given knowledge base) or not. This task is also constructed in several previous work (Bordes et al., 2013; Wang et al., 2014; Lin et al., 2015b) and is widely used in many NLP scenarios such as question answering. For example, the result of triple classification can be directly applied to answer questions like "Does Taylor Swift publish the song Fifteen". We use the data set FB15K (Lin et al., 2015b), which contains 1,345 relations among 14,951 entities. We use 483,142 triples as training data to learn embeddings of all subjects. We then use 50,000 triples as validation data and 59,071 triples as test data.

We compare the proposed GAKE method with several state-of-art knowledge base embedding baselines, which includes NTN (Socher et al., 2013), TransE (Bordes et al., 2013), TransH (Wang et al., 2014), TransR (Lin et al., 2015b) and TransD (Ji et al., 2015). For each baseline method, we first learn representations of all entities and relations. For a query (h, r, t), we define a relation-specific threshold ρ_r by maximizing the classification accuracy on validation set. After that, we calculate the conditional probability $P(t|h, r)$ by regarding h and r as the context of t, while in GAKE, we construct the neighbor context with h and r's corresponding subjects. At last, we say (h, r, t) is positive (correct) if $P(t|h, r) \geq \rho_r$, where ρ_r is estimated according to the validation data.

Results. We show the evaluation results on triple classification in Figure 3. As the figure shows, it is clear that our approach outperforms others by 11.04% in terms of accuracy on average, as the graph context brings more information especially indirect relations between entities when learning the knowledge representations.

[1] https://github.com/JuneFeng/GAKE

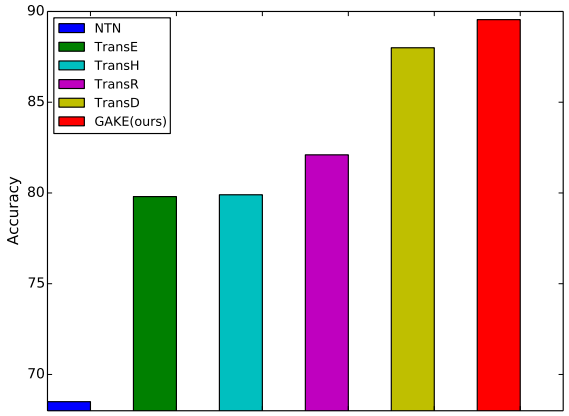

Figure 3: Evaluation results of triple classification.

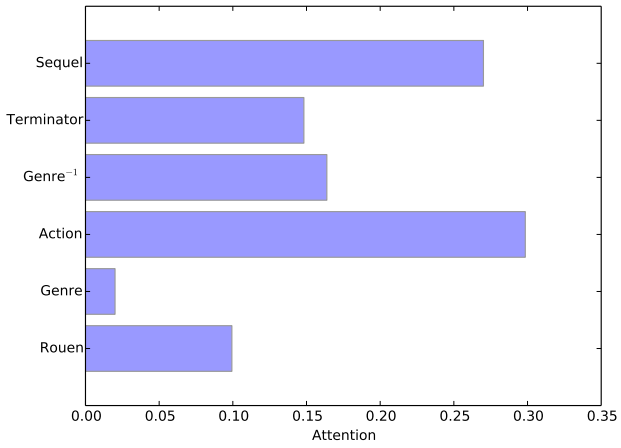

Figure 4: Attentions of subjects as the path context of the entity "Terminate2:JudgementDay".

Furthermore, to better understand the attention mechanism in our approach, we demonstrate attentions of 6 different subjects when they are regarded as the path context of the entity "Terminate2:JudgementDay", which indicates a movie. Figure 4 shows the results. From the figure, we see that two entities, "Action" and "Sequel", have the largest attention to represent the target entity, as "Action" reflects the type of the movie while only some of the movies have sequels. Meanwhile, the relation "Genre" has the least attention as every movie entity connects with "Genre".

4.2 Link Prediction.

Setup. As reported in (Bordes et al., 2011; Bordes et al., 2013), link prediction is to predict the missing h or t given (h, r) or (r, t) respectively. In this task, we conduct the evaluation by ranking the set of candidate entities in knowledge graph, instead of offering a best matching entity. This experiment is conducted on FB15K.

For the baseline methods, we compare our model models with the baselines which include Unstructured (Bordes et al., 2014), RESCAl (Nickel et al., 2011), SE (Bordes et al., 2011), SME(linear/bilinear) (Bordes et al., 2014), LFM (Jenatton et al., 2012) and TransE (Bordes et al., 2013).

Following the protocol in TransE (Bordes et al., 2013), for each test triple (h, r, t), we replace the head entity h by every entity in the knowledge graph, and rank these corrupted triples in descending order by the similarity score which is given by f_r. Similarly, we repeat this procedure by replacing the

Table 2: Experimental results on link prediction.

Metric	Mean Rank		Hits@10(%)	
	Raw	Filter	Raw	Filter
Unstructured (Bordes et al., 2014)	1,074	979	4.5	6.3
RESCAl (Nickel et al., 2011)	828	683	28.4	44.1
SE (Bordes et al., 2011)	273	162	28.8	39.8
SME (linear) (Bordes et al., 2014)	274	154	30.7	40.8
SME (bilinear) (Bordes et al., 2014)	284	158	31.3	41.3
LFM (Jenatton et al., 2012)	283	164	26.0	33.1
TransE (Bordes et al., 2013)	243	125	34.9	47.1
GAKE (ours)	**228**	**119**	**44.5**	**64.8**

tail entity t. After collecting all these triples, we use two evaluation metrics: the mean rank of the correct entities (denotes as *Mean Rank*); the proportion of correct entity ranks within 10 (denotes as *Hits@10*). We expect lower *Mean Rank* and higher *Hits@10* for a better predictor. However, some corrupted triples should be considered as correct ones, since they actually exist in knowledge graph. Ranking such triples ahead of the original correct one should not be counted as an error. To eliminate such cases, we filter out those corrupted triples which appear either in the training, validation or test datasets. We term the former evaluation setting as "Raw" and the latter as "Filter".

Results. Table 2 lists the results on link prediction. It shows that our method GAKE, gets better experiment results than other baselines including Untructured, RESCAL, SE, SME (linear/bilinear), LFM and TransE models. The result demonstrates the superiority of the idea that fully utilizes the graph information to learn representations for entities and relations.

5 Conclusion

In this paper, we propose a graph aware knowledge embedding model to address graph-level contexts. Most existing methods regard knowledge graph as a set of independent triples, and ignore the indirect dependency between subjects (i.e., entities or relations). To deal with this issue, we propose a novel method, GAKE, for learning the representation of a given knowledge graph by formulating a given knowledge base as a directed graph and leveraging graph context, which includes path context, neighbor context, and edge context. We further design an attention mechanism to learn representative power of different subjects. To validate our model, we conduct extensive experiments on benchmark datasets for two tasks, i.e., triple classification and link classification. Experimental results show that GAKE outperforms several state-of-art knowledge embedding methods.

Learning knowledge graph representations is an interesting and new research direction, and there are many potential future directions for this work. For instance, it will be interesting to incorporate the power of explicit knowledge (Wang et al., 2015) into our method to further improve the performance. In addition, the framework of this model is flexible to handle sundry information except the graph context. In other words, we can also build text context by using descriptions of entities or additional text information from other sources like Wikipedia.

Abstract

For automatic chatting systems, it is indeed a great challenge to reply the given query considering the conversation history, rather than based on the query only. This paper proposes a deep neural network to address the context-aware response ranking problem by end-to-end learning, so as to help to select conversationally relevant candidate. By combining the multi-column convolutional layer and the recurrent layer, our model is able to model the semantics of the utterance sequence by grasping the semantic clue within the conversation, on the basis of the effective representation for each sentence. Especially, the network utilizes attention pooling to further emphasis the importance of essential words in conversations, thus the representations of contexts tend to be more meaningful and the performance of candidate ranking is notably improved. Meanwhile, due to the adoption of attention pooling, it is possible to visualize the semantic clues. The experimental results on the large amount of conversation data from social media have shown that our approach is promising for quantifying the conversational relevance of responses, and indicated its good potential for building practical IR based chat-bots.

1 Introduction

There exist two query intentions in Intelligent Agents: the task completion oriented intention and the open-domain chat intention. As the applications of dialog systems, task completion oriented agents are designed to accomplish users' requirements in a few rounds of conversations. This kind of intentions reflect users' basic needs on the agents, thus studies on dialog systems have a longer history and achieved great process (Weizenbaum, 1966; Ferguson et al., 1996; Shawar and Atwell, 2007; Williams, 2010).

The open-domain chat intention, by contrast, represents users' communicating needs. Apparently, automatic chatting systems with good using experience will significantly attract people's interests, even make people form the habits of communicating with agents, hence it is possible to be a new platform for any task-oriented services to plug in (see Duer[1]). One challenge directly brought by open-domain Chat-bots is, indeed, user queries can be related to any topic in any possible forms, that is, it's NOT wise to transform chatting queries into slot-value sequences to further trace users' intentions within the conversation, as task-oriented dialog systems do.

The even more essential challenge chat-bots have to face is to guarantee the semantic and logic continuity of conversations, that is, a response from bots should be relevant with both the adjacent query and the corresponding short conversation history. Actually, such "context-aware" chatting ability is the critical feature of a human-like chat-bot, thus much attention has been paid on this task. The basic requirement for chat-bots is to semantically understand conversations like humans, which is abstracted as the conversation modeling problem. This paper discusses the approaches to addressing the context-aware chatting problem, by investigating and simulating the inner mechanism of human conversations.

Basically, two methodologies can be utilized to provide responses according to the given query, or more complicated, conversation history as discussed in this paper. The first method is to directly generate

Figure 1: A conversation example.

responses for a given query and its context (Ritter et al., 2011; Vinyals and Le, 2015; Shang et al., 2015), which provides an end-to-end solution for chat-bots. Despite its meaningful integrated architecture, it seems still a great challenge for generation based approaches to give responses with good readability and diversity. This problem can be directly addressed by another option, that is, finding proper methods to rank candidate responses selected from large amount of human dialog utterances by information retrieval (IR) method (Ji et al., 2014; Xian et al., 2016). Such Candidate Re-Ranking based solutions (Lowe et al., 2015; Sordoni et al., 2015; Hu et al., 2014) are of great value for building the practical chat-agents like Duer and XiaoIce[2], for which readability and diversity of responses are critical metrics.

For both generation and re-ranking approaches, indeed, their very basis is capturing the semantic clues within conversations, so as to select proper responses or generate them directly, and this procedure is generally named as "conversation modeling". As denoted by Grosz and Sidner (1986), the sequential utterances' structure, purposes and the state of focus of attention are the key components in a discourse. Correspondingly, to provide a conversationally reasonable response for a given session, the following abilities are needed for conversation modeling approaches: a) achieving the semantic representations of short sentences with the oral style; b) obtaining the focus of the entire dialog session; and c) selecting or generating responses based on the modeling of utterance sequences.

This paper aims to explore an integrated model framework to achieve the above goals, so as to find the context-aware responses from the candidates given by IR modules. Especially, our model will pay much attention to obtaining dialog focuses, that is, the model is designed to capture the semantic clues implicitly existing in human conversations. Such clues are always composed of phrases scattered in the utterances of conversations, and play a significant role in determining whether a given candidate is context-aware or not. Take the session in Figure 1 for example, some implicit clues flowing throughout the context (marked in **bold**) can be observed. Some of them like "temperature drops", "goes down to freezing", are more about the conversational topic, meanwhile, the words "weather", "temperature" stand for the key ingredient of the sentences. But, the keywords marked in *italic* maybe not helpful for judging A1 as a better response than A2. By contrary, we should task focus on some relatively meaningless phrases, such as "so much". So the clues detection is related with the end-to-end modeling task, and it is difficult and useless to treated this as a pre-processing.

This paper presents a convolution neural network (CNN) with attention pooling strategy to capture semantic clues within conversations by performing the sequential learning, so as to pick out context-aware replies based on the corresponding dialog history. According to the analysis on semantic relationships of the historical contexts, present-posted query and candidate responses, we propose to employ attention mechanism to model sentence upon convolutional layers, so as to provide meaningful semantic representations of contexts. After that, a Gated Recurrent Unit (GRU) based layer accomplishes the sequence modeling for response selection. Experiments with various structures of sentence and sequence modeling are conducted on the dataset from a Chinese Social Network Service (SNS), which has shown the good potential of our approach. Especially, due to the utilization of attention pooling, the obtained conversational clues can be visualized, which is very useful for the conversational state tracing and the interpretability of ranking results.

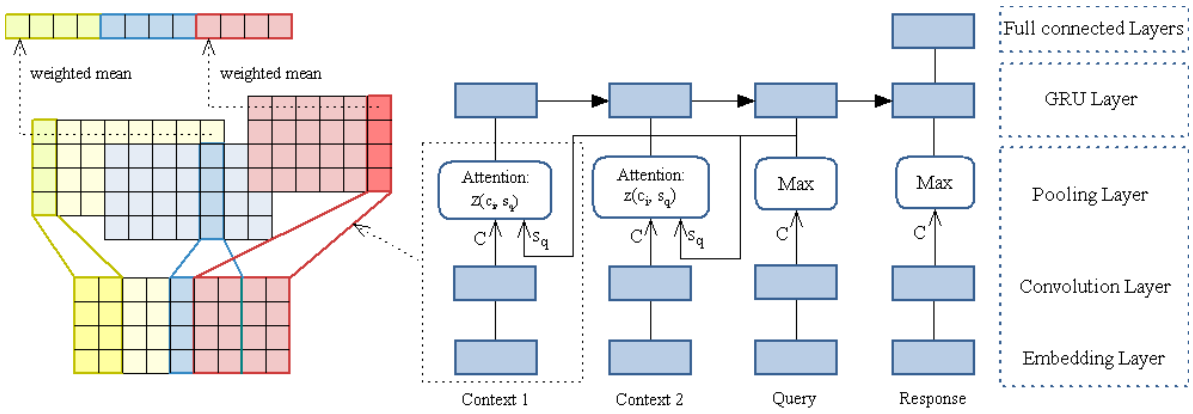

Figure 2: Architecture for modeling the conversation.

2 CNN with Attention Pooling for Quantifying Conversational Relevance

As mentioned in Section 1, the three abilities are needed for modeling open domain conversations, and our motivation is to design an integrated neural network framework to provide these abilities for response selection. This section will detail our approach that mainly takes Chinese characters as basic input elements[3], as well as the specially designed pooling strategy.

2.1 Model Architecture

As illustrated by Figure 2, the architecture of our model is composed of the following three modules:

Sentence Representing: As the essential part of our deep learning architecture, the Sentence Representing module aims to basically map short sentences into the real-valued semantic space. Moreover, the sentence modeling part in our work has to be able to locate the conversationally essential phrases of utterances, which can be jointly absorbed by the upper layer as the semantic clue for modeling conversations. For this purpose, we take the multi-width convolutional function and special designed pooling functions performing on the character-embedding layer, to build the sentence representing part.

CNN based sentence models have achieved success in some NLP tasks (Collobert et al., 2011; Kalchbrenner et al., 2014; Hu et al., 2014), especially, the recent character-level CNN (Kim et al., 2015; Zhang and LeCun, 2015) has even got some state-of-the-art results. Our sentence representing module continues this series of work, employing an one-dimensional valid convolutional layer over char embeddings.

Suppose there are n characters in a sentence, and let $x_i \in \mathbb{R}^k$ be the k-dimensional char vector corresponding to the i-th character, X present a $n \times k$-dimensional matrix made up of x_i, and $w \in \mathbb{R}^{1*m}$ is the weight of a convolutional filter (we'll use $m \in \{2, 3, 5\}$ to represent the bi-gram, tri-gram and 5-gram level abstraction). C stands for the output of this feature map, and represents the meaning of sub-phrases, each element vector c_i is computed by:

$$c_i = f(x_{i::i+m-1} \cdot w + b) \tag{1}$$

Where $b \in \mathbb{R}$ indicates the bias term and f stands for a non-linear function, e.g., the rectifier. Various potential features of the words or phrases are generated by multiple filters. For each of these candidate features will be screened by higher level pooling layers.

At present, the max pooling and average pooling are widely applied. In image modeling scenarios, max pooling can depict the texture better, while average pooling results represent more information about background (Boureau et al., 2010). The heuristics can be applied to NLP tasks similarly, that is, the whole meaning of sentences can be obtained by average strategy; on the other hand, the max pooling concentrates on the significant points relied on established tasks, and this is the reason for max pooling being utilized for solving many challenging text classification problems (Collobert et al., 2011; Kalchbrenner et al., 2014; Zhang and LeCun, 2015).

[3]Different from the European languages such as English, each Chinese character may keep special semantic independently.

In the conversation scenario, context-aware response selection basically relies on two major aspects: a) the relevance between the present query and the candidate response; and b) the additional background information provided by the dialog history. For quantifying the semantic relevance between the present query and candidate, the key phrases within them are playing the great role, and the irrelevant words should be ignored. By contrast, the phrases in a history utterance tend to act as a whole background, to supply and maintain a topic for the conversation. Consequently, as illustrated by Figure 2, we employ the max pooling for extracting the key points in the present query and the candidate for relevance judgment, and for the context sentences, the average pooling strategy is taken to introduce complete background.

Indeed, for each word in the dialog history (previous two sentences as shown by Figure 2), its contribution varies for selecting context-aware candidates, thus it is reasonable to give different weights to the words in the dialog history. For this purpose, in the sentence modeling module demonstrated in the left colorized part of Figure 2, we further present a new attention pooling strategy to learn the weights of each word, according to its contribution for determining whether a candidate is conversationally relevant. This attention pooling strategy will be detailed in Section 2.2.

Conversation modeling: Generated by the sentence modeling layer, the sentence vectors are adopted by a GRU layer for sequentially modeling the entire conversation. The motivation for selecting GRU is to naturally utilize its internal memory to process sequential inputs, and its performance is comparable with LSTM by controlling the gradient vanishing/exploding problems of ordinary RNNs (Bengio et al., 1994; Chung et al., 2014). To further investigate the balance between computational complexity and modeling ability, we also explored the RNN with identity initialized weights (iRNN for short) in practice as Mikolov et al. (2014) did.

Candidate Ranking: Given a sequence representation from conversation modeling, the candidate ranking module takes the full-connected layer to quantify the relevance of candidate responses. We employ the cross entropy as the point-wise ranking loss, and various ranking objective functions can be used to learn the parameters of the whole model.

2.2 Attention Pooling

As mentioned in the previous section, we wish to enhance the modeling of the context utterances for better understanding of the whole conversation, by employing the attention mechanism to learn the weights of words reasonably, meanwhile, it is possible to visualize the semantic clues in conversations according to the learnt weights. The attention strategies have been widely used in machine translation (MT) (Bahdanau et al., 2014; Meng et al., 2015; Li et al., 2015) and question answering (Weston et al., 2014; Hermann et al., 2015; Kumar et al., 2015). Especially for the Encoder-Decoder framework, the attention mechanism may introduce weighting functions of the encoding state and current decoding hidden state, so as to determine the elements that should be focused on.

This paper proposes a new pooling function with attention mechanism to model conversational contexts. Noticing that a posted utterance mainly pays attention to some specific points of the previous utterances in the same session, our pooling approach aims to emphasize such points while obtaining the whole meaning of sentences in the context. As mentioned in Section 2.1, the average pooling can cover the overall information, and our attention pooling tries to assign weights to the words and perform weighted averaging, to find the more important words or phrases in contexts.

The given c_i is the i-th combination of chars as defined previously, and $s_q \in \mathbb{R}^{(k(n-m+1))*1}$ presents the sentence embedding of the posted query upon the max pooling layer. The feature set $z(c_i, s_q)$ for weighting and the attended result a_i can be computed following:

$$z(c_i, s_q) = [c_i, s_q, c_i^T W^{(a)} s_q], \quad a_i = \frac{e^{(z(c_i,s_q)\cdot W^{(1)}+b^{(1)})}}{\sum_{j=0}^{n-m+1} e^{(z(c_j,s_q)\cdot W^{(1)}+b^{(1)})}} \tag{2}$$

Where $W^{(a)} \in \mathbb{R}^{(k(n-m+1))*k}$, $W^{(1)} \in \mathbb{R}^{(k(n-m+2)+1)*1}$, and $b^{(1)}$ is the bias term. The sentence vector

$s_j^{context}$ by the j-th convolutional filter is the weighted average of each c_i instead of ordinary mean:

$$s_j^{context} = \sum_{l=0}^{n-m+1} c_l^j \circ a_l^j \tag{3}$$

The $\circ$ indicates element-wise dot, c_l^j and a_l^j are computed by the j-th filter.

For similar purposes, there are some works take the attention strategy on RNN based dialogue generation (Yao et al., 2015; Shang et al., 2015), different from these works, the model described in this paper aims to apply the attention pooling upper the character level convolutional layer. Besides, Yin et al. (2015) applied an attention method upper convolutional layers to reflect the sub-phrases' interaction between sentence pairs, while we mainly focus on the sentence modeling about contexts in the conversations, and we proposed different attention function to model the relationship between context and query, other than matching units in two feature maps.

3 Experiments

Our proposed model is utilized on the response selecting task, that is, our goal is to distinguish the conversationally relevant responses from the irrelevant ones.

3.1 Dataset & Metrics

The dataset contains totally 1,025,000 sessions collected from the threads in a popular Chinese SNS, each session is composed of 4 utterances including a one-turn context, a present query and a context-aware response. Each sentence's character count varies from 3 to 50, with 10 as average. All the examples used in this paper are included in the dataset. For each conversation, we replace the response with another one randomly sampled from the corpus as the negative sample like (Hu et al., 2014; Lowe et al., 2015; Al-Rfou et al., 2016). This operation repeats 4 times, and we duplicate the real conversations 4 times as positive samples. For all the experiments, we split our dataset into training, validation and test sets, with 8,000,000, 100,000 and 100,000 conversations respectively.

Except evaluating the classified performance by accuracy, we introduce **1 in t P@k** to evaluate the ranking ability with $t-1$ negative cases, where P@k denotes the precision at top k.

3.2 Competitor Models & Parameter settings

The baseline approaches taken by our work can be basically categorized into two groups: the classic methods include the Logistic Regression (LR) models trained on Tri-Gram based TF-IDF features or LDA (Blei et al., 2003) based distributed representations of sentences. Besides, several neural network combinations of different components' implementation are adopted in our experiments, whose general frameworks are the same with the one illustrated in Figure 2, and their details are given as follows:

- GRU+MLP: This model takes GRU to model sentences, which is different from our CNN based sentence modeling layers. Above that, the multi-layer perceptron (MLP) is used to model the conversations without consideration about the sequential characteristic of conversations;

- GRU+iRNN/GRU: In these models, iRNN or GRU takes the position of conversation modeling module, and the sentences modeling part still employs GRU;

- Attention GRU+iRNN: Employing GRU with attention for modeling the sentences in contexts and iRNN for sequence modeling;

- CNN+iRNN: This model takes iRNN for conversation modeling, and in the CNN based sentence representation module, several pooling strategies are tried, including max pooling, mean pooling, and their mixture, to replace our attentional average pooling in the architecture in Figure 2;

Group	Model	Accuracy	1 in 2 P@1	1 in 5 P@1	1 in 5 P@2
#1	Random	50.0%	50.0%	20.0%	40.0%
	TF-IDF+LR	53.2%	58.4%	24.2%	43.0%
	LDA+LR	59.7%	66.7%	35.6%	52.8%
#2	GRU+MLP	65.8%	72.0%	43.4%	67.6%
#3	GRU+iRNN	72.5%	80.3%	54.7%	78.5%
	bi-GRU+iRNN	**73.6%**	**81.7%**	**55.7%**	**80.2%**
	GRU+GRU	**75.8%**	**84.5%**	**63.1%**	**83.3%**
	Attention GRU+iRNN	70.3%	78.0%	51.5%	75.0%
#4	Max CNN+iRNN	73.1%	81.0%	55.1%	80.0%
	Mean CNN+iRNN	73.5%	81.7%	55.8%	80.8%
	Mix CNN+iRNN	74.2%	82.9%	56.9%	81.9%
	Attention CNN+iRNN	**75.7%**	**84.3%**	**60.5%**	**83.5%**
	Attention CNN+GRU	**78.6%**	**87.0%**	**65.1%**	**86.1%**

Table 1: Comparison of different approaches on the context-aware candidate selection task.

The implementation with online learning for LDA (Hoffman et al., 2010) is used for our experiments, with α and β fixed at 0.01 and the number of topics $K = 400$. In all the neural network based experiments, we initialize the learning rate with 0.005, and the network is trained with the Adam update rule (Kingma and Ba, 2014). Early stopping (Giles, 2001) and Dropout (Hinton et al., 2012) are taken to prevent overfitting. As recommend by Krizhevsky et al. (2012), we utilize ReLU as the non-linear active function of convolutional and full-connected layers, and $tanh$ is used for the hidden states of GRU. The dimension of character embedding is 100 for all the NN models. For CNN based sentence modeling layers, the widths of the filter windows are set to 2, 3 and 5 in parallel, and the pooling window covers all the element after convolutional function. The GRU based sentence modeling module holds a 100-unit hidden layer. For conversation modeling layers, the size of the hidden states of iRNN and GRU is set to 300. Finally, the size of the hidden layer of MLP is 50.

3.3 Results & Analysis

Table 1 details the results, and groups them into four categories for the following analysis perspectives:
(a) traditional methods vs. neural networks based ones for modeling short sentences with oral style;
(b) GRU vs. CNN on sentence representation;
(c) aligning sentence embeddings vs. modeling sentence sequences for conversation understanding;
(d) separately modeling sentences vs. sentence representation with attention mechanism;
(e) GRU with attention vs. CNN with attention for sentence representation.

From the results in Table 1, it can be observed that all the models adopting neural network components have notably outperformed TFIDF-LR and LDA-LR. This phenomenon reflects the difficulty of modeling the short sentences with oral style, since the information introduced by pure lexical features introduce is very limited for such text samples. By contrast, both GRU and CNN have the ability of catching the richer semantic information in short texts, according to the layer-by-layer learning upon the distributed character embeddings. Thus, the comparison of aspect (a) shows NN based sentence models are more suitable for conversation utterances.

Further, by comparing GRU+iRNN with CNN+iRNN, aspect (b) tries to figure out which deep learning architecture works better as the sentence modeling module, and our observation is CNN outperforms GRU on the whole task. We ascribe this result to the information bias of sentence embeddings generated by GRU, that is, GRU tends to pay more attention to the words in the end of a sentence. However, for the task discussed by this paper, complete semantics provide more help to context-aware candidate selection as discussed in Section 2.1. The limited improvement of CNN with max pooling also supports our inference. This problem has been partially solved by introducing bi-direction GRU (see bi-GRU+iRNN), it can also be seen that the special defined mixture pooling strategy (Mix CNN+iRNN) can achieve

context	The weather is so bad today, the temperature dips so much! Terrifying, isn't it? The temperature goes down to freezing.				
query	Then, what are you going to do?				
Mix CNN+iRNN	Attention CNN+iRNN	Label	Rank Label	No.	Response
0.782	**0.826**	1	1	#1_1	Let's go to hibernate then.
0.573	0.422	0	2	#1_2	I'll go to work later.
0.150	0.029	0	3	#1_3	How to prove it?
context	What's the point of keeping my phone if it can't connect to Wifi anymore? So what are we waiting for? Buy a new one!				
query	You sponsor me.				
0.808	**0.940**	1	1	#2_1	No phone, no money!
0.840	0.824	1	2	#2_2	How to sponsor?
0.384	0.226	0	3	#2_3	Curiously, this's across both 3G and Wifi.

Table 2: Samples of the response selection. Sentences are translated to English for better understanding.

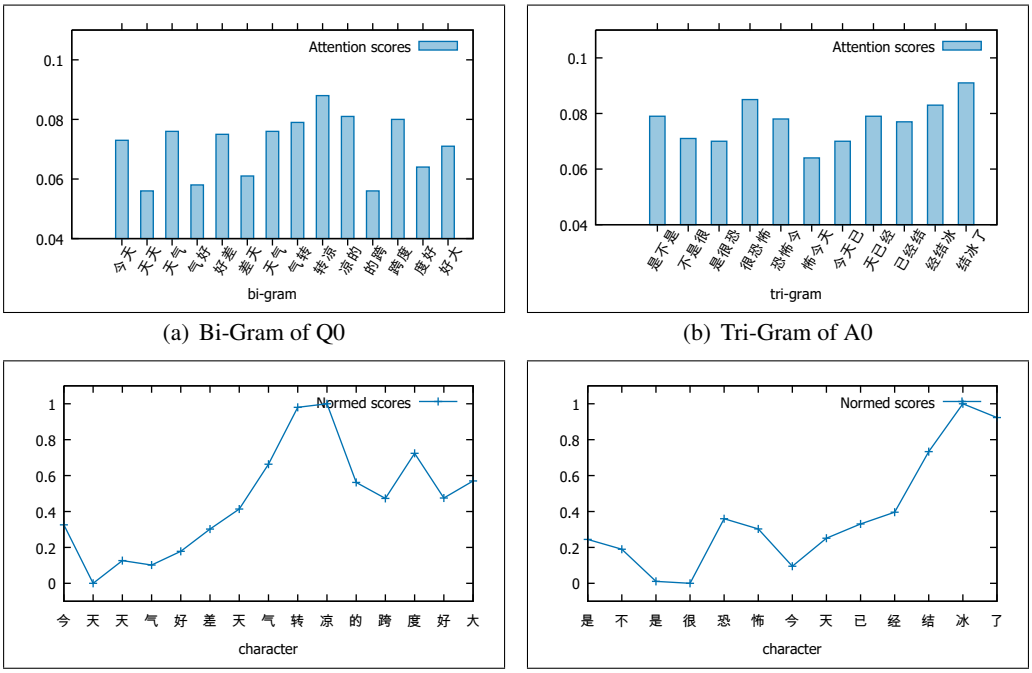
more competitive results, because the advantages of different pooling methods have been integrated for complete semantic representation.

We can easily observe the huge gap between the performances of models in group #2 and group #3. All of these methods take GRU as the sentence modeling layer, but the ones in group 3 adopt RNN based layers for conversation modeling. Since the conversation modeling task is naturally a sequential modeling problem, it is reasonable that models with GRU components achieve better results, which is the motivation of aspect (c). Another observation is iRNN performs fairly well as the conversation modeling layer, with good potential for practical usage. Besides, the comparisons suggest that GRU is indeed more powerful for modeling conversations.

As shown in the results of group #3 and #4, the attention pooling is helpful to improve the precisions, especially on 1 in 5 P@1, which meets the expectation of aspect (d). Nevertheless, when considering aspect(e), it is noticed that GRU with attention (attention GRU+iRNN) gets unsatisfying performance comparing with the ones without attention function. This observation is different from the general impression, since quite a number of studies adopting attention mechanism have good results (Bahdanau et al., 2014; Yao et al., 2015; Hermann et al., 2015; Kumar et al., 2015). We attribute the performance gap to the character-level inputs. In detail, since the attention function is applied on each hidden state, which mainly contains the information of the current input, despite a small amount of previous information involved. Meanwhile, a single Chinese character keeps very limited semantic information, thus the information obtained by the attention function of GRU is incomplete, reflecting some single characters in fact. By contrast, the convolution layer can extract the combinations of characters indicating words or even phrases, and the attention function performed upon such combinations is possible to figure out the important segments with complete semantics, for the upper layer to understand the whole sequence. This is the main reason for our proposed "Attention CNN+GRU" model finally get the best results.

3.4 Case study

To get a better intuition for what the model and attention pooling is learning, we give some cases to illustrate the details. Table 2 gives two groups of query-response pairs, with the predicted scores by Mix CNN+iRNN (MCNN) and Attention CNN+iRNN (ACNN) models. **Label=1** indicates the suitable response to the given context, and the **Rank Label** reflects the candidates' recommendation degrees. It can be seen that scores of both models are aligned with the overall ranking trend, which reflects the models having the ability to quantify the conversational relevance reasonably. It should be noted that the scores given by ACNN are more closed to the labels. More specifically, all the predictions of ACNN are correct, while MCNN makes some incorrect decisions on #1_2 and #2_2. Different from other candidates, the sentences (#1_2 and #2_2) are very sensitive to contexts, in other words, they are natural to answer the corresponding query without considering the contexts. #1_2 has wandered off topic, by contrary, #2_2 can also be a suitable response even it seems #2_1 have better maintenance of the information in the conversation flow. The results of ACNN reflect these phenomena, as the ranking scores express the right disposition and offer higher scores to the more appropriate responses. Besides, the gaps within the



(a) Bi-Gram of Q0

(b) Tri-Gram of A0

(c) Relative attention on chars of Q0

(d) Relative attention on chars of A0

Figure 3: Attention values on the Bi-Gram of Q0 and Tri-Gram of A0 are detailed in sub-figure (a) and (b), where y-axis is the attention value. Sub-figure (c) and (d) give the focus on each char.

groups of ACNN are larger than those scores by MCNN. All these enhancement of the model's ability can be ascribed to the capability of differentiating the matching degree not only correspond to the posted query but also corresponding with to the whole session, obtained by attention pooling to lay particular emphasis on the phrases that the previous conversation focused on.

In order to further illustrate the effect of attention pooling, Figure 3 details the distribution of probabilities given by the attention function to the phrases of the case in Figure 1. Actually, the extra advantage of our framework is that we can locate the key information for candidate selecting, by visualizing the attention weights of phrases and performing proper transforming on them. In detail, we firstly visualize the pooling weights for each character combination in each convolutional kernel as shown by Figure 3(a)-(b), then we assign the weights averaged by the frequencies of the characters in each kernel, and get the curves in Figure 3(c)-(d). According to this operation, we can clearly see which positions in the context considered to be more important when given a query. While it can be seen that, obvious higher weights appeared along the positions of significant words and phrases (marked in **bold**) in Figure 1. Another observation from the histograms is the overall scores of the essential words and phrases are higher than the other char-combinations, which indicates the sentence embedding is mostly draw from the meaningful words. This group of results shows the attention pooling, rather than simple mean pooling, are effective to draw focus on the words and phrases composing the semantic clue in a given conversation.

4 Related Work

Before open-domain chat agents, the task-completion oriented dialog system has been a subject of study for a long time, and most of these studies pay attention to particular vertical domains. Such as *ELIZA* based on simple text parsing rules (Weizenbaum, 1966). Ferguson et al. (1996) built a rule-based system to solve problems in transportation domain; Shawar and Atwell (2007) leverage answer template in generating the *ALICE*; Williams (2010) focus on tracing pre-defined dialogue state. These systems rely on pre-designed rules or templates, which can be hardly generalized on open domain chat-style robots.

Until recently, some works such as (Ritter et al., 2011) demonstrate that the sentences can be generated corresponding to a given post or context using MT techniques. Since the encoder-decoder based Recurrent Neural Networks (RNN) outperforms other methods on MT tasks in the past two years (Bahdanau

et al., 2014; Sutskever et al., 2014), several approaches are directly applied on the conversation modeling task by concatenating the context that modeled by one recurrent encoder (Vinyals and Le, 2015; Shang et al., 2015). Yao et al. (2015) and Serban et al. (2015) model the sentences of context separately by an encoder, and address the sequential embeddings by cumulative hidden units. The main drawback of these approaches is they can't guarantee the readability and variety of generated sentences.

By contrast, the response ranking strategies can avoid the problems caused by direct generation, since this methodology tries to pick up reasonable responses from the human-generated sentences. Ji et al. (2014) proposed an IR approach to generate candidates, and rank them with many kinds of features such as MT, keywords, similarity, etc; Sordoni et al. (2015) and Luan et al. (2016) directly utilize the generating loss of the response for ranking, with the adjusted RNN based encoder-decoder framework. Generally, the architectures introducing CNN or RNN to learn representations of sentences and modeling the relevance of context and candidate response on hyper layers, tend to achieve state-of-the-art performance (Hu et al., 2014; Lowe et al., 2015).

5 Conclusion

In this paper, we have presented a deep learning architecture to quantify the conversational relevance of responses for candidate ranking. The contributions of this paper can be summarized as follows: a) According to the investigation on the role of contexts in conversations, this paper proposes the attention pooling to provide more reasonable context representations, by taking the phrases' different contributions to the semantic clue into consideration. b) We have combined the multi-column convolutional layer and the GRU based layer to build the candidate ranking model, so as to take the advantages of both CNN on sentence modeling and RNN on sequence modeling. c) The proposed model enables the visualization of the achieved essential phrases, and our analysis on them shows the importance of capturing semantic clues for finding conversationally relevant responses.

Abstract

Besides providing the relevant information, amusing users has been an important role of the web. Many web sites provide serendipitous (unexpected but relevant) information to draw user traffic. In this paper, we study the representative scenario of mining an amusing quiz. An existing approach leverages a knowledge base to mine an unexpected property then find quiz questions on such property, based on prototype theory in cognitive science. However, existing *deterministic model* is vulnerable to noise in the knowledge base. Therefore, we instead propose to leverage probabilistic approach to build a prototype that can overcome noise. Our extensive empirical study shows that our approach not only significantly outperforms baselines by 0.06 in accuracy, and 0.11 in serendipity but also shows higher relevance than the traditional relevance-pursuing baseline using TF-IDF.

1 Introduction

Unlike the traditional purpose of the web providing relevant information or answers to user questions, conversely, recent web services ask users unexpected trivia questions to amuse them. Bing provides a set of interesting quizzes with an image of the day on the front page. Figure 1 describes an amusing quiz question generation on a long 'neck' of `giraffe`, which we use as a motivating scenario throughout this paper.

Inspired by Figure 1, we study the problem of finding a "serendipitous" property a such as 'neck' for any given entity e. Table 1 categorizes existing automatic quiz generation efforts pursuing relevance and unexpectedness, respectively. Inspired by Jeopardy!, Seyler et al. (2015) focus on relevance to the domain and a certain difficulty level. Inspired by Bing questions, Lee et al. (2016) seek unexpected entity-property pair (e, a).

In clear contrast, we complement the solution space by pursuing the intersection of finding unexpected but still relevant properties, which is often named as *serendipitous* (or Case B). As the existing *deterministic* model (DM, Lee et al. (2016)) fails to distinguish Case B and C, we propose a new *probabilistic* model (PM).

- DM: Unexpectedness of 'neck' can be found by building a deterministic prototype using the average of (normalized) property frequencies of all MAMMALS. As the frequency of 'neck' for a `giraffe` is far higher than the average, this can be found.

- PM: DM is effective when the underlying data (*i.e.*, knowledge base) to derive probabilities are not noisy, but an automatically harvested knowledge base inevitably contains noise. For example, Probase, mining textual patterns such as "<property> of <category>," may contain 'some part' as a property of a `giraffe`, which can be recognized as a desirable unexpected property by DM. We propose a probabilistic model that overcomes this problem.

2 Related work

This paper studies the serendipitous property mining problem of finding relevant yet unexpected properties for a given entity based on a knowledge base. Therefore, our work is closely related to knowledge acquisition. Also, mining unexpected part of knowledge can be considered as serendipitous mining or outlier detection.

2.1 Knowledge acquisition

Our serendipitous property mining system leverages automatically harvested knowledge on the web. Particularly, measuring unexpectedness requires knowing the expectation, which requires worldly knowledge. The basis of such knowledge acquisition works is taxonomies that contain categories and their entities (Carlson et al., 2010; Suchanek et al., 2007; Wu et al., 2012). Among them, Probase (Wu et al., 2012) provides a conditional probability of an entity for a category, and also that of a property given an entity, from which we probabilistically model the expectation (*i.e.*, prototype in our approach).

Besides the automatically harvested knowledge bases, other types of knowledge such as a traditional DB (Merzbacher, 2002) or a linked open data (Marie et al., 2013) are manually generated and often do not cover new entities, like new idols possibly attracting click-through. Therefore, we rely on an automatically harvested knowledge base.

2.2 Serendipitous mining

The primary metric for recommender system is prediction accuracy. However, focusing solely on this metric is reported to limit user satisfaction by always recommending predictable items, such as a new comedy for a comedy fan who can discover it without recommendation. To amuse users, serendipitous mining is studied in recommendation and search. Several approaches (Onuma et al., 2009; Nakatsuji et al., 2010) focus on finding serendipitous items such as funny zombie movie, which is both relevant and unexpected, from user-item matrices. Another direction is pursuing serendipity in search: The existing approaches propose to consider emotional expressions (Hauff and Houben, 2012; Bordino et al., 2013) or presentations such as bold font (O'Brien, 2011), to detect surprises and apply that in search results. These efforts cannot be applied to our problem as a user-item matrix or the text format is unavailable, but our knowledge-based signals are orthogonal and thus can be straightforwardly applied to improve both lines of the work.

2.3 Outlier detection

The unexpected property mining can be considered as an outlier detection problem. Outlier detection has been extensively studied with different approaches. Deviation-based approaches find observations whose removal greatly reduces the sample variance (Arning et al., 1996). Distance-based approaches define a distance measure and consider observations whose distance to others is above a threshold as outliers (Knorr and Ng, 1997; Ramaswamy et al., 2000; Fan et al., 2006). Density-based approaches

consider observations which have little or no neighbors as outliers (Jin et al., 2006). Most of these approaches are designed, trained, or tuned for a target domain using labeled data or using user specified parameters, which is not suitable for our scenario targeting diverse categories. Moreover, these solutions categorize observations into two: normal observations and outliers. Lee et al. (2016), mining quiz questions given images, also leverage the similar notion of classifying the properties into the two, which we use as a baseline and show their ineffectiveness in our experiments, due to their inability to distinguish noise and serendipitous properties.

3 Knowledge base

We leverage an automatically harvested knowledge base for human-like unexpected and relevant property mining. In particular, we leverage Probase *'is-a'* knowledge and its property data to mine probabilities, which is essentially equivalent to deriving probabilities from a huge corpus. Probase is a large knowledge base containing millions of categories and their information including *entities*, *properties*, and their *typicalities* which we describe below.

Is-A knowledge

The backbone of Probase is probabilistic knowledge of huge amount of *'is-a'* relations between entities and categories (Wu et al., 2012)[1]. For example, Probase contains a relation: "`giraffe` *is-a* MAMMAL" where `giraffe` is an entity and MAMMAL is a category. A category may contain many entities (*e.g.*, MAMMAL contains `giraffe` and `platypus`), and an entity may also belong to several categories (*e.g.*, `giraffe` belongs to both MAMMAL and ANIMAL). Such relationships are mined from a huge amount of web documents using patterns (Wu et al., 2012).

Property knowledge

Properties are words representing a certain aspect of an entity. For example, 'neck' is a property of the entities in category MAMMAL. Properties of an entity are obtained by several approaches including pattern-based extraction methods (Lee et al., 2013).

Typicality

Based on the number of pattern occurrences, we can compute the conditional probability of a certain element given a condition, which we also call *typicality*. For example, given category MAMMAL, people would usually think of typical mammals such as `dog`. In particular, Probase has diverse types of typicalities including the *entity typicality for a category*, and *property typicality for an entity*.

$P(E|C)$ is a conditional probability of entity E given category C. For example, we can obtain the probability $P(E = \text{giraffe}|C = \text{mammal})$, representing how typical entity `giraffe` is for category MAMMAL. Such probability can be obtained using all occurrences of MAMMAL, and the co-occurrences of MAMMAL and `giraffe`:

$$P(E = \text{giraffe}|C = \text{mammal}) = \frac{\text{Freq}(\text{mammal}, \text{giraffe})}{\text{Freq}(\text{mammal})} \quad (1)$$

where $\text{Freq}(x, y)$ represents the co-occurrence of x and y, and $\text{Freq}(x)$ indicates the occurrence of x in Probase. We can similarly compute other probabilities including $P(C)$, $P(E)$, $P(C|E)$. Also, we can obtain $P(A|E)$ where A is a property and E is an entity.

We can consider a typicality as the amount of people's interest in the topic since it is derived from how frequently we discuss the topic. We usually have general topics of interest for entities in a certain category: 'lifespan', 'diet', 'size' and so on for mammals. But, if the heart of a giraffe is often discussed in comparison to other mammals, it can be an unexpected topic about a giraffe.

[1]Probase knowledge base is publicly available online at https://concept.research.microsoft.com/.

4 Methods

In this section, we describe our approach to model prototype and mine serendipitous properties. We follow the framework presented in (Lee et al., 2016) that leverages the category of a given entity, and propose a method for unexpected property mining. Therefore, we assume that we have the given topic entity e, and its category c.

4.1 Modeling a prototype

Identifying an unexpected property of an entity requires comparison to what we consider expected. If we expect most mammals have a heart with the size in a specific range, the extra large heart of a `giraffe` can be unexpected. Therefore, defining the prototype of a category—which represents the human expectation for entities in the category— is the key step to find serendipitous properties. We may consider selecting a typical entity among the existing entities in the category (such as `dog` for MAMMAL). However, typical properties such as 'lifespan' can be missing with `dog` due to data sparsity. In this case, 'lifespan' of any entity can be rather considered unexpected.

DM (Lee et al., 2016) models a deterministic prototype model $\mathcal{R}_c^{\text{DM}}$ as a *hypothetical* entity using the average typicalities in the category. Note that, instead of the values of properties, their typicalities are leveraged to directly capture the human interest on the properties for entities and the category. That is, high $P(\text{height}|\text{giraffe})$ means that 'height' draws human interest so that it is discussed frequently with `giraffe` on the web. If some property is frequently mentioned with most entities in a category, it can be considered the representative property of the category. Then, we can consider some property of an entity is unexpected if the property is particularly more frequently mentioned with the entity than with other entities in the category.

Thus, using the average of typicalities allows us to compute the representativeness of the property for the category (*e.g.*, MAMMAL). Formally, $\mathcal{R}_c^{\text{DM}}$ is defined as an ordered set of the average of property typicalities in the category c as follows:

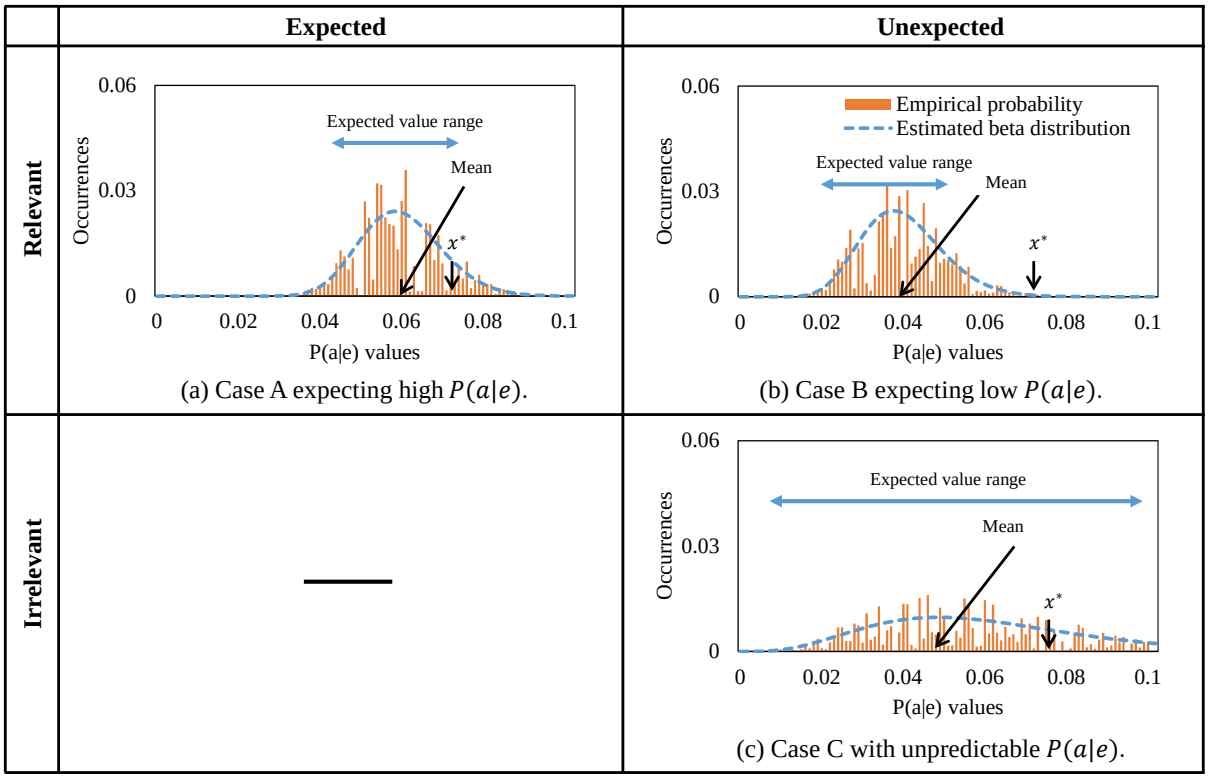
$$\mathcal{R}_c^{\text{DM}} = \{\text{avg}_{e \in c}\, P(a|e)P(e|c) \mid a \text{ is a property}\} \tag{2}$$

where $P(a|e)$ is the property typicality given entity, and $P(e|c)$ is the entity typicality given category (Section 3). This hypothetical prototype does not suffer from missing properties caused by data sparsity. However, this approach is vulnerable to noise of another cause: 'some part', wrongfully identified as a property, would be considered unexpected due to its infrequency.

Instead of this deterministic approach, we leverage a probabilistic method similar to (Eskin, 2000), which is originally designed for intrusion detection, to model the prototype. Unlike its category-agnostic approach using a Markov chain, we leverage the category information to model the prototype with beta distributions. In particular, we define a prototype of category c hypothetically as an ordered set of random variables $\mathcal{R}_c = \{X_{a,c}|a \text{ is a property}\}$ (an example distribution of $X_{a,c}$ is shown as the blue dashed line in Figure 2(b)). That is, unlike DM using averages to produce an ordered set of expected typicalities, we build probability distributions.

Given this model, we can consider that the properties of an entity in the category are realizations of the random variables. To illustrate, suppose we have $\mathcal{R}_c = \{X_{lifespan,mammal}, X_{tail,mammal}, X_{heart,mammal}\}$, and typicalities of `dog` $P(\text{lifespan}|\text{dog})$, $P(\text{tail}|\text{dog})$, and $P(\text{heart}|\text{dog})$ are 0.3, 0.6, and 0.1 respectively. Then, we consider 0.3, 0.6 and 0.1 are realizations of $X_{\text{lifespan,mammal}}$, $X_{\text{tail,mammal}}$ and $X_{\text{heart,mammal}}$ with the corresponding probabilities $P(X_{\text{lifespan,mammal}} = 0.3)$, $P(X_{\text{lifespan,mammal}} = 0.6)$, and $P(X_{\text{lifespan,mammal}} = 0.1)$. By measuring the likelihood of this event (having 0.3, 0.6, and 0.1) using these probabilities, we can measure how unexpected this entity or its properties are. Later in Section 4.2, we will argue how this model distinguishes Case B and C in Figure 2 and explain how we measure the unexpectedness.

Formally, we consider an entity of the category as an ordered set of properties represented as $\{P(a|e)\}$ (*e.g.*, $\{0.3, 0.6, 0.1\}$) each of which is drawn from the corresponding random variable in $\mathcal{R}_c$. The co-occurrences of properties and entities can be modeled to be drawn from a multinomial distribution. Then,



(a) Case A expecting high $P(a|e)$.

(b) Case B expecting low $P(a|e)$.

(c) Case C with unpredictable $P(a|e)$.

Figure 2: Distribution of $X_{a,c}$.

the typicality $P(a|e)$ for each a constitutes parameter probabilities $p_1, \ldots, p_k$ of the multinomial distribution $Mult(n|p_1, \ldots, p_k)$. We exploit a Dirichlet distribution of a single dimension, which is a beta distribution, to model $P(a|e)$ since a Dirichlet distribution is a conjugate prior of a multinomial distribution. That is, each random variable $X_{a,c}$ in prototype $\mathcal{R}_c$ is modeled as a beta distribution corresponding to a property of entities in category c: $X_{a,c} \sim Beta(x; \alpha_{a,c}, \beta_{a,c})$.

Now we have to learn the parameters specifying the beta distributions $Beta(x; \alpha_{a,c}, \beta_{a,c})$ of the prototype $\mathcal{R}_c$. In particular, we use a set $O_{a,c}$ of property typicality $P(a|e)$ for each entity e in the identified category c as samples together with its occurrence probability $P(e|c)$, that we obtain from Probase. That is, we give a larger weight to a more typical entity in the model. Let $X_{a,c}$ be a random variable modeled by a beta distribution $Beta(x; \alpha_{a,c}, \beta_{a,c})$. We find parameters $\alpha_{a,c}$ and $\beta_{a,c}$ so that $X_{a,c}$ generates the observation $O_{a,c} = \{x^e_{a,c} = P(a|e) | e \in c\}$ with their associated occurrences $P(e|c)$. Then, we have $P(x_1 \leq X_{a,c} < x_2) = \sum_{e \text{ s.t. } x_1 \leq P(a|e) < x_2} P(e|c)$. Thus, the mean μ of the beta distribution $Beta(x; \alpha_{a,c}, \beta_{a,c})$ is $\sum_{e \in c} P(a|e)P(e|c)$, and the variance σ^2 is $\sum_{e \in c} (P(a|e) - \mu)^2 P(e|c)$. The parameters $\alpha_{a,c}$ and $\beta_{a,c}$ can be fitted by the widely adopted method of moments using the mean and the variance, of exploiting the first and second moments of $Beta(x; \alpha_{a,c}, \beta_{a,c})$.

4.2 Mining unexpected properties

With the obtained probabilistic prototype $\mathcal{R}_c = \{X_{a,c} | a \text{ is a property}\}$ for category c, we discover serendipitous properties of the given entity, and show why noisy properties are not mined. We can consider that entities in the category are created by drawing each property typicality $P(a|e)$ from the beta distribution of the prototype. If a property typicality of the given entity is unlikely based on the prototype, we can consider the property is serendipitous.

We show how a property of the topic entity can be compared with that of the prototype. We divide the comparison into three cases that we have described in the introduction (Table 1): relevant and expected, unexpected but relevant (serendipitous), and noisy. Figure 2 shows examples of the component random variables $X_{a,c}$ of the model for Case A, B, and C in Table 1. Then, we consider how likely the given entity to be generated.

Case A: Property is relevant and expected

First, Figure 2(a) depicts a distribution skewed to high values. For example, 'lifespan' is a common property for the most of entities in MAMMAL. Therefore, high $P(\text{lifespan}|\text{giraffe})$ does not mean `giraffe` has an unexpected property.

Case B: Property is unexpected, but relevant (serendipitous)

In contrast, Figure 2(b) shows a distribution skewed to low $P(a|e)$. In this case, we expect a relatively low value, and thus high $P(a|e)$ of the topic entity implies a serendipitous event. For example, although the most entities in MAMMAL have a property 'neck,' it is not frequently mentioned, and hence we expect to have low $P(\text{neck}|e)$ value. Therefore, the distribution of $X_{\text{neck,mammal}}$ is skewed to low values. Then, the high value of $P(\text{neck}|\text{giraffe})$ indicates that `giraffe` has an serendipitous property 'neck.'

Case C: Property is noisy

Unlike Case A and B modeling relevant properties, the prototype may include a random variable representing a noisy property. Specifically, when a noisy property is modeled, it looks like Figure 2(c). A noisy property does not show a general tendency, and it is rather randomly distributed as often modeled by a uniform distribution. That is, since a noisy property is modeled like a uniform-esque distribution as shown in Figure 2(c), the most value of $P(a|e)$ is expected to happen, and would not be considered serendipitous.

Computing unexpected relevance

Based on these observations, we compute our measure of serendipitous properties. Formally, as exploited in (Eskin, 2000), we compute the log-likelihood of an entity-property probability $P(X_{a,c} = x^e_{a,c})$ of the given topic entity using the obtained distribution for $X_{a,c}$ of $\mathcal{R}_c$. In addition, we use a minus sign to obtain a measure indicating a more serendipitous property with a greater value.

$$\begin{aligned} I(x^e_{a,c}) &= -\log(P(X_{a,c} = x^e_{a,c})) \\ &= -\log Beta(x; \alpha_{a,c}, \beta_{a,c}) \end{aligned} \tag{3}$$

Upon this value, we also consider that a serendipitous property of a well-known or more typical entity can more easily draw user attention. Thus, we quantify the degree of being serendipitous for property a of entity e that belongs to category c as follows.

$$H(c, e, a) = I(x^e_{a,c})P(e|c) \tag{4}$$

We measure this value for each property of the given topic entity, and consider one with the highest score the most interesting, so that we present it to users.

5 Evaluation

In this section, we evaluate our systems using various measures evaluating several facets of the proposed work. Throughout the evaluation, we compare our method PM with DM (Lee et al., 2016) in the same setting of using Flickr and Yahoo! Answers.

5.1 Serendipitous property discovery

In this section, we analyze and evaluate serendipitous property mining. Table 2 first shows examples of the top serendipitous entity-property pairs for diverse categories returned by PM and DM. We can observe that DM is prone to pick long phrasal nouns or noisy properties, which are less commonly mentioned. DM considers (possum, plural) and (intel, fourth piece) unexpected because the conditional probabilities $P(\text{plural}|\text{mammal})$ and $P(\text{fourth piece}|\text{company})$ are very low while $P(\text{plural}|\text{possum})$ and $P(\text{fourth piece}|\text{intel})$ are not. On the other hand, our approach does not propose noisy properties, by modeling such noises together. Instead, our approach suggests entity-property pairs such as (marsupial, embryo), (microsoft, founder), or (china, population) that would lead to interesting information. For

Table 2: Mined unexpected entity-property pairs for diverse categories.

Category	PM	DM
mammal	(marsupial, embryo), (giraffe, heart), (chimpanzee, brain), ...	(wolf, strength), (muskrat, best part), (otter, presence), ...
company	(microsoft, founder), (facebook, founder), (amazon.com, success), ...	(intel, fourth piece), (dell, model number), (coca-cola, original color), ...
country	(china, great wall), (china, population), (india, population), ...	(china, great wall), (china, choices), (india, reserve bank), ...
metal	(copper, resistivity), (gold, price), (gold, purity), (lead, density), ...	(copper, discovery), (lead, presence), (iron, presence), (aluminum, presence), ...
drug	(cocaine, price), (marijuana, legalization), (marijuana, odor), ...	(marijuana, 80 pounds), (cocaine, freebase form), (cocaine, last use), ...

Table 3: Unexpectedness of discovered properties

Method	SS@5
PM	0.31
DM	0.25

example, unlike other mammals, a marsupial has a pouch on her stomach to carry her babies. China is known to have the largest population in the world.

We also quantitatively evaluate the accuracy, or how well the discovered serendipitous properties are aligned with human judges. The serendipitous property (Case B in Table 1) should be relevant to the given entity and category pair, but peculiar in the category. In addition, the property is the most useful in our scenario drawing users if the property leads to a novel information (less known). We build a labeled dataset by annotating the mined property with the serendipitous score on a scale of 0, 1/3, 2/3 and 3/3. In particular, 3/3 point is given if the property is relevant, peculiar, and novel; 2/3 point is given if the property is relevant, and peculiar; 1/3 point is given if the property is relevant; and 0 point is given if the property is irrelevant. For example, the population of China is extraordinarily large which is serendipitous, but this property is well known so that we give 2/3. We have built a gold standard of size 386 independently labeled by three assessors from which we observe sufficient agreement (0.64 pairwise cosine similarity), and thus use the average of the scores assigned by the assessors. We leverage *SS@5*, the average serendipitous scores of the top-5 properties for each entity.

Table 3 shows the evaluation result of serendipitous property discovery methods. We see that ours show the highest score. While our approach might find a typical property for a typical entity (*e.g.*, 'size' for `dog`), the discovered properties are mostly relevant, and often peculiar. On the other hand, DM frequently present irrelevant ones such as noisy properties (*e.g.*, 2 cups, oldddddddd guns), and thus show the lower scores.

5.2 Trivia question mining evaluation

We plug in our method into the framework of (Lee et al., 2016) that seeks trivia quizzes from image tags. We compare the trivia quiz mining results using our serendipitous property mining module and that of (Lee et al., 2016). Our evaluation procedure is based on an serendipitous document mining work (Bordino et al., 2013). Bordino et al. (2013) use both rank-agnostic accuracy of top-N results (Section 5.2.1) and rank correlation of treating its rank differently (Section 5.2.2).

5.2.1 Relevance and serendipity

We measure both relevance, and *serendipity* (*i.e.*, pleasant surprise) using the evaluation procedure introduced by (Ge et al., 2010). to evaluate a recommender system or a serendipitous web search method. It shares the same spirit as our goal that we amuse users with serendipitous properties.

Both for relevance and serendipity, we label question relevance into *relevant* (1) and *irrelevant* (0). We randomly show a query image and one of the top N result questions from any methods so that an assessor is not biased to a certain method. Note that no other information is shown to the assessor.

Then, we first measure the average relevance of the results for all images in J for each method. Formally, we compute the relevance as follows.

$$Average\ relevance@N = \frac{\sum_j \sum_k^N rel_{j,k}}{N|J|} \tag{5}$$

where $rel_{j,k}$ is the relevance (1 or 0) of the rank k question for $j \in J$.

Measurements of serendipity have been established in the context of evaluating recommendation systems (Ge et al., 2010; Shani and Gunawardana, 2011). Specifically, (Ge et al., 2010) evaluates serendipity as the ratio of unexpected but relevant results based on a *benchmark model* that generates expected recommendations, which are relevance-pursuing results. That is, from the result questions of each method, we remove the expected ones that are retrieved by the benchmark model. Then the remainder is considered unexpected. By checking the relevance of the remainder, we measure the relevance of the unexpected results.

As a benchmark model, we might consider Yahoo! Answers search results or TF-IDF-based results using the host page keywords. Unfortunately, Yahoo! Answers returns very few or no results when there are more than two keywords, which is often much less than the number of keywords an image has (*e.g.*, "giraffe zoo savanna" gives no result on Yahoo! Answers). To make the matters worse, obtaining top 100 results for subsets of keywords on Yahoo! Answers and joining the results also gives few or no intersection. Therefore, we use TF-IDF to obtain the benchmark results.

Formally, suppose that $BM@N$ is the top N questions retrieved by the benchmark model, and $RS@N$ is the top N questions retrieved by a method we want to test. Then, we calculate the unexpected recommendation set as follows.

$$UNEXP@N = RS@N - BM@N \tag{6}$$

These unexpected recommendations may or may not be relevant to the query, but we want unexpected but still relevant ones. Therefore, we measure the serendipity based on the relevance of each item in $UNEXP$. Based on relevance labels $rel_{j,k}$ of k-th result for image j, serendipity is defined as follows.

$$SRDP(RS)@N = \frac{\sum_{(j,k)\in UNEXP@N} rel_{j,k}}{N} \tag{7}$$

Table 4: Average question relevance and serendipity at N.

Method	*Rel.*@5	*Rel.*@10	*SRDP@5*	*SRDP@10*
PM	**0.6689**	**0.6607**	**0.6662**	**0.6275**
DM	0.5672	0.5820	0.5562	0.5819
TF-IDF	0.6190	0.6048	-	-

Table 4 shows the average relevance and the serendipity of each method. As a reference, we also include TF-IDF, which does not consider unexpectedness, to show the results of a typical relevance-pursuing model. Note that TF-IDF is the benchmark model and hence it does not provide unexpected questions for serendipity.

We may anticipate that the methods pursuing serendipity may have lower relevance, since such methods would avoid highly relevant results, which are often expected. Thus, DM shows lower relevance

Table 5: Average Kendall coefficient for the questions.

Methods	Q1.	Q2.	Q3.	Q4.
PM	**0.4960**	**0.3980**	**0.2486**	**0.3538**
DM	-0.0558	-0.0764	-0.2567	-0.2026

than PM because it gives lower score to those close to the average, but it may instead acquire and leverage noisy properties as unexpected. For example, DM may consider 'fourth piece' of `Intel`, which is extracted due to ambiguity and hence rare in the category, as unexpected. Therefore, it leverages such a property and in turn mines irrelevant trivia quizzes. We can also see that our approach shows higher serendipity than the baseline regardless of N. As in relevance, the baseline shows low serendipity because they highlight noisy properties as we have already seen in Section 5.1. Note that we can see PM show comparable or better relevances with TF-IDF as our approach pursuing serendipitous properties distinguishes noises.

5.2.2 Kendall's tau-b rank correlation coefficient

We evaluate the results considering their ranks using *Kendall's tau-b rank correlation coefficient* (Kendall, 1938). Kendall's coefficient ranges from -1 (perfect ranking disagreement) to +1 (perfect ranking agreement).

We build a reference ranking according to the several evaluation dimensions since "pleasant" in serendipity (pleasant surprise) can be interpreted in different ways. Therefore, we use several criteria such as 'more relevant questions rank higher' based on (Bordino et al., 2013) and evaluate individual dimensions. Specifically, we generate a task with a photograph and two randomly chosen result trivia quizzes out of those returned by all tested methods. A result trivia quiz that is more suitable for each of the following criteria is labeled as 'better.'

- Q1. The trivia quiz is relevant to the image.
  (*i.e.*, 'pleasant' means 'relevant')
- Q2. If someone is interested in the image, they would also be interested in the trivia quiz.
  (*i.e.*, 'pleasant' means 'interesting given interest to the image')
- Q3. Even if you are not interested in the image, the trivia quiz is interesting to you personally.
  (*i.e.*, 'pleasant' means 'interesting regardlessly to the image')
- Q4. You learn something new about the image from the trivia quiz.
  (*i.e.*, 'pleasant' means 'novel')

Note that Q2 and Q3 try to evaluate both the image or topic-centric view of interestingness (Q2), and the intrinsic interestingness of the trivia quiz (Q3) as in (Bordino et al., 2013). For example, if a method shows high performance on Q3 but not on Q2, its trivia quiz tends to deviate much from the image/topic. However, the method is anyway presenting interesting trivia quiz.

A human assessor has to label each of criteria for a given task. As used in (Bordino et al., 2013), the reference ranking for each criterion is built by a simple voting-based approach, by ranking items with the greater number of 'better' votes higher. Since this evaluation may heavily depend on human assessors, we validate the gold standard by measuring the agreement. Thirty tasks are randomly sampled and evaluated by four human assessors. We measure Fleiss' kappa (Fleiss, 1971) to obtain $\kappa = 0.57$, which shows moderate agreement (Landis and Koch, 1977). In addition, considering only confident answers by removing those tasks with any 'not sure' vote, we obtain higher agreement $\kappa = 0.71$, which shows substantial agreement.

The evaluation result using Kendall coefficient is shown in Table 5. We can see that our method outperforms the baseline. In particular, our approach retains a high positive correlation with the reference rankings based on user perception. On the other hand, the baseline method shows low or negative correlation with all reference rankings.

6 Conclusions and future work

This paper studies the serendipitous property mining problem of finding relevant yet unexpected properties for a given entity. Although the serendipitous information mining is important for industry to increase website traffic, it has not been studied actively on general knowledge due to lack of knowledge or having noisy knowledge. Such noisy knowledge is challenging as noisy properties can be evaluated as unexpected. We empirically show that probabilistic modeling of a prototype for each category alleviates the noise problem, while the existing approach is prone to pick up the noisy properties that may significantly detract the user experience of the applications like trivia questions. Our evaluation results suggest that our approach shows not only higher serendipity than the baselines, but also higher relevance than a traditional baseline using TF-IDF optimized for relevance.

We expect many research topics can be stemmed from our work. One possibility of modeling a prototype would be neural embedding. Comparing its performance with our probabilistic model will be a good research direction. Meanwhile, our approach is limited to properties, and the proposed framework evaluates one property of an entity at each time. But taking relations into account, or considering more than one properties/relations may give even more interesting questions and facts. Also, we expect a similar approach can be exploited to mine outstanding issues from social network data which have a considerable amount of noise.

Identifying Cross-Cultural Differences in Word Usage

Aparna Garimella and **Rada Mihalcea**
University of Michigan
{gaparna,mihalcea}@umich.edu

James Pennebaker
University of Texas at Austin
pennebaker@utexas.edu

Abstract

Personal writings have inspired researchers in the fields of linguistics and psychology to study the relationship between language and culture to better understand the psychology of people across different cultures. In this paper, we explore this relation by developing cross-cultural word models to identify words with cultural bias – i.e., words that are used in significantly different ways by speakers from different cultures. Focusing specifically on two cultures: United States and Australia, we identify a set of words with significant usage differences, and further investigate these words through feature analysis and topic modeling, shedding light on the attributes of language that contribute to these differences.

1 Introduction

According to Shweder et al. (1998), "to be a member of a group is to think and act in a certain way, in the light of particular goals, values, pictures of the world; and to think and act so is to belong to a group."

Culture can be defined as any characteristic of a group of people, which can affect and shape their beliefs and behaviors (e.g., nationality, region, state, gender, or religion). It reflects itself in people's everyday thoughts, beliefs, ideas, and actions, and understanding what people say or write in their daily lives can help us understand and differentiate cultures. In this work, we use very large corpora of personal writings in the form of blogs from multiple cultures[1] to understand cultural differences in word usage.

We find inspiration in a line of research in psychology that poses that people from different cultural backgrounds and/or speaking different languages perceive the world around them differently, which is reflected in their perception of time and space (Kern, 2003; Boroditsky, 2001), body shapes (Furnham and Alibhai, 1983), or surrounding objects (Boroditsky et al., 2003). As an example, consider the study described by Boroditsky et al. (2003), which showed how the perception of objects in different languages can be affected by their gender differences. For instance, one of the words used in their study is the word "bridge," which is masculine in Spanish and feminine in German: when asked about the descriptive properties of a bridge, Spanish speakers described bridges as being *big*, *dangerous*, *long*, *strong*, *sturdy*, and *towering*, while German speakers said they are *beautiful*, *elegant*, *fragile*, *peaceful*, *pretty*, and *slender*.

While this previous research has the benefit of careful in-lab studies that explore differences in world view for one dimension (e.g., time, space) or word (e.g., bridge, sun) at a time, it also has limitations in terms of the number of experiments that can be run when subjects are being brought to the lab for every new question being asked. We aim to address this shortcoming by using the power of large-scale computational linguistics, which allows us to identify cultural differences in word usage in a data-driven bottom-up fashion.

We hypothesize that we can use computational models to identify differences in word usage between cultures, regarded as an approximation of their differences in world view. Rather than starting with predetermined hypotheses (e.g., that Spanish and German speakers would have a different way of talking about bridges), we can use computational linguistics to run experiments on hundreds of words, and

[1] Throughout this paper, we use the term culture to represent the nationality (country) of a group of people.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 674–683, Osaka, Japan, December 11-17 2016.

consequently identify those words where usage differences exist between two cultures. We explore this hypothesis by seeking answers to two main research questions.

First, given a word W, are there significant differences in how this word is being used by two selected cultures? We build cross-cultural word models in which we use classifiers based on several classes of linguistic features and attempt to differentiate between usages of the given word W in different cultures. By applying them to a large number of words, these models are used to identify those words for which there exist significant usage differences between the two cultures of interest.

Second, if such significant differences in the usage of a word are identified, can we use feature analysis to understand the nature of these differences? We perform several analyses: (1) Feature ablation that highlights the linguistic features contributing to these differences; (2) Topic modeling applied to the words with significant differences, used to identify the dominant topic for each culture and to measure the correlation between the topic distributions in the two cultures; and (3) One-versus-all cross-cultural classification models, where we attempt to isolate the idiosyncrasies in word usage for one culture at a time.

2 Data

We base our work on personal writings collected from blogs, and specifically target word usage differences between Australia and United States. These two countries are selected for two main reasons: (1) they both use English as a native language, and therefore we can avoid the noise that would otherwise be introduced by machine translation; and (2) they have a significant number of blogs contributed in recent years, which we can use to collect a large number of occurrences for a large set of words.

We obtain a large corpus of blog posts by crawling the blogger profiles and posts from Google Blogger. For each profile, we consider up to a maximum of 20 blogs, and for each blog, we consider up to 500 posts. Table 1 gives statistics of the data collected in this process. We process the blog posts by removing the HTML tags and tagging them with part-of-speech labels (Toutanova et al., 2003).

Country	Profiles	Blogs	Posts
Australia	469	1129	320316
United States	374	1267	471257

Table 1: Blog statistics for the two target cultures.

Next, we create our pool of candidate target words by identifying the top $1,500$ content words based on their frequency in the blog posts, additionally placing a constraint that they cover all open-class parts-of-speech: of the $1,500$ words, 500 are nouns, 500 verbs, 250 adjectives, and 250 adverbs. These numbers are chosen based on the number of examples that exist for the target words; e.g., most (> 490) of the 500 selected nouns have more than 300 examples; etc. We consider all possible inflections for these words, for instance for the verb *write* we also consider the forms *writes*, *wrote*, *written*, *writing*. The possible inflections for the target words are added manually, to ensure correct handling of grammatical exceptions.

To obtain usage examples for the two cultures for these words, we extract paragraphs from the blog posts that include the selected words with the given part-of-speech. Of these paragraphs, we discard those that contain less than ten words. We also truncate the long paragraphs so they include a maximum of 100 words to the left and right of the target word, disregarding sentence boundaries. The contexts of the target words are then parsed to get the dependency tags related to the target word (Klein and Manning, 2003). We also explicitly balance the data across time. Noting there could be cases where the number of blog posts published in a specific year is higher compared to that in other years due to certain events (e.g., an Olympiad, or a major weather related event), we draw samples for our dataset from several different time periods. Specifically, for each culture, we consider an equal number of instances from four different years (2011-2014). Table 2 shows the per-word average number of data instances obtained in this way for each part-of-speech for each culture for the years 2011-2014.

Note that we do not attempt to balance the data across topics (domains), as we regard potentially different topic distributions as a reflection of the culture (e.g., Australia may be naturally more interested

in water sports than United States is). We do instead explicitly balance our data over time, as described above, to avoid temporal topic peaks related to certain events.

Country	Noun	Verb	Adj	Adv
Australia	22461	18396	19206	19377
United States	15199	12347	12513	12952

Table 2: Average number of instances for the 1,500 target words for the years 2011-2014.

3 Finding Words with Cultural Bias

We start by addressing the first research question: given a word W, are there significant differences in how this word is being used by two different cultures? We formulate a classification task where the goal is to identify, for the given target word W, the culture of the writer of a certain occurrence of that word. If the accuracy of such a classifier exceeds that of a random baseline, this can be taken as an indication of word usage differences between the two cultures. We run classification experiments on each of the $1,500$ words described in the previous section, and consequently aim to identify those words with significant usage differences between Australia and United States.

3.1 Features

We implement and extract four types of features:

Local features. These features consist of the target word itself, its part-of-speech, three words and their parts-of-speech to the left and right of the target concept, nouns and verbs before and after the target concept. These features are used to capture the immediately surrounding language (e.g., descriptors, verbs) used by the writers while describing their views about the target word.

Contextual features. These features are determined from the global context, and represent the most frequently occurring open-class words in the contexts of the word W in each culture. We allow for at most ten such features for each culture, and impose a threshold of a minimum of five occurrences for a word to be selected as a contextual feature. Contextual features express the overall intention of the blogger while writing about the target word.

Socio-linguistic features. These features include (1) fractions of words that fall under each of the 70 Linguistic Inquiry and Word Count (LIWC) categories (Pennebaker et al., 2001); the 2001 version of LIWC includes about 2,200 words and word stems grouped into broad categories relevant to psychological processes (e.g., emotion, cognition); (2) fractions of words belonging to each of the five fine-grained polarity classes in OpinionFinder (Wilson et al., 2005), namely strongly negative, weakly negative, neutral, weakly positive, and strongly positive; (3) fractions of words belonging to each of five Morality classes (Ignatow and Mihalcea, 2012), i.e., authority, care, fairness, ingroup, sanctity; and (4) fractions of words belonging to each of the six Wordnet Affect classes (Strapparava et al., 2004), namely anger, disgust, fear, joy, sadness, and surprise. These features provide social and psychological insights into the perceptions bloggers have about the words they use.

Syntactic features. These features consist of parser dependencies (De Marneffe et al., 2006) obtained from the Stanford dependency parser (Klein and Manning, 2003) for the context of the target word. Among these, we select different dependencies for each part-of-speech: (1) nouns: root word of context (`root`), governor[2] if noun is nominal subject (`nsubj`), governor verb if noun is direct object (`dobj`), adjectival modifier (`amod`); (2) verbs: root, nominal subject (`nubj`), direct object (`dobj`), adjectival complement (`acomp`), adverb modifier (`advmod`); (3) adjectives: root, noun being modified (`amod`), verb being complemented (`acomp`), adverb modifier (`advmod`); (4) adverbs: root, adverb modifier (`advmod`). These features capture syntactic dependencies of the target word that are not always obtained using just its context.

[2]We follow the convention provided in `http://nlp.stanford.edu/software/dependencies_manual.pdf`

3.2 Cross-cultural Word Models

The features described above are integrated into an AdaBoost classifier.[3] This classifier was selected based on its performance on a development dataset, when compared to other learning algorithms. We compare the performance of the classifier with a random choice baseline, which is always 50%, given the equal distribution of data between the two cultures. This allows us to identify the words for which we can automatically identify the culture of the writers of those words, which is taken as an indication of word usage differences between the two cultures.

Throughout the paper, all the results reported are obtained using ten-fold cross-validation on the word data. When creating the folds, we explicitly ensure that posts authored by the same blogger are not shared between the folds, which in turn ensures no overlap between bloggers in training and test sets. This is important as repeating bloggers in both the train and the test splits could potentially overfit the model to the writing styles of individual bloggers rather than learning the underlying culture-based differences between the bloggers.

To summarize the cross-validation process: First, for each of the 1,500 target words, we collect an equal number of instances containing the given target word or its inflections from Australia and United States, from each of the selected years (2011-2014). We then divide the posts belonging to Australia and United States each into ten approximately equal groups, such that no two groups have bloggers in common. We finally combine the corresponding groups to form a total of ten bi-cultural groups that are approximately of equal size, which form our cross-validation splits. [4]

To compute the statistical significance of the results obtained, we perform a two-sample t-test over the correctness of predictions of the two systems namely, Adaboost and random chance classifiers. Disambiguation results that are significantly better ($p < 0.05$) than the random chance baseline of 50% are marked with $*$.

On average, the classifier leads to an accuracy of 58.36%*, which represents an absolute significant improvement of 8.36% over the baseline (a random chance of 50%). Table 3 shows the average classification results for each part-of-speech, as well as the number of words for which the AdaBoost classifier leads to an accuracy significantly larger than the baseline. These results suggest that there are indeed differences in the ways in which writers from Australia and United States use the target words with respect to all the parts-of-speech.

Part-of-speech	Average accuracy	Words with significant difference
Nouns	57.51*	393
Verbs	58.01*	395
Adjectives	59.25*	207
Adverbs	61.77*	215
Overall	58.36*	1210

Table 3: Average ten-fold cross-validation accuracies and number of words with an accuracy significantly higher than the baseline, for each part-of-speech, for United States vs. Australia.

4 Where is the Difference?

We now turn to our second research question: Once significant differences in the usage of a word are identified, can we use feature analysis to understand the nature of these differences?

4.1 Feature Ablation

We first study the role of the different linguistic features when separating between word usages in Australia and United States through ablation studies. For each of the feature sets specified in Section 3,

[3] We use the open source machine learning framework Weka (Hall et al., 2009) for all our experiments. We use the default base classifier for AdaBoost, i.e., a DecisionStump.

[4] This condition of equal data in each group is only approximate, as there will generally not be an exact division of bloggers with equal data. The average size of a cross-validation train split for a target word is 6246.57, while that for a test split is 819.88.

we retrain our concept models using just that feature set type, which helps us locate the features that contribute the most to the observed cultural differences.

The left side of Table 4 shows the ablation results averaged over the 1,500 target words for the four sets of features. We observe that the contextual and socio-linguistic features perform consistently well across all the parts-of-speech, and they alone can obtain an accuracy close to the all-feature performance.

Part-of-speech	Loc	Con	Soc	Syn	All	LIWC	OF	ML	WNA
Nouns	49.06	57.22*	56.52*	46.54	57.28*	56.62*	56.21*	54.17*	52.94
Verbs	47.97	57.65*	57.04*	47.71	57.90*	56.90*	56.28*	53.73*	53.25*
Adjectives	48.67	58.63*	57.90*	47.52	59.01*	58.03*	57.31*	55.42*	54.30*
Adverbs	50.72	61.09*	59.80*	46.85	60.81*	60.27*	59.80*	57.00*	56.57*
All	48.91	58.25*	57.47*	47.14	58.36*	57.55*	57.01*	54.70*	53.87*

Table 4: Feature ablation averaged over 1,500 target words. Loc: Local features, Con: Contextual features, Soc: Socio-linguistic features, Syn: Syntactic features, All: All feature types, LIWC: Linguistic Inquiry and Word Count, OF: OpinionFinder, ML: Morality Lexicon, WNA: WordNet Affect.

We also perform a feature ablation experiment to explore the role played by the various socio-linguistic features. The right side of Table 4 shows the classification accuracy obtained by using one socio-linguistic lexicon at a time: LIWC, OpinionFinder, Morality, and WordNet Affect. Among all these resources, LIWC and OpinionFinder appear to contribute the most to the classifier; while the morality lexicon and WordNet Affect also lead to an accuracy higher than the baseline, their performance is clearly smaller.

4.2 Topic Modeling

We next focus our analysis on the top 100 words (25 words for each part-of-speech) that have the most significant improvements over the random chance baseline, considered to be words with cultural bias in their use. The average accuracy of the classifier obtained on this set of words is 65.45%; the accuracy for each part-of-speech is shown in the second column of Table 7.

We model the different usages of the words in our set of 100 words by using topic modeling. Specifically, we use Latent Dirichlet Allocation (LDA)[5] (Blei et al., 2003) to find a set of topics for each word, and consequently identify the topics specific to either Australia or United States.

As typically done in topic modeling, we preprocess the data by removing a standard list of stop words, words with very high frequency ($> 0.25\% \times$datasize), and words that occur only once. To determine the number of topics that best describe the corpus for each of the 100 words, we use the average corpus likelihood over ten runs (Heinrich, 2005). Specifically, we choose that number of topics ($>= 2, <= 10$) for which the corpus likelihood is maximum.

For each data instance, we say that a topic dominates the other topics if its probability is higher than that of the remaining topics. For a given word, we then identify the *dominating topic* for each culture as the topic that dominates the other topics in a majority of data instances. We use this definition of dominating topic in all the analyses done in this section.

Quantitative Evaluation. To get an overall measure of how different cultures use the words that were found to have significant differences, we compute the Spearman's rank correlation between the topic distributions for the two cultures. For each topic, we get the number of data instances in which it dominates the other topics, in both cultures (Australia and United States). Subsequently, we measure the overall Spearman correlation coefficient between the dominating topic distributions for all 100 words. In other words, the distribution of topics is compared across cultures for each word. The Spearman coefficient is calculated as 0.63, which reflects a medium correlation between the usages of the words by the two cultures.

Qualitative Evaluation. For a qualitative evaluation, Table 5 shows five sample words for each part-of-speech, along with the identified number of topics and the dominating topic for Australia and United

[5]LDA has been shown to be effective in text-related tasks, such as document classification (Wei and Croft, 2006).

States. We associate labels to the hidden topics manually after looking at the corresponding top words falling under each of them.

As seen in this table, the number of topics that best describe each word can vary widely between two topics for words such as *start* and *economic*, up to ten topics (which is the maximum allowed number of topics) for words such as *color* or *support*. The dominating topics illustrate the biases that exist in each culture for these words; for instance, the word *teach* is dominantly used to describe academic teaching in Australia, whereas in United States it is majorly used to talk about general life teaching. Several additional examples of differences are shown in Table 5.

4.3 One-versus-all Classification

For additional insight into word usage differences between United States and Australia, we expand our study to develop word models to separate word usages in Australia (or United States) from a mix of ten different cultures. In other words, we conduct a one-versus-all classification using the same process as described in Section 3, but using Australia (United States) against a mix of other cultures to examine any features specific to Australia (United States).

In order to do this, we collect data from nine additional English speaking countries, as shown in the left side of Table 6. As before, the data for each country is balanced over time, and it includes an equal number of instances for four different years (2011-2014). The right side of Table 6 shows the average number of instances per word collected for each part-of-speech.

In this classification, for a given target word, one half of the data is collected from Australia (United States), and the other half is collected from the remaining countries, drawing 10% from each country. We run these classifiers for all the 100 words previously identified as having cultural bias in their use.

The average classifier accuracy for the Australia-versus-all classification, using ten-fold cross validation, is 64.23%, as shown in the third column of Table 7. We repeat the same one-versus-all classification for United States, with an average accuracy of 54.89%; the results of this experiment are listed in the last column of Table 7.

Overall, the performance improvement over the baseline is higher for Australia versus other countries (14.23% absolute improvement) than it is for United States versus others (4.89% absolute improvement). From this, we can infer that that the performance improvement over the baseline for the Australia versus United States task can be majorly attributed to the different word usages in Australia from the remaining countries. In other words, United States is more aligned with the "typical" (as measured over ten different countries) usage of these words than Australia is.

5 Related Work

Most of the previous cross-cultural research work has been undertaken in fields such as sociology, psychology, or antropology (De Secondat and others, 1748; Shweder, 1991; Cohen et al., 1996; Street, 1993). For instance, Shweder (1991) examined the cross-cultural similarities and differences in the perceptions, emotions, and ideologies of people belonging to different cultures, while Pennebaker et al. (1996) measured the emotional expressiveness among the northerners and southerners in their own countries, to test Montesquieu's geography hypothesis (De Secondat and others, 1748). More recently, the findings of Boroditsky et al. (2003) indicate that people's perception of certain inanimate objects (such as bridge, key, violin, etc.) is influenced by the grammatical genders assigned to these objects in their native languages.

To our knowledge, there is only limited work in computational linguistics that explored cross-cultural differences through language analysis. Our work is most closely related to that by Paul and Girju (2009), in which they identify cultural differences in people's experiences in various countries from the perspective of tourists and locals. Specifically, they analyzed forums and blogs written by tourists and locals about their experiences in three countries, namely Singapore, India, and United Kingdom, using an extension of LDA. One of their findings is that while topic modeling on tourist forums offered an unsupervised aggregation of factual data specific to each country that would be important to travelers (such as destination's climate, law, and language), topic modeling on blogs authored by locals showed cultural differences between the three countries with respect to several topics (e.g., fashion, pets, religion, health).

Yin et al. (2011) used topic models along with geographical configurations in Flickr to analyze cultural differences in the tags used for specific target image categories, such as cars, activities, festivals, or national parks. They performed a comparison over the topics across different geographical locations for each of the categories using three strategies of modeling geographical topics (location-driven, text-driven, and latent geographical topic analysis (LGTA) that combines location and text information), and found that the LGTA model worked well not only for finding regions of interest, but also for making effective comparisons of different topics across locations.

Ramirez et al. (2008) performed two studies to examine the expression of depression among English and Spanish speakers on the Internet. The first study used LIWC categories to process depression and breast cancer posts to identify linguistic style of depressed language. Significantly more first person singular pronouns were used in both English and Spanish posts, supporting the hypothesis that depressed people tend to focus on themselves and detach from others. The second study focused on discovering the actual topics of conversation in the posts using Meaning Extraction Method (Chung and Pennebaker, 2008). It was found that relational concerns (e.g., family, friends) were more likely expressed by depressed people writing in Spanish, while English people mostly mentioned medical concerns.

6 Conclusions

In this paper, we explored the problem of identifying word usage differences between people belonging to different cultures. Specifically, we studied differences between Australia and United States based on the words they used frequently in their online writings. Using a large number of examples for a set of $1,500$ words, covering different parts-of-speech, we showed that we can build classifiers based on linguistic features that can separate between the word usages from the two cultures with an accuracy higher than chance. We take this as an indication that there are significant differences in how these words are used in the two cultures, reflecting cultural bias in word use.

To better understand these differences, we performed several analyses. First, using feature ablation, we identified the contextual and socio-linguistic features as the ones playing the most important role in these word use differences. Second, focusing on the words with the most significant differences, we used topic modeling to find the main topics for each of these words, which allowed us to identify the dominant topic for a word in each culture, pointing to several interesting word use differences as outlined in Table

5. We also measured the correlation between the topic distributions for the top 100 words between the two cultures, and found a medium correlation of 0.63. Finally, we also performed a one-versus-all classification for these 100 words, where word use instances drawn from one of Australia or United States were compared against a mix of instances drawn from ten other cultures, which suggested that United States is a more "typical" culture when it comes to word use (with significantly smaller differences in these one-versus-all classifications than Australia).

In future work, we plan to extend this work to understand differences in word usages between a larger number of cultures, as well as for a larger variety of words (e.g., function words).

The cross-cultural word datasets used in the experiments reported in this paper are available at http://lit.eecs.umich.edu.

Abstract

The *Dundee Eyetracking Corpus* contains eyetracking data collected while native speakers of English and French read newspaper editorial articles. Similar resources for other languages are still rare, especially for languages in which words are not overtly delimited with spaces. This is a report on a project to build an eyetracking corpus for Japanese. Measurements were collected while 24 native speakers of Japanese read excerpts from the *Balanced Corpus of Contemporary Written Japanese* Texts were presented with or without segmentation (i.e. with or without space at the boundaries between *bunsetsu* segmentations) and with two types of methodologies (eyetracking and self-paced reading presentation). Readers' background information including vocabulary-size estimation and Japanese reading-span score were also collected. As an example of the possible uses for the corpus, we also report analyses investigating the phenomena of anti-locality.

1 Introduction

Corpora of naturally-produced texts such as newspapers and magazines marked with detailed morphological, syntactic and semantic tags, are often used in human language-production research. In contrast, texts created by psycholinguists exclusively for research purposes, are commonly used in language-comprehension research.

We introduce a reusable linguistic resource that can help bridge this gap by bringing together techniques from corpus linguistics and experimental psycholinguistics. More concretely, we have collected reading times for a subset of texts from the *Balanced Corpus of Contemporary Written Japanese* (BCCWJ) (Maekawa et al., 2014), which already contains syntactic and semantic types of annotations. The goal is to produce a resource comparable to the *Dundee Eyetracking Corpus* (Kennedy and Pynte, 2005), which contains reading times for English and French newspaper editorials from 10 native speakers for each language, recorded using eyetracking equipment. The English version of the *Dundee Eyetracking Corpus* is composed of 20 editorial articles with 51,501 words.

The *Dundee Eyetracking Corpus* does not target a specific set of linguistic phenomena; instead, it provides naturally occurring texts for the testing of diverse hypotheses. For example, Demberg and Keller (2008) used the corpus to test Gibson's Dependency Locality Theory (DLT), (Gibson, 2008), and Hale's surprisal theory (Hale, 2001). The corpus also allows for replications to be conducted, as in Roland et al. (2012), who concluded that previous analyses (Demberg and Keller, 2007) had been distorted by the presense of a few outlier data points.

Our goal is to produce a similar resource that can serve as a shared, available foundation for research in Japanese text processing. Once completed, the corpus will allow us to address two issues that are specific to Japanese. The first issue is related to two types of reading-time measurements commonly used, namely, eyetracking and self-paced reading. Although eyetracking provides detailed recordings of eye movements, it requires specialized equipment. Self-paced reading requires only a regular computer to collect button presses, which have been shown to be an effective alternative that correlates well with

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 684–694, Osaka, Japan, December 11-17 2016.

eyetracking data in English (Just et al., 1982). However, to date, no similar correlation analyses have been conducted for Japanese. A second issue related to Japanese is that its texts do not contain spaces to mark boundaries between words (or other linguistic units such as *bunsetsu*, in other words, a content word plus functional morphology), and the question arises as to the best way to show segments in self-paced reading presentations.

Here, we present specifications and basic statistics for the *BCCWJ Eyetracking Corpus*, which makes available reading times for BCCWJ texts that have been previously annotated with syntactic and semantic tags. This should allow for detailed analyses of human text processing having a diverse range of purposes (e.g., readability measurements, evaluations of stochastic language models, engineering applications).

The rest of the paper is organized as follows. Section 2 provides basic information about the reading-time annotations, participants (§2.1), articles (§2.2), apparatus/procedure (§2.3), and data format and basic statistics (§2.4). Section 3 presents an analysis investigating a phenomenon of anti-locality (Konieczny, 2000). These are followed by the conclusion and future directions.

2 Method

2.1 Participants

Twenty-four native speakers of Japanese who were 18 years of age or older at the time, participated in the experiment for financial compensation. The experiments were conducted from September to December 2015. Profile data collected included age (in five-year brackets), gender, educational background, eyesight (all participants had uncorrected vision or vision corrected with soft contact lenses or prescription glasses), geographical linguistic background (i.e. the prefecture within Japan where they lived until the age of 15), and parents' place of birth (See Table 1 for a summary).

Vocabulary size was measured using a Japanese language vocabulary evaluation test (Amano and Kondo, 1998). Participants indicated the words they knew from a list of 50 words and scores were calculated taking word-familiarity estimates into consideration.

As a measure of working-memory capacity, the Japanese version of the reading-span test was conducted (Osaka and Osaka, 1994). Each participant read sentences aloud, each of which contained an underlined content word. After each set of sentences, the participant recalled the underlined words. If all words were successfully recalled, the set size was increased by one sentence (sets of two to five sentences were used). The final score was the largest set for which all words were correctly recalled, with a half point added if half of the words were recalled in the last trial (See Table 2 for the scores in the vocabulary and working memory tests).

Table 1: Profile data for the participants

Age range (years)	Females	Males	Gender not given	Total
-20	1	1		2
21-25		2		2
26-30	2			2
31-35	3			3
36-40	9		1	10
41-45	3			3
46-50	1			1
51-		1		1
total	19	4	1	24

Table 2: Results for reading span test and vocabulary-size test

Vocab. size	Reading span test score 1.5	2.0	2.5	3.0	3.5	4.0	4.5	5.0	Total
36,000 -		1	1						2

58,000 -			1						1
60,000 -		1							1
Total	2	8	8	2	1	1	1	1	24

2.2 Texts

Reading times were collected for a subset of the core data of the *Balanced Corpus of Contemporary Written Japanese* (BCCWJ) (Maekawa et al., 2014), consisting of newspaper articles (PN: published

newspaper) samples. Articles were chosen if they were annotated with information such as syntactic dependencies, predicative clausal structures, co-references, focus of negation, and similar details, following the list of articles that were given annotation priority in the BCCWJ.[1]

The 20 newspaper articles chosen were divided into four sets of data containing five articles each: sample sets A, B, C, and D. Table 3 shows the numbers of words, sentences, and screens (i.e. pages) for each set of data. Each article was presented starting on a new screen.

Articles were shown segmented or unsegmented, that is, with or without a half-width space to mark the boundary between segments. Segments conformed to the definition for *bunsetsu* units (a content word followed by functional morphology, e.g., a noun with a case marker) in the BCCWJ as prescribed by the National Institute for Japanese Language and Linguistics. Each participant was assigned to one of the eight groups of three participants each, one group for each of the eight experimental conditions with varying combinations of measurement methods and boundary marking for different data sets presented in different orders (see Table 4). The next section provides explanations for the two measurement methods (eyetracking and self-paced reading). Order of the tasks was fixed with eye movements collected in the first session, and keyboard presses recorded during a self-paced reading presentation in the second session. Each participant saw each text once, with task and segmentation for the texts counter-balanced across participants.

Table 3: Data set sizes

Data set	Segments	Sentences	Screens
A	470	66	19
B	455	67	21
C	355	44	16
D	363	41	15

Table 4: Experimental Design

Group	Eye tracking		Self-paced reading	
1	A unseg	B seg	C unseg	D seg
2	A seg	B unseg	C seg	D unseg
3	C unseg	D seg	A unseg	B seg
4	C seg	D unseg	A seg	B unseg
5	B unseg	A seg	D unseg	C seg
6	B seg	A unseg	D seg	C unseg
7	D unseg	C seg	B unseg	A seg
8	D seg	C unseg	B seg	A unseg

'seg' stands for with spaces, and 'unseg' stands for without spaces.

2.3 Apparatus and Procedure

Eye movements were recorded using a tower-mounted EyeLink 1000 (SR Research Ltd). View was binocular but data were collected from each participant's right eye using 1000-Hz resolution. Participants looked at the display by way of a half-mirror as their heads were fixed with their chins resting on a chin rest. Unlike self-paced reading, in eyetracking all segments are shown simultaneously thus allowing more natural reading as the participant can freely return and reread earlier parts of the text on the same screen (but, participants were not allowed to return to previous screens). Stimulus texts were shown in a fixed full-width font (MS Mincho 24 point), displayed horizontally as is customary with computer displays for Japanese, with five lines per screen on a 21.5-inch display.[2] In the segmented condition, a half-width space was used to indicate the boundary between segments. In order to improve vertical tracking accuracy, three empty lines intervened between lines of text. A line break was inserted at the end of sentence or when the maximum 53 full-width characters per line was reached. Moreover, line breaks were inserted at the same points in the segmented and unsegmented conditions to guarantee that the same number of non-space characters were shown in both conditions.

The same procedure was adopted for the self-paced reading presentation, except that the chin rest was not used and participants could move their heads freely while looking directly at the display. Doug Rohde's Linger program, Version 2.94[3] was used to record keyboard-press latencies while sentences were shown using a non-cumulative self-paced moving-window presentation, which had the best correlation with eyetracking data when different styles of presentation were compared for English (Just et al., 1982). Sentence segments were initially shown masked with dashes. Participants pressed the space key of the

[1] `https://github.com/masayu-a/BCCWJ-ANNOTATION-ORDER`

[2] EIZO FlexScan EV2116W (resolution 1920×1080), set 50 cm from the chin rest.

[3] `http://tedlab.mit.edu/~dr/Linger/`

keyboard to reveal each subsequent segment of the sentence while all other segments reverted to dashes. Participants were not allowed to return to reread earlier segments.

Figure 1 shows two types of segmentations in the self-paced reading setting. In order to illustrate the difference between full-width underscore and half-width underscore, their heights are slightly altered in the figure. In the original Linger software presentation, these are shown at the same height.

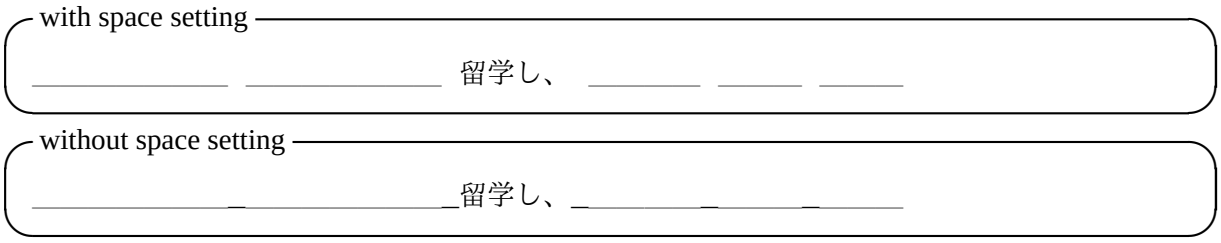

Figure 1: Types of segmentations in the self-paced reading experiment

2.4 Analysis

2.4.1 Reading-Times Tabulation

In the self-paced reading session, each segment was displayed separately, and participants could not return to reread earlier parts of the text. Therefore, the latencies for the button presses are straightforward measures of the time spent on each segment.

For the eyetracking data, five types of measurements are included, namely, First Fixation Time (FFT), First-Pass Time (FPT), Regression Path Time (RPT), Second-Pass Time (SPT), and Total Time (TOTAL), which will be explained using Figure 2.

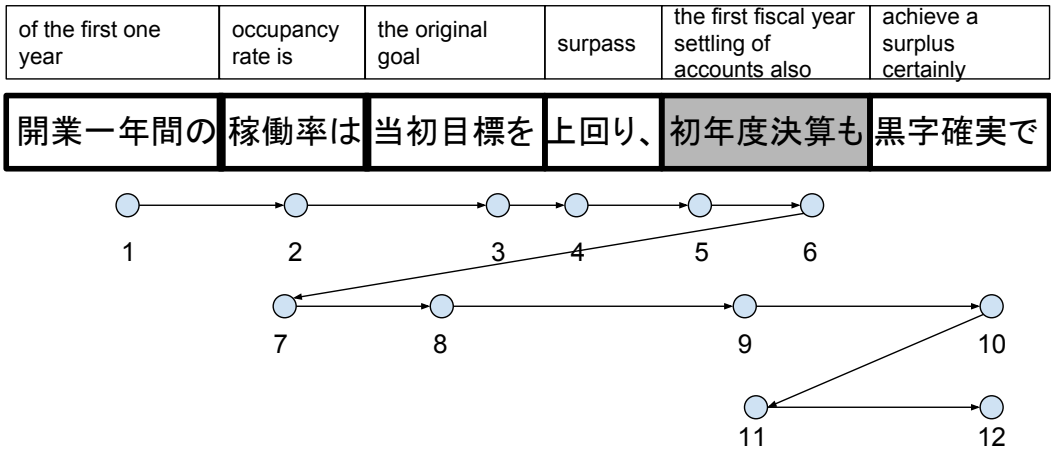

Figure 2: Example of fixations

First Fixation Time (FFT) is the fixation duration measured when the gaze first enters the area of interest. In Figure 2, the FFT for 'the first fiscal year settling of accounts also' (hereafter 'the area of interest') is the duration of fixation 5.

First-Pass Time (FPT) is the total duration of fixation from the moment the gaze first stops within the area of interest until it leaves the focus area by moving to the right or left of this area. In the figure, the FPT is the sum of the durations of fixations 5 and 6.

Regression Path Time (RPT) is the total span of from the moment the gaze enters the area of interest until it crosses the right boundary of this area for the first time. In the figure, the RPT is the sum of the

Table 5: Data format

Column name	Type	Description
surface	factor	Word surface form
time	int	Reading-time
measure	factor	Reading time types
sample	factor	Sample name
article	factor	Article information
metadata_orig	factor	Document structure tag
metadata	factor	Metadata
sessionN	int	Session order
articleN	int	Article display order
screenN	int	Screen display order
lineN	int	Line display order
segmentN	int	segment display order
sample_screen	factor	Screen identifier
length	int	Number of characters
space	factor	segment boundary with space or not
setorder	int	Segmentation-type order
subj	factor	Participant ID
rspan	num	Reading-span test score
voc	num	Vocabulary-test score
dependent	int	Number of dependents

durations for fixations 5, 6, 7, 8 and 9. The RPT can includes fixations to the left of the left boundary (e.g., 7 and 8) and durations of fixations when the gaze returns to the area of interest (e.g., 9).

Second-Pass Time (SPT) is the total span of time the gaze spend in the area of interest excluding the FPT. In the figure, the SPT is the sum of the durations of fixations for 9 and 11.

Total Time (TOTAL) is the total duration that the gaze spends within the area of interest. In other words, it is the sum of the SPT and the FPT. In the figure, TOTAL is the sum of the durations of fixations 5, 6, 9 and 11.

Only fixation times have been tabulated thus far. In the future, saccade information will also be made available.

2.4.2 Data Format and Basic Statistics

Data will be made available in tab-separated valuses (TSV) format for each of the reading-time measurements described in the previous section, along with information about the original articles and profiles of the participant. Table 5 summarizes the data format.

Word surface form (Surface: factor) refers to the text strings shown to the participants. These are organized according to the segment standards of the National Institute for Japanese Language and Linguistics, with full-width blank spaces removed.

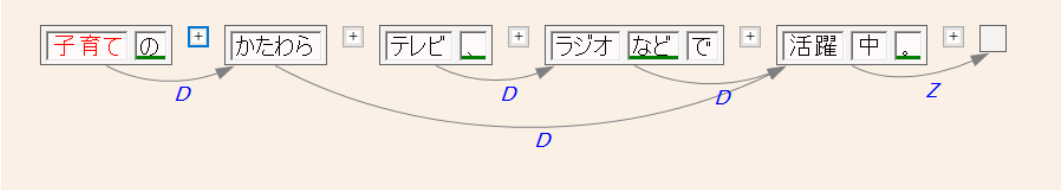
Reading time (time: int) is the `time` measurement expressed in milliseconds. For self-paced reading, this is the button-press latency for a single segment. For eyetracking, numbers are provided for each of the five measurements discussed in the previous section: First Fixation Time (FFT), First-Pass Time (FPT), Second-Pass Time (SPT), Regression Path Time (RPT) and Total Time (TOTAL). The *reading time types* (`measure`: factor) are defined as {'Self-Paced', 'EyeTrack: FFT', 'EyeTrack: FPT', 'EyeTrack: SPT', 'EyeTrack: RPT', 'EyeTrack: Total'}.

There are four types of information provided for the newspaper articles: `sample`, `article`, `metadata_orig` and `metadata`. The *sample name* (`sample`: factor) is derived from the data sets prepared for each session 'A', 'B', 'C', 'D'; each sample consists of five newspaper articles. *Article in-*

formation (`article`: factor) is a unique identifier for the individual articles, which is connected with an underscore to the BCCWJ annotation priority rankings, the BCCWJ internal sample IDs, and the article numbers. *Document structure tag* (`metadata_orig`: factor) is a BCCWJ internal document structure tag, which is connected with the tag information in the BCCWJ XML ancestor axis using a slash. *Metadata* (`metadata`: factor) is generated through the extraction of the properties of the article from the previously mentioned `metadata_orig`. It is set to one of {'authorsData', 'caption', 'listItem', 'profile', 'titleBlock', or 'undefined'}, and indicates manual revisions of mistakes or omissions in the BCCWJ internal document structure tag.

There are five types of information related to presentation order. *Session order* (`session`: int) indicates the session number (1 or 2). *Article display order* (`articleN`: int) indicates the article display sequence (1–5) within each session. *Screen display order* (`screenN`: int) indicates the screen's display sequence number within each article. *Line display order* (`lineN`: int) indicates the line number within each screen (1–5). Segment display order (`segmentN`: int) indicates the segment sequence number within each line.

Screen identifier (`sample_screen`: factor) is a unique identifier for the screens displayed to the participants. *Number of characters* (`length`: int) is the number of characters in the segment. *Segmented or unsegmented* (`space`: factor) indicates whether there is a half-width space between segment units ('1'), or not ('0'). *Segmentation-type order* (`setorder`: factor) is set to '0-1' if the participant saw unsegmented texts followed by segmented texts, and it is set to '1-0' otherwise. *Number of dependents* (`dependent`: int) is the number of segment units that are syntactically dependent on the current segment. Segment dependency relationships were annotated manually. Figure 3 shows an example of a dependency annotation on segments. Note, the dependency arcs are written from dependent to head following convention in Japanese annotations.



She raises her twins and is also active as a broadcaster of TV and radio programs.

Figure 3: Example of Dependency Annotation

There are three types of information assigned for each participant. *Experiment participant ID* (`subj`: factor) is a unique identifier for each participant, and is associated with two pieces of information. The first is the *reading span test score* (`rspan`: num), ranging from 1.5 to 5.0 in gradations of 0.5. The second is the *Vocabulary test score* (`voc`: num), which is the original result divided by 1,000 (37.1-61.8).

Table 6 shows means, standard deviations (SDs), and quartiles for each measurement. For eyetracking, the numbers shown exclude reading times of zero milliseconds (i.e. instances where segments were not fixated).

After each article, a simple yes-no question verified readers' comprehension. Overall accurary was 88.5% (ranging from 70%-100%). Accuracy was higher in eye-tracking (99.2%; 238/240) than in self-paced reading (77.9%; 187/240: $p < 0.001$). One possible factor favoring eye-tracking is that participants could reread texts freely. Another factor is that self-paced reading data was always collected in the second session, therefore participants may have been more tired.

3 Example Analysis

3.1 Anti-locality

As an example of the possible uses for the corpus, we conducted analyses investigating *anti-locality* phenomena, in which a head is read faster if it is preceded by more dependents as first reported for

Table 6: Mean reading times (in milliseconds)

	Mean	SD	Min.	1st Qu.	Median	3rd Qu.	Max.
Self-paced	699	506	62	415	550	798	9454
Eye tracking (excl. 0)							
First Fixation Time	235	142	12	162	219	292	1700
First-Pass Time	475	497	14	205	321	548	7340
Second-Pass Time	330	253	20	173	258	418	2553
Regression Path Time	698	1013	19	235	391	745	21577
Total Time	597	589	18	247	416	721	8397

German (Konieczny, 2000; Konieczny and Döring, 2003) and later replicated for Japanese (Uchida et al., 2014). Such speedu gains in head-final constructions are not easily explained by working-memory models, which either predict that attaching a large number of dependents should be costly (Gibson, 2008) or predict that the cost of an upcoming head should not be affected by the number of dependents preceding it (Nakatani and Gibson, 2010). Although the phenomenon is compatible with surprisal (Hale, 2001; Levy and Gibson, 2013), previous results were limited to reports that a ditransitive verb was read more quickly when preceded by two dependents (an accusative-marked argument and a dative-marked argument) than when preceded by just one dependent (the accusative argument). Therefore, these results do not necessarily support *anti-locality*, instead they may be related to ditransitive verbs being more natural when the dative noun phrase is expressed overtly. We report corpus analyses that show that *anti-locality* holds more generally.

3.2 Modeling Results

Linear mixed models were constructed for reading times to the main texts of the articles (i.e. excluding reading times that had the metadata field labelled as authorsData, caption, listItem, profile, or titleBlock). The first and last segments on a line may be exceptional as they may be affected by large eye movements going from the end of the line to the beginning of the following line, or backtracking to reread content at the end of the previous line. Therefore, factors were included in the analyses encoding whether the segment is the first (`is_first`), second to last (`is_second_last`) or last (`is_last`) on a line. We also excluded zero-millsecond data points from the eyetracking data. Because the models with maximal or close-to-maximal random structure did not converge, we performed forward model selections for each time setting and report the model with the smallest AIC that converged. After model-based trimming was used to eliminate points beyond three standard deviations, the model was rebuilt (Baayen, 2008). Tables 7, 8, 9, 10, 11, and 12 show the results of the smallest-AIC models for 'Self-Paced Reading (Self)', and eyetracking data for 'First Fixation Time (FFT)', 'First-Pass Time (FPT)', 'Second-Pass Time (SPT)', 'Regression Path Time (RPT)', and 'Total Times (Total)', respectively.

In the tables, the baseline (i.e. the intercept) encodes the False value for binary factors. Therefore, a factor name followed by '1' (e.g., `is_first1`) indicates what happens to the model prediction when the factor changes from FALSE to TRUE. For example, in Table 7, the intercept is the baseline (634.08 ms) which excludes reading times to the first, penultimate, and last segments (i.e. `is_first=FALSE`, `is_second_last=FALSE`; `is_last=FALSE`). Therefore, the row starting with `is_first1` (i.e. it is the first segment of the line) indicates that the first segment was 69.73 ms slower than the segments included in the baseline.

Table 13 shows the summary of the results from the linear mixed model. In this table, if the absolute *t*-value of the effect is larger than 1.96, we regard the factor as statistically significant and put the sign of the estimate. Otherwise, we put 0, indicating nonsignificant factors.

Texts presented that were segmented with a blank space had shorter first pass times, second pass times, total-reading times than unsegmented texts (factor `space`). These results are interesting because texts are usually unsegmented in Japanese writing, therefore the result is the opposite of what would be expected based on participants' reading habits. The result is also not compatible with previous results,

Table 7: Parameters of the linear mixed model for the self-paced reading data

	Estimate	Std. Err.	*t* value
Intercept	634.08	31.05	20.42
space1	3.04	4.03	0.75

77 data points (1.61%) were excluded in the 3-SD trimming. We choose the converged model with smaller AIC as follows: `lmer (time ~ space * sessionN + length + dependent + is_first + is_last + is_second_last + articleN + screenN + lineN + segmentN + (1 + articleN + segmentN | subj) + (1 + is_last + is_second_last + articleN | article)`

in which segmentation did not have a reliable effect in texts mixing *kanji* and *kana* characters (Sainio et al., 2007), but that may have been due to lack of statistical power or perhaps because the segmented texts were too short for participants to accommodate to this type of presentation and use segmentation information effectively.

An unsurprising finding is that longer segments (i.e. segments having more characters) took longer to read (factor `length`) except for the first fixation time. The result suggests that longer segments do not require longer first fixation, but nevertheless affect later measures as they may require further fixations.

Compared to the intermediate segments (i.e. second segment to the antepenultimate segments) on each line, longer reading times were observed for the first segment (`is_first=TRUE`; in self-paced reading, first fixation, first pass, and total reading time), for the penultimate segment

screenN + lineN + segmentN + (1 + articleN + segmentN
| subj) + (1 + articleN | article)
```

Table 13: Summary of the results from the linear mixed models

	Self	FFT	FPT	SPT	RPT	Total
space=True	0	0	-	-	0	-
length	+	0	+	+	+	+
is_first=True	+	+	+	-	0	+
is_last=True	+	0	0	0	+	0
is_second_last=True	0	0	+	+	0	+
articleN	-	0	0	0	0	0
screenN	-	0	-	-	-	-
lineN	-	-	-	-	-	-
segmentN	-	+	0	-	-	-
dependent	-	-	-	-	-	-

(second_last_bunsetsu=TRUE; in first pass time, second pass time, and total time), and for the last segment (last_bunsetsu=TRUE; in self-paced reading and regression path time).

Within a session, reading times from self-paced reading became faster with each article (articleN); however, the effect was not reliable in any of the eye-tracking measures. Within an article, reading times got faster with each screen (screenN) in all measures except for first fixation time. In the vertical ordering within a screen, all reading times got faster with each line (lineN). In the horizontal ordering within a line, reading times except for first fixation time and first pass time became faster with each segment (segmentN). These speed gains are expected as readers gain speed as they process more information.

Apart from the effects described above related to the physical aspects of the presentation of the texts, we also observed a reliable *anti-locality* effect as words were read faster when more dependents preceded them (factor dependent). This generalizes previous findings (Konieczny, 2000; Konieczny and Döring, 2003; Uchida et al., 2014) and confirms that dependent phrases provide information that facilitates the processing of an upcoming head.

4 Conclusion

We created a data set with the reading times of 24 native speakers of Japanese. Preliminary analyses illustrate the uses of this type of data. First, although spaces are not commonly used to segment Japanese text, readers were nevertheless faster to read segmented texts. Second, we reported an analysis on *anti-locality* effects, which confirmed previous reports and generalized them to more natural texts.

The reading time data, excluding the original texts, will be licenced through Creative Commons Attribution-Noncommercial 4.0 (CC BY-NC 4.0: `https://creativecommons.org/licenses/by-nc/4.0/`). Apart from the data files described in Section 2.4.2, the original eye-tracking data can be obtained as EyeLink Data Viewer files, by contacting the first author. The original texts can be obtained by purchasing the BCCWJ DVD edition `http://pj.ninjal.ac.jp/corpus_center/bccwj/en/subscription.html`.

Future planned developments are as follows. First, we will extend the corpus with more participants and data. This initial data set was restricted to newspaper articles, and we are currently investigating the possibility of assigning reading times to other texts, such as books and magazines.

Other types of annotations will be added. Apart from information on the number of dependents already available in the current data, we are considering including other types of information such as dependency length, scope of coordinate structure. Other types of information that may be added in the future include morphological information such as word class, vocabulary classification table number, predicate clause structure (*ga*-case:subj, *o*-case:dobj, *ni*-case:iobj), co-reference information, clause boundary information, and information structure.[4]

Finally, we intend to examine possible applications for information processing. Participants were required to write a summary for each text they read. Contrast analysis of the reading times and the summaries may allow us to augment automatic summarization systems tailored to individual readers.

Abstract

Cyberbullying statistics are shocking, the number of affected young people is increasing dramatically with the affordability of mobile technology devices combined with a growing number of social networks. This paper proposes a framework to analyse Tweets with the goal to identify cyberharassment in social networks as an important step to protect people from cyberbullying. The proposed framework incorporates latent or hidden variables with supervised learning to determine potential bullying cases resembling short blogging type texts such as Tweets. It uses the LIWC2007 - tool that translates Tweet messages into 67 numeric values, representing 67 word categories. The output vectors are then used as features for four different classifiers implemented in Weka. Tests on all four classifiers delivered encouraging predictive capability of Tweet messages. Overall it was found that the use of numeric psychometric values outperformed the same algorithms using both filtered and unfiltered words as features. The best performing algorithms was Random Forest with an F1-value of 0.947 using psychometric features compared to a value of 0.847 for the same algorithm using words as features.

1 Introduction

Harassment and bullying as common forms of unacceptable behaviour have been topics in psychological research for a long time. Harassment aims to discriminate people on the basis of race, sex, disability etc. and bullying aims to intimidate people. The use of the terms "cyberharassment" and "cyberbullying" is relatively new. Both terms involve the application of modern technologies to support negative human behaviour. The ubiquitousness and affordability of modern technology makes it easy for organisations and individuals to easily communicate via e-mails, chat rooms, message boards and social media which generates a huge amount of public and private data containing information reflecting the pulse of the society. Unfortunately, this accessibility of the technology has also created a forum for the expression of negative human emotions, some of which also gives rise to tragic outcomes such as suicides, self harm and mental illnesses. The aim of our research is to create a framework for detecting cyberharassment from textual communication data, so that systems can be implemented to catch and eliminate harassing texts before it is able to inflict harm.

Bullying is a relationship issue that could result in significant emotional and psychological suffering with some even resulting in suicides (Boyd, 2007). Cyberbullying is even worse because it can follow the victim everywhere, happen at anytime and it is frequently anonymous. The number of victims in all age groups is growing worldwide. It is urgent to progress the research in this area in order to develop advanced methods for fast detection and prevention of cyberbullying cases. This involves analysis of a huge amount of social network textual data which is largely unstructured and chaotic.

A range of challenging tasks are associated with cyberharassment research. For example, bullying is to a great extent connected to the nature of the victim rather than solely on the language and topic of text. It generally involves the use of known weaknesses of victims that they cannot change. Texts can still contain profanities and include sensitive topics without being bullying or any psychological effect on the

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 695–706, Osaka, Japan, December 11-17 2016.

victim. In order determine whether if cyberbullying occurred, we would need to attain information on the victim's reaction and classify this reaction. This is a challenging task in itself and not part of our work. The context or background knowledge can also determine if a text is bullying or not. It is possible for individuals in close friendship to communicate using profanities and on sensitive topics, without causing a negative psychological effect. The actual context is normally not included in texts since it is difficult to determine, especially for short pieces which is typical of social media type communications.

To be able to computationally detect cyberbullying, one would need texts on time-line based conversational threads between individuals, which is difficult to obtain due to privacy and propriety implications. Although there has been an abundance of studies on cyberbullying from the social and psychological perspectives, good computational systems to identify cyberbullying are rare. The existing computational studies (Dinakar et al., 2011; Yin et al., 2009; Xu et al., 2012b; Van Royen et al., 2015; Cortis and Handschuh, 2015; Squicciarini et al., 2015; Han et al., 2015; Kansara and Shekokar, 2015) use predominantly keywords as features in classification algorithms. Those approaches deliver results which are good indicators of harassment and they provide text which can be processed further to find bullying cases. Identification of harassment in singleton blogging texts would be extremely useful on social media platforms as a monitoring tool. Once a blog has been found to be harassing, the corresponding conversations could then be monitored more closely over a certain time in order to identify the progress from cyberharassment to cyberbullying.

In this paper, we apply a well established theory from psychology integrated in a freely available software tool to develop a framework with the goal to classify pieces of texts as bullying. Instead of using a lexicon of profanities, the framework applies a much richer dictionary of words and weights, referred to as psychometric measurements in the psychology literature, to create a rich set of numeric features which are then used four different classification algorithms. We train four different classifiers using two types of filtered and unfiltered inputs (high correlation features and annotated text). All classifiers delivered reasonable results, however, the "Random Forest" classifier achieved the highest precision rate.

1.1 Psychometric Analysis

Harassment and bullying are manifestations of negative emotions which are described as *variables* in psychology (Browne, 2000). In many scientific experiments, we obtain exact measurements of well defined features and then we normally derive answers for correlated questions under investigation. It is not straightforward to find answers to questions that deal with aspects of human psychology such as bullying and harassment. Features related to psychological constructs are typically not clearly defined and cannot be directly measured. Additionally, indirect determinations of values are often subject to substantial measurement errors and varying degrees of correlation with the question under investigation. Psychologists declare those features as latent or hidden variables. *Latent variables* are those that are indirectly measured by deducing relations between manifest, or *observed variables* (Browne, 2000).

Psychometrics is a discipline that deals with the quantification and analysis of capacities and processes in human brains, which often manifest as latent variables. Psychometrics deals with the construction of procedures for measuring psychological constructs and the development of mathematical or statistical models for the analysis of the psychological data. Typically, psychological constructs are multi-variate consisting of a large proportion of latent variables. Researchers generally measure observed variables and then find correlations with the latent variables under investigation.

Psychometrics has been used in applications where measurements of some aspects of human psychology are required. For instance, it has been used to determine an individual's personality alignment to a given set of characteristics. In this study, the psychometric variables are measured to evaluate strengths and weaknesses of a person for specific tasks. The results have been mapped to their cognitive abilities and general social behavioural style as described by Kline (2013). Many companies perform psychometric evaluations on candidates to identify potential matches for specific job roles. It has also been used to identify individuals' suitability towards specific career paths using psychometric techniques on observed variables.

An individual's writing style is an example of an observed variable, hence its psychometric evaluation

would be able to provide insights into the individual's latent characteristics on a range of psychological processes. Further, psychometric evaluation performed on texts collectively generated by various people on a similar topic can provide insights into the psychological processes of this group as a whole. Twitter, for instance, provides the ability to use "hashtags" which allows multiple users to easily write on a designated topic. This makes it easy to collate Tweets on a topic for the purpose of carrying out psychometric evaluations such as opinion mining on the topic. For example, Poria et al. (2014) provide dependency based rules for sentiment analysis. Apart from binary classification of opinions, more advanced psychometric evaluations can even distinguish between different degrees of individual opinions on a topic.

1.2 Related Work

Detecting cyberharassment is a special case of text classification which is an older research area compared to research on cyberharassment. Text classification involves use of generic machine learning algorithms to classify texts into two or more categories using features extracted from the words in the text. In order to be able to extract features there maybe various types of preprocessing tasks such as Part-of-Speech tagging, stop word removal, named entity recognition, etc., applied which differentiates the various systems and adapts them better for the type of classification application at hand. Text classification techniques developed in the areas of sentiment analysis and opinion mining are especially applicable to cyberharassment detection as they also deal with human psyche expressed as online texts. For example, Bollen et al. (2011) report the results of a text classification framework applied to support business decision. This paper presents the results for analysing 10 million Tweets from three million users over a 10 month period to predict changes in the stock market. The authors aim to answer whether the analysed mood expressed in the Tweets from a cross section of three million people is related to the Down Jones Industrial Average(DJIA). The authors applied the following two mood tracking tools:

- OpinionFinder, a system that processes Tweets and separates them into positive versus negative sentiments
- Google-Profile of Mood States (GPOMS), a system that classifies Tweets based on the mood categories; happy, vital, alert, calm, sue, kind.

Granger Causality Analysis and fuzzy neural network classifiers were used for cross-validation of the resulting mood time series against large public events such as US presidential election and Thanksgiving in this paper. The paper reports a correlation of the changes in DJIA value with predicted values from the classifier with an accuracy of 87%.

Cortis and Handschuh (2015) report cyberbullying analysis in the backdrop of Tweets related to two top trending world events in 2014, namely Ebola virus outbreak in South Africa and shooting of Michael Brown in Ferguson, Missouri. These events generated bullying comments on Africa people with no connection to Ebola virus and racist comments regarding the shooting for each of the events respectively. The authors of this paper used only limited number of key terms (*whore, hoe, bitch, gay, fuck, ugly, fake, slut, youre, thanks*) to classify Tweets against ground truth classifications as annotated by trained curators. The combined precision values for key terms such as "Whore" ranged from 0.75 to extremely low values of 0.2 for key terms such as "youre" with an average precision of approximately 0.53.

Dadvar and de Jong (2012) also present a cyber bullying detection framework based on MySpace posts. This paper uses a large dataset of 2,200 posts annotated by students and use a SVM classifier. The interesting aspect of this work is that they used four types of features. All the profane words were treated as in one category and the ratio of foul words to the length of the post was used as the feature for the classifier.The other features used were second person pronouns, all other pronouns and TF-IDF all the words in each post. Additionally, the posts were also split by gender based on the hypothesis that bullying characteristics are between the genders. The reported precision value for male specific corpus was 0.44 and for female specific corpus was 0.40. However, the respective recall values were 0.21 and 0.05, which is rather low even after considering the data set size of 2,200 posts. The performance numbers from this

study in addition to similar numbers from others such as (Ptaszynski et al., 2010; Nandhini and Sheeba, 2015; Xu et al., 2012a) was the motivation for us to use the whole text instead of a keyword list based approach to detect cyberharassment in the previous works. The framework presented in this paper uses the psychometric analysis of all the work in the text and converts them to numeric values before using them as features in the classification algorithms. The next section describes this framework in detail.

2 Proposed Framework

In this paper, we describe a framework for processing Tweets to generate a model for the prediction of cyberbullying. Four main groups of experiments were done in order to determine the best performing classifier for the different forms of input data. The following variations of the Tweet data were tested after cleaning it for extra punctuations and repeated words. Various combinations of

1. All words.
2. Words with stopwords removed.
3. Words above a threshold correlation value with 2 types of filters, Correlation Feature Selection (CFS) and Infogain Attribute Evaluator (IAE).
4. Psychometric values for all words.
5. Psychometric values for stopwords removed.
6. Psychometric values for filtered words.

2.1 Architecture

Figure 1 shows a schematic representation of the framework. We divided our model into the following phases:

1. Extraction of Tweets with typical keywords for bullying using the TAGS tool.
2. Pre-processing of archived Twitter data.
3. Human annotation of Tweets to establish ground truth.
4. The LIWC2007 software generates a vector for each Tweet and the results are saved in two EXCEL files, corresponding to true positives and true negatives.
5. Vectors are filtered (using two different techniques) to reduce the number of attributes before classification.
6. Combined files (filtered or unfiltered) are used to train four machine learning classifiers in WEKA.
7. Evaluation of the classification results.

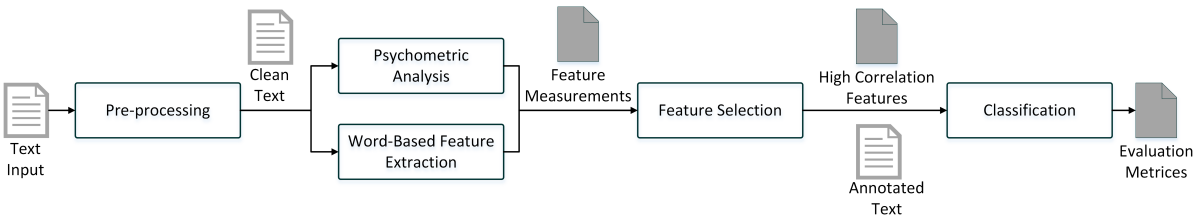

Figure 1: Schematic representation of the Architecture

2.2 Extraction of Tweets

We used the Twitter Archiving Google Spreadsheet[1] (TAGS) available for the public to explore opportunities for the exploitation of the huge amount of data generated everyday by the Twitter community.

2.3 Data preparation/Pre-processing

Tweets have a size restriction of 140 characters and typically originate from mobile devices, and due to small keypads they contain excessive amounts of noise. Apart from the "typo" errors, a range of other types of noise are usually contained in Tweet messages, such as, extra space and non-ASCII characters, due to the nature of the platform. In order to be able to extract the maximum possible semantics, we eliminated the following types of noise using techniques described by Nand et al. (2014).

Word Variations - e.g., tmro and 2moro replaced by tomorrow

Multi Word Abbreviation - e.g., lol replaced by laugh out loud

Slangs - e.g., gonna replaced by going to.

One of the major hurdles in researching online harassment is access to data, which, by the nature of the purpose, is usually private to an individual or to a closed group. Twitter, however, does have publicly available conversational data exhibiting harassment characteristics. For this research we downloaded a total of 2500 public Tweets using the TAGS archiving tool to generate Google Spreadsheets over a period of 2 months. The Tweets were retrieved by entering typical keywords for bullying as recommended in psychology literature (Ortony et al., 1987; Cortis and Handschuh, 2015; Squicciarini et al., 2015; Browne, 2000; Ybarra, 2010).

Keywords used to download Tweets: nerd, gay, loser, freak, emo, whale, pig, fat, wannabe, poser, whore, should, die, slept, caught, suck, slut, live, afraid, fight, pussy, cunt, kill, dick, bitch.

After removing the duplicates and ReTweets we had a sample of 1689 instances containing one or more of the keywords. In addition, @Usernames. #Hashtags and Hyperlinks were removed because the LIWC (Linguistic Inquiry and Word Count) - tool accepts only plain ASCII text files. The cleaned texts were then manually classified by a set of 3 trained annotators into either "cyberbullying" and "non-cyberbullying". The sample was divided into three lots containing 563 instances each. Each lot was assigned to two different annotators which meant that each Tweet was annotated twice by two different annotators. The annotators tagged the instances based on following guide lines:

Character Attacks: the reputation, integrity and morals of an individual are targeted with the purpose of defamation.

Competence attacks: bullies denigrate individuals ability to do something.

Malediction: an attack in which bullies curse and express a wish for some type of misfortune or pain to materialize in an individuals life.

Physical appearance: targeted on an individuals look and bodily structures. Typically, physical attributes of humans are found to shape and develop their personality and social behavioral relations. Due to the need of an individual to be socially accepted, these types of attacks make victims feel socially neglected making a long lasting negative impact on their self-esteem.

Insults: profanity is used as an attack wherein bullies use extremely offensive language that typically include foul, lewd, vulgar language in addition to swearing and cursing words.

Verbal abuse: includes false accusations or blames, extreme criticisms and judgements about an individual and/or statements that negatively define the victim.

[1] https://tags.hawksey.info/

Teasing: hurtful in nature and done as a spectacle for others to witness resulting in harassment and humiliation of the victim. It is perceived as a form of emotional abuse.

Threats: generally anonymous in cyberbullying. Due to this anonymity victims tend to live in constant fear that leads to long-lasting depression, low self-esteem and delinquent behaviours.

Name-calling: bullies use denigrating, abusive names and associate them to the victims leaving them humiliated in front of others.

Mockery: pass comments on victims making them feel worthless, disrespecting them and make fun of them in front of others. Escalated form of mockery leads to low self-esteem of the victims.

In order to ensure that all true positives were identified each of the three sets of Tweets were annotated twice by two different annotators with a Cohen's kappa of 0.833. This resulted in a total of 427 instances as harassing Tweets (true positives). In order to further validate the true positives, we did a second round of annotation by randomly dividing the 427 true positives into three lots, and had two annotators to again check each true positive instance. If a true positive instance was rejected by two annotators in the second round we rejected that instance and assigned it as non-cyberbullying or true negative. If a tweet was annotated as bullying by one annotator and non-bullying by the second, then it was looked at together and an agreement was reached. After the second round we had a total of 376 true positive instances which was taken as the ground truth.

2.4 LIWC2007, Psychometric Analysis

Linguistic Enquiry Word Count (LIWC) is a free text analysis application, originally designed to study emotions in text files. It started with counting words in psychology which were relevant to certain categories and it has been developed into a continuously improving software tool. At the beginning, human emotion words were categorized only into negative and positive words. The system architecture of the LIWC too is described in (Pennebaker et al., 2015) and the psychological categories can be found in (Tausczik and Pennebaker, 2010). The default dictionary of LIWC2007 is composed of 4,500 "dictionary words" grouped into four high level categories. The input text is a set of so-called "target words". LIWC2007 processes text files in one of many provided formats and writes the analysis in one output file. If a target word has been found in the dictionary, it will be assigned to one or more categories and the count of each of the categories to which the word belongs is incremented. For example, the word "cried" is part of five categories: sadness, negative emotion, overall affect, verb and past tense verb. The target words are the elements of the pre-processed Tweets in our study, where each Tweet is a unique instance. The output is a vector with 67 numeric values per Tweet corresponding to the number of counts for each of the word category divided by the total number of assignments. The average number of words per Tweet in all of the used, 1313 Tweet, was 18 and 89% of our target words have were found to be in the dictionary. The average number of words in a cyberbullying Tweet was 13 out of which an average of 11 words were assigned to the psychometric word categories. Mostly internet slang words or names of locations were not found in the dictionary.

3 Results and Evaluation

The graph in Fig. 2 shows the average psychometric measurement values for a subset of all 67 features generated by the LIWC tool for the Tweets manually identified as cyberbullying (blue or left line) and those that are not identified as cyberbullying (red or right line). The differences between the calculated values (length of the red and the blue line) for some word categories such as "you", "swear", "negemo", "anger", "bio" and "death" are relatively large and we can assume that the discriminatory power for true positives would be high for these features. But the results have shown that the classifier accuracies dropped by about 6% when the filters reduced the number of features to these features with high correlation. Another observation is that the value for the "sexual" category is almost equal for positive and negative instances because the downloaded Tweets have been selected based on a majority of words

belonging with the "sexual" category. From this we can infer that the words which are elements of the "sexual" category is not necessarily a good predictor of cyberbullying.

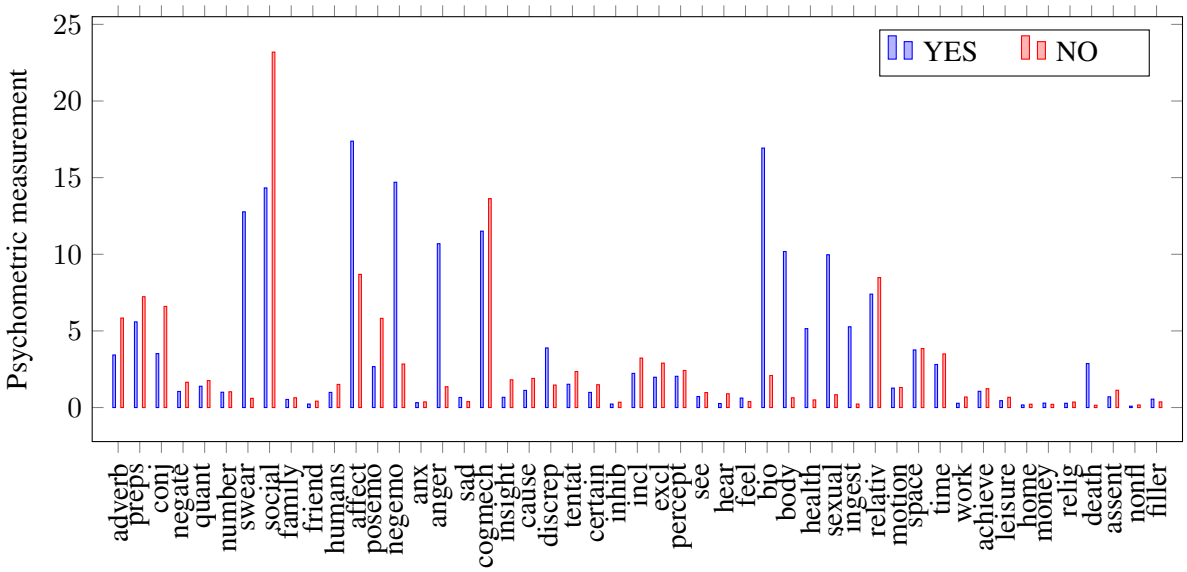

Figure 2: Graph showing the average psychometric measurements for positive and negative instances

The four classifiers have been tested in three lots. The first experiment used all 67 numerical values per instance generated by the LIWC software. Table 1 shows the numerical results for precision and recall for our selected classifiers. The second column in Table 1 provides the results of the cross validation of our trained model using the training data set and the third column shows the results for the test data. We used the usual split of available data, that means 66% for the randomly selected training set and the remaining 34% for the test set. The precision values for the Random Forest classifier are almost equal. SMO achieved the largest value for precision of the training set compared to the other classifiers, but the Random Forest classifier delivered a higher value for the test set. The Random Forest classifier for identifying cyberbullying Tweets had the best performance in this experiment.

Classifier	Cross-Val. 10 Training	Split (66-34) Testing	Results"YES"
Random Forest	0.984	**0.983**	Precision
	0.963	**0.935**	Recall
SMO	0.986	0.965	Precision
	0.912	0.902	Recall
Multilayer Perceptron	0.963	0.873	Precision
	0.912	0.894	Recall
J 48 Decision Tree	0.947	0.935	Precision
	0.941	0.935	Recall

Table 1: WEKA Classifier Outputs for Unfiltered Inputs

The second experiment used only the filtered attributes for classification. Table 2 shows the results for the two different filters for the training set (left two columns) and the test set (right two columns). Precision and recall values for the test data are significantly lower Random Forest, Multilayer Perception and J 48 Decision Tree. The SMO classifier performs best with respect to precision and the ING filter delivered slightly better results for the this classifier. Both filters result in equal results for precision of the training data set when the the Random Forest classifier has been selected, but ING performed slightly better for the test data. Only the J48 Decision Tree classifier delivers for the test data the same results for with respect to filtered and unfiltered inputs, for all other classifiers the achieved values (shown in Table 1 and

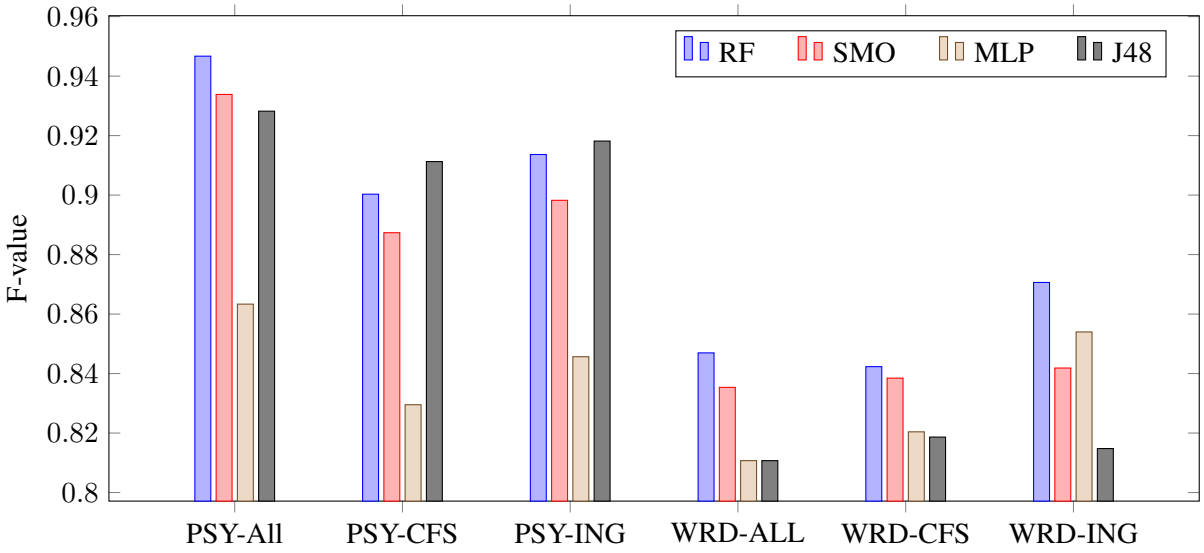

Figure 3: Graph showing the comparison of the F-values for Psychometric versus Words as Features in four classifiers.

Table 2) are equal or better for unfiltered input data.

	Cross-Val. 10		Split (66-34)		
Classifier	CFS	ING	CFS	ING	Results"YES"
Random Forest	0.978	0.978	0.967	0.951	Precision
	0.960	0.952	0.943	0.943	Recall
SMO	0.982	0.986	0.965	0.974	Precision
	0.894	0.910	0.886	0.902	Recall
Multilayer Perceptron	0.951	0.964	0.940	0.866	Precision
	0.939	0.918	0.894	0.894	Recall
J 48 Decision Tree	0.954	0.944	0.932	0.935	Precision
	0.931	0.941	0.894	0.935	Recall

Table 2: WEKA Classifier Outputs for Filtered Inputs

The third experiment was done to determine the effectiveness of the psychometric values generated by the LIWC tool, used as features for the prediction of cyberbullying. Table 3 provides the values for precision, recall and F-value for our test data, filtered and unfiltered applying psychometric features in the upper part of this table. The lower part of the table is a summery of values for the case when we use cleaned Tweets as inputs for the same filtering and classification procedures without applying the LIWC tool to compare the results. The integration of psychometric features produced for all classifiers (filtered or unfiltered attributes) better values. The outcome of our third experiment is a clear vote for transferring the clean text into the 67 LIWC attributes to identify cyberbullying Tweets.

The computed F-values in Table 3 are plotted as a graph in Fig. 3. Table 3 shows that the best performing algorithm was Random Forest with 0.98 precision and 0.91 recall using all 67 psychometric features. The filtered subsets of attributes delivered an approximately 5% drop in accuracy for the Random forest classifier and similar results for the other algorithms. Table 3 also shows that all algorithms performed better with psychometric features compared to word features. For example, the Random Forest precision is 0.983 using psychometric features compared to 0.869 using word features. The graph in Fig. 3 shows that all classifiers using psychometric features perform better than the same classifiers

Psychometric Value Features	**RF**	**SMO**	**MLP**	**J48**

Table 3: Table showing the evaluation metrics for Psychometric and Words as features used on Random Forest, SMO, MLP and J48 classifiers

using words. There were two marked observations from the experiments; Firstly, All four of the chosen classifiers perform better with all of the features rather than a subset of higher correlation features. This was true for both the techniques used to filter the features and for both types of features, the psychometric values as well as words used as features. Secondly, the performance of the classifiers were higher for all the classifiers using psychometric values compared to use of raw words as features. Again, this was true for all the cases of using all features as well as subset of features using the two filtering algorithms.

Many text classification approaches have been performed with Support Vector Machines (SVM) (SMO is a special version of SVM) and the results have shown in many cases that SVM's are the best classifiers for text (Liu et al., 2005; Lee et al., 2012; Isa et al., 2008; Simanjuntak et al., 2010). In our case, the results show that the Random Forest classifier performed slightly better than SVM in both cases (psychometric numeric measurements as well as words used for features). Its noteworthy, to mention that the J48 algorithm also did comparatively well with an F-value over 0.9 for psychometric measurements used as features. While Random Forest, Support Vector Machine and J48's performance are quite close in most of the cases, the Multi Layer Perceptron performed is consistently lower with F-values around 0.8. The results have shown that the unsuitability of MLPs for cyberbullying, reaffirmed the suitability of SVMs for text classification. However, in addition, the results show that decision tree based algorithms, Random Forest and J48, can also perform well in short text classification, which is contrary to most of the previously reported results.

4 Discussion on Cyberharassment and Future

The issue of cyber harassment in this study as well as other studies have shown that it is complex, both in terms of definition of the problem as well as finding a solution for the problem. Almost all of the prior works (Cortis and Handschuh, 2015; Nandhini and Sheeba, 2015; Kansara and Shekokar, 2015; Xu et al., 2012a; Dinakar et al., 2011; Dadvar and De Jong, 2012; Han et al., 2015) on cyberbullying have worked on the generic problem of cyberharassment, however have referred to them as cyberbullying. However, Hosseinmardi et al. (2015) have analyzed the issue in detail and distinguished between targeted bullying, which has been referred to as cyberbullying in this paper, and general cyber aggression, referred to as cyberharassment in this paper. The broader definition of cyber aggression includes any form of digital media use to intentionally harm another person or persons. This includes targeting individuals by name calling, flaming, denigration, exclusion, etc. as well as indirect forms such as use of profanities, slangs and comments which are indirectly applicable to the individual's group, or the choice(s) made by the individual. Hosseinmardi et al. (2015), provide two additional criteria for cyberbullying as an imbalance of power between the aggressor and the victim. Their second criteria is the repetition of the act over time. The imbalance of power could be in several forms such as physical, psychological or social. For instance, an individual who is more popular bullying a less popular one or one who is physically stronger bullying a weaker one. This characteristic adds an additional level of complexity for automatic detection systems since all forms of the power imbalance is rarely known for members on social media platforms. The second criteria of repetition poses yet another level of complexity, which would require nested layers of data collection and analysis corresponding to threads of conversation rather than contents of individual posts. Research on cyberharassment will continue to be based on contents of individual posts unless the social media sites relax the data access policies and give access to thread based data. Nevertheless, research has continued to progress in detecting different forms of cyberbullying cases, especially in light of increased number of cyberbullying cases resulting in suicides and other forms of self harm. In addition to the text based platforms such as Twitter, there are several social media platforms, such as MySpace and Instagram which use a multi-modal communication model. Use of pictures and videos in addition to texts gives additional ammunition to potential bullies and presents an even greater challenge for bullying detection researchers. In spite of these challenges researchers (Han et al., 2015; Hosseinmardi et al., 2015) have attempted to work on systems to detect bullying on multi-modal social platforms by using a combination of pictures and text to detect true positives with reasonably good accuracy. For instance, Hosseinmardi et al. used a combination of text, pictures and user metadata to classify Intagrams with a recall of 76% and a precision of 62% using a MaxEnt classifier. The authors used linear SVM classifiers text based n-grams with stop word removal and used crowd sourced CrowdFlower website to establish ground truth. Although the use of the images in this study was at a basic level with categorization of images into categories such as Person, Drugs, Car, Nature and Celebrity as features for the classifier, this is a step in the right direction towards processing multimedia blogs. A lot more effort is required before it would be possible to build systems to detect harassment on multimedia social media platforms.

5 Conclusion

The results presented in this paper show that firstly it is possible to detect cyberharassment with fairly good precision. Secondly, we have shown that the use of psychometric measurements from the LIWC tool as features delivers slightly better results compared to the use of words for all of the algorithms tested. Further, out of the four classifiers tested, the Random Forest classifier proved to be the best performing both with words as classifiers as well as with psychometric measurements. The psychometric measurements uses the classification of all of the in the text which implies that cyberharassment is not only a function of profane words, but use of other category of words such as use of pronouns also determine whether a piece of text is harassing or not. As future work, we plan to use psychometric measurements with thread based social media texts instead of individual pieces of texts as this will be able to better determine the level of bullying rather than harassment as has been the case in this study.

Abstract

Learning word categories is a fundamental task in language acquisition. Previous studies show that co-occurrence patterns of preceding and following words are essential to group words into categories. However, the neighboring words, or frames, are rarely repeated exactly in the data. This creates data sparsity and hampers learning for frame based models. In this work, we propose a paradigmatic representation of word context which uses probable substitutes instead of frames. Our experiments on child-directed speech show that models based on probable substitutes learn more accurate categories with fewer examples compared to models based on frames.

1 Introduction

Children abstract grammatical rules from individual words (e.g. baby, talk) and eventually apply them to word categories (e.g. noun, verb, adverb). A word category represents a group of words that can be substituted for one another without altering the grammatical appropriateness of a sentence. Learning word categories is an important step in language development.

The Distributional Hypothesis (Harris, 1954) suggests that words occurring in similar contexts tend to have similar meanings and grammatical properties. Studies on extraction of word categories have shown that distributional information of word co-occurrences is a reliable cue for the learning of word categories (Mintz, 2003; St Clair et al., 2010; Redington et al., 1998). Children need to extract word categories from incoming speech stream in order to be able to predict how words behave in various grammatical contexts and to produce words in appropriate grammatical constructions. Children tend to form word categories that group words used in similar contexts.

To judge how similar two contexts are, one can use syntagmatic or paradigmatic representations of the word context: A syntagmatic representation is based on the neighbors of the target word whereas a paradigmatic representation uses potential substitutes for the target word.

In this paper, we hypothesize that children judge context similarity using a paradigmatic representation: a context is similar to another if the same words can be substituted in both. The following two examples[1] illustrate the advantage of paradigmatic representations in uncovering latent similarities where a syntagmatic representation would fail to see any overt similarities. The word "you" from the first sentence and the word "I" from the second sentence have no common neighbors within the same sentence. The paradigmatic representation, shown below the sentences as substitute word probabilities, captures the similarity of these contexts by suggesting similar top substitutes for both:

(1) *"they fall out when* **you** *put it in the box ."*
you: you(.8188), I(.1027), they(.0408), we(.0146) . . .

(2) *"what have* **I** *got here ?"*
I: we(.8074), you(.1213), I(.0638), they(.0073) . . .

*Work was done when authors were at Koç University.

[1]These examples are extracted from the Anne corpus from CHILDES (MacWhinney, 2000). The computation of substitute word probabilities is described in Section 3.3.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 707–716, Osaka, Japan, December 11-17 2016.

The high probability substitutes reflect both semantic and grammatical properties of the context. The top substitutes for "I" and "you" are pronouns. As an additional example, the top substitutes for the word "fall" in the first sentence are other motion verbs: come(.7875), go(.0305), fall(.0232), . . .

These examples show that the paradigmatic representation can relate a pair of words according to the substitute word distribution of their contexts even when the surface forms of the contexts do not share any common neighbors. This makes the paradigmatic representations of word context more robust to the data sparsity compared to the syntagmatic representations, due to low re-occurrence frequency of large frames.

The rest of the paper is organized as follows. In the next section, we describe prior distributional approaches to word category acquisition. In Section 3, we provide a detailed explanation of our calculations of substitute words. In Section 4, first we introduce the experimental setup we used and give the details of the experiments to contrast the paradigmatic approach with the syntagmatic approach. The last section summarizes our contributions.

2 Related Work

In this section we review distributional approaches to word category acquisition and evaluate them based on two success criteria: accuracy and completeness. Accuracy measures how accurate the predictions were at grouping the words into the same word category together. Completeness, on the other hand, measures how well a given category is predicted.

Redington et al. (1998) define the context of a word as the previous and following words. They construct context vectors of target words for clustering. Using average link clustering, target words are separated into categories. Although the resulting categorizations are generally accurate, the method is weak in completeness because words that do not appear in frequent frames cannot be covered.

Mintz (2003) proposes top-N frequent frames surrounding a target word as a more fitting context to derive word categories from. A frequent frame consists of left and right neighbors that co-occur frequently. Experiments on child-directed speech reveal that frequent frames have the ability to assign word categories with high accuracy. However, this method also lacks satisfactory completeness. St Clair et al. (2010) combine the bigram's coverage power (Redington et al., 1998; Monaghan and Christiansen, 2008) and the accuracy of frequent frames (Mintz, 2003). Their experiments suggest that to match the performance of infants both bigram and trigram sources may need to be used.

Freudenthal et al. (2005) identify a complication of distributional methods for constructing word categories. Distributional methods suggest that words occurring in a similar context can be used interchangeably. They claim the evaluation methods used in studies like (Redington et al., 1998; Monaghan and Christiansen, 2008; Mintz, 2003) could be misleading. Specifically, if a word is substituted with another one in its category, the resulting sentences could be erroneous in a way that they are not observed in infants' speech. As a success criterion, they argue that the proposed categorization should generate plausible sentences. They introduce a chunking mechanism merging words that are seen frequently. The mechanism is successful in generating meaningful sentences, still, the proposed solution is computationally too complex as a learning mechanism in infants.

Alishahi and Chrupała (2012) propose an incremental learning scheme inducing soft word categories while learning the meaning of words. Thothathiri et al. (2012) examine the role of prosody in infants' distributional learning of syntactic categories and concludes that the prosody shows little influence. Reeder et al. (2013) discuss the use of distributional knowledge when the evidence in the possible context of a word is not enough. Furthermore, they explain how and when language users form new categories depending on the overlaps between the context words.

In the related part-of-speech induction literature[2], Schütze (1995) incorporates paradigmatic information by concatenating the left and the right co-occurrence vectors of the right and left neighbors respectively, and groups words that have similar vectors. The limitation of this model is that it uses only bi-gram information and suffers from sparsity as the context size gets larger. Yatbaz et al. (2012) calculate the most probable substitutes of a given context using a 4-gram statistical language model. Their

[2]See (Christodoulopoulos et al., 2010) for a comprehensive review of the part-of-speech induction literature.

model achieves the state-of-the-art result in the part-of-speech induction literature. Part-of-speech induction aims to induce word-categories from large amounts of unannotated text (mostly news corpora). Our paper evaluates the substitute-based context representation by Yatbaz et al. (2012) as a possible feature for classifying words in relatively small amounts of child-directed speech.

3 Method

In this section we explain the experimental methodology we used, including how the input corpora was processed, the language model was trained, the evaluation metrics, and the computational model to learn grammatical categories.

3.1 Input Corpora

To compare results with (St Clair et al., 2010) and (Mintz, 2003), we use the same six corpora of child-directed speech from the CHILDES[3] corpus (MacWhinney, 2000): Anne and Aran (Theakston et al., 2001), Eve (Crystal, 1974), Naomi (Sachs, 1983), Nina (Suppes, 1974), Peter (Bloom et al., 1974; Bloom et al., 1975). Following (Mintz, 2003) we only analyze the adult utterances in sessions where the target child is 2.6 years old or younger. Table 1 summarizes the number of target word tokens and types in each corpus.

Table 1: Summary of the total number of tokens, utterances and types in each child corpus together with the number of utterances and types that are observed as target word in a three word window aXb.

Corpus	Tokens	Utterances	Utterances Categorized		Types	Types Categorized	
			Count	%		Count	%
Anne	121726	93371	42789	45.82	2623	1846	70.37
Aran	129823	104997	54768	52.16	3256	2595	79.69
Eve	78778	59095	27315	46.22	2184	1465	67.07
Naomi	38302	28793	13002	45.15	1883	1194	63.40
Nina	89957	72879	39335	53.97	2036	1580	77.60
Peter	94521	72834	34997	48.05	2145	1472	68.62

The target grammatical categories of words in CHILDES are extracted by first applying the MOR parser (MacWhinney, 2000) and then using the POST disambiguator (Sagae et al., 2004). The accuracy of CHILDES grammatical categories is approximately 95% (Parisse and Le Normand, 2000) and is encoded in the MOR line of the CHILDES corpus.

3.2 Algorithm

We use supervised learning with a feed-forward connectionist model (a single hidden layer neural network) to compare the effect of distributional cues from various context representations on the word category learning. The input is a representation of the word context and the output is a word category. We evaluate two models with different input representations:

- $aX + Xb$ **model:** This is the flexible frames model of St Clair et al. (2010), the best performing syntagmatic model. Consider a five word window $a_1a_2Xb_1b_2$ where X is the target word. The input to the model consists of two one-hot vectors, one that correspond to the preceding bigram (a_1a_2) and one to the succeeding bigram (b_1b_2). Thus two input units are activated to represent the context of each target word.

- $a * b$ **model:** This is the paradigmatic model investigated in this paper. First, a small number of substitutes are sampled for the target word based on an n-gram language model as described in the next section. The input to the model consists of the counts of the substitutes in the sampled set. The length of the input vector is equal to the size of the substitute vocabulary.

[3]Specifically, CHILDES version 2.0.1 is used in experiments.

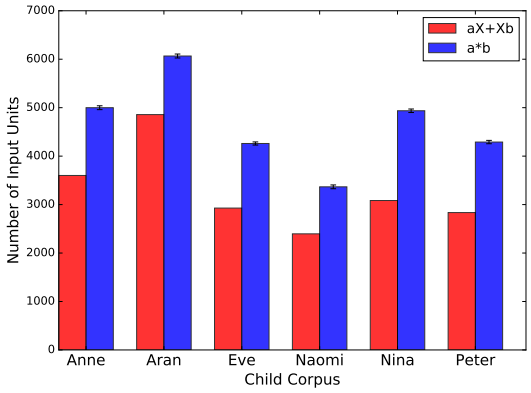

Figure 1: Number of input layer units of the flexible frame ($aX + Xb$) and the substitute based ($a * b$) models. ($a * b$) samples 16 substitutes per target word. Standard errors are reported with error bars.

Figure 1 gives the number of input layer units of syntagmatic ($aX + Xb$) and paradigmatic ($a * b$) models on each child corpus separately. The number of distinct frames is fixed for any given corpus while the number of distinct substitutes varies due to the random sampling. Both models have 10 output units due to the standard labeling (Mintz, 2003).

Unless stated otherwise, all connectionist models in this paper use the following parameters: (1) number of hidden units is set to 200 and initialized randomly for each model. (2) The non-linearity is sigmoid and the learning rate is 0.2.

3.3 Substitute Words

In the paradigmatic ($a * b$) model, we predict the word category of a word in a given context based on its most likely substitute words. We measure the likelihood of substitute words using an n-gram language model. Here, we first describe how substitute probabilities can be computed using an n-gram model and give details on training the n-gram model.

It is best to use both the left and the right context when estimating the probabilities for potential lexical substitutes. For example, in *"He lived in San Francisco suburbs."*, the token *San* would be difficult to guess from the left context but it is almost certainly determined looking at the right context.

We define the context c_w of a given word w as the $2n-1$ word window centered around the position of w : $w_{-n+1} \dots w \dots w_{n-1}$. The probability of a substitute word w in a given context c_w is estimated as:

$$
\begin{aligned}
P(w_0 = w|c_w) &\propto P(w_{-n+1} \dots w_0 \dots w_{n-1}) && (1)\\
&= P(w_{-n+1})P(w_{-n+2}|w_{-n+1}) \dots P(w_{n-1}|w_{-n+1}^{n-2}) && (2)\\
&\approx P(w_0|w_{-n+1}^{-1})P(w_1|w_{-n+2}^{0}) \dots P(w_{n-1}|w_0^{n-2}) && (3)
\end{aligned}
$$

where w_i^j represents the sequence of words $w_i w_{i+1} \dots w_j$. In Equation 1, $P(w_0 = w|c_w)$ is proportional to $P(w_{-n+1} \dots w_0 \dots w_{n+1})$ because the words of the context are fixed. Terms without w_0 are identical for each substitute in Equation 2 therefore they have been dropped in Equation 3. Finally, only the closest $n-1$ words are used in the experiments. Note that the substitute word distribution is a function of the context only and is indifferent to the target word.

Near the sentence boundaries the appropriate terms were truncated in Equation 3. Specifically, at the beginning of the sentence shorter n-gram contexts were used and at the end of the sentence terms beyond the end-of-sentence utterance were dropped.

To train the n-gram model, we first extracted training data of approximately 6.8 million tokens[4] of child-directed speech data from CHILDES. We trained a 4-gram language model on this data with Kneser-Ney discounting using SRILM (Stolcke, 2002). Words that were observed less than 2 times in the language model training data were replaced with an unknown word tag, which gave us a vocabulary size of 21734.

[4] Anne, Aran, Eve, Naomi, Nina, and Peter corpora are excluded.

3.4 Evaluation

To evaluate classification accuracy we use the standard labeling (Mintz, 2003)[5] that categorizes target words as: nouns (including pronouns), verbs (including copula and auxiliaries), prepositions, adjectives, adverbs, determiners, conjunctions, wh-words, negation (i.e., "not") and interjections. Following St Clair et al. (2010), we also report the asymmetric lambda value (Goodman and Kruskal, 1979) to compare the association among the classification of grammatical categories.

3.5 Training and Testing

We measure and compare the classification accuracy of models by applying 10-fold cross validation on the union of six child corpora. We randomly split each child corpus into 10 folds. The main advantage of the cross validation is that all sentences are eventually used both for testing and training.

To compare the effects of paradigmatic representation ($a * b$) with the syntagmatic one ($aX + Xb$) we train and test both models using the identical 10-fold cross validation split. Thus every model in this paper is exposed to the identical sequence of training and testing patterns. Unless stated otherwise, in the rest of this paper, we stopped the training phase of feed-forward connectionist model on each corpus after $100K$ input patterns, used the standard labeling to evaluate model accuracies, calculated substitute distributions as described in Section 3.3, and sampled 16 substitutes per target word in models using the paradigmatic representation.

Section 4 compares the classification accuracies of syntagmatic and paradigmatic representation based models. The effects of the number of substitutes and the language model n-gram order on the paradigmatic model performance are inspected in Section 5 and 6, respectively.

4 Experiment 1: Syntagmatic vs Paradigmatic

To compare the distributional information of syntagmatic and paradigmatic representations, we train separate feed-forward connectionist models for each child corpus based on these representations. St Clair et al. (2010) showed that flexible frames have richer distributional information than other frame types both in terms of classification accuracy and coverage. Thus we only report results of the models based on substitute words ($a * b$) and flexible frames ($aX + Xb$).

Method. All models are trained and evaluated according to steps summarized in Section 3.5. To see the effect of training data size, similar to the analysis in (St Clair et al., 2010), we split the training of each model into short and long training phases in which we stop and evaluate the models on the corresponding test sets after presenting identical 10K and 100K training patterns, respectively.

Results of Short Training Phase. Table 2 gives the overall classification accuracies of $aX + Xb$ and $a * b$ models on each child corpus. The accuracy of $a * b$ model significantly outperforms the $aX + Xb$ model on each child corpus even with a limited amount of training patterns. Lambdas of the $a * b$ model are significantly closer to the perfect association than lambdas of the $aX + Xb$ model. Lambdas of both models are significantly different from zero association.

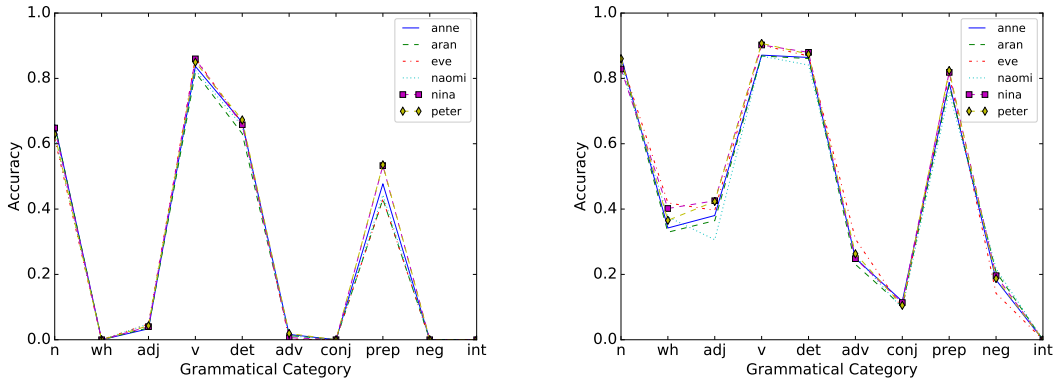
To further investigate the accuracy gap between $aX + Xb$ and $a * b$ models, we plot the classification accuracies of each grammatical category in the standard labeling for both models in Figure 2. Even after 10K training patterns both models are able to achieve relatively high accuracies on nouns (*n*), verbs (*v*), determiners (*det*) and prepositions (*prep*) than the rest of the word categories. The $a * b$ model is more successful than the $aX + Xb$ model in learning word categories such as wh-words (*wh*), adjectives (*adj*), adverbs (*adv*), conjunctions (*conj*), and negations (*neg*).

Finally, with limited amount of training patterns, the $a * b$ model is able to categorize nine out of ten grammatical categories in each child corpus with some accuracy. On the other hand, the $aX + Xb$ model performs poorly on *wh*, *conj*, *adv*, *neg* and *int* and can not correctly classify any members of these word groups in at least one of the child corpora.

[5] (Mintz, 2003) also defined an expanded labeling in which pronouns, auxiliaries and copula forms have their own categories.

Table 2: 10-fold cross-validation classification accuracies of models based on flexible frames ($aX + Xb$) and substitutes ($a * b$) on each child corpus after 10K training patterns are summarized. Standard errors are reported in parentheses. Lambdas of $aX + Xb$ and $a * b$ are both tested against each other and zero association by using two tailed z-test. All tests have $p < .001$.

Corpus	$aX + Xb$		$a * b$	
	Accuracy	λ	Accuracy	λ
Anne	.6252 (.0231)	.4323 (.0352)	.7970 (.0069)	.6925 (.0111)
Aran	.5968 (.0218)	.3908 (.0327)	.7783 (.0083)	.6653 (.0123)
Eve	.6193 (.0192)	.4248 (.0306)	.8091 (.0100)	.7116 (.0141)
Naomi	.6054 (.0236)	.3960 (.0395)	.7771 (.0100)	.6598 (.0178)
Nina	.6438 (.0216)	.4521 (.0362)	.8146 (.0096)	.7150 (.0162)
Peter	.6255 (.0246)	.4402 (.0372)	.8086 (.0088)	.7140 (.0130)



(a) $aX + Xb$ (b) $a * b$

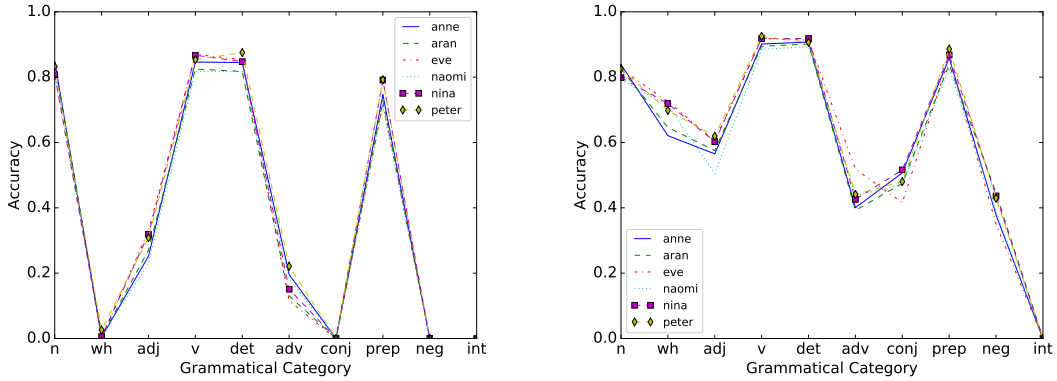
Figure 2: Individual tag accuracies of $aX + Xb$ and $a * b$ on each child corpus after $10K$ training patterns are presented.

Results of Long Training Phase. The previous section shows that the $a * b$ model is more accurate than the $aX + Xb$ model on learning word categories with limited amount of language exposure. In this section each model is trained with 100K input patterns to observe the effect of more extensive language exposure on learning.

Table 3 summarizes the overall classification accuracies of $aX + Xb$ and $a * b$ models on each child corpus. Although differences between corresponding accuracies and lambda values of $aX + Xb$ and $a * b$ models are less than 10K experiments, the $a * b$ model is still significantly more accurate than the $aX + Xb$ model on all child corpora. The $a * b$ model benefits less from the extensive training than the $aX + Xb$ model. One possible explanation for this behavior is that the number of input units of the $a * b$ model on each child corpus is significantly higher than the $aX + Xb$ (see Figure 1) while the number of hidden units is fixed to 200 for both models. Following St Clair et al. (2010), we experimented with the number of hidden units such that the ratio between the number of input units and the number of hidden units is the same for both models. We did not observe significant changes on the result.

Table 3: 10-fold cross-validation classification accuracies of models based on flexible frames ($aX + Xb$) and substitutes ($a * b$) on each child corpus after 100K training patterns are used. Standard errors are reported in parentheses. Lambdas of $aX + Xb$ and $a * b$ are both tested against each other and zero association by using two tailed z-test. All tests have $p < .001$.

Corpus	$aX + Xb$		$a * b$	
	Accuracy	λ	Accuracy	λ
Anne	.7628 (.0075)	.6407 (.0124)	.8311 (.0068)	.7442 (.0109)
Aran	.7337 (.0059)	.5977 (.0081)	.8139 (.0073)	.7189 (.0108)
Eve	.7580 (.0068)	.6351 (.0083)	.8396 (.0107)	.7576 (.0160)
Naomi	.7316 (.0086)	.5892 (.0113)	.8041 (.0090)	.7000 (.0169)
Nina	.7755 (.0040)	.6547 (.0075)	.8389 (.0097)	.7523 (.0165)
Peter	.7670 (.0071)	.6518 (.0088)	.8379 (.0073)	.7579 (.0112)



(a) $aX + Xb$ (b) $a * b$

Figure 3: Individual tag accuracies of $aX + Xb$ and $a * b$ on each child corpus after $100K$ training patterns are presented.

Similar to the 10K results, $aX + Xb$ model performs poorly on *wh*, *conj*, *neg*, and *int* as shown in Figure 3. Both models accurately learn the noun, verb, determiner, and preposition groups. However, the $a * b$ model is significantly more accurate on adjectives, conjunctions, and negation.

5 Experiment 2: Number of Substitutes

In this experiment we analyze the effect of the number of substitutes sampled per context on the classification accuracy.

Method. We used the same experimental settings except that the number of substitutes per target word is varied between 1 and 64. We did not observe any significant difference on model classification accuracies for the number of substitutes that are more than 64.

Results and discussion. Figure 4 plots the model classification accuracy of each child corpus versus the number of substitutes. The classification accuracy dramatically increases on each child corpus until the number of substitutes reaches 16. After 16 substitutes, increasing the number of substitutes does not significantly change the classification accuracy. Thus, the model is fairly robust to the number of substitutes as long as the model can observe at least 16 substitutes per target word.

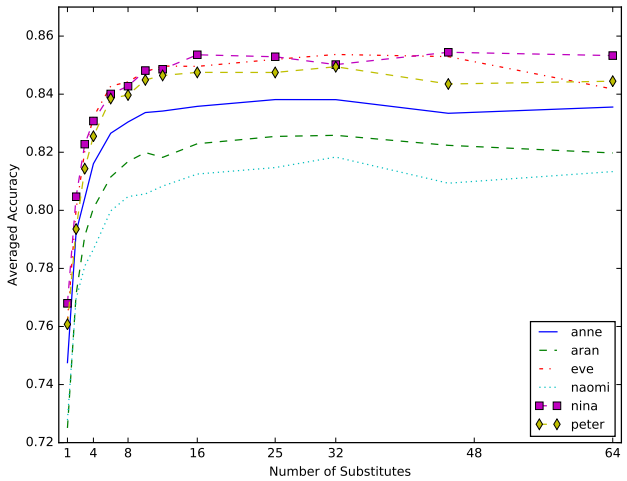


Figure 4: 10-fold cross validation accuracy of each child corpus for different number of substitutes.

6 Experiment 3: Language Model N-gram Order

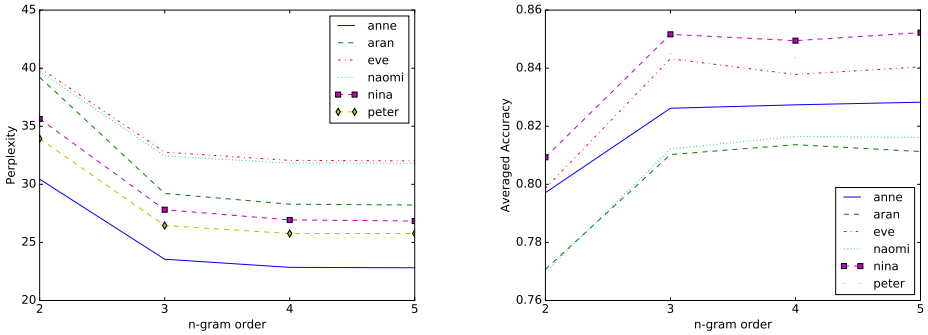
In this set of experiments, we test the paradigmatic model by changing the n-gram order of the language model that is used to sample substitutes. A language model defines probabilities for the sequences of

strings in a language. The n-gram order of language model determines the number of preceding items taken into account while determining the probability of the upcoming word. The previous studies show that young children are sensitive to statistical properties of language (Saffran et al., 1996) and are able to store 4-word sequences (Bannard and Matthews, 2008). Experiments with adults also suggest that the language users are sensitive to co-occurrence patterns beyond bigram (Arnon and Snider, 2010).

The perplexity of the language model is a measurement of the variation of words that can be observed in a given n-gram context window and is determined by n-gram order of the language model. Therefore, as the n-gram order increases the model assigns more relevant substitutes to the context[6].

Method. We used the same experimental settings except that the n-gram order of the language model that is used to sample substitutes is varied from 2 to 5.

Results and discussion. The perplexity of each child corpus is dramatically improved when the n-gram order of the language model is increased from 2 to 3 and varies slightly for orders higher than 3. Figure 5(a) plots the perplexity versus the n-gram order. Figure 5(b) plots the model classification accuracy versus the n-gram order on each child corpus which slightly improve for orders higher than 3 which is in fact parallel to the perplexity trends in Figure 5(a). Overall, the classification accuracy of paradigmatic model is highly correlated with the perplexity of the language model that is used to sample substitutes.



(a) (b)

Figure 5: Language Model perplexities on each child corpus for different n-gram orders are presented on the left figure while 10-fold cross validation accuracies calculated based on these models are presented on the right.

7 Conclusion

In this work, we proposed representing word context with substitute-based paradigmatic representations as opposed to neighbor-based syntagmatic representations for word category acquisition. The paradigmatic approach suggests using probable substitutes of word ($a * b$). On the other hand, the syntagmatic approach we used proposes using the preceding bigram and the succeeding bigram, whichever is fruitful ($aX + Xb$). Our experiments showed that paradigmatic representation of context is more accurate in learning word categories.

To contrast these two representations we replicated the experimental setup of St Clair et al. (2010). Experiments showed that when the models exposed to limited amount of training patterns the $a * b$ is significantly more accurate than $aX + Xb$. Results of the long training phase demonstrated the same pattern, however, the gap between these approaches decreased.

We investigated the dependency of the model to the number of substitutes sampled for each context. In this experimental setup the number of substitutes varies from 1 to 64. The results showed that the accuracy of the model dramatically increases up to 16. After 16 substitutes, no significant improvement in accuracy was observed. We conclude that the model is robust as long as 16 substitutes are sampled.

[6](Goodman, 2001) showed that the perplexity plateaued when the order is higher than 5 for datasets of about 10^8 words.

We explored the effect of the n-gram order of the language model to the accuracy of the model. While determining the probability of the next word in a sequence of words, n-gram order determines how many preceding words should be used. Our results demonstrated that the model's performance depends on the n-gram order of the language model up to order 3, larger contexts do not seem to improve the performance.

Understanding the Lexical Simplification Needs of Non-Native Speakers of English

Gustavo Henrique Paetzold and **Lucia Specia**
Department of Computer Science
University of Sheffield, UK
{g.h.paetzold,l.specia}@sheffield.ac.uk

Abstract

We report three user studies in which the Lexical Simplification needs of non-native English speakers are investigated. Our analyses feature valuable new insight on the relationship between the non-natives' notion of complexity and various morphological, semantic and lexical word properties. Some of our findings contradict long-standing misconceptions about word simplicity. The data produced in our studies consists of 211,564 annotations made by 1,100 volunteers, which we hope will guide forthcoming research on Text Simplification for non-native speakers of English.

1 Introduction

Text Simplification is a useful application both to improve other Natural Language Processing tasks and to assist language-impaired readers (Chandrasekar et al., 1996). When a simplifier aims to help people, understanding their needs becomes very important. In Lexical Simplification – the task of replacing complex words and expressions with simpler alternatives – this has been shown to be the case (Rello et al., 2013b; Rello et al., 2013a; Rello et al., 2013c). They describe several user studies conducted with readers suffering from Dyslexia and outline the most recurring challenges faced by them, as well as the most effective ways to overcome these challenges.

Given the widespread availability of content in English, non-native speakers of English become an important group to focus on. Reves and Medgyes (1994) elaborate on the differences between native and non-native English teachers from an educational and behavioural standpoint. However, we were not able to not find user studies that investigate the needs of non-native speakers from the perspective of Text Simplification. In this paper, we introduce three user studies that aim to do so.

Each user study pertains to one of three steps in the usual Lexical Simplification pipeline (Figure 1): Complex Word Identification, Substitution Selection and Substitution Ranking. In the sections that follow, we describe the findings of each user study.

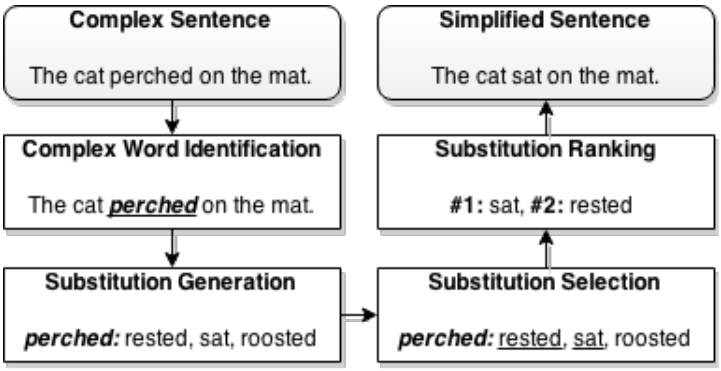

Figure 1: Common Lexical Simplification Pipeline

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 717–727, Osaka, Japan, December 11-17 2016.

2 Complex Word Identification

Complex Word Identification (CWI) is the task of deciding which words should be simplified in a text. Effective CWI strategies identify words which should not be simplified, and hence prevent LS systems from making inappropriate replacements (Paetzold, 2015). As shown in (Paetzold and Specia, 2013; Shardlow, 2014), ignoring CWI can considerably decrease the quality of the output produced by a simplifier. The goals of our user study on CWI are to:

- Provide a better understanding on features of words that challenge non-native English speakers, and
- Create a dataset that allows us to conceive models that automatically identify complex words.

2.1 Data Sources

We selected 9,200 sentences with 20-40 words in length, at random, from three sources:

- **CW Corpus** (Shardlow, 2013b): Composed of 731 sentences from the Simple English Wikipedia in which exactly one word has been simplified by editors from the standard English Wikipedia. 231 sentences that conformed to our criteria were extracted.
- **LexMTurk Corpus** (Horn et al., 2014): Composed of 500 sentences from the Simple English Wikipedia containing one word simplified from the standard English Wikipedia. 269 sentences were extracted.
- **Simple Wikipedia** (Kauchak, 2013): Composed of 167,689 sentences from the Simple English Wikipedia, each aligned to an equivalent sentence in the standard English Wikipedia. We selected a set of 8,700 sentences from the Simple Wikipedia version that were aligned to an identical sentence in Wikipedia.

2.2 Annotation Process

400 non-native English speakers participated in this study, all students and staff from various universities around the world. Volunteers provided information about their native language, age, education level and English proficiency level according to CEFR (Common European Framework of Reference for Languages). They were given a set of sentences and asked to judge whether or not they could understand the meaning of each content word and to annotate all words that they could not understand individually, even if they could comprehend the meaning of the sentence as a whole. The exact instructions given to annotators are as follows:

> *For each sentence, mark all the words you do not understand, even if you understand the sentence as a whole. If you understand all of them, just select the "I understand all words!" option.*

In order to offer some form of financial compensation for their work, all annotators who successfully completed the task were automatically included in a monetary prize draw (£50). This compensation method was used in all user studies described in this paper.

For agreement analysis purposes, 200 sentences were annotated by 20 volunteers each, while the remaining 9,000 sentences were annotated by only one volunteer (i.e. each volunteer annotating an average of 22 sentences from the 9,000).

3 Dataset Analysis

The resulting dataset contains 158,624 annotations. 3,854 distinct words (6,388 in total) were deemed complex by at least one annotator. In the following sections, we discuss details of the data collected.

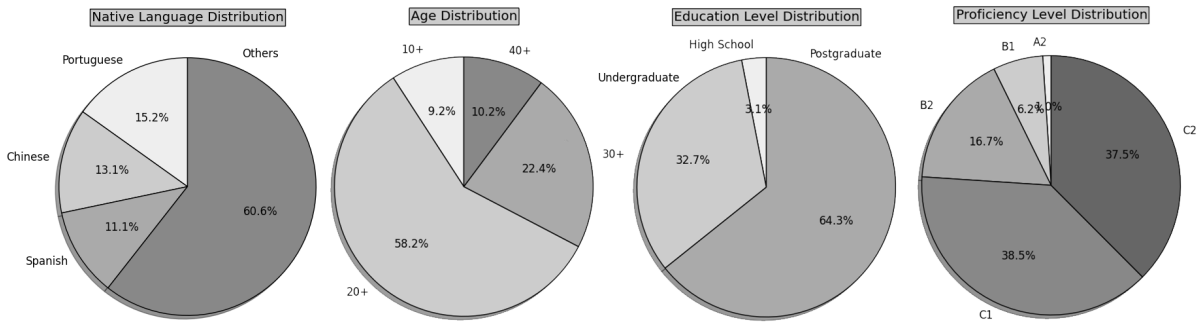

Figure 2: Annotators' backgrounds

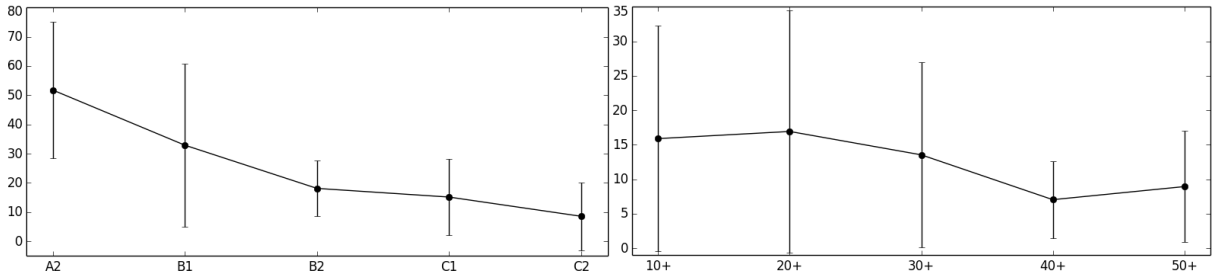

(a) Proficiency level versus words deemed complex

(b) Age bands versus words deemed complex

Figure 3: Relationship between number of words deemed complex and the annotators' profiles

3.1 Profile of Annotators

Annotators spoke 45 different languages. The distributions with respect to native language, age, education and English proficiency levels are illustrated in Figure 2. As shown in Figures 3a and 3b, the data reveals interesting correlations between the number of complex words annotated and volunteers' age or English proficiency level.

Through F-tests, we found a significant difference ($p < 0.01$) between the band of 40+ years of age and the bands of 10+, 20+ and 30+ years of age. We also found significant differences between almost all English proficiency levels above A2, except between B2 and C1. Interestingly, B2 and C1 happen to have the same description in the London School Level Scale[1]: "*I speak and understand well but still make mistakes and fail to make myself understood occasionally*". We did not find significant differences among education levels.

3.2 Analysis of Data Sources

We found that the target words from the CW and LexMTurk datasets were deemed complex at least once by our annotators in only 51.9% and 40.8% of the instances, respectively. As for the remaining Simple Wikipedia instances, we discovered that at least one word in 27.3% of the instances was deemed complex by an annotator, which suggests that the simplified version of Wikipedia may still challenge non-native English speakers.

3.3 Features of Complex Words

We extracted and analysed 15 features that highlight the differences between simple words and those deemed complex by the annotators. We choose these features because they are the most widely used word complexity indicators in current work in Text Simplification. The features can be grouped in three types:

- **Morphological:** Word length and number of syllables, according to Morph Adorner (Burns, 2013).

[1] http://www.londonschool.com/level-scale

- **Semantic:** Number of senses, synonyms, hypernyms and hyponyms, according to WordNet (Fellbaum, 1998).

- **Lexical:** N-gram language model log-probabilities from the SubIMDB (Paetzold and Specia, 2016), Subtlex (Brysbaert and New, 2009) and Simple Wikipedia (Kauchak, 2013) corpora. We trained a specific language model using SRILM (Stolcke, 2002) from each of these corpora in order to estimate n-gram log-probabilities.

Table 1 shows the average feature values and standard deviations for all complex and simple words in the part of the dataset annotated by 20 volunteers. We define as complex any word which has been judged so by at least $n \in \{1, 5, 10\}$ annotators. The $[i, j]$ indicators present in the n-gram features of Table 1 refer to the number of tokens to the left (i) and right (j) of the words that was considered. Consequently, $[0, 0]$ refer to single-word frequencies. The column succeeding feature values indicate whether there was ($\bullet$) or not ($\circ$) a statistically significant difference between complex and simple words ($p < 0.01$), given the results of an F-test.

	$\mathbf{n=1}$			$\mathbf{n=5}$			$\mathbf{n=10}$

Table 1: Average and standard deviation of features of words deemed complex or simple by at least n annotators. The $[i, j]$ indicators refer to the number of tokens to the left (i) and right (j) considered by n-grams. The p columns' values indicate the presence ($\bullet$) or not ($\circ$) of a statistically significant difference.

The results shed some light on word complexity for a non-native English speaker. They show that, unlike semantic and lexical features, length and number of syllables have little to do with complexity. Although it has been found that shorter words do promote understandability for readers suffering from Dyslexic (Rello et al., 2013b), our findings reveal that long words are not necessarily more difficult to understand for non-native English speakers.

When it comes to semantic properties, it can be noticed that, while both average and standard deviation values for complex words decrease as the number of complex judgements increase, the same does not happen for simple words. This phenomenon suggests a relationship between ambiguity and complexity, where complex words are more likely to be unambiguous. This finding is in line with those of (Shardlow, 2013a), who successfully modelled word complexity by exploring the hypothesis that complex words tend to be less ambiguous.

Interestingly, a somewhat similar relationship can be observed between lexical properties and word simplicity: while the n-gram log-probabilities of complex words are low on average and have high variance across all scenarios, the average log-probabilities of simple words are much higher, and they vary much less.

3.4 Agreement Analysis

Here we calculated Kappa's pairwise inter-annotator agreement coefficient (Carletta, 1996) for all pairs of annotators who were presented with sentences from the overlapping portion of the data. The values average to 0.616 ± 0.05, which is much higher than the agreement scores obtained in previous work in similar tasks. For example, the Lexical Substitution tasks of SemEval 2007 (McCarthy and Navigli,

2007) and 2010 (Mihalcea et al., 2010) obtain an agreement of 0.277 for their annotations, while the English Lexical Simplification task of 2012 obtains an agreement of 0.398 (Specia et al., 2012).

Perhaps more impressive is the agreement within certain classes of annotators. Although the agreement for annotators with the same proficiency level is lower (0.575 ± 0.07), the agreements within education levels and age bands are noticeably higher, reaching 0.638 ± 0.08 and 0.671 ± 0.08, respectively. The highest agreement is reached by annotators with the same native language: 0.718 ± 0.1. Inspecting the annotations, we found that the speakers of certain languages are sometimes challenged by words which, in most cases, are not considered complex by native speakers of any other languages. Table 2 illustrates the words with the highest percentage of variance (Brysbaert and New, 2009) between the number of times that they were deemed complex by the speakers of a specific native language, and the rest of the annotators.

Language	1	2	3	4	5	6
Arabic	fur	juvenile	apprenticed	city	serologic	link
Chinese	canton	inscribed	opium	referendum	thorax	contaminants
French	sewerage	subsequent	warships	escudo	dye	ridges
German	escape	strong	early	city	escudo	iconoclastic
Portuguese	rather	hurricane	undergo	southern	ruler	crude
Spanish	bailed	cryptanalysis	plaque	debris	demise	perm

Table 2: Words with highest percentage of complexity variance per native language. Indexes in the first row indicate the words' percentage of variance rank, from highest to lowest.

4 Substitution Selection

Substitution Selection (SS) is the task of deciding which candidate substitutions can replace a complex word in a given context. Its goal is to prevent a simplifier from performing replacements that compromise the sentence's grammaticality and/or meaning. The goals of this user study were to:

- Understand what makes a good candidate substitute for a complex word, and
- Create a dataset to build more effective substitution selectors.

Notice that we skip the step of Substitution Generation in our user studies. We do so because we believe that the extensive experiments of Horn et al. (2014) and De Belder and Moens (2012) already provide sufficient insight with respect to the relationship between Substitution Generation and the needs of non-native English speakers.

4.1 Data Sources

We first created a list of 1,471 complex words by filtering any numbers, names, colours and stop words from the ones obtained in the CWI study. We then produced an average of 50 candidate substitutions for each word by combining the output of all Substitution Generation systems in the LEXenstein framework (Paetzold and Specia, 2015). These systems exploit complex-to-simple parallel corpora (Horn et al., 2014), word embedding models (Glavaš and Štajner, 2015; Paetzold and Specia, 2016), WordNet (Devlin and Tait, 1998; Biran et al., 2011) and the Merriam Dictionary[2] (Kajiwara et al., 2013). Using the strategy described in (Paetzold and Specia, 2015), we selected the 10 candidates with the highest semantic similarity to each complex word. Using the Text Adorning module of LEXenstein, we ensured that all candidates have the same conjugation form as the complex word itself.

Finally, we extracted, according to availability, up to three sentences from Wikipedia in which each of these complex words appear (2,554 in total), and created 25,540 annotation instances by replacing the complex word in each sentence with one of the 10 candidate substitutions selected.

[2]http://www.merriam-webster.com

4.2 Annotation Process

400 fluent speakers of English participated in this study, all students and staff from different universities around the world. We recruited native English speakers for this task because it requires that the annotator understands the meaning of the complex word in question in order to make the necessary judgements.

Each annotator was presented with 80 annotation instances accompanied by the original complex word for reference. The exact instructions given to annotators are as follows:

> *Judge the following candidate substitutions of complex words with respect to their grammaticality and meaning preservation. When judging, please ignore any grammatical errors that are not caused by the substitution.*

For each instance, annotators were presented with two options:

- The substitution preserves the sentence's *grammaticality*, and
- The substitution preserves the original sentence's *meaning*.

Volunteers could select both, either or none of them. The resulting dataset contains 25,540 annotated instances. For agreement analysis purposes, 1,600 instances were annotated by 5 volunteers each, while the remaining 23,940 instances were annotated by a single volunteer. In total, 31,940 annotations were gathered. Notice that word simplicity is not taken into account in this user study, given that we wish to study how here readers interpret word replaceability only.

4.3 Dataset Analysis

We calculated several features to compare the grammatical and/or meaning preserving substitutions against the remaining substitutions. Table 3 illustrate the average and standard deviation feature values of candidates annotated positively by at least three out of five annotators (Good), and not (Bad), with respect to their grammaticality, meaning preservation, and both of them jointly. We chose six features, which can be grouped as:

- Language model probabilities of the sentence with the candidate in place of the target, given four 3-gram language models trained over the SubIMDB (Paetzold and Specia, 2016), Subtlex (Brysbaert and New, 2009) and Simple Wikipedia (Kauchak, 2013) corpora. Language model sentence probabilities have been used in previous work to create very effective Lexical Simplification systems (Horn et al., 2014; Glavaš and Štajner, 2015; Paetzold and Specia, 2016). Language models were trained with SRILM.

- The cosine word vector similarity between the candidate and the target (Target Sim.), as well as the average cosine similarity between the vector of the candidate and the vectors of content words in the sentence (Context Sim.). These features have been used in the creation of unsupervised lexical simplifier (Glavaš and Štajner, 2015). The embeddings model was trained with word2vec (Mikolov et al., 2013) with the CBOW architecture and 500 dimensions over a corpus of 7 billion words extracted from various sources (Paetzold, 2015; Brysbaert and New, 2009; Kauchak, 2013).

- The probability of the candidate receiving the same POS tag attributed to the target (POS Prob.). This feature has been shown a strong indicator of grammaticality (Aluisio and Gasperin, 2010; Nunes et al., 2013). The POS tag conditional probability models were trained over POS tags produced by the Stanford Parser (Klein and Manning, 2003) over the NewsCrawl corpus[3].

The column following the average values for Good and Bad candidates contain • for features for which we found a statistically significant difference between the averages through a F-test ($p < 0.01$), and ∘ for the remainder. The results suggest that, even though they are able to account for context, n-gram

[3]http://www.statmt.org/wmt11/translation-task.html

language model probabilities are much less effective in distinguishing good from bad candidates than the word vector distance between target and candidate words. Nonetheless, the same cannot be observed for the average similarity between candidate and context words.

Another interesting finding from our results that agree with previous contributions (Aluisio and Gasperin, 2010; Nunes et al., 2013) refers to the probability of the candidate receiving the POS tag of the target (POS Prob.), which does indeed show a strong relationship with grammaticality.

	Grammaticality			**Meaning**			**Joint (G/M)**		
Feature	**Good**	**Bad**	p	**Good**	**Bad**	p	**Good**	**Bad**	p
Prob. Subimdb	-0.9 ± 0.3	-1.0 ± 0.3	∘	-1.0 ± 0.3	-0.9 ± 0.3	∘	-0.9 ± 0.2	-1.0 ± 0.3	•
Prob. Subtlex	-3.1 ± 1.3	-3.2 ± 1.7	•	-3.2 ± 1.4	-3.2 ± 1.7	•	-3.1 ± 1.5	-3.4 ± 1.8	∘
Prob. Simple	-4.2 ± 1.6	-4.3 ± 1.9	•	-4.2 ± 1.8	-4.3 ± 1.9	•	-4.2 ± 1.7	-4.4 ± 2.0	∘
Target Sim.	0.41 ± 0.2	0.29 ± 0.2	•	0.39 ± 0.2	0.28 ± 0.2	•	0.34 ± 0.2	0.27 ± 0.2	•
Context Sim.	0.08 ± 0.1	0.06 ± 0.1	∘	0.08 ± 0.1	0.06 ± 0.1	∘	0.07 ± 0.1	0.06 ± 0.1	•
POS Prob.	0.62 ± 0.4	0.44 ± 0.4	•	0.53 ± 0.4	0.46 ± 0.4	∘	0.58 ± 0.4	0.32 ± 0.4	•

Table 3: Average and standard deviation of features of those words which were deemed grammatical, meaningful, or both by at least 3 annotators, and those that were not.

Out of the 356 candidates judged both grammatical and meaning preserving by at least three annotators, 171 (48%) are not listed in WordNet as either synonyms, hypernyms or hyponyms of the target word. This suggests that simplification strategies such as the ones of (Devlin and Tait, 1998) and (Biran et al., 2011), which extract candidate substitutions of complex words from WordNet, can suffer from low coverage.

4.4 Agreement Analysis

The average Kappa inter-annotator agreement scores for the data in this user study are 0.391 ± 0.16 for grammaticality, 0.424 ± 0.16 for meaning preservation, and 0.450 ± 0.16 for both of them jointly. Inspecting the data, we found that most disagreements resulted from situations in which the target word was part of a multi-word expression. Consider for example the target word *turn* in the sentence "*That in turn makes it difficult to affect policies to curb distracted driving*", which, in this case, is part of the multi-word expression *in turn*. Annotators were very much divided on whether or not candidate *reverse* preserved either grammaticality or meaning in this case: some judged it to be neither grammatical nor meaningful, while others claimed it to be grammatical or meaningful.

5 Substitution Ranking

In Substitution Ranking (SR), candidates are ranked according to their simplicity so that the complex word is replaced with the simplest candidate available. The goals of our user study are to:

- Discover which metrics best capture simplicity for non-native speakers, and
- Create a dataset for the evaluation and training of SR strategies.

5.1 Data Sources

We extracted 901 sentences from those collected in our Substitution Selection user study which had a minimum of two and maximum of four candidates annotated as both grammatical and meaning preserving by at least three annotators. In order to access the simplicity of these substitutes, we added the target complex word of each sentence to the set of candidates, and then replaced the target word in each sentence with a gap marker. Finally, we created an annotation instance for each pair of candidates, totalling 4,200 pairs (438 sentences * 3 pairs (3 candidates including complex word itself) + 436 * 6 pairs (4 candidates including complex word) + 27 * 10 pairs (5 candidates including complex word)).

5.2 Annotation Process

300 non-native English speakers participated in this study, all students and staff from different universities around the world. Volunteers provided anonymous information about their native language, age,

education level and English proficiency level. Each volunteer was presented with 70 annotation instances, each composed of a sentence with a gap and two candidates to fill it with.

For each instance, volunteers were asked to judge which candidate made the sentence easier to understand. They could also indicate that both candidates made the sentence equivalently complex/simple. The exact instructions given to annotators are as follows:

For each of the following instances, select which candidate makes the sentence easier to understand. If the words are equally complex/simple, select the "The words are equally simple" option. Please overlook any grammatical or spelling errors.

All instances were annotated by 5 volunteers. A total of 21,000 annotations were produced.

Once instances were annotated, we used the algorithm introduced by (Wauthier et al., 2013) to infer rankings from binary comparisons, and hence produce 901 instances composed of a sentence, a target complex word, and a set of candidate substitutions ranked according to their simplicity.

5.3 Dataset Analysis

For validation purposes, we computed the correlation between the simplicity rankings and the same 15 features used in the dataset analysis for our Complex Word Identification user study, described in Section 3.2. Notice that in our work we measure simplicity as the ease with which one can understand a given portion of text, which is the opposite of the definition of complexity used in our study on CWI. We use three evaluation metrics: Spearman correlation (r), Pearson correlation (ρ) and TRank. The TRank metric was introduced by (Specia et al., 2012) and measures the proportion of times in which the word ranked simplest by a given feature is also ranked simplest by the annotators.

The values in Table 4 reveal that word length and number of syllables correlate poorly with word complexity, while simpler words tend to be more ambiguous and occur more frequently in corpora. These findings reinforce the ones from our CWI user study. More importantly, our results show that correlation and TRank scores of [1,1] (one token to the left and right) n-grams consistently outperform the scores of single-word frequencies ([0,0]) according to all metrics used. These findings contradict a long-standing assumption that context is not an important factor in word simplicity estimation (Devlin and Tait, 1998; Carroll et al., 1999; Biran et al., 2011; Rello et al., 2013b; Shardlow, 2013a).

Feature	r	ρ	**TRank**
Length	0.172	0.179	0.386
Syllables	0.097	0.095	0.340
Senses	−0.345	−0.349	0.505
Synonyms	−0.288	−0.297	0.454
Hypernyms	−0.289	−0.297	0.472
Hyponyms	−0.309	−0.300	0.453
Subimdb[0,0]	−0.419	−0.436	0.539
Subtlex[0,0]	−0.465	−0.467	0.556
Simple[0,0]	−0.490	−0.468	0.578
Subimdb[1,1]	−0.463	−0.473	0.579
Subtlex[1,1]	−0.496	−0.496	0.590
Simple[1,1]	**−0.501**	**−0.475**	**0.593**

Table 4: Simplicity correlation analysis between features and annotations

5.4 Agreement Analysis

The average Kappa inter-annotator agreement scores for this user study resemble the ones reported in Section 3.4: although the agreement between all annotators is encouraging (0.454 ± 0.05), the scores are even higher for annotators with similar backgrounds. Annotators within the same education level,

age band and proficiency level reach agreement scores of 0.468 ± 0.01, 0.482 ± 0.02 and 0.486 ± 0.01, respectively. Like what was observed in our user study on Complex Word Identification, the highest agreement comes from annotators that speak the same native language (0.601 ± 0.15). This serves as further evidence that one's native language plays an important role on vocabulary acquisition.

6 Conclusions

We have described three user studies conducted with the goal of understanding the simplification needs of non-native speakers of English.

In our Complex Word Identification study we learned that words which are simpler to non-native English speakers have much higher probabilities according to language models, both alone and in context, while those which are more complex to them tend to have a smaller number of senses in WordNet. In contrast with what was reported by (Rello et al., 2013b) in experiments with readers who suffer from Dyslexia, we found no evidence of a relationship between the non-natives' perception of complexity and neither word length or number of syllables. Our experiments also showed that while a reader's English proficiency level indicates how many words will pose a challenge to them, their native language indicates which words these will be.

In our Substitution Selection study we found that, despite disregarding contextual information altogether, word vector distances between a complex word and a candidate substitution are more reliable than language model probabilities in capturing both grammaticality and meaning preservation. We also found that the conditional probability of a candidate with respect to the grammatical role of the complex word is a reliable indicator of grammaticality. From our agreement analysis, we found evidence that single-word replacements tend to compromise the understanding of multi-word expressions.

In our Substitution Ranking study, we found further evidence that, unlike ambiguity indicators and language model probabilities, length and number of syllables have little to do with word simplicity for non-native speakers of English. N-gram probabilities proved the most reliable simplicity indicators among the features evaluated, which contradicts the assumption often made in earlier work that context offers no important clues on a word's simplicity.

Table 5 summarises the data produced from each of these studies. Some examples of models and applications that could be built from these datasets are readability assessment tools, semantic analysers, text profilers and full lexical simplifiers. All of the datasets described herein can be downloaded from `http://ghpaetzold.github.io/data/User_Studies_NNS.zip`.

User Study	Sentences	Words	Word Pairs	Annotators	Annotations

How Interlocutors Coordinate with each other within Emotional Segments?

Firoj Alam, Shammur Absar Chowdhury, Morena Danieli, Giuseppe Riccardi
Department of Information Engineering and Computer Science,
University of Trento, Italy
{firoj.alam, shammur.chowdhury, morena.danieli, giuseppe.riccardi}@unitn.it

Abstract

In this paper, we aim to investigate the coordination of interlocutors behavior in different emotional segments. Conversational coordination between the interlocutors is the tendency of speakers to predict and adjust each other accordingly on an ongoing conversation. In order to find such a coordination, we investigated 1) lexical similarities between the speakers in each emotional segments, 2) correlation between the interlocutors using psycholinguistic features, such as linguistic styles, psychological process, personal concerns among others, and 3) relation of interlocutors turn-taking behaviors such as competitiveness. To study the degree of coordination in different emotional segments, we conducted our experiments using real dyadic conversations collected from call centers in which agent's emotional state include *empathy* and customer's emotional states include *anger* and *frustration*. Our findings suggest that the most coordination occurs between the interlocutors inside anger segments, where as, a little coordination was observed when the agent was empathic, even though an increase in the amount of non-competitive overlaps was observed. We found no significant difference between anger and frustration segment in terms of turn-taking behaviors. However, the length of pause significantly decreases in the preceding segment of anger where as it increases in the preceding segment of frustration.

1 Introduction

Behavioral and social signal processing are emerging interdisciplinary areas of research, which combine social science, psychology, and computer science. The aim of the research is to design computational models for processing human behavioral aspects, which can facilitate different domain experts while counseling, consulting and (or) providing services (Narayanan and Georgiou, 2013; Vinciarelli et al., 2009; Pantic et al., 2011; Vinciarelli et al., 2012; Stepanov et al., 2015). The idea is to analyze different overt and covert behavioral signals during social interactions and label them with some short and long term functional aspects (i.e., states and traits) in order to quantitatively measure them. The functional aspects include empathy, politeness, agreement, engagement, uncertainty, competitiveness and other typical, atypical, distressed and affective social behaviors. Using these short and long term states and traits, one can design an informative behavioral profile of an individual from the daily-life interactions. The measured behavioral profile can help to predict the next behavioral outcome/consequence and/or actions of an individual. This kind of behavioral profile can help domain experts in different application scenarios such as call center, health-care and teacher-student interactions.

In the field of social and psychological science, researchers have been trying to understand these functional aspects for a very long time, however, very recently there are attempts to design automatic computational models for real-world applications. Designing such automatic systems for measuring these behavioral and social functional aspects is still infancy due to many different challenges.

One of the important challenges is to understand how different behavioral cues are associated with one another and how we express them in different interaction scenarios. In this study, *we investigated, the coordination of interlocutors behavior in different emotional segments and how conversational turn-taking*

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 728–738, Osaka, Japan, December 11-17 2016.

dynamics are associated with emotional manifestations of the agent and customer. For the study, the conversational coordination between the interlocutors is defined as the tendency of speakers to predict and adjust each other accordingly on an ongoing conversation. We explored the coordination in terms of psycholinguistic features, lexical and turn-taking features using correlation analysis, cosine similarity, and regression analysis, respectively. For this study, we analyzed dyadic human-human spoken conversations, collected from the call centers in the domain of after-sale customer care, which has been annotated with turn-taking dynamics and emotional expressions. The turn-taking dynamics include competitiveness of overlaps, pauses, and lapses among others. Emotional expressions has been annotated for agent and customer separately with agent's emotional state include *empathy*, and customer's emotions include *anger* and *frustration*.

It has been a few decades to the study of automatically recognizing emotion in affective computing, which has been done in the lab as well as in real settings. The study includes classifying Ekman's six basic categorical emotions (Ekman, 1999) or dimensional levels of emotion such as valence and arousal (Russell, 1980). Still, there are challenges to make emotion recognition research in its practical use, which includes lack of publicly available realistic databases, issues of fusing multi-modal information, automatic segmentation, robustness in terms of generalizability across the domain, cross-corpus (Zeng et al., 2009; Schuller et al., 2011). A detailed overview of emotion recognition research in terms of theories, computation models, and relevant applications is provided in (Calvo and D'Mello, 2010).

The study of turn-taking dynamics such as speech overlap has also a long history. One of the first studies on speech overlap, as discussed in (Sacks et al., 1974), suggested that turn changes with overlap is a very rare case and occurs as a result of self-selection, which projects turn endings. Where as a recent study of (Heldner and Edlund, 2010) suggests that overlap is, in fact, a frequent phenomenon and is much more than just a turn-taking signal, which has also been discussed in (Chowdhury et al., 2015b).

There has been a very few study, which explores finding how different turn-taking features are associated with emotional states. The association of turn-management labels, such as grab, accept, back-channel, and emotional states have been studied in (Koutsombogera et al., 2015). The importance of turn-taking information for predicting user-satisfaction in terms of user manifested emotion have been studied in (Chowdhury et al., 2016). They discussed that turn-taking cues significantly helps in the automatic prediction of user-satisfaction. To the best of our knowledge, a very little study have been conducted to examine what actually happens within an emotional segment in terms of turn-taking. In our study, we present a call center conversation corpus (in Section 2) in which we have the manual annotation of emotional states and overlap discourse. Using which we explored the coordination of interlocutors behaviors as our preliminary study, presented in Section 3 and 4, which can shade a light in future for designing automated computational model.

2 Corpus and Annotation

2.1 Corpus Description

The data used for our research is a collection of Italian human-human spoken conversations, sampled from a large set of call center conversations providing after-sales customer care support in the energy sector. We randomly selected these conversations over six months, which were recorded on two separate channels at a sample rate of $8kHz$, 16bits. The average duration of these conversations was 406 seconds. The corpus has been annotated with emotional states such as empathy, anger and frustration, and overlap-discourse such as competitive and non-competitive.

2.2 Annotation of Emotional States

As mentioned earlier, we annotated *empathy* on the agent channel, and *anger* and *frustration* on the customer channel. In the literature, there is a lack of operational definition of empathy. Therefore, we adopted the *modal model* of emotion by Gross (1998) in order to define empathy and design annotation guidelines for the annotators. Gross's modal model is based on appraisal theory, which has been studied by many psychologists for the investigation of emotional states. Appraisal models of emotion suggest

that organisms appraise (i.e., evaluate, interpret, explain) events/situations based on the appraisal process in order to determine the nature of ensuing emotion as discussed by Scherer (2000).

According to the *modal model*, *"emotions involve person-situation transections that compel attention, have meaning to an individual in light of currently active goals, and give rise to coordinated yet flexible multisystem responses that modify the ongoing person-situation transection in crucial ways"* (Gross and Thompson, 2007; Gross, 2011). The key idea of the modal model is that emotional states unfold over time, and their response may change the environmental stimuli, and that may alter the subsequent instances of that and other emotional states. It is a useful framework for describing the dynamics of emotional states, which manifests over time, leads to the generation of an emotional sequence from the interlocutors' emotional manifestations. For example, the sequence of emotional states between an agent and a customer could be Frustration (C) → Empathy (A) → Satisfaction (C). A for the agent and C for the customer.

To design the annotation guideline, we have done an extensive analysis of one hundred conversations (more than 11 hours), and selected dialog turns where the speech signal showed the emergence of empathy, basic emotion, such as anger, and complex emotion such as frustration. In our qualitative analysis, we investigated the relevant emotional speech segments, which were often characterized by some perceivable variation in the speech signal. We observed that such variations could co-occur with emotionally connoted words, but also with functional parts of speech, such as adverbs and interjections, which could play the role of lexical supports for the variations in emotional states. We hypothesized that perceivable variations in the speech are a possible signal of an appraisal process. On the basis of those observations, we have designed annotation guidelines whose critical principle was to focus annotators' attention on their own perception of the variations in the speech signal as well as the variations in the linguistic content of the utterances. For example the annotation guidelines include the following recommendations for the annotators: 1) annotating the onset of the signal variations that supports the perception of the manifestation of emotions, 2) identifying the speech segments preceding and following the onset position, and 3) annotating the context (left of the onset) and target (right of the onset) segments with a label of an emotional state (e.g., frustration, empathy, etc.). In addition, the annotation guidelines include operational definitions of emotional states related to the given domain of application. For example, in this annotation task, the operational definition of empathy is defined as "an emotional state triggered by another's emotional state or situation, in which one feels what the other feels or would normally be expected to feel in his situation" (Hoffman, 2008).

The annotation task was performed by two expert annotators who worked on non-transcribed spoken conversations by following the annotation scheme reported above. In this task, the annotation unit is the speech segment. They annotated *Empathy* on the agent channel and *Frustration* and *Anger* on the customer channel. The annotators labeled *Neutral* on the segment that appeared before any emotional segment to define the context, as mentioned earlier. Finally, the annotated corpus includes 1894 customer-agent conversations (210 hours and 23 minutes in total). In order to evaluate the reliability of the annotation we measured inter-annotator agreement on the annotated segments, and obtained an average kappa 0.74. More details can be found in (Danieli et al., 2014; Danieli et al., 2015).

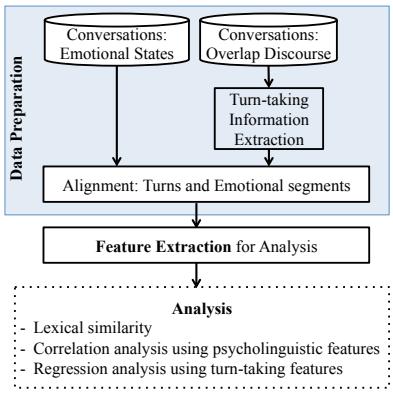
2.3 Annotation of Overlap Discourse

For the annotation of overlap discourse, we selected a subset of 565 conversations with approximately 62 hours of spoken content. Annotators manually segmented overlapping speech, then, categorized and labeled them with the competitive and non-competitive acts. The annotations were performed by two Italian native expert annotators by following the guideline described in (Chowdhury et al., 2015a). The guideline includes Competitive (Cmp) scenarios, in which the intervening speaker (overlapper) starts prior to the completion of the current speaker (overlappee), and both the speakers display interest in the turn for themselves, and also the speakers perceive the overlap as problematic. As for Non-Competitive (Ncm) scenarios, the overlapper starts in the middle of an ongoing turn. No evidence is shown by both the speakers to grab the turn for themselves. The overlapper used the overlap to signal the support for the current speaker's continuation of speech. Both of the speakers perceive the overlap as non-problematic.

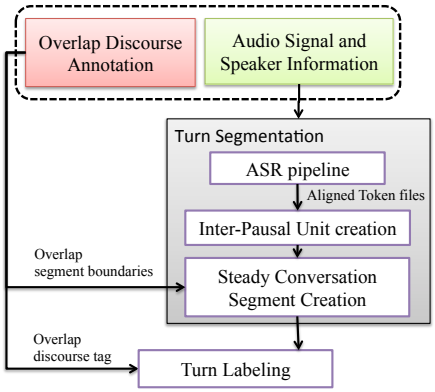
The inter-annotator agreement of the annotations is 0.70, which was measured using kappa statistics.

3 Methodology

In Figure 1, we present the experimental system of our study. In the data preparation phase, we selected a subset of conversations in which we have annotations of emotional states and overlap discourse. The turn-taking information extraction system utilized an Automatic Speech Recognition (ASR) system (Chowdhury et al., 2014) to create turn segments and extract turn information (see Section 3.1.1). Later, this information was aligned with the annotations of emotional segments to find the turn-taking information (more details can be found in Section 3.1.2). Using the aligned turn-taking information for an emotional segment, we extracted turn-taking features. We also used turn information to obtain lexical and psycholinguistic features per speaker from the segment. In the analysis phase of our experiment, we investigated lexical similarities and correlation of psycholinguistic features between speakers for different emotional segments. We also used multilevel logistic regression method to understand the association between turn-taking features and emotional segments, and how the association differs from one emotion to another.



(a) Experimental pipeline of this study.



(b) Turn-taking information extraction system.

Figure 1: System diagrams.

3.1 Data Preparation

For the analytical study, we selected a set of 523 conversations with the manual annotation of emotional states and overlap discourse. This set includes 310 conversations with emotional segments. Among the emotional segments around 11.28% of emotion are annotated as anger, 26.11% as frustration and 62.61% of annotated emotion in agent channel has empathy. From the rest of the 213 conversations, containing no emotional annotations, we selected segments and labeled them with no-emotion (NoEmo).

During the data preparation, we faced two important problems in order to define and align the emotional segment in association with turn-taking discourse: 1) emotional segment are very short in length, which made the task very difficult to get sufficient turn information, 2) an speaker respond to other speaker's emotion with a latency. To overcome these problems, we re-defined the following boundary of manual emotion segment with an impact window of length $2 * d$, where d is the length of the manual annotation of the emotional segment. Hence, the length of our emotional segment is $d+2*d = 3*d$. We also investigated preceding context of each customer's emotional segment and defined it as $Pre.Emo$ with a window of length $3 * d$. The $NoEmo$ segments have been selected from conversations where no emotion in both agent and customer side has been annotated. From the middle of each conversation, we selected and extracted two $NoEmo$ segments with a length of the average emotional segment, ($\approx$ 42 sec). We extracted the $NoEmo$ segments from both agent and customer channels. As mentioned earlier, empathy, Emp, has been annotated in the agent channel only. Thus the preceding context of agent's emotional segment is defined as $Pre.Emp$. Hence, the investigated emotional and non-emotional segments include Pre.Emp, Emp, Ang, Fru, Pre.Ang, Pre.Fru and NoEmo.

3.1.1 Turn-taking Information Extraction

The Turn-Taking Information Extraction System, described in Figure 1 (b), consists of a *turn segmentation and labeling system*. The system uses lexical and manual overlap discourse annotation information to segment and labels the turn types. The pipeline uses the time aligned ASR output as tokens to create Inter-Pausal Units (IPUs) for each input channel. IPUs are defined as the consecutive tokens with no less that 50 ms gaps in between. Using the start and end time information of inter-IPUs and intra-IPUs, we created a steady time line and binary representation (presence or absence of speech information) segments for both the channels. We then defined these segments as *steady conversation segments*. The labels of each segment were then defined by a set of rules. Labels of the segments are as follows:

- Turn (T): Maximal sequences of IPUs where one single speaker has the floor, and none of the IPUs from the interlocutor are present (Beňuš et al., 2011). T_A and T_C represent agent and customer's turns respectively.
- Pause (P): Gaps between the turns of the same speaker with no less than 0.5 sec. P_A and P_C represent agent and customer's pauses respectively.
- Overlap Types Ov= $\{Cmp, Ncm\}$: Overlapping turns between the two interlocutors with competitive or non-competitive intention (see section 2.3 for details).
- Lapse between speakers (L_B): Floor switches between the speakers with a silence duration of 2 sec or more.
- Lapse within speaker (L_W): Gaps between a speakers' turns with a silence duration of 2 sec or more.
- Switch (S): Floor switches between the speakers with silence less than 2 secs or with overlapping frames, not more than 20 ms.

3.1.2 Alignment: Turns and Emotional Segments

For the turn level analysis, it is important to align the turn sequences with the boundary of emotional segments. It is evident from manual annotation that an emotional segment consist of different turn types and not all the turns start inside the boundary. There are some cases where the start/end of emotional episode can be at the middle of a turn. We solved this problem using a rule-based approach. For example, if half of a mismatched turn fall inside an emotional segment we considered that as a part of emotional segment.

3.2 Feature Extraction

3.2.1 Lexical Features

We extracted lexical features from automatic transcriptions from an in-house developed Automatic Speech Recognition (ASR) System (Chowdhury et al., 2014). The word error rate of the system is 31.78% on the test set. To understand the utility of the automated transcriptions with such as error rate, in a different study we compared the performance between automatic and manual transcriptions for a automatic classification of emotions. The results show that performance differences are very low, only 1.2% drop with automated transcriptions (Alam et al., 2016). Therefore, we found that the use of automatic transcriptions are reasonable for the experiment given that manual transcriptions are not available in call cases. For the experiments, the transcriptions of each segment were converted into bag-of-words vectors weighted with logarithmic term frequencies (tf) multiplied with inverse document frequencies (idf). We also reduced the size of the dictionary by removing stop-words and lower frequent words.

3.2.2 Psycholinguistic Features

Psycholinguistic features were extracted from the transcriptions, using Linguistic Inquiry Word Count (LIWC) (Pennebaker et al., 2001). It has been used to study personality, the role of speakers in overlaps (Alam and Riccardi, 2014; Chowdhury et al., 2015b) among other social behaviors in order to understand the correlation between these attributes and word uses. The feature category includes linguistic (e.g., preposition, verb, word count), psychological (affect, positive, negative emotion, anxiety), personal concern (e.g., work, home, money), swear words, relativity among others. The LIWC is a knowledge-based system, which was designed using a set of dictionaries for different languages including Italian.

In the dictionary, each word was labeled with feature categories mentioned above. During the feature extraction process the word in the transcriptions was matched with the dictionary. Then, the matched category was computed as frequency or relative frequency. The Italian version of the dictionary contains 85 word categories (Alparone et al., 2004). We also extracted 5 general and 12 punctuation categories constituting a total of 102 features. We then removed LIWC features that are not observed in our training dataset.

3.2.3 Turn-Taking Features

The turn-taking features were generated using the turn sequence output of the Turn-Taking Information Extraction System, described in Section 3.1.1. The sequences were first aligned with each corresponding emotional segment (see Section 3.1.2). To understand the impact of the choice of turn-taking behavior, we divided the feature sets, at both segment and individual speaker levels, into two groups. A brief description of extracted features, in the segment, are as follows:

- General information about emotional segment (G1):
  - Participation equality, $P_{eq} = 1 - (\frac{\sum_i^N (T_i - T)^2 / T}{E})$ where T is the average speech duration of the speakers. T_i is the total speech duration for each speaker. E represents the total speech duration. $N = 2$, represents two speakers as agent and customer inside the emotional segment.
  - Percentage of overlaps.
  - Percentage of Cmp and Ncm on total overlap duration.
- Length of different turn types (G2):
  - Median duration of T_A, T_C, P_A, P_C, Cmp, Ncm, L_W and L_B, inside emotional segment normalized by the median of speaker's respective turn in the whole conversation.

4 Analysis and Results

For different feature sets, we investigated different experimental configurations. For the study of lexical similarities, our experimental conditions include: 1) lexical features from paired (i.e., agent and customer channel from same conversation) speakers' non-overlapping *vs* overlapping turns, 2) lexical features from non-paired (i.e., agent and customer channel extracted from unrelated conversation) speakers' non-overlapping *vs* overlapping turns. Where as for psycholinguistic features, we investigated features obtained from non-overlapping *vs* overlapping turns. For turn-taking features, we have not made any such distinctions. The non-overlapping turns include all the turns of the speakers excluding the overlaps. Where as the overlapping turns includes competitive (Cmp) and non-competitive (Ncm) overlaps.

4.1 Lexical Similarities

For the analysis, we computed cosine similarity of the agent and customer aligned segment representing different emotional states. For the lexical similarity we designed feature vector for agent $\overrightarrow{V_{S_A}}$ and customer $\overrightarrow{V_{S_C}}$ emotional segment using bag-of-word model and transformed them into tf-idf. Then, we computed cosine similarity, $sim(S_A, S_C) = \frac{\overrightarrow{V_{S_A}} \cdot \overrightarrow{V_{S_C}}}{\left|\overrightarrow{V_{S_A}}\right| \cdot \left|\overrightarrow{V_{S_C}}\right|}$ between the feature vector of the agent and customer's segment. For a pair-wise comparison of emotional states, then, we computed mean and standard deviation with statistical significance using t-test.

As mentioned earlier, we have four different experimental configurations for the analysis of lexical similarities. As a baseline, we computed the similarities between non-paired speakers using the lexical features from non-overlapping turns for different emotional segments. The results are presented in a form of similarity map in Figure 2. From the results, we observed that the interlocutors entrain each other in non-overlapping turns when the customer is expressing anger, and the value of similarity ($sim = 0.181$) is significantly ($p < 0.05$) higher than the similarities in any other emotional segment.

In the experiment with competitive overlapping turns, we observed the highest similarity of 0.035 and 0.031 in preceding-anger and anger segments, respectively. In the case of non-competitive overlapping

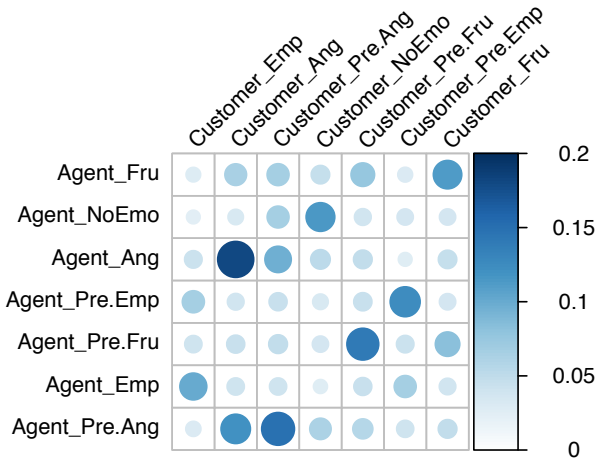


Figure 2: Lexical similarity between the emotional segment of the agent and the customer channel. Pre. represents preceding segments. Ang - anger, Fru - frustration, Emp - empathy, NoEmo - no-emotion

turns, a similarity of 0.034 was observed between the interlocutors in frustration segments. The results on overlapping turns are insignificant.

4.2 Psycholinguistic Features

We explored the degree of coordination using Pearson correlation coefficient (r) between the interlocutors' behaviors by correlating psycholinguistic features obtained from overlapping and non-overlapping turns, presented in Figure 3. For the sake of simplicity, the magnitude of r values are presented using colors where as '✕' symbol represent the corresponding r is not significant. These analyses are based on entire emotion segments from the agent and customer channels, irrespective of turns. The r is calculated for each psycholinguistic feature by correlating the agent and customer feature vectors of the conversations. We calculated the significance of the correlation coefficient r using t-test with a degree of freedom equal to $n - 2$, where n represent the total number of instances.

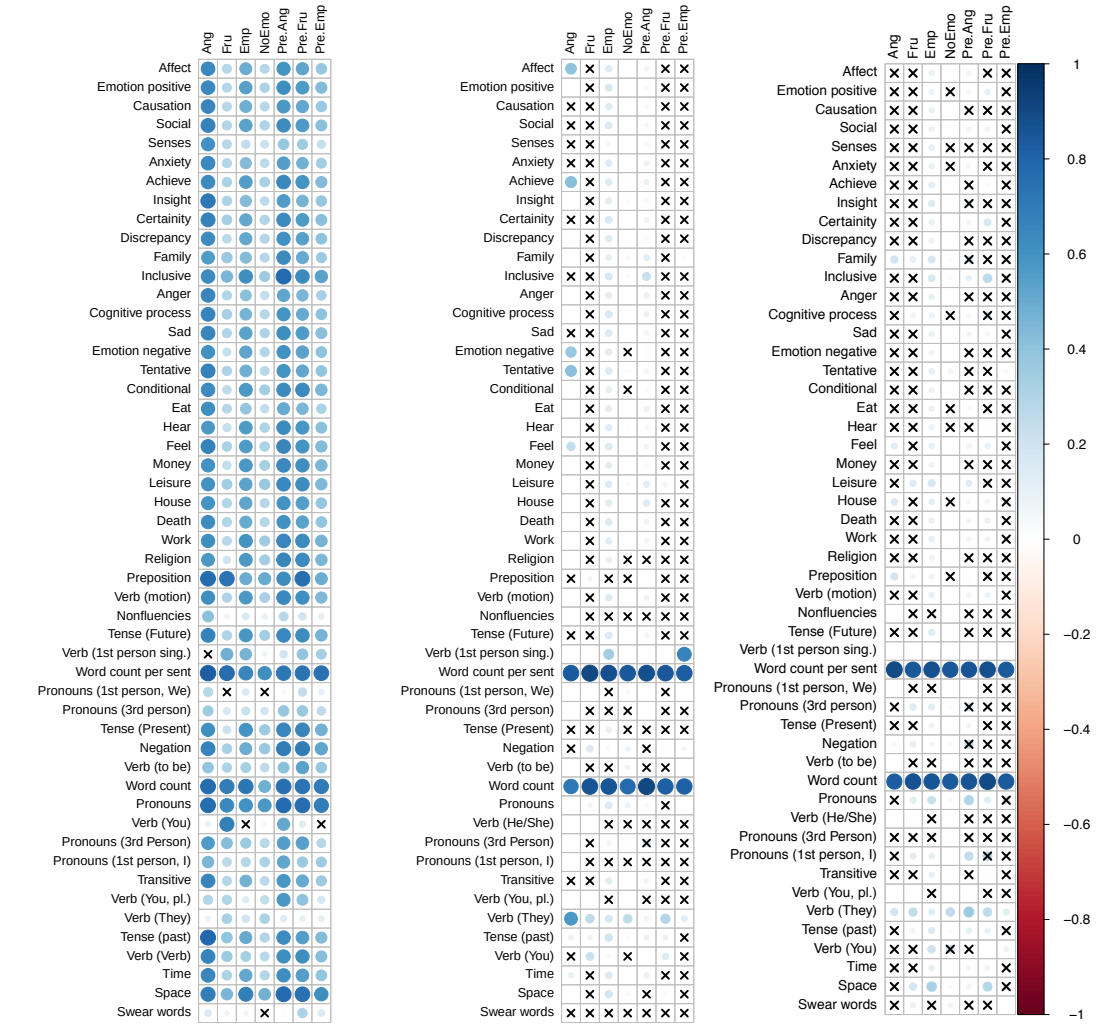
From the correlation plot, it is apparent that the non-overlapping turns of the interlocutors in anger (Ang) segments has high correlation values compared to other emotional segments non-overlapping turns and also compared to overlapping turns (Ncm and Cmp). Not surprisingly the magnitude of the correlation is significantly higher for psychological features like anxiety, affect, and sad between anger segments compared to frustration and empathy segments. Looking at the preceding-anger segments, we observed that the magnitude of r for personal concern along with psychological features are also stronger. It indicates that the cues of anger segment can be found in its preceding segments. The results also show that the uses of pronouns or negation words is directly proportional to the another speaker's usage. We also observed similar patterns in the uses of tenses. The magnitude of r is much higher for past-tense uses in anger compared to others emotional segment and preceding emotional context.

In the case of frustration, the strength of r decrease compared to the preceding segment of frustration. Unlike preceding-frustration segment, we observed that in frustration, there is less coordination between the interlocutors with an exception in preposition and word count features. Though a slight increase in r is observed in verb (they) feature. It is also observed that the interlocutors seem to be more coordinated in the use of swear words in preceding-frustration segments compared to all other segments.

In empathy segments, the coordination of the agent and customer improves compared to preceding-empathy, frustration, and no-emotion segments but the magnitude of coordination is not as impressive as anger segments.

In competitive and non-competitive overlapping turns, a very few significant coordination has been observed. The experiment with non-competitive turns shows that the interlocutors coordinate in anger segment with the features such as affect, achieve, negative emotion, tentative, and verb (they). In the case of competitive overlaps, we observed weak positive correlations between the interlocutors in preceding-

frustration segment with feature inclusive, preceding-anger segment with a verb (they), and in empathy segment with space feature.



(a) Non-overlapping segments (b) Ncm overlapping turns (c) Cmp overlapping turns

Figure 3: Correlation analysis at the non-overlapping segment, and overlapping segments, where '✕' symbol represents that the corresponding r is not significant. Pre. represents preceding segments. Ang - anger, Fru - frustration, Emp - empathy, NoEmo - no-emotion

4.3 Turn-taking Features

For the experiment with turn-taking features, we applied a multilevel logistic regression to understand the association of turn-taking features with emotional expressions and how they differ from one emotional state to another. The association of turn-taking features with emotional segments are presented in Table 1, in terms of regression coefficients. In Table 1 (a), the coefficients are reported with respect to the preceding segment of each emotion, where as in Table 1 (b), the coefficients represents the association of each turn-taking feature with the preceding emotion segment *vs.* no-emotion segments.

The results indicates that compared to the preceding context of empathy (Pre.Emp) and no emotion (NoEmo) segments, $participationEquality$, $MedianTurnC$ and $MedianPauseC$ has a negative effect on empathy (Emp) segment, where as $\%Overlap$ and length of non-competitive overlap ($MedianNcm$) has a significant positive effect. Thus indicating the importance of non-competitive overlap in the empathic segment (Emp). The results also hypothesize that during this emotional episode, agents tends to talk more allowing less participation equality between the agent and the customer. The duration of customer's turn and pause tends to be small.

The features $\%Overlap$, the length of overlaps ($MedianNcm$ and $MedianCmp$) has a positive effect

for anger segment compared to no-emotion segment. We also observed similar findings for $MedianCmp$ for preceding-anger w.r.t to no-emotion segment. It is observed that the length of non-competitive overlaps ($MedianNcm$) has a positive association where as the length of the lapse between the speakers ($MedianLb$) has a negative effect on anger with respect to preceding context (Pre.Ang). From the result of comparing preceding-anger w.r.t to no-emotion segments, we noticed that the positive association of the length of competitive overlap is present from the preceding context as an indication of anger.

The features $\%Overlap$, the length of overlaps ($MedianNcm$ and $MedianCmp$) has a positive effect for anger segment compared to the no-emotion segment. We also observed similar findings for $MedianCmp$ for preceding-anger w.r.t to the no-emotion segment. It is observed that the length of non-competitive overlaps ($MedianNcm$) has a positive association where as the length of the lapse between the speakers ($MedianLb$) has a negative effect on anger with respect to preceding context (Pre.Ang). From the result of comparing preceding-anger w.r.t to no-emotion segments, we noticed that the positive association of the length of competitive overlap is present from the preceding context as an indication of anger.

Apart from the results presented in Table 1, we also compared the association of turn-taking features with empathy, anger, and frustration with respect to each other. We found no significant difference between anger and frustration segments. However, the preceding context of anger and frustration shows that compared to the preceding-frustration, decrease of pause length is positively associated with preceding-anger segment, especially in agent's side. It is observed that an increase in the length of competitive overlap duration, $MedianCmp$, is positively associated with anger segments w.r.t empathy segments.

Figure 4: Duration distribution of competitive and non-competitive overlaps in different emotional segments.

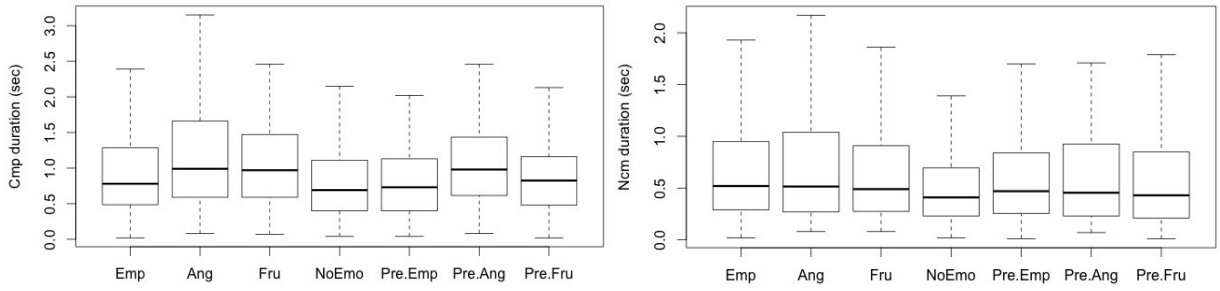


Table 1: Regression coefficient w.r.t preceding segment of each emotion and no-emotion segments.

Groups	Features	(a) Compared to preceding segment			(b) Compared to noemo segment					
		Emp	**Ang**	**Fru**	**Emp**	**Ang**	**Fru**	**Pre.Emp**	**Pre.Ang**	**Pre.Fru**

	MedianTurnC	**-0.003**	0.001	**0.003**	-0.001	0.002	**0.003**	**0.002**	0.001	0.000
	MedianPauseA	0.001	0.001	-0.004	0.002	-0.005	-0.002	0.001	-0.004	**0.005**
	MedianPauseC	**-0.005**	-0.008	**-0.008**	**-0.003**	0.002	-0.002	0.002	0.003	**0.006**
	MedianCmp	0.001	0.002	0.001	**0.003**	**0.006**	**0.005**	0.002	**0.004**	**0.005**
	MedianNcm	**0.004**	**0.007**	0.002	**0.003**	**0.003**	0.002	0.001	0.001	0.000
	MedianLb	-0.002	**-0.011**	**-0.006**	**-0.005**	-0.004	-0.003	**-0.002**	0.000	0.000
	MedianLw	0.000	-0.002	-0.001	**-0.002**	-0.003	-0.001	-0.001	0.000	0.000

We also compared the duration of competitive and non-competitive overlap within different emotions and preceding emotional segments. In case of competitive, as shown in Figure 4, we observed that duration of mean competitive overlap in anger ($1.25s$) and frustration ($1.09s$) are significantly more compared to the empathy ($0.93s$), no-emotion ($0.80s$) while there is not significant difference between the duration of competitive in anger and frustration segment. In the case of preceding emotion segments, the duration

of competitive overlap in frustration is significantly higher than that of preceding-frustration ($0.91s$), where as preceding-anger ($1.12s$) and preceding-frustration is significantly higher than no-emotion. It is also observed that competitive duration in empathy segment is also longer ($p < 0.05$) than no-emotion segments. As for non-competitive duration, shown in Figure 4, there is no significant difference between anger ($0.72s$), frustration ($0.68s$) and empathy ($0.69s$) segment. But it is observed that empathy has significantly longer non-competitive overlap compared to no-emotion ($0.53s$) and preceding-empathy ($0.61s$) segment. Even, the preceding context of empathy (Pre.Emp) has significantly longer non-competitive overlap duration than the non-competitive overlap where there is no emotion. While in anger and frustration, the non-competitive overlap length is significantly higher than the no-emotion segment.

5 Conclusions

In this study, we explored the coordination of interlocutors in different emotional segments using lexical, psycholinguistic and turn-taking features. We investigated such feature sets in terms of regression coefficients, cosine similarity and correlation analysis, respectively. We observed that the interlocutors match each other turns, in terms of lexical similarity and psycholinguistic features, significantly more in anger segment compared to other emotional segments. We also observed that in preceding segment of anger the speakers shows significant correlation with each other in terms of psycholinguistic features. In terms of turn-taking features, no significant differences between anger and frustration have been noticed, apart from the difference in length of pauses in the preceding segment of the emotion. It indicates that preceding context of anger has shorter pause with respect to frustration. Unlike anger, we found less coordination in the segment where the agent is empathic even though an increase in the percentage of non-competitive overlaps has been observed. This is our preliminary study towards utilizing these feature sets for the classification of emotional states and turn-taking discourse, which we will investigate in future.

Abstract

We propose a hierarchical clustering approach designed to group linguistic features for supervised machine learning that is inspired by variationist linguistics. The method makes it possible to abstract away from the individual feature occurrences by grouping features together that behave alike with respect to the target class, thus providing a new, more general perspective on the data. On the one hand, it reduces data sparsity, leading to quantitative performance gains. On the other, it supports the formation and evaluation of hypotheses about individual choices of linguistic structures. We explore the method using features based on verb subcategorization information and evaluate the approach in the context of the Native Language Identification (NLI) task.

1 Introduction and related work

Native Language Identification (NLI) is the task of inferring the native language (L1) of writers from texts they wrote in another language. NLI started to attract attention in computational linguistics with the work of Koppel et al. (2005). Since then interest has steadily risen, leading to the First NLI Shared Task in 2013, with 29 participating teams (Tetreault et al., 2013).

NLI is usually considered as a text classification problem with the different L1s as labels. A range of features reaching from character and word n-grams to dependency- and constituency-based features have successfully been used in standard supervised machine learning setups, yielding accuracies of up to around 83% for the 11 classes in the First NLI Shared Task. Some more recent papers further advance the best result from that competition, namely 83.6% (Jarvis et al., 2013), reaching around 85% (Bykh and Meurers, 2014; Ionescu et al., 2014).

While pushing the quantitative side is one option of advancing the NLI work further, another avenue of research tries to improve our understanding of how the different feature types work and what conclusions one can draw from these observations for Second Language Acquisition (SLA) research. Swanson and Charniak (2013) utilized Tree Substitution Grammars as well as different measures of relevancy and redundancy to extract indicative linguistic patterns. Swanson and Charniak (2014) adopted the approach to dependencies. Malmasi and Dras (2014) proposed a technique to detect over- and underuse of certain patterns by writers with a particular L1-background using linear SVM weights derived from Adaptor grammar collocations or Stanford Dependencies. Meurers et al. (2014) employed verb subcategorization patterns as features and showed that there are differences in the usage patterns of verbs between native English writers and, e.g., writers with Chinese L1-background. Bykh and Meurers (2014) systematically explored constituency-based features and discussed the distinctive power of the different variants realizing lexical and phrasal categories. Malmasi and Cahill (2015) investigated the correlation between various features in a feature set commonly used in NLI.

Many of the current NLI approaches rely on large feature sets, which makes it difficult to qualitatively interpret the findings. We therefore want to explore grouping features together which behave alike to advance linguistic insight and improve classification. In place of zooming in on single features, with the potential danger of overfitting the training data, feature grouping can help make explicit underlying

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 739–749, Osaka, Japan, December 11-17 2016.

linguistic properties within a set of features. Thus, on the one hand, it can support the identification of linguistic generalizations, which is relevant for qualitative analysis and theoretical interpretation. On the other hand, we also expect quantitative benefits due to the potential reduction of data sparsity, especially in cases where the particular single feature realizations might be rare but the underlying structure captured by a group is more common.

One of the well-established techniques for building feature groups is hierarchical clustering (Park, 2013; Krier et al., 2007; Butterworth et al., 2005). It can be an effective method for capturing linguistic generalizations. For example, Pate and Meurers (2007) show in the context of PCFG parsing that contextually enriching categories followed by clustering the categories with similar distributions results in a performance improvement.

In this paper, we propose to employ hierarchical clustering for feature grouping in a way that is informed by the classification label – here the L1 of the writer. Adopting a variationist linguistic perspective that attempts to identify variants of an underlying variable (Tagliamonte, 2011), we illustrate and evaluate the feature grouping technique in detail for features encoding the different subcategorization options realized by a given verb – a feature type that is well-motivated in related SLA research (Tono, 2004; Callies and Szczesniak, 2008; Stringer, 2008). Using the technique, we first test the hypothesis, whether writers with different L1-backgrounds prefer certain subcategorization patterns when realizing particular verbs. Then we show how the technique can be used to investigate specific hypotheses about L1-transfer suggested in the SLA research; we focus on the subject in the subcategorization pattern and explore some of its realization options in L1 Chinese following Wang (2009). The results presented below confirm that feature grouping can indeed provide theoretical and practical benefits.

2 Feature grouping

We propose a label-informed feature grouping technique that can be used to group structured linguistic features in line with a variationist perspective. We first introduce the variationist perspective and the nature of variationist features, before we turn to our implementation of the technique.

Variationist sociolinguistics In variationist sociolinguistics, the focus is on the possible linguistic choices made by a speaker. This makes it possible to connect the choices in the language with extralinguistic variables, such as the gender or the age of a speaker. For example, in Labov's seminal study "The Social Stratification of (r) in New York City Department Stores" (Labov, 1972), he found that the presence or absence of the consonant [r] in postvocalic position (e.g., *fourth*) correlates with the ranking of people in status (social stratification). Hence, under a variationist perspective, one observes which of the possible *variants* of a *variable* is chosen by a particular speaker (Tagliamonte, 2011). Recent research in the language learning context argues that a preference for particular variants can also be indicative of individual characteristics such as proficiency or L1-background (Lüdeling, 2011; Callies and Zaytseva, 2011; Meurers et al., 2014; Bykh and Meurers, 2014).

Variationist features To obtain *variationist features* one has to implement the logic described in the previous paragraph. It requires choosing some language *variables* that can be realized by a particular set of *variants*. For our first explorations of the proposed technique, we chose verb lemmas as variables and the different subcategorization (subcat) patterns of that lemma as variants.

Grouping technique As motivated above, we want to explore whether writers with a given L1 prefer certain subcat variants when realizing a particular verb lemma variable.

In the training corpus, we can record the relative frequencies for the different subcat variants used to realize a lemma. Individual lemmas occur quite rarely, though, so we want to group together all those lemmas that behave alike with respect to their subcat variants.

Can we also take the classification label into account when clustering the variables by the frequency proportions of their variants? In other words, how can we group those lemmas together that for a given L1 have similar proportions of subcat variant realizations? In order to incorporate the classification label into the grouping procedure, we do not generate a single vector of variants for a variable, but k vectors, where k is the number of L1 labels in the training data. Each of the k vectors contains the proportions of

the variants for a given variable, calculated using the subset of the training data for a particular L1. Then the k vectors for each variable are concatenated in order to get an instance for clustering. Hierarchical clustering then groups variables together that for writers of a specific L1 realize a similar set of variants in similar proportions, i.e., it groups lemmas together that for a specific L1 label pattern alike with respect to the realized subcat variants. Since the feature set for clustering is informed by the L1 labels, we refer to this technique as *label-informed feature grouping*. Viewed from the variationist perspective, the method is designed to group those variables together that in terms of their variants behave alike with respect to the classification label.

Let us spell this out in an example. Assume that writers with Spanish L1 prefer the subcat variant $p \in \{p, q\}$, whereas writers with Chinese L1 prefer the variant q in connection with a particular set of verbs A. That information is captured by the difference in relative frequencies for the variants p and q in connection with A in the training data subsets for the two different L1s. Using separate vectors for the different L1s, explicitly provides that relevant information to the clustering algorithm. Clustering thus can identify the group A of verbs that is indicative for the classification purposes in terms of the choice of variants made by different L1s, and also of interest from the perspective of interpreting these effects in terms of SLA research.

We cluster the variables via *agglomerative hierarchical clustering*, employing some standard parameters, namely, Euclidean distance[1] and complete-linkage. We set the number of clusters $c = 1$, which means that after clustering we obtain a *dendrogram* corresponding to a *single-rooted binary tree*.

Now, the question is, how to decide, which grouping is the most appropriate one? I.e., where do we want to cut the dendrogram? We approach that issue experimentally, by systematically applying different branch length cut-offs with step $s = 0.1$ to the dendrogram, and then evaluating every grouping via text classification using the different groupings as features.

In connection with using subcat variants, realized by groups of verbs, as features there are two more points to clarify. First, how to merge clustered variables with different sets of variants? Here, we simply take the union of the variant sets as the resulting variant set of the variables group. Second, how to compute the feature values for the groups? For that we use the *micro average* measure adapted to the variationist perspective (Krivanek, 2012; Meurers et al., 2014). In sum, we apply the following steps:

1. For each of the n variables V_i and each of the m variants v_j occurring in the whole training data, calculate the matrices M_{ij}^k using the corresponding label-distinct data subset l_k:

$$M_{ij}^k = \frac{f(v_j, V_i, l_k)}{\sum_{q=1}^{m} f(v_q, V_i, l_k)}$$

   where $f(v, V, D)$ yields the frequency of the variant v realizing the variable V in the data D. Here $D = l_k$. If a variant v does not occur in the context of V using data D, $f(v, V, D) = 0$.

2. Perform a horizontal matrix concatenation of the k matrices M_{ij}^k resulting in a single matrix M_{ij} containing the variable based instances for clustering (the rows of M_{ij}).

3. Perform hierarchical clustering with the number of clusters $c = 1$, Euclidean distance, and complete-linkage as parameters.

4. Systematically apply different branch length cut-offs r using a suitable step s (here we employed $s = 0.1$). Evaluate the resulting clusters, i.e., groups of variables by using them as features in a classification setup.

[1] We also explored using other distance measures, such as the Manhattan or the Hellinger distance. Especially, the latter is supposed to be more suitable for probability-based features. However, the Euclidean distance performed best.

(a) Merging groups: Let a group (cluster) C contain x variables, each realized by a particular variant set X_i. Then the resulting variant set X^c for the variables group C is defined as the union of all variant sets X_i:

$$X^c = \bigcup_{i=1}^{x} X_i$$

(b) Encoding groups as features for classification: Calculate *micro average* for each variant $v \in X^c$ associated with the group $C = \{V_1, ..., V_n\}$, using data t:

$$mic(v, C) = \frac{\sum_{i=1}^{n} f(v, V_i, t)}{\sum_{i=1}^{n} \sum_{j=1}^{m} f(v_j, V_i, t)}$$

where $f(v, V, D)$ is defined as above (1), and $D = t$ is a given text.

5. Terminate evaluation (at the latest) after a particular cut-off r yielded one single group containing the whole variables set.

Note that the same technique can also be used to group *variants* based on their frequency proportions for all variables using the k label-based data subsets – an option we here do not go into further to keep things clear and within the space constraints.

3 Data

For the experiments described in this paper, we use the TOEFL11 corpus (Blanchard et al., 2013) introduced for the NLI Shared Task 2013 (Tetreault et al., 2013), which has become a common frame of reference for NLI research. It consists of essays written by English learners with 11 L1-backgrounds (Arabic, Chinese, French, German, Hindi, Italian, Japanese, Korean, Spanish, Telugu and Turkish) at three proficiency levels (low, medium, high). Each of the 11 L1s is represented by 1,100 essays (900 training, 100 development, 100 test). We use the union of the training and development sets for training and the standard test set for testing. In total for all L1s, we thus train on 11,000 and test on 1,100 essays.

4 Tools

We utilized the MATE tools[2] (Björkelund et al., 2010) for data preprocessing (tokenization, lemmatizing, POS-tagging) and the MATE dependency parser (Bohnet, 2010) to identify the arguments of a verb realized in a sentence, i.e., the subcat frame that was realized. For hierarchical clustering we employed WEKA (Hall et al., 2009). To process the resulting dendrograms we used the Libnewicktree[3] tree parser. Finally, classification was carried out using L2-regularized Logistic Regression from the LIBLINEAR package (Fan et al., 2008) accessed through WEKA.

5 Features

The hypothesis we are testing is whether writers with different L1s prefer different subcat variants. To systematically explore the potential benefits of feature grouping, we start with *simple features*, where every variable, i.e., verb lemma, is considered separately. We then infer sets of *complex features*, i.e., sets of various groups of variables using the proposed technique, abstracting from individual verb lemmas to classes of verbs. All feature values are calculated using *micro average* as introduced in section 2 (4b), with simple features being a special case of the complex ones, where the group C consists of a single variable ($C = \{V_1\}$).

[2] https://code.google.com/p/mate-tools

[3] https://github.com/cjb/libnewicktree

5.1 Simple features

We dependency parsed the data and extracted the corresponding argument realization patterns, i.e., the realized subcat variants, for all verbs occurring in the data. We consider the following labels as arguments:

- *sbj*: subject
- *lgs*: logical subject
- *obj*: (in)direct object or clause complement
- *bnf*: benefactor in dative shift
- *dtv*: dative in dative shift
- *prd*: predicative complement
- *oprd*: object complement
- *put*: locative complements of the verb put
- *vc*: verb chain

Utilizing the verb lemmas with their extracted subcat variants, we generated features, such as:

- *believe*_sbj
- *believe*_sbj_obj
- *may*_sbj_vc
- *put*_sbj_put
- *help*_sbj_obj
- *make*_sbj_obj_oprd

Feature reduction We performed the following three feature reduction steps due to some theoretical and practical considerations:

1. Verbs as features are rather rare. In order to reduce data sparsity issues, at this point we opted for ignoring the *different permutations* of arguments within a subcat variant. This step reduced the number of distinct variants from 355 to 218.

2. Some of the subcat variants are still rather specific and unlikely to occur frequently enough in the data. Some of them also suffer from tagging or parsing errors. So, in a second reduction step we grouped all *argument labels into three coarse-grained classes* in order to get more general patterns and to cope with data sparsity:

   - $\{sbj, lgs\} \rightarrow s$ (subject)
   - $obj \rightarrow o$ (object)
   - $\{bnf, dtv, prd, oprd, put, vc\} \rightarrow x$ (rest group)

   The number of distinct subcat variants reduced from 218 to 48. Applied to the examples listed above, we obtain features of the following form:

   - *believe*_sbj $\rightarrow$ *believe*_s
   - *believe*_sbj_obj $\rightarrow$ *believe*_s_o
   - *may*_sbj_vc $\rightarrow$ *may*_s_x
   - *put*_sbj_put $\rightarrow$ *put*_s_x
   - *help*_sbj_obj $\rightarrow$ *help*_s_o
   - *make*_sbj_obj_oprd $\rightarrow$ *make*_s_o_x, etc.

3. The last reduction step is conceptually different from the first two. It is based on theoretical considerations in connection with the variationist perspective: We are interested in the linguistic choices made by a speaker. If there is only a single variant for using a verb, we cannot observe a *choice* being made. We therefore dropped all features for verb lemmas that only occur with a single subcat variant in the training data. That reduced the number of distinct verb lemmas from originally 11,401 to 3,785.

Feature reduction clearly also means a loss of potentially indicative subcat information. A more fine-grained reduction therefore constitutes an important topic for future work.

As a result of feature reduction, we obtain 3,785 distinct verb lemmas (variables) with 14,389 subcat variants as features. That means that on average there are roughly four subcat variants per variable.

5.2 Complex features

We refer to the features defined by grouping the verb lemmas as proposed in section 2 as *complex features*. The purpose of these complex features is to abstract away from individual verb lemmas to more general classes. In contrast to Meurers et al. (2014), where verb lemmas realizing *exactly the same* subcat variants were grouped together, the technique proposed here makes it possible to systematically explore a range of different groupings of lemmas based on the *similarity* of the realized subcat variants, and to take into account the classification label. Each group of verb lemmas C and the corresponding set of subcat variants X^c constitutes a complex feature in the sense of (4a) of section 2.

6 Results

An overview of the results is presented in Figure 1. On the x-axis, the leftmost point (marked "s") corresponds to using only simple features (every verb lemma with the corresponding subcat variants is considered separately), i.e., no clustering. With increasing x-values, we go up in the dendrogram to obtain groups of verbs. The x-values are the branch length cut-offs applied to the dendrogram using a step of 0.1. The y-axis represents the accuracy of the classification on the test set, using the training-test split described in section 3 and the classifier spelled out in 4. The random baseline is 9.1%.

Model with simple and complex features ([s/c]): This is the basic setting using simple and complex features. The figure shows that 44.5% at point "s" is the highest accuracy, so feature grouping does not provide a quantitative edge. For settings incorporating complex features, the best result is 44.2%, obtained for the cut-off 0.3. The clustering technique groups verb lemmas in terms of the proportion of

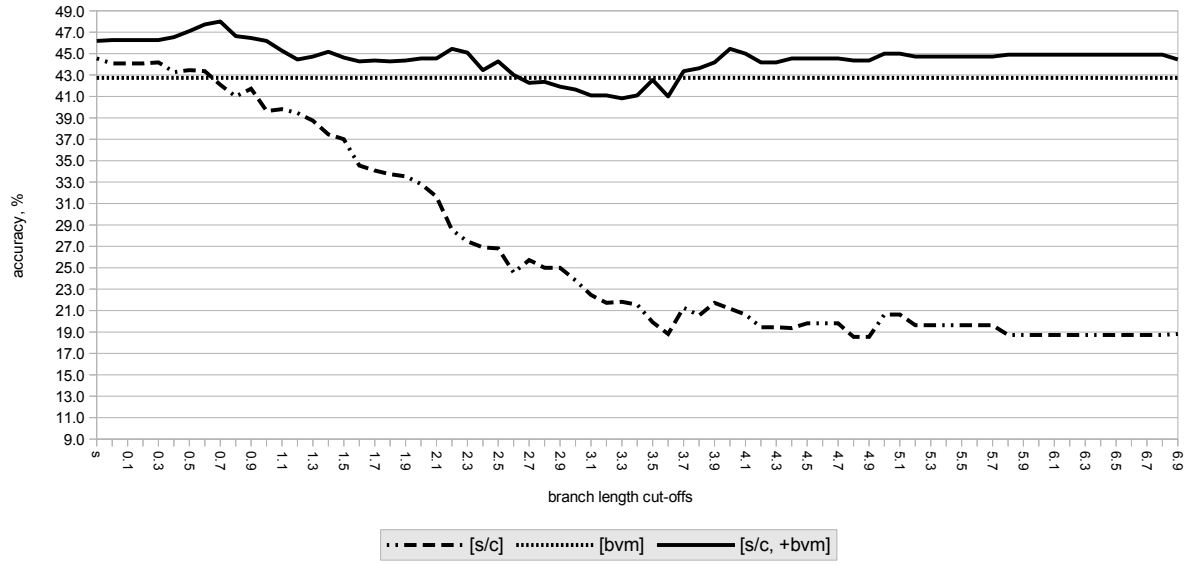

Figure 1: Accuracy of classification for different feature sets

their subcat variants. The particular verb lemmas, i.e., surface forms, which are part of a group, are not by themselves encoded in the feature space any more. For complex features the classifier therefore does not have an access to the potentially highly indicative surface based properties. Even different misspellings of the verbs can be indicative of the native language – distinctions that the basic method counting variants glosses over.[4] The disadvantage of loosing indicative surface information seems to outweigh the potential advantage of the generalization in terms of reducing data sparsity. We can validate that assumption by creating a binary verb lemma model and then combining it in a model with the simple and complex variant features.

Binary verb lemma model ([bvm]): To be able to identify the contribution of the subcat variants of individual verbs and groups of verbs, we need a way to separately quantify the information provided by the verb lemma itself (i.e., the presence of the variable, as separate from the choice of variants). In the bvm model, we thus only encode the presence/absence of the 3,785 verb lemmas for each text. The accuracy for that model is 42.7%. We included that result as a line in Figure 1 to visualize the performance relative to the other two models, which make use of subcat pattern information. Comparing the other models to that one shows the benefits of incorporating the subcat variants as features. Indeed, the other curves discussed below show better results, confirming that such features are useful.

Binary verb lemma combined with simple and complex features ([s/c, +bvm]): To validate our assumption regarding the role of surface properties, we tried a combined setup, where the [*s/c*] setting was used in combination with the binary verb lemma model [*bvm*] described above. We assume the [*bvm*] model to restore the surface information lost due to the generalization, which should improve the classification performance. Indeed, the classification performance increased compared to the basic [*s/c*] setting. For simple features, the accuracy is 46.2%, and thus 1.7% higher. Including [*bvm*] therefore is beneficial even for settings not involving clustering. For settings including complex features, the difference depends on the actual cut-off. The best performance is 48.0% obtained using the cut-off 0.7 (273 complex and 3016 simple features). The difference between the best complex feature results is 3.8%. In most of the cases, the difference is even much higher, as seen when comparing the [*s/c*] and the [*s/c, +bvm*] curves at corresponding cut-offs in Figure 1. That result supports our assumption regarding the role of the surface properties. It is also supported by the shape of the [*s/c, +bvm*] curve only. The best model using complex features (cut-off 0.7) outperforms the model solely based on simple features ("s") by 1.8%[5]. Thus, when built on top of a surface-based model such as [*bvm*], the proposed grouping and generalization technique shows practical advantages in terms of accuracy. The findings confirm the hypothesis that in general learners with different L1s seem to prefer different subcat patterns. Finally, using more data or some more frequent variables resulting in more reliable frequency distributions of the variants, is expected to increase the quantitative gains. We plan to explore this issue in our future work.

Relative performance In comparison with previous research, the proposed automatic feature grouping method outperforms the approach presented in Meurers et al. (2014), where only verb lemmas with equal subcat variant sets constituted a group. A replication of that approach employing the verb subcat features and the data setup used in this paper, showed an accuracy of 38.7%, and after adding the *[bvm]* model, we obtained 44.4%. This result is 3.6%[6] lower than our best accuracy obtained in [*s/c, +bvm*].

In order to further investigate the potential quantitative advantages of the proposed features and the clustering method, we combined a range of features using the meta-classifier approach described in Bykh and Meurers (2014). The results are summarized in Table 1. First, we combined the core 16 feature types employed in Bykh et al. (2013), namely features based on n-grams, dependencies, local trees, suffix information, linguistic complexity and lemma realization, with the best performing model in Bykh and Meurers (2014), which is based on constituency variation features plus 40 different types of n-grams, i.e., word- and lemma-based n-grams as well as two types of n-grams incorporating POS,

[4]For example, we discovered that some of the clusters contained misspelled versions of the same verbs, such as *commmunicate/communicat*, *tounderstand/ubderstand*, *exaggrate/exxagarate*, etc.

[5]$p < 0.05$ using McNemar's test.

[6]$p < 0.001$ using McNemar's test.

with $1 \leq n \leq 10$ each (see also Bykh and Meurers, 2012). This model yielded an accuracy of 85.2%.[7] Second, we added the best performing system in this paper, namely [*s/c, +bvm*] with cut-off 0.7[8] to that ensemble, and alternatively the basic setting of [*s/c, +bvm*] without clustering, i.e., using simple features only ("s"). Both options showed an increase in accuracy by the same value of 0.2%, resulting in 85.4%. To the best of our knowledge, the highest outcome obtained so far on the same data was 85.3%, reported by Ionescu et al. (2014). Thus, by using the new features explored in this paper, it was possible to slightly outperform the already very high best previous accuracy on the standard TOEFL11 data setup. However, in the comprehensive ensemble model used here, there was no quantitative difference between adding the best performing [*s/c, +bvm*] setting (cut-off 0.7), which incorporates complex features, and the lower performing version containing simple features only ("s"). Yet, there is a difference in terms of the feature counts for the two models, namely, 16,841 vs. 18,174 respectively. Thus, the version incorporating complex features is more efficient, providing the same quantitative advantage with a more compact model. This supports the assumption that the generalizations made by the technique are reasonable. The findings suggest that the approach can further advance the already high performance of the state-of-the-art NLI systems.

Rank	Id	System	Accuracy
1	A	D + E + F/G	85.4%
2	B	Ionescu et al. (2014)	85.3%
3	C	D + E	85.2%
4	D	Bykh and Meurers (2014)	84.8%
5	E	Bykh et al. (2013)	82.5%
6	F	[*s/c, +bvm*], cut-off 0.7	48.0%
7	G	[*s/c, +bvm*], s	46.2%

Table 1: Relative performance. System B is the best previously reported system based on the same data.

7 Qualitative explorations

In the previous sections we explored in detail the quantitative gains of the proposed technique using verb subcat features. In this section we sketch, how the method can be used to advance the qualitative analysis in the context of the SLA research. In particular, we investigate the hypothesis by Wang (2009), suggesting that learners with L1 Chinese overuse *pronoun-subjects* over *noun-subjects* in Chinese-English translations.[9] The findings of Wang (2009) based on translations by 81 students support the hypothesis.

In order to investigate this hypothesis, we slightly modify our features, i.e., we use only the subject part of the verb subcat, and in addition we consider only those subjects, which are tagged as personal pronouns (*prp*) or nouns (*nn*). So, based on our training data, we extract features such as *believe*_sbj+prp and *believe*_sbj+nn, or *study*_sbj+prp and *study*_sbj+nn, etc. Then we run *one vs. rest* classifiers with L1 Chinese vs. the western L1s in our set, namely French, German, Italian and Spanish. The classifiers follow the logic of the [*s/c*] and [*s/c, +bvm*] settings discussed in section 6. To determine distinctive patterns, we used the weights assigned to the features by the classifier (Malmasi and Dras, 2014).

First, we explored the general usage pattern for *sbj+prp* and *sbj+nn* variants, detached from particular verb lemmas. That was done by cutting off the dendrograms for the [*s/c*] settings at the root (cut-off 3.0), which results in having all of the considered verbs in a single cluster and hence, just the two variants, i.e., *sbj+prp* and *sbj+nn*, encoded by the relative frequency for each text. It turned out that both weights are negative, showing that there do not seem to be any pattern indicative for L1 Chinese compared to the

[7] Best ensemble optimization parameters for all ensembles in this paper: *+all, -opt* (Bykh and Meurers, 2014).

[8] This cut-off turned out to yield best results in our evaluations on both, the TOEFL11 *test* and *development* sets, thus it seems to be relatively reliable for TOEFL11 data.

[9] "Chinese people always hold the idea that human being and nature are mingled together, so Chinese people intend to make themselves as the start to narrate object things and are used to taking the pronoun as the subject. However, in the western philosophy, object is emphasized and it is believed that human being and nature are separated. So western people intend to express things from an object view and are used to taking non-pronoun such as things or abstract concept as the subject. The choice of pronoun-subject or non-pronoun-subject between Chinese and English will lead to negative transfer of mother tongue, which will make the translation of subject an improper one." (Wang 2009, p. 139)

western L1s. Second, we bring the actual verbs back into the equation, and explore the best performing [*s/c, +bvm*] setting (cut-off 2.6). Here, all verb lemmas are grouped into five clusters. The findings are summarized in Table 2.

Cluster id	# Verb lemmas	Pattern indicative for L1 Chinese	Weight
1	166	sbj+nn	< 0.01
2	100	-	-
3	312	-	-
4	65	sbj+prp	0.73
5	68	sbj+prp	0.19

Table 2: Usage pattern for L1 Chinese at the best performing dendrogram cut-off yielding five clusters.

For the cluster 1 there is some very weak (a positive weight ≈ 0) indication for the variant *sbj+nn*, which essentially can be ignored. For the two clusters 2 und 3 there is no indicative pattern for L1 Chinese, whereas for the two clusters 4 and 5, there is a clear indicative preference for the variant *sbj+prp*. In sum, for most of the verbs in our data set, there is no indicative usage pattern for L1 Chinese compared to the western L1s. However, in connection with some particular verb groups, there is an indicative preference indeed, namely, for the variant *sbj+prp*, supporting the given hypothesis. Interestingly, the method does not simply support a known hypothesis, but it makes it possible to observe subsets of verbs for which the characteristics emerge. Studying what the 65 verbs grouped in the most indicative cluster have in common thus provides the opportunity for a more fine-grained qualitative analysis in SLA research.

8 Conclusions

In this paper, we proposed and explored a grouping technique for linguistic features. The method is inspired by a variationist linguistic perspective and uses hierarchical clustering on the basis of label-informed feature representations. The approach emphasizes how the underlying linguistic structure informs the classification label, reducing potential problems arising from idiosyncrasies and sparsity of individual features. We evaluated the approach in the context of NLI using a linguistic feature type well-suited to a variationist perspective, verb subcategorization patterns, treating the verb lemmas as variables and the different patterns as variants.

We motivated why we consider the technique to be of interest from a theoretical and a practical perspective. Grouping verb lemmas based on the subcategorization information, and thus abstracting from individual occurrences to the underlying linguistic structure, resulted in a significant improvement in terms of accuracy, confirming the hypothesis that in general learners with different L1s seem to prefer different subcategorization patterns. We then turned to investigating a particular hypothesis from SLA regarding the usage of the subject as part of the verb subcategorization information. We showed that the method can discover differences in the variant realization patterns in connection with different automatically induced classes of verbs, supporting a fine-grained qualitative analysis. Linking the analysis to a theoretical perspective informed by traditional SLA research, the method seems well capable of advancing the qualitative insights in NLI – a primary concern in that field of research today. Combining features obtained by the approach proposed in this paper with a set of previously used features resulted in an accuracy of 85.4%, which is the best result reported so far on the standard TOEFL11 data setup.

In terms of future work, we plan to explore different syntactic and morphological features under a variationist perspective, to extend the qualitative analysis, and to establish a firm enough link between the data-induced patterns and the traditional insights into L1-transfer to be able to test specific SLA hypotheses. Regarding the label-informed feature grouping technique, we are also considering applying it to NLP tasks other than NLI in order to obtain a more comprehensive assessment of the method.

Abstract

Previous linguistic research on scientific writing has shown that language use in the scientific domain varies considerably in register and style over time. In this paper we investigate the introduction of information theory inspired features to study long term diachronic change on three levels: lexis, part-of-speech and syntax. Our approach is based on distinguishing between sentences from 19th and 20th century scientific abstracts using supervised classification models. To the best of our knowledge, the introduction of information theoretic features to this task is novel. We show that these features outperform more traditional features, such as token or character n-grams, while leading to more compact models. We present a detailed analysis of feature informativeness in order to gain a better understanding of diachronic change on different linguistic levels.

1 Introduction

Supervised classification has been applied to various natural language processing tasks over the past decades. To date, however, distinguishing between time periods has not received extensive attention. Early research on classifying time periods is presented in de Jong et al. (2005) for Dutch. Dalli and Wilks (2006) and Kumar et al. (2011) use word frequencies for temporal classification of documents, while Sagi et al. (2009) and Kim et al. (2014) predict semantic changes over time. While lexical features are commonly used for classification approaches of time periods, features based on more abstract linguistic levels have not yet been widely investigated.

In our study, we use supervised classification to distinguish scientific abstracts written in the 19th and 20th century at the sentence-level. From previous work, we know that in the scientific domain, shared expertise among authors and audience affects their language use. Over a longer time period, it drives the evolution of domain-specific language with respect to lexis (Halliday, 1988; Teich et al., 2016) and a more standardized and convention-driven style with respect to grammar (Biber and Gray, 2011; Biber and Gray, 2016; Banks, 2005).

Considering that language variation affects *all* linguistic levels — from sounds and words to syntactic structure — we investigate a set of features extracted at the lexis, part-of-speech and syntactic levels to test how well they act as predictors of time period-specific language use. Moreover, based on psycholinguistic evidence it has been shown that language users choose those linguistic options that they know to be relatively predictable in a specific context to optimize communication (Hale, 2001; Levy, 2008; Demberg and Keller, 2008). To model communication in this sense, in our research we employ features based on the information-theoretic notion of *surprisal* or *information density*.

Specifically, we make use of information theory inspired features on the linguistic levels of lexis, part-of-speech and syntax. In addition, these features allow an unlexicalized dense-vector representation, which enormously reduces the amount of features used for classification. Besides achieving high performance in classification, we are particularly interested in insights on long-term diachronic linguistic change, which are important to historical linguistics, sociolinguistics and the like. We do this by inspecting classification results and discriminative features more closely.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 750–761, Osaka, Japan, December 11-17 2016.

Our analyses are driven by the following assumptions:

1. *Lexical diversification*: On the lexical level, scientific abstracts from the 19th and 20th century will be well distinguished from one another, due to topical changes in the scientific domain.
2. *Grammatical consolidation*: On more abstract linguistic levels, scientific abstracts from the 19th and 20th centuries will be less well distinguished from one another, as grammatical changes develop rather slowly over time, but we expect a tendency towards denser grammatical encodings in the 20th century texts.

The remainder of the paper is structured as follows. In Section 2, we present previous work on classification of time periods, diachronic change and information density. Section 3 describes the experimental setup up followed by the results and detailed analysis in Section 4. Finally, Section 5 provides a short summary and conclusions.

2 Related work

2.1 Classification of time periods

Classification of time periods has been less investigated so far in comparison to other classification tasks. Most of the existing work is based on lexical features and the classification of documents rather than individual sentences. In the study conducted by de Jong et al. (2005), the authors classify Dutch texts according to time (considering the time span 1999 to 2005) using uni-gram language models achieving around 65% accuracy. Dalli and Wilks (2006) (considering weekly to yearly levels, with an accuracy of the yearly classifier of $\sim$88%) and Kumar et al. (2011) (yearly classification) use classification methods based on word frequencies to determine the time period a text was written.

Other approaches – also based on lexical features – investigate semantic change over time. For instance, Sagi et al. (2009) focus on specific words to identify their semantic change from Early to Modern English. Mihalcea and Nastase (2012) use supervised learning to predict a word's time period given the context it occurs in. More recently, Kim et al. (2014) use neural language models to identify words that have changed semantically from 1900 to 2009. So far, only few studies have used features other than lexical ones for time period classification. Štajner and Zampieri (2013) have used stylistic features (such as average word and sentence length, pos tag n-grams, etc.) for classification of Portuguese texts into centuries achieving an F-measure of 0.92.

Besides the fact that most approaches use lexical features to predict time periods, the common experimental setup involves document-level classification of texts. To the best of our knowledge, there has been no work on sentence-based classification of time periods. Classifying sentences rather than texts allows us to build finer-grained classification models. In our approach, we classify sentences according to time periods going beyond lexis-based representations by using information theory inspired features, which inherently account for the context of use.

2.2 Information Density (ID)

Assuming that language users strive for efficient communication, they will tend to encode their message using an approximately uniform information density that exploits channel capacity while avoiding to overload the recipient or being uninformative. Information theory (Shannon, 1949) measures the amount of information conveyed by a unit in a given context in *bits* (Shannon, 1949). This notion is also known as *surprisal* (Levy, 2008) and is formulated as the negative log probability of a unit (e.g. a word) in context (e.g. its preceding words): $S(unit_i) = -\log p(unit_i|Context)$. Based on a limited context of size n words, the surprisal value of the following word w_{n+1} corresponds to the negative log-probability: $S(w_{n+1}) = -\log P(w_{n+1}|w_1 \dots w_n)$.

There are two properties inherent to surprisal: (1) units with low probability convey more information than those with high probability, and (2) information conveyed by a unit is crucially dependent on its context. Thus, linguistic units that are highly predictable in a given context convey less information with troughs in surprisal, while less predictable units convey more information with peaks in surprisal.

Over a longer period of time, the predictability of a word will change according to its use in specific contexts. In the scientific domain, shared expertise among researchers, for example, will affect language

use and give rise to domain-specific language. Particular words (e.g. terminology) will become more predictable over time (showing lower surprisal values) and may result in shorter encodings (consider e.g. acronym use in scientific fields such as genetics). Among researchers this will optimize communication. A more conventionalized use of scientific language will result in changes of surprisal values over time with conventionalized expressions (e.g. formulaic expressions) showing lower surprisal.

However, not only changes in lexis will be reflected in changes of surprisal values. From studies on language change, we know that diachronically there has been, for example, a shift from a more verbal towards a more nominal style (cf. notably Biber and Gray (2011)). This will have an impact on surprisal values with respect to grammatical units (such as parts of speech or syntactic units), motivating the use of information theory inspired features to classify between time periods.

So far, these kinds of features have been successfully used in classification of Gospels (see Islam and Dundia (2015) being able to identify the Greek Gospel as the original text and the American and Georgian ones as translations) and classification of human translated texts (see Rubino et al. (2016) distinguishing original from manually translated texts of different levels of expertise).

2.3 Language Change

Previous computational work on diachronic change in scientific language mostly discusses short-term change (see e.g. Blei and Lafferty (2006; 2007) on changes in scientific topics and Hall et al. (2008) on the ACL anthology corpus, both using topic models) rather than long-term change and is mostly concerned with change related to lexis (such as topical shifts) rather than change on more abstract linguistic levels.

In corpus-linguistic work on language change, approaches are typically frequency-based (e.g. Biber and Gray (2011; Biber and Gray (2013; Biber and Gray (2016), Taavitsainen and Pahta (2012), Moskowich and Crespo (2012)) and do not inherently account for context – diachronic change being observed through the lens of unconditioned probabilities. In contrast, information density measures as we apply them here, are based on conditional probabilities and thus inherently take context into account. Based on our previous work on long-term change using information-theoretic features (Degaetano-Ortlieb and Teich, 2016), we have shown how these features help model diachronic change, further motivating their use to classify different time periods.

3 Experimental Setup

The experiments presented in this paper focus on the use of sentence-level information density measures — in particular n-gram log-probabilities according to a language model and n-gram distribution according to frequency quartiles — to classify texts from different time periods. In this section, we present the supervised classification setup and the set of features as well as the data used.

3.1 Supervised Classification

A linear Support Vector Machine (SVM) (Cortes and Vapnik, 1995) is used to train our time-period classification model based on a feature representation of sentences which aims at capturing the density of information. All training, development and test sentences are represented as feature vectors $\mathbf{x}_i$, and the two corpora (19th century and 20th century) are associated with a class y_i, resulting in instance-label pairs $(\mathbf{x}_i, y_i)$ with $\mathbf{x}_i \in R^n$, and $y \in \{0,1\}^l$ as a binary classification task. We use the $L2$-regularized $L2$-loss SVC implementation of LIBLINEAR (Fan et al., 2008) to solve the following optimization problem:

$$min_w w^T \frac{w}{2} + C \sum_{i=1}^{l} max(0, 1 - y_i w^T x_i)^2 \quad (1)$$

The cost parameter C is selected with grid-search using the accuracy obtained on the held-out development set. Finally, the model is evaluated using the precision, recall, f-measure per class and general accuracy obtained on the test set.

Corpus	Sentences		Tokens		Types

Corpus	Sentences	Tokens	Types
19cLM	623.2	16,541.7	320.0
20cLM	423.4	11,137.8	261.9

(b) Corpora used as resources to train the language models and to extract n-gram frequencies.

Table 1: Statistics (in thousands) of the corpora used in our experiments.

3.2 Datasets

Four corpora are used in our experiments, two for each time period (early 19th century: 1800-1850; late 20th century: 1970-2007). Two corpora compose our training, development and test sets (henceforth: 19cA and 20cA) while two others allow us to train language models and extract n-gram frequencies (henceforth 19cLM and 20cLM). Statistics about these corpora are presented in Table 1a and Table 1b.

For the 19th century time period, we use a corpus of research articles from the Royal Society of London (Kermes et al., 2016). Abstracts are taken from this corpus to form the 19cA classification subset. For feature extraction full research articles (19cLM) are taken from the same corpus, filtering out articles with abstracts included in 19cA. For the 20th century time period, abstracts are taken from a corpus of research articles (Degaetano-Ortlieb et al., 2013) covering several disciplines[1] as our 20cA classification subset. For feature extraction, we collected abstracts from several fields (20cLM) matching those of 20cA. The main difference between 19cLM and 20cLM is the type of document used to extract them, the former being composed of full articles due to research abstract scarcity for this time period, while the latter is composed of abstracts. The classification subsets (19cA and 20cA) are pre-processed by means of regular expressions and manually verified in order to remove headlines preceding abstracts, dates, formulas and mathematical expressions, etc.

3.3 Feature Sets

We consider three sets of features: shallow base-line features, n-gram frequency features, and information density features. Both n-gram and features specifically referred to as information density features capture aspects of information density and rely on the external resources presented in Table 1b.

Shallow features Here we consider popular lexical features such as bags of character and token n-grams as a baseline, as well as bags of part-of-speech (POS) n-grams ($n \in [1; 3]$). For POS tagging and syntactic parsing, we use the Stanford NLP toolkit (Manning et al., 2014).[2] For bags of token n-grams, three feature sets are built: one taking into account all n-grams, one considering n-grams appearing at least 200 times in the training corpus and one keeping only n-grams appearing at least 500 times, noted *Tokens All*, *Tokens 200* and *Tokens 500* respectively. The two latter sets allow for more compact models and less sparsity in the feature vectors. Additionally, 13 surface features are used, extracted from the surface-level of each sentence, which aim to capture meta representations of sentences' lexical form including sentence and average word lengths, the number of punctuation marks, letter and word casing, binary values encoding whether the sentence ends with a period and starts with an uppercase letter, etc.

N-gram Frequency Features To capture the rarity of n-grams used in the sentences to classify, the percentage of n-grams in frequency quartiles are extracted ($n \in [1; 5]$). The corpora used to model the frequency quartiles are the same resources as the ones used for the language models (19cLM and

[1] computer science, computational linguistics, bioinformatics, computer-aided design, microelectronics, mechanical engineering, electrical engineering, biology, linguistics

[2] We use the bidirectional maximum entropy POS tagger with a pre-trained English model based on the WSJ sections 0-18, including word shape and distributional similarity features. The probabilistic context free grammar lexicalized parser is used to obtain syntactic information from text (Manning et al., 2014).

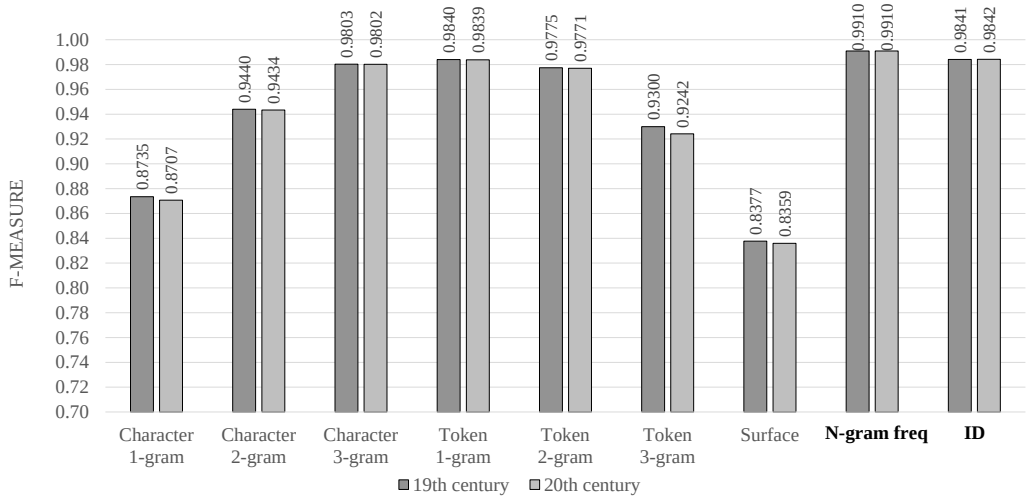

Figure 1: Classification results of 19th century and 20th century abstracts for lexis (LEX).

20cLM). Frequencies of word, part-of-speech and delexicalized flattened syntactic sequences are averaged at the sentence level, leading to 4 features per sentence (one per quartile) given one value of n, for each of the external resource used to model the quartiles (the corpora 19cLM and 20cLM). This approach leads to a dense representation of the information encoded in a sentence based on lexical, POS and syntactic information, without encoding raw word sequence n-gram features.

Information Density Features Using language models trained on sentences, delexicalized part-of-speech sequences and delexicalized flattened syntactic trees, a set of 120 sentence-level features are extracted: 15 features per individual LM resource (presented in Table 1b) and type of language model (lexical, POS and syntactic). We extract n-gram ($n \in [1; 5]$) log-probabilities (surprisal) as well as perplexities, with and without the tags indicating the beginning and ending of sentences, using the SRILM toolkit (Stolcke et al., 2011).

4 Results and Analysis

In the following, we present classification results of 19th vs. 20th century abstracts based on shallow as well as n-gram and information density features on three linguistic levels: lexis (LEX), part-of-speech (POS), and syntax (SYN). Moreover, by considering feature rankings obtained by the classification results, we analyze diachronic changes on these three linguistic levels.

4.1 Classification Results

Classification results on the lexical level (LEX) are shown in Figure 1. The bags of token n-grams features are unpruned (*Tokens All*). The best performing features are n-gram frequency (F-measure of 0.991) and ID features ranking second (0.984), both outperforming shallow features (bags of character and token n-grams, and surface features). Considering classification results on the part-of-speech level (POS), Figure 2 shows that POS 3-grams work best (0.9224) in classifying 19th c. and 20th c. abstracts, followed by POS 2-grams (0.9222) and ID features (0.9112).

Regarding classification at the syntactic level (SYN), Figure 3 shows that 19th c. and 20th c. abstracts are less well distinguished from one another in comparison to the lexical and part-of-speech level. Nevertheless, ID features work best on this task, achieving an F-measure of 0.88. Overall, ID features work relatively well on all three linguistic levels targeted in this study in comparison to other features, which work well on some levels (e.g. n-gram frequencies for lexis or POS 3-grams on the part-of-speech level), but less well on the other linguistic levels.

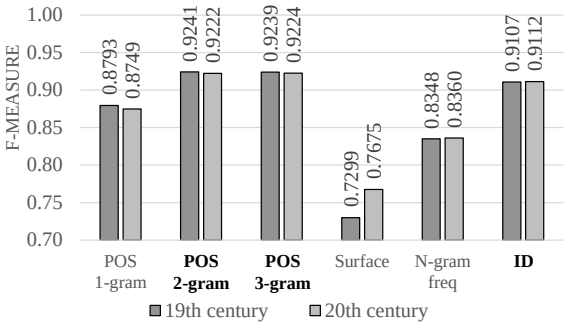

Figure 2: Classification results of 19th century and 20th century abstracts for part-of-speech (POS).

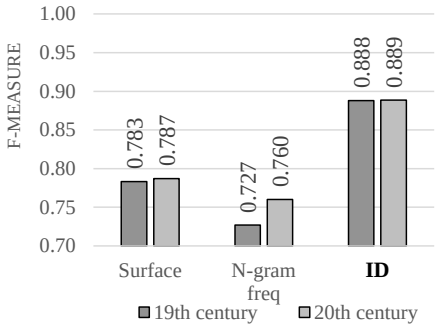

Figure 3: Classification results of 19th century and 20th century abstracts for syntax (SYN).

By considering combinations of feature sets, the best classification performance of 99.18 accuracy is obtained by a combination of n-gram frequency and ID features at all three linguistic levels (LEX, POS and SYN) (see Table 2). Moreover, looking at the number of features used for classification, better results can be obtained with a very small number of features (216) using n-gram frequency and ID features in comparison to the high number of features when using shallow features (e.g. more than 1 million features for surface tokens; see again Table 2). Pruning the low frequency n-grams considered in the bags of tokens features does not lead to accuracy improvement, but the resulting models are more compact with $3,081$ and 996 features for the *Tokens 200* and *Tokens 500* sets respectively.

			19cA			20cA		
Feature set	**Number of features**	**Accuracy**	**P**	**R**	**F**	**P**	**R**	**F**
Characters (LEX)	37,367	98.05	98.14	98.86	98.50	98.85	98.13	98.49
Tokens All (LEX)	1,896,263	98.12	97.43	98.84	98.13	98.82	97.39	98.10

4.2 Diachronic Changes at the Lexical Level

To investigate changes between 19th and 20th c. abstracts and evaluate the performance of the different feature types, we conduct a non-linear feature selection using the forest of randomized trees approach (Geurts et al., 2006) and describe the results for the top n-gram frequency and ID features in the paragraphs below. These two types of features are the focus of our study and lead to the best classification results as shown in Figure 1.

Lexis and N-gram frequency Inspecting the n-gram frequencies in detail based on feature ranking, we can observe general tendencies in lexis related change across the 19th and the 20th century. The highest ranking n-gram frequency features are based on 20cLM, comprising among the top 10 features 1- to 4-grams of very high (quartile 4) and low (quartile 1) frequency. This might be an indicator of conventionalized/formulaic language use with respect to high frequency high-order n-grams (4-grams quartile 4), on the one hand, and diversified language use with respect to low frequency low-order n-grams (1-grams quartile 1), on the other. Figure 4 shows the n-gram frequency distribution for 1- to

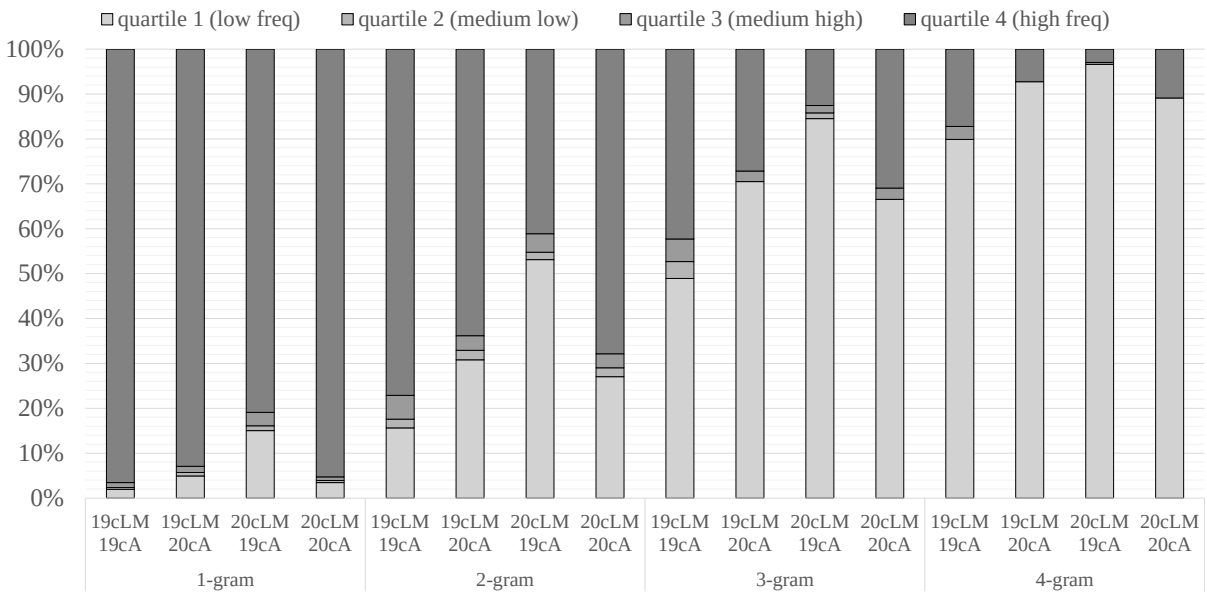

Figure 4: N-gram frequency distribution for 1- to 4-grams based on four frequency quartiles. 19cLM: 19th c. LM resource, 19cA: 19th c. abstracts, 20cLM: 20th c. LM resource, 20cA: 20th c. abstracts.

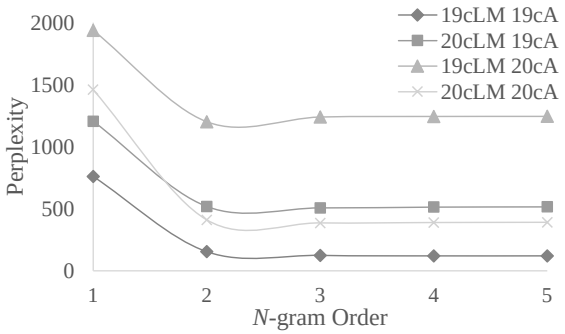

Figure 5: Averaged perplexity values obtained for 1- to 5-grams (LEX).

4-grams based on four quartiles (from high to low frequency) and on the resources used for language modeling (19cLM and 20cLM). Obviously, the higher the n-gram order, the higher the percentage of low frequency n-grams, i.e. rare n-grams. More specifically, Figure 4 shows that the 19cLM covers the 19th c. abstracts (19cA) quite well in terms of lexis, as the percentage of high frequency 1-grams (quartile 4) is high ($\sim$97%). The same can be observed for the 20cLM and the 20th c. abstracts (20cA) ($\sim$95%). However, while the 20cLM also covers relatively well the 19cA ($\sim$93% of high frequency 1-grams, quartile 4), the 19cLM on the 20cA shows a higher amount of low frequency 1-grams (quartile 1) covering high frequency 1-grams only by $\sim$80%. This indicates that while the vocabulary of 19th c. abstracts is relatively well covered by the 20th c. LM resource, the 20th c. abstracts make use of new words not covered by the 19th c. LM resource.

Considering 2-grams, which rank highest in classification, a similar but even more pronounced tendency can be observed, i.e. while the percentage of high frequency 2-grams is still relatively high for 20cLM and 19cA ($\sim$64%), 19cLM and 20cA show a relatively high amount of low frequency 2-grams ($\sim$53%). Nevertheless, the percentage of 20cLM and 19cA high frequency (quartile 4) n-grams remains higher than for 19cLM and 20cA. Thus, 20th c. abstracts have more diverse lexical n-grams than those written in the 19th c.

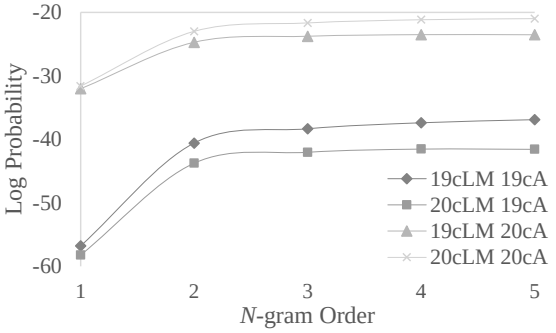

Figure 6: Averaged log probability values obtained for 1- to 5-grams (POS).

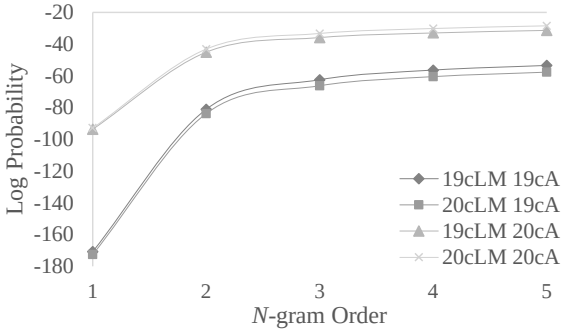

Figure 7: Averaged log probability values obtained for 1- to 5-grams (SYN).

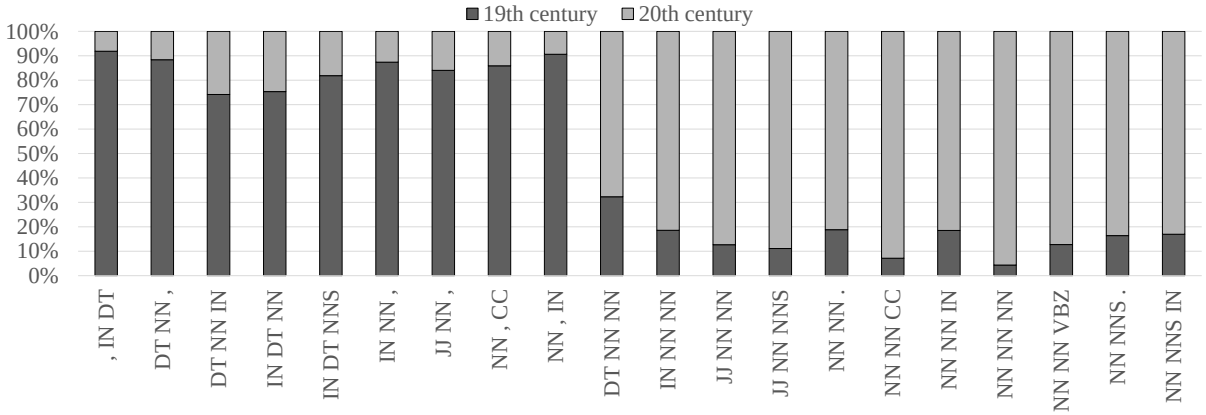

Figure 8: Distribution of top 20 POS 3-grams for the 19th c. and 20th c. abstracts. DT: determiner, CC: conjunction, JJ: adjective, IN: preposition, NN: singular common noun, NNS: plural common noun, VBZ: verb *be* present

In addition, the amount of high frequency (quartile 4) n-grams of the 19cLM and 19cA is higher than the ones for the 20cLM and 20cA. This might indicate a process of diversification in scientific writing, i.e. 19th c. texts in science are lexically closer than texts written in the 20th c.

Lexis and ID Feature ranking shows that perplexity values from 2- to 5-grams are the most discriminative ID features. Inspecting the perplexity values more closely (see Figure 5), we observe that from 2- to 5-grams 19cLM has relatively low average perplexity values for 19cA compared to the ones obtained for 20cA. While 19cLM is relatively close to 19cA, i.e. the abstracts' lexis is relatively predictable and obtains low perplexities according to the language model trained on 19cLM, lexis of 20th c. abstracts is less well predictable. This observation matches the results obtained with n-gram frequencies presented in Figure 4.

Considering 20cLM (see again Figure 5), it shows lower perplexity values for 20cA than for 19cA. However, the difference is relatively small in comparison to the difference observed for 19cLM on 19th and 20th c. abstracts. Thus, 20cLM is better in predicting lexical choices in both 19th c. and 20th c. abstracts compared to 19cLM. In terms of diachronic changes, this reflects how new lexical choices have entered scientific language, which were not present in the 19th century, while 19th c. language can still be understood by a contemporary language model. These results support the assumption of lexical diversification over time.

4.3 Diachronic Changes at More Abstract Linguistic Levels

Table 3: Most frequent lexical realizations of top 5 POS 3-grams for 20th c. and 19th c. abstracts

POS Sequences To investigate diachronic changes at the POS level, we consider POS 3-gram sequences, which perform best in POS-based classification (see again Figure 2). We inspect the top 20 features of the POS 3-gram sequences obtained by feature ranking and look at their frequency distribution in the training data of the 19th and 20th c. abstracts. Figure 8 shows how complex nominal structures (consisting of compounds with a at least two nouns, e.g. DT NN NN such as *the heat transfer*) are discriminative for the 20th c. abstracts, while shorter nominal structures (consisting of POS sequences with one noun, e.g. followed by a comma (DT NN , such as *the heat,*)) and prepositional phrases (e.g. IN DT NN such as *on the eye*) are discriminative for the 19th c. abstracts. This clearly reflects a shift towards a denser linguistic encoding in 20th c. abstracts, where information is more densely packed into longer nominal structures. Table 3 shows the top 5 POS 3-gram sequences of both periods with examples. We can see from the examples that while in the 19th c. there are relatively general and short nouns (such as *author*, *water*, *action*), in the 20th century more specific compound nouns are used. Inspecting these examples in their sentential context confirms the use of quite complex nominal phrases in abstracts of the 20th century (see examples (1) and (2)) vs. shorter, less complex ones in the 19th century (see examples (3) and (4)).

(1) *We have determined* ***the complete DNA nucleotide sequence of the carp Cyprinus carpio fast skeletal myosin heavy chain (MYH) gene***. (20th century)

(2) ***Nitric oxide generation rate and concentration distribution in combustors containing regions of recirculating flow*** *are calculated using* ***a computer program developed for two-dimensional elliptic compressible flows***. (20th century)

(3) *Those who cultivate* ***chemistry*** *with* ***any degree of ardour****, will be gratified to see in* ***this paper the pains*** *taken by* ***the author****, and* ***the various modes*** *he has devised, to produce* ***this compound metal*** *in its most perfect state of combination.* (19th century)

(4) ***The substance*** *here examined by* ***the author****, we are told, was first made known by* ***the celebrated Klaproth***. (19th century)

POS and ID We also inspect ID features as they achieve an F-measure above 0.90 (see Figure 2), indicating that 19th c. and 20th c. abstracts differ with respect to ID. The top three features refer to the log probabilities of 3- to 5-grams. In Figure 6, for both time periods the log probabilities increase with higher n-gram order, indicating lower surprisal values for POS n-grams of higher order. However, 19th c. abstracts differ from 20th c. abstracts as the log probabilities for the earlier period are lower (wrt both LM resources) than the ones for the 20th c. This indicates that POS sequences of 20th c. abstracts are

more predictable than those of the 19th c. abstracts, thus pointing to a more conventionalized use of POS sequences in 20th c. abstracts. These findings support our hypothesis of grammatical consolidation over time.

Syntax and ID The top three features on the syntactic level are again log probabilities of 3- to 5-grams. By inspecting the log probability distribution (see Figure 7), we see a very similar tendency to the results on POS. Thus, for both time periods the log probabilities increase with higher n-gram order, i.e. syntactic n-grams of higher order can be better predicted, indicating also on the syntactic level a more conventionalized use in 20th c. abstracts, which supports again our hypothesis of grammatical consolidation.

5 Conclusion

We have presented a sentence-based classification approach of time periods based on information theory inspired features. Our classification task focused on distinguishing 19th century and 20th century research abstracts. For this, we used features at three linguistic levels: lexis, part of speech, and flattened syntactic structure. This allows us to model not only lexical but also grammatical/stylistic long-term change in scientific writing.

Regarding classification, we show that while shallow features such as character and token n-grams achieve good results at the lexical level, applying features based on information density measures (log probability, perplexity) – achieves similar results and even outperforms shallow features at different linguistic levels. Furthermore, the best classification results were obtained by a combination of information density features considering all three linguistic levels with only a minimum number of features as we use unlexicalised dense feature-vector representations.

By a deeper analysis of the classification results, we obtained insights on long-term diachronic change with respect to our assumptions of *lexical diversification* and *grammatical consolidation*. Considering lexical diversification, new lexical choices have entered scientific writing from 19th to 20th century. Considering grammatical consolidation, a trend towards a denser linguistic encoding in terms of compact nominal structures was observed. Beyond lexical variation, we assume the methodology to be domain- and language independent. This will be pursued in future work with application on other genres/registers and languages.

Different Contexts Lead to Different Word Embeddings

Abstract

Recent work for learning word representations has applied successfully to many NLP applications, such as sentiment analysis and question answering. However, most of these models assume a single vector per word type without considering polysemy and homonymy. In this paper, we present an extension to the CBOW model which not only improves the quality of embeddings but also makes embeddings suitable for polysemy. It differs from most of the related work in that it learns one semantic center embedding and one context bias instead of training multiple embeddings per word type. Different context leads to different bias which is defined as the weighted average embeddings of local context. Experimental results on similarity task and analogy task show that the word representations learned by the proposed method outperform the competitive baselines.

1 Introduction

Different from traditional one-hot sparse vector representation, word embeddings are dense and low-dimensional. Due to natural advantage in word similarity computation, word embeddings are useful in a variety of applications, such as information retrieval (Uddin et al., 2013; Ganguly et al., 2015), sentiment analysis (Santos et al., 2014; Nguyen et al., 2015), question answering (Tellex et al., 2003) and parsing (Socher et al., 2013). Researchers learn word embeddings in various ways. Matrix Factorization methods for generating dense word embeddings have been used for years (Lund et al., 1996). While in recent years, neural network and deep learning have become popular approaches for learning word embeddings since Bengio et al. (2003) introduced feed forward neural network into traditional n-gram language models. For example, Collobert and Weston proposed a new objective function to learn word embeddings and improved word embeddings' quality (Collobert et al., 2008). Huang et al. (2012) presented a new neural network architecture which incorporated both local and global document context, and offered an impressive result. The word2vec toolkit developed by (Mikolov et al., 2013a; Mikolov et al., 2013b) implemented both Skip-gram and CBOW models which could provide high-quality word embeddings.

In spite of many successful applications, most word embeddings have a common problem that each word is represented by a single vector, subsequently ignoring polysemy. For example, the word *bank* cannot have high cosine similarity with the word *river* and *money* at the same time since these two words are so dissimilar and the single vector representation of word *bank* cannot express two different meanings. Thus, several multi-prototype models have been proposed to alleviate the problem caused by the polysemy and homonymy. Guo et al. (2014) took advantages of bilingual resources and affinity propagation clustering algorithm to learn multiple embeddings corresponding with multiple word senses. Due to the limitation of bilingual resources, they couldn't train their model on large scale corpus. Huang et al. (2012) pre-clustered the contexts of a word into K classes, and then learned K embeddings per word. K was a predefined value that would make matters confusion because different words usually had different number of senses. Neelakantan et al. (2014) shifted clusters into the training progress and

* The authors contributed equally to this paper

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 762–771, Osaka, Japan, December 11-17 2016.

proposed a non-parametric clustering model which could dynamically generate new cluster center by similarity threshold λ and thus could learn different number of embeddings per word type. Although they solved the problem caused by predefined K cluster centers, hyper-parameter λ was still hard to be defined, because the similarity thresholds for different words might be different. Moreover, they were sensitive to noise. Once a noise point happened, a new cluster center would be created. Therefore it would lead to mistakes due to no actions were taken to remove these incorrect clusters. Yang et al. (2016) proposed a supervised fine tuning framework to transform the existing single-prototype word embeddings into multi-prototype word embeddings based on lexical semantic resources. It was a good idea to obtain multi-prototype word embeddings, but it depended on the existing embeddings which had lost some information during the training process.

To the best of our knowledge, most of the prior work deal with the polysemy problem by learning multiple embeddings per word type. In this paper, we present a novel approach to take the polysemy phenomena into consideration. It is based on the assumption that the same word in different contexts has different meanings and so the polysemy problem appears. Traditional single word embedding is approximately the weighted mean of its different contextual semantics. Polysemic words owning the same appearance may mean that they share a common intrinsic quality, and the differences among them are reflected by different contexts. In other words, the different contexts of a word exert different influences, and the given context is a good indication of the direction of the word meaning. Therefore, we propose a method to model the intrinsic quality of words and obtain the influences affected by contexts.

In this paper, we make the following contributions:

- The composition and structure of our word embeddings are the word center adding the offset induced by the word contexts, which make it flexible to deal with the polysemy problem.
- There is no need to cluster before or during training process, which removes the inaccuracy caused by clustering. Each component of our word embeddings can be updated or trained thousands of times during the training process which makes it robust and less susceptible to outliers.
- We quantify the influencing degree of the local contexts by training weighted parameters. In this way, the first part in our word embeddings named word center can be trained more accuracy and less ambiguous.

2 Background: CBOW (Continuous Bag-of-Words Model)

As a popular toolkit provided by Mikolov et al., word2vec[1] has gained lots of attractions in recent years. Two models CBOW and Skip-gram (Mikolov et al., 2013a; Mikolov et al., 2013b) are used, which make it possible to train on more than 100 billion words in one day and generate high-quality word embeddings. Word2vec provides two frameworks for these two models. One is based on Hierarchical Softmax and the other is based on Negative Sampling. According to (Mikolov et al., 2013b), Negative sampling (NEG) is a simplification of Noise Contrastive Estimation (NCE) (Gutmann et al., 2012), which can improve both of the training speed and the quality of word embeddings. So we choose Negative sampling to optimize our model.

The CBOW model uses the contexts of word w to predict w. Thus, for the given contexts, word w is a positive sample and other words are negative samples. In the CBOW model, $v(w) \in R^d$ is the word embedding of word $w \in W$, where W is the word vocabulary and d is the dimension of the embedding. $C(w) \in R^d$ is the average embedding of the context for word w.

Given the context of word w, the probability that a word u can be observed is given by,

$$P(u|Context(w)) = \sigma(C(w)^T\theta^u) = \frac{1}{1+e^{-C(w)^T\theta^u}} \tag{1}$$

where θ^u are training parameters of word u according to the source code of Word2vec. For the positive samples where $u = w$, the CBOW model is maximizing formula (1), while for the negative samples

[1] https://code.google.com/p/word2vec/.

$u \in NEG(w)$ the model will minimize it which can be done as maximize $1 - \sigma(C(w)^T \theta^u)$. $NEG(w)$ is the sets of negative samples for word w. So rewrite formula (1), given a samples u, CBOW model will maximize:

$$g(w) = \prod_{u \in w \cup NEG(w)} p(u|Context(w)) \tag{2}$$

where

$$p(u|Context(w)) = \begin{cases} \sigma(C(w)^T \theta^u), & L^w(u) = 1; \\ 1 - \sigma(C(w)^T \theta^u), & L^w(u) = 0, \end{cases}$$

$$L^w(u) = \begin{cases} 1, & u = w; \\ 0, & u \neq w, \end{cases}$$

Then the whole expression of $g(u)$ can be written as:

$$g(w) = \prod_{u \in w \cup NEG(w)} [\sigma(C(w)^T \theta^u)]^{L^w(u)} \cdot [1 - \sigma(C(w)^T \theta^u)]^{1 - L^w(u)}$$

Given a training corpus $\mathcal{C}$, the word embeddings are learned by maximizing the following objective function:

$$G = \prod_{w \in \mathcal{C}} g(w) \tag{3}$$

For compute easily, the objective function take the $\log$ and switchs from product to sum:

$$\begin{aligned} \mathcal{L} = \log G &= \log \prod_{w \in \mathcal{C}} g(w) = \sum_{w \in \mathcal{C}} \log\ g(w) \\ &= \sum_{w \in \mathcal{C}} \sum_{u \in \{w\} \cup NEG(w)} \mathcal{L}(w, u) \end{aligned}$$

where

$$\mathcal{L}(w, u) = L_w(u) \cdot \log[\ \sigma(\ C_w^T\ \theta^u)] + [1 - L^w(u)] \cdot \log[1 - \sigma(C_w^T\ \theta^u)] \tag{4}$$

For the negative sampling method, Mikolov et al. found that the powered unigram distribution $U(m)^{3/4}$ outperformed significantly the unigram and the uniform distributions. The distribution that the noisy contextual words are randomly sampled by is as following:

$$P(w) = \frac{p_{unigram}(w)^{3/4}}{Z} \tag{5}$$

where $p_{unigram}(w)^{3/4}$ is the number of occurrences of the words and Z is the normalization constant.

3 The RLC (Reuse Local Context) Model

3.1 The Embedding Structure of RLC

Different from traditional one-hot vector representation approach, each dimension of word embedding represents a latent feature of the word, mentioned by (Guo et al., 2014). And the word analogical task introduced by (Mikolov et al., 2013a) means that the influence between words can be simply computed by addition and subtraction. Because of these, we can assume that the dimensions between a word embedding are relatively independent which means there are no cross influence between them. Then we introduce a weighted parameter for each word as a filter to control the influence degree given by the context of the word. And the center of the word embedding will be shifted after adding the contextual influences to word embeddings.

In our approach, the word embedding structure of word w can be written as following:

$$[Xe_w; Xm_w] \tag{6}$$

where $Xe_w \in R^d$ is the word embedding center point of word w, $Xm_w \in R^d$ is the weighted parameters.

Using this structure can obtain different word embeddings according to different contexts. If there are no contextual words, the center point of word embedding Xe_w can be used instead. Considering a context and a word sampled from it, it is impossible for the context to have negative influence to the word. So we use the sigmoid function to limit Xm_w within the range of 0 to 1. And the combination formula of word embedding for w is as follows:

$$X_w = Xe_w + \sigma(Xm_w) \cdot \frac{1}{m} \sum_{i=1}^{m} Xe^w{}_i \tag{7}$$

where m represents the number of words in the context of w; $Xe^w{}_i$ is the *i*th word in the context of w.

3.2 The Algorithm of RLC

We introduce our algorithms into CBOW model, named RLC on CBOW (RLCC). Then, we build our objective function. Unfortunately, the probability computing method that used by CBOW model is not suitable for our approach according to formula (1-3). Because they calculate the probability of word u given context $Context(w)$ using inner product of $C(w)$ and θ^u. While, θ^u are training parameters corresponding to the sample word u, which are of no use after training. So we cannot combine the influences of the given context with parameters u. If we combine every word in $Context(w)$ by formula (7), then the computational complexity of our model will be heavily increased. But we find that the function of θ^u is semantic representation for word u and it is also a kind of word embedding for word u which can be replaced by the true word embedding. So we update the probability $p(u|Context(w))$ by:

$$p(u|Context(w)) = \begin{cases} \sigma(C(w)^T X_u), & L^w(u) = 1; \\ 1 - \sigma(C(w)^T X_u), & L^w(u) = 0, \end{cases} \tag{8}$$

where

$$X_u = Xe_u + \sigma(Xm_u) * Xc$$

$$Xc = \frac{1}{m} \sum_{i=1}^{m} Xe^w{}_i = C(w) \tag{9}$$

where "$*$" denotes the product of corresponding vector components, Xc denotes the average embeddings for the current context of word w.

Negative sampling maximizes the probability of positive samples given the context and at the same time minimizes the negative ones. But there are some problems for our approach to simply use Negative sampling. In the training process, negative samples are treated completely irrelevant with the given context, and the probability that they are observed would be minimized. This is beneficial for the model to differentiate data from noise. While from the right part in formula (7) recorded as $X_{influence} = \sigma(Xm_w) \cdot \frac{1}{m} \sum_{i=1}^{m} Xe^w{}_i$ we can see that minimizing observed probability will be achieved by decreasing Xm_w, and this satisfies our goal. Unfortunately, the decreased value of $\sigma(Xm_w)$ for every iteration is $||C(w)||_2^2$ which has a mean greater than zero and should not be considered as probability. Meanwhile, according to the paper of (Mikolov et al., 2013b), we should ensure the effect that the number of negative samples should be in the range of 5-20 for small training datasets and in the range of 2-5 for large datasets. That means the number of negative samples is at least two times bigger than positive samples which makes matter worse. So we introduce extra learning rates to solve the problem:

$$\eta = L^w(u) * \alpha + \beta \tag{10}$$

where α and β are hyperparameters.

The influences of context to positive samples must be positive, so we introduce the sigmoid function to limit Xm_u within the range of 0-1. But it is not reasonable for negative samples, because the influences of context to negative samples could be negative. Meanwhile, Xc given as in formula (9) still has strong

correlation with the context embedding $C(w)$ after multiply by the weight $\sigma(Xm_u)$ which is harmful to the update of Xe_u in positive samples during the training process. We introduce new extra weighted parameters Tm during training process to solve the problem which can be seen as the weight for negative samples:

$$Xm_{u\_new} = (1-\gamma) \cdot Tm_u + \gamma \cdot \sigma(Xm_u) \tag{11}$$

where $\gamma = L^w(u) * (1-\lambda) + (1-L^w(u)) * \lambda$,$\lambda \in [0,1]$. For example, if we set $\lambda = 0$, then $\sigma(Xm_u)$ will be used as the weighted parameter when the sample is positive one.

In this case, formula (7) should be rewritten according to formula (11):

$$X_w = Xe_w + Xm_{w\_new} \cdot \frac{1}{m} \sum_{i=1}^{m} Xe^w{}_i \tag{12}$$

Combining the given objective function (3-4) and the above analysis, we can infer the update gradient in each iteration as follows and the pseudo-code is showing in the Algorithm 1.

$$\begin{aligned}
\frac{\partial \mathcal{L}(w,u)}{\partial Xe^w} &= [L^w(u) - \sigma(C(w)^T X_u)] * \frac{1}{m} * (\, X_u + C(w) * Xm_{u_new}) \\
\frac{\partial \mathcal{L}(w,u)}{\partial Xe_u} &= [L^w(u) - \sigma(C(w)^T X_u)] * C(w) \\
\frac{\partial \mathcal{L}(w,u)}{\partial Xm_u} &= [L^w(u) - \sigma(C(w)^T X_u)] * C(w) * Xc * \sigma(Xm_u) * (1-\sigma(Xm_u)) * \eta * \gamma \\
\frac{\partial \mathcal{L}(w,u)}{\partial Tm_u} &= [L^w(u) - \sigma(C(w)^T X_u)] * C(w) * Xc * (1-\gamma)
\end{aligned} \tag{13}$$

Algorithm 1 : Training Algorithm of RLC model

4 Experiments

Following previous work (Huang et al., 2012; Neelakantan et al., 2014), we choose Wikipedia corpus[2] (Shaoul et al., 2010) snapshotted at April 2010 to train embeddings. The Wikipedia corpus contains a total of about 2 million articles and 990 million tokens. In all of our experiments we remain 220682 words as the vocabulary by removing all the words with less than 55 occurrences and set the maximum context window ($m/2$) to be 8 which means 8 words before and after the word occurrence. Our hyper-parameter values are selected by manual exploration of results when using a small corpus attached by Word2vec toolkit, named text8 which has 31893 words in the vocabulary and 16 million words in the corpus after removing the words with the occurrences less than 20. In RLCC we set $\lambda = 0.5,\ \alpha = 0.4,\ \beta = 0.6$. Also we train embeddings in different dimensions and compare our methods with many state-of-the-art models.

Table 1 shows the training time of our models on the small data set text8, compared with other models from previous work. All the methods are evaluated using a single-machine with 16 threads. We see that the training speed of our model is faster than Skip-gram model but is slower than CBOW model. This indicates that our model can be acceptable with respect to efficiency.

Model	**Time (minute second)**		
	dim-50	dim-100	dim-300
CBOW	55s	1m10s	2m33s
Skip-gram	5m35s	7m32s	18m57s
RLCC	1m52s	3m1s	7m14s

Table 1: Training Time Comparison

4.1 Word Similarity

The two datasets that we used to evaluate our word embeddings are as follows: the WordSim-353 (Finkelstein et al., 2001) dataset and the Contextual Word Similarities (SCWS) dataset (Huang et al., 2012). WordSim-353 is a standard dataset for evaluating word embeddings which consists of 353 pairs of word types. The similarity of each word pair is manually rated in a scale from 0 to 10 by 13 to 16 human judgements, and each pair receives an average score. But these scores are given without any information of the context which makes our embeddings hard to use. Fortunately, we are surprised to see that our embeddings outperform competitive baselines and even the state-of-the-art embeddings by only using the word center embeddings Xe.

Because of the absence of contextual information in the WordSim-353 dataset, Huang et al. (2012) developed Stanford's Contextual Word Similarities (SCWS) dataset which consists of 2003 word pairs and associated sentential contexts. So the SCWS dataset overcomes the issue caused by no contextual information in WordSim-353 and the models designed to deal with polysemous problems could have a good testbed. Most of those models train multiple embeddings per word type to tackle the polysemous problems and there are many approaches to measure the similarities of multi-prototype embeddings according to (Reisinger et al., 2010). Then we select the best results for each model to compare with our model.

Table 2 shows our results compared to previous methods on WordSim-353 dateset and Table 3 gives the results on SCWS dataset. All the models mentioned are trained in the same Wikipedia corpus snapshotted at April 2010. The scores Huang et al. we used in the table is using the word embeddings trained and provided by (Huang et al., 2012). MSSG and NP-MSSG are the best scores provided by (Neelakantan et al., 2014). We train Skip-gram and CBOW models using 10 negative samples and a context window size of 8 on the same corpus. RLCC* is our model, and the results shown in the table are gained by only using Xe in our models. Some results are not provided in these tables because we could not find the embeddings or results provided by the authors. From Table 2 we can see that our model is able

Model	Different dimensions		$\rho \times 100$
	dim-50	dim-100	dim-300
Huang et al.	64.2	-	-
C&W	55.3	-	-
MSSG	63.2	-	70.9
NP-MSSG	62.4	-	68.6
CBOW	65.0	66.5	65.8
Skip-gram	68.6	71.7	72.7
RLCC*	**70.8**	**73.0**	**75.0**

Table 2: Experimental Results on the WordSim-353 dataset. The numbers in the table are Spearmans correlation recorded as $\rho \times 100$ between the model's similarities and human judgments. The best results according to each dimension are in bold face.

to learn more semantic word embeddings and noticeably improves upon previous models. We believe that the improvement is mainly attributed to the fact that the learned center word embedding Xe is less ambiguous.

Table 3 shows that our model gets the best result on both the 50-dimension embeddings and the 300-dimension embeddings. Obviously, our approach can better deal with polysemous problems than the traditional multi-prototype word embeddings.

Model	Dim	NUContext	UContext
C&W	50	57.0	-
CBOW	50	64.7	-
Skip-gram	50	63.4	-
Huang et al.	50	58.6	65.7
MSSG	50	62.1	66.9
NP-MSSG	50	62.3	66.1

CBOW	100	65.8	-
Skip-gram	100	64.9	-
RLCC	100	66.0	68.4
CBOW	300	66.6	-
Skip-gram	300	66.7	-
MSSG	300	65.3	69.3
NP-MSSG	300	65.5	69.1
RLCC	300	**67.6**	**69.7**

Table 3: Experimental results on the SCWS dataset. "NUContext" is the abbreviation for "Not use the contextual information". For those multi-prototype embeddings, the $globalSim$ metric which is each word's global context vector ignoring the many senses is used. While in our model, we still use Xe for each word, ignoring the weighted parameters. "UContext" is the abbreviation for "Use the contextual information". In this time, for multi-prototype embeddings models, $avgSimC$ method is applied which weights the similarity by how well each sense fits the context at hand (Neelakantan et al., 2014). All of the best results for each dimension are marked by underline, while in the two situations of using context or not, they are marked by bold.

4.2 Word Analogies

The word analogy task is introduced by (Mikolov et al., 2013a). It is a comprehension test task which is designed to measure the quality of word embeddings. This task consists of questions like, "a is to b

as c is to ___ ?". The dataset we applied in this task is built by Mikolov et al., which contains five types of semantic questions and nine types of syntactic questions with 8869 and 10675 questions respectively. The questions, for example, "Tokyo is to Japan as Beijing is to ___ ?", are answered by finding the word whose embeddings are the most similar one with $W_{Japan} - W_{Tokyo} + W_{Beijing}$ under cosine similarity.

According to (Neelakantan et al., 2014), both MSSG and NP-MSSG models achieve 64% accuracy which exceed (Huang et al., 2012) but are worse than the Skip-gram model. So we compare our model with CBOW and Skip-gram models only in this task. The results shown on Table 4 demonstrate that our model outperforms both the CBOW and Skip-gram models in most words' analogy task especially in answering semantic questions. It means that our embeddings are less constrained by syntax and are more semantic.

Model	Dim	Sem.	Syn.	Tot.
CBOW	50	59.6	59.4	59.5
Skip-gram	50	52.5	55.9	54.6
RLCC*	50	66.3	60.1	62.5
CBOW	100	72.8	70.2	71.2
Skip-gram	100	67.8	69.2	68.6
RLCC*	100	80.0	70.8	74.3
CBOW	300	77.9	**75.4**	76.4
Skip-gram	300	83.1	73.4	77.2
RLCC*	300	**90.7**	71.8	**79.0**

Table 4: Experimental results of the word analogy task show as percent accuracy. We trained CBOW and Skip-gram using the same corpus as our model used, and the training parameters were also the same as we described before.

5 Related Work

In recent years, neural network and deep learning have become popular approaches for learning word embeddings, which make it possible to study dense and high quality word embeddings. Bengio et al. (2003) introduced feed forward neural network into traditional n-gram language models, which might be the foundation work for neural network language models(NNLM). In NNLM, words were represented by a low-dimensional vector and the parameters could be learned in unsupervised methods. Collobert et al. (2008) proposed a new objective function to learn word embeddings instead of the time consuming softmax layer presented in (Bengio et al., 2003) and much improved training speed. Mnih et al. (2007) reduced the computational complexity of the Bengio's model by replacing the softmax layer with a tree-structured probability distribution.

Mikolov et al. (2013a) and Mikolov et al. (2013b) removed the hidden layers of neural network and proposed log-liner neural language models named Skip-gram and CBOW. These two models extremely reduced the computational complexity and could train word embeddings on more than 100 billion words in one day with a single machine. With the help of negative sampling method, both of the two models could obtain state-of-the-art word embeddings.

In the previous work, several multi-prototype models have been proposed to alleviate the problem caused by the polysemy and homonym. Guo et al. (2014) took advantages of bilingual resources and affinity propagation clustering algorithm to learn multiple embeddings corresponding with multiple word senses, because a polysemous word in one language could not be exactly a polysemous word in another language. Huang et al. (2012) pre-clustered the corpus into specified classes, and relabeled the tokens into different classes, then learned specified numbers of embeddings per word type. The number of each word senses was predefined as a fixed value that would make matters confusion because the different words might have different number of senses. Neelakantan et al. (2014) shifted clusters into the training progress and proposed a non-parametric clustering model which could dynamically generate new clusters based on word meaning. Fine tuning was also a good idea to generate muti-prototype word embeddings.

Yang et al. (2016) proposed a supervised fine tuning framework to transform the existing single-prototype word embeddings into multi-prototype word embeddings based on lexical semantic resources.

6 Conclusion

In this paper, we present a novel model to reuse the local context and enhance word embeddings for both monosemous and polysemous words. The proposed model is an extension to CBOW and it is designed to embed a word as a word semantic center and a weighted parameter. Weighted parameter denotes the influences given by the contexts. Experimental results show that embeddings trained by our model outperform competitive baselines and even state-of-the-art embeddings. When we focus on polysemy, our approach could shift the embedding of polysemous word into the corresponding semantic space according to the given context. In the future, we plan to make our model more explainable.

Abstract

In this work we tackle the challenge of identifying rhythmic patterns in poetry written in English. Although poetry is a literary form that makes use standard meters usually repeated among different authors, we will see in this paper how performing such analyses is a difficult task in machine learning due to the unexpected deviations from such standard patterns. After breaking down some examples of classical poetry, we apply a number of NLP techniques for the scansion of poetry, training and testing our systems against a human-annotated corpus. With these experiments, our purpose is establish a baseline of automatic scansion of poetry using NLP tools in a straightforward manner and to raise awareness of the difficulties of this task.

1 Introduction

Automatic analysis of the rhythmic patterns in poetry may appear deceptively simple. In fact, however, it presents a challenge for structured prediction methods in NLP on par with the most difficult language analysis tasks tackled today. What makes assigning rhythm to written poetry—i.e. "scansion"—a particularly knotty puzzle as a sequence labeling task in NLP is that, while the rhythm in most lines encountered in a work of poetry appears mundanely repetitive on the surface, poetry, while mostly a constrained literary form, is prone to unexpected deviations of such standard patterns. These departures of form, effortlessly understood and analyzed by competent speakers of the language, are tied to multiple levels of language processing. Sometimes, a simple lengthening of a line, the removal of a syllable, an onomatopoetic element, or even a semantic twist to the plot-line in a stanza of poetry can cue a sensitive human reader to assign an apparently deviant rhythmic pattern onto a line of verse.

As an example of the simple and straightforward, consider a line from the ninth book of *Paradise Lost*, by John Milton (Pickering, 1832, p. 128):

No more of talk where God or Angel guest

The even syllables of this line —*more*, *talk*, *God*, *An-* and *guest*—for most readers tend to appear naturally more prominent. At first glance, we might be tempted to assume that this repeats itself through the poem, which indeed is the case.

No more of talk where God or Angel guest
With Man, as with his friend, familiar us'd,
To sit indulgent, and with him partake

However, even here complications arise: in the second line above, we see that the word **with** appears as both unstressed and stressed, showing that the process of assigning prominence to certain syllables cannot depend purely on the lexical items themselves. Still, a naive sequence modeler that simply assumed that the poem follows an unstressed-stressed alternation would fare reasonably well here.

In contrast, consider the first and the fourth quatrains from a well-known poem by Theodore Roethke (1908–1963), *My Papa's Waltz* (1942), which tells the awkward story of a young boy in first-person whose father foists a late-night drunken waltz upon him in the kitchen.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 772–781, Osaka, Japan, December 11-17 2016.

The whiskey on your breath *You beat time on my head*
Could make a small boy dizzy; *With a palm caked hard by dirt,*
But I hung on like death: *Then waltzed me off to bed*
Such waltzing was not easy. *Still clinging to your shirt.*
from Roethke (2011)

The poem, which starts off in the first line with a seeming monotonous regularity of *iambic trimeter*—three syllable-pairs of DE-DUM per line—quickly departs from the form, as if mimicking the angular and erratic 3/4 waltz beats of the drunken father's performance. By the time we reach the word **dizzy** in the second line we find a peculiar extra syllable that needs to be accommodated. But this breaks the pattern, and we now need to decide whether to end the line **small boy di***zzy*, or perhaps **small** *boy* **di***zzy*? The rhymes also become slanted (as in **dizzy/easy**) perhaps invoking images of slurring, and the natural departure of the DE-DUM rhythmic patterns in what, for most readers, becomes a sequence of two stressed syllables, **beat time** *on my* **head**, conjures up images of the father's whacking the boy in an off-beat fashion.[1]

Most "standard" structured prediction methods effortlessly produce 80%-90% accuracy when assigning levels of stress to syllables, and do so by simply marking the most prominent rhythmic pattern mechanically. One cannot, however, conclude from this that automatic scansion of poetry is a simple task. It merely reflects the pattern of alternation between a large number of regular lines and the unexpected irregular interlude. Moving significantly beyond the accuracies that can be achieved with straightforward machine learning methods remains a challenge for NLP.

In this paper we explore a number of machine learning techniques to automatically assign stress to written poetry against human-annotated gold standards. While we do not expect to be able to tackle highly problematic cases whose solutions require meta-readings, such as understanding the effects of whiskey on the human sense of rhythm, our purpose is to set up a strong baseline and to explore the low-hanging fruits available to us, and to establish the inherent difficulty of the task.

2 Scansion

Conventionally, the metrical scansion of a line of poetry should yield a representation which marks every syllable with its level of stress and divides groups of syllables into units of feet. Typically two or more levels of stress are used. Consider, again, the example line from *Paradise Lost*, whose natural analysis is

```
 x  /    x   /      x    /   x  /   x    /
No more |of talk |where god |or An|gel guest
```

where we use the symbol `/` to denote stressed (ictic) syllables,[2] and `x` to denote unstressed (non-ictic) ones, as is done in Steele (1999) and the *Princeton Encyclopedia of Poetry and Poetics* (Preminger et al., 2015). The line in question follows the stress pattern

DE-DUM DE-DUM DE-DUM DE-DUM DE-DUM

and consists of five feet of two syllables each with an unstressed-stressed pattern. Indeed, this is the most common meter in English poetry, *iambic pentameter*.

The above example is rather clear-cut. How a particular line of verse *should* be scanned, however, is often a matter of contention. Consider, for example, the first three lines from the poem *Sudden Light* by the English poet Dante Gabriel Rossetti (Rossetti, 1881):[3]

Then, now,–perchance again!
O round mine eyes your tresses shake!
Shall we not lie as we have lain

[1] We are lucky to have a recording of Roethke's own rendering of the poem and know that the intended readings of the passages mentioned are **small boy di***zzy* and **beat time** *on my* **head**; see `https://www.poets.org/poetsorg/poem/my-papas-waltz-audio-only`.

[2] In the case of inline examples, we will make use of **bold** letters to denote stress.

[3] This stanza did not appear in the first edition of Rossetti's poem book, but did in the second.

The third line is the one that is somewhat ambiguous. The line in question can be read as a sequence of iambs, because the entire poem follows an iambic pattern (*Shall **we** not **lie** as **we** have **lain***). But, in a similar manner as is done in the first line from Shakespeare's 18th sonnet (Shakespeare, 1609) (***Shall** I com**pare** thee to a **sum**mers **day***), a commonplace substitution can be made, changing the first iambic foot to a trochee[4] (***Shall** we*). This leads to a so-called *trochaic substitution*. Apart from these two different options, the line could also be analyzed as consisting of two double iambs[5] (*Shall we **not lie** as we **have lain***). Finally, a last possible scansion would be to have assume a trochaic and a pyrrhic foot followed by a double iamb (***Shall** we **not lie** as we **have lain***). In other words, there exists a set of possible analyses for this line which may all be accepted as correct, or at least reasonable.

2.1 State of the art

Automatic scansion of poetry has attracted attention from numerous scholars in recent years and in the following section we discuss some of them. Some works rely on statistical analyses, like Hayward (1996) and Hayes et al. (2012). Others make use of linguistic knowledge obtained by generalizing observations found in different kinds of poetry and propose hand-written rules for the assignment of stress. Recently, as in other NLP tasks, data-driven approaches have emerged in automatic poetry analysis (Estes and Hench, 2016).

Statistics about scansion

Hayward (1996) has as its goal to investigate whether it would be possible to differentiate among the metrical patterns developed by individual writers and also the stylistic differences among periods. To this end, the authors collected a corpus of work by several poets from different time periods and built a neural network model (Rumelhart et al., 1988) to scan poems. Using this technique, Hayward analyzes the work of ten different poets and reports that the neural model of poetic meter was successful in determining "significant differences" among the analyzed poets.

Hayes et al. (2012) propose in their article a new approach to analysis in metrics. Their research is built upon two main works: generative metrics (Halle and Keyser, 1971) and their own earlier work (Hayes and Wilson, 2008) in the use of MaxEnt Grammars for the analysis of phonotactics. They propose a set of constraints that can be assumed to be active when scanning a verse line, and according to the number of times each of these constraints is not fulfilled and according to weights that each constraint have, they determine if a line is metrical or not.

Rule-based scansion

Logan (1988) documents a set of programs to analyze sound and meter in poetry. This work falls in a general genre of techniques that attempt to analyze the phonological structure of poems following the generative phonological theory outlined by Chomsky and Halle (1968) and described by Brogan (1981).

Scandroid is a program that scans English verse written in either iambic or anapestic meter, designed by Charles O. Hartman (Hartman, 1996; Hartman, 2005). The source code is publicly available.[6] The program can analyze poems and check if the predominant stress pattern is iambic or anapestic. However, if the input poem's meter is not one of those two, the system forces each line into one of them. This system represents the current state of the art in the rhythmic analysis of poetry.

AnalysePoems is another tool for identification of metrical patterns written by Plamondon (2006). In contrast with other programs, its main goal is not to perform a perfect scansion, but to only identify the predominant meter in a poem. The program also returns the rhyme scheme that the line follows, such as, **ABCB** for poems whose even lines rhyme.

Calliope is a similar tool, built on top of Scandroid (McAleese, 2007). It is an attempt to leverage syntactic information in order to improve scansion. The program does not appear to be freely available.

[4] A sequence of syllables where the first one is stressed and the second one unstressed.
[5] Double iamb: two unstressed syllables and two stressed syllables [xx//].
[6] `http://oak.conncoll.edu/cohar/Programs.htm`

One of the recent scansion implementations is *ZeuScansion* (Agirrezabal et al., 2016), a tool for scansion of English poetry, which performs poetry scansion using a simplified version of various stress assignment 'rules-of-thumb' developed by (Groves, 1998). We use this work as a baseline for our experiments.

The rule-based systems mentioned above were designed to work only with poetry in English. There exist, however, several rule-based implementations for other languages, such as Spanish (Gervás, 2000; Navarro-Colorado, 2015).

Supervised Learning & sequential modeling

Estes and Hench (2016) is a current work that makes use of supervised learning tools in order to metrically analyze poems written in Middle High German. Middle High German poetry is a hybrid between qualitative and quantitative verse, which means that both the length and the stress of syllables are taken into account for patterning in the lines. In order to perform supervised learning, they use a corpus of 825 manually annotated lines, which are annotated by the authors. They report an F-score of 0.894 on 10-fold cross-validated development data and 0.904 on held-out testing data.

Unsupervised scansion

Greene et al. (2010) uses statistical methods in the analysis of poetry. For the learning process, *The Sonnets* by Shakespeare was used, as well as a number of other works freely available online.[7] They learn word-stress patterns from the corpus using unsupervised learning and with the incorporation of rhyme and discourse models, they use this system to generate English love poetry. In addition, they also apply their models for the automatic translation of poetry, testing them with Italian three-line stanzas as a source language and English iambic pentameter verse as the target language. We have not obtained an implementation to review.

3 Corpora

As the gold standard material for training our scansion systems, we use a corpus of syllabified and scanned poetry, For Better For Verse (4B4V), from the University of Virginia (Tucker, 2011).[8] This website was originally built as part of an interactive on-line tutorial to train people in the scansion of English poetry in traditional meter. These manually annotated poems can be downloaded from a public repository on GitHub.[9]

The entire collection comprises 78 poems containing approximately 1,100 lines in total. It includes poetry covering a time-span from the 16th century until the 20th and for each century there are at least 6 poems and a maximum of 32 works. Sometimes, several analyses are given as correct in the gold standard to accommodate a natural ambiguity when performing scansion. When two or more analyses are available, we set the error-rate to be the minimum Levenshtein distance to each of the possible analyses, in the same way as in ZeuScansion (Agirrezabal et al., 2016, p. 22) was evaluated.

4 Techniques / Features

We used several Machine Learning algorithms to test our feature configurations, some of them yielding independent outputs, used as a greedy labeler, and some others resulting in structured output. As independent predictors we used an implementation of Naive Bayes (Garner, 1995), Support Vector Machines (Cortes and Vapnik, 1995; Fan et al., 2008) and the averaged Perceptron (Rosenblatt, 1958; Freund and Schapire, 1999).[10] As sequence-based predictors we used the widely employed Hidden Markov Models (Rabiner, 1989; Halácsy et al., 2007) (HMMs) and Conditional Random Fields (Lafferty et al., 2001; Okazaki, 2007) (CRFs).

[9] https://github.com/waynegraham/for_better_for_verse/tree/master/poems

[10] We used an Averaged Perceptron implementation publicly available at https://bitbucket.org/mhulden/pyperceptron

Feature template set

Below we show the set of feature templates that our supervised learning scansion systems use, which include:

- Basic features that are (almost) language agnostic
  - Syllable number within the word (SNOW): This specifies the syllable within the word in which we are working currently. E.g., for the word *ha-zel*, whose lexical stress is /x, the specification of the current syllable gives information about the lexical stress of the current syllable.
  - Syllable number within the line (SNL): This feature helps to model the sequence in many types of specially metered lines, e.g., iambic lines. It can resolve possibly ambiguous cases such as the verb re-cord, whose lexical stress could be said to be x/. If we know that this word appears in the last two positions of a trochaic poem, we can ensure that it will have the /x pattern.
  - Number of syllables in the line (NSL): The combination of this feature and the previous one helps in identifying the syllables at the end of a line which are usually more regular because of rhyme patterns.
  - Syllable phonological weight (SWEIGHT): this relies on a generalization that states that heavy syllables—ones which end with a coda consonant or have diphthong nucleus—attract stress. Our hypothesis is that this would be useful in the scansion system, as reflected in John Keats' poem, "*to **swell** the **gourd** and **plump** the **hazel** **shells***".[11]
  - The last 5 characters of the word (last character, last two characters, last three characters, last four characters, and last five characters) (LC1...LC5): As primary stress of the words in English is usually concentrated in the last syllables of the word (roughly the last three syllables), we expected the last characters to be informative (Hayes, 1995, p. 50). Although it could be better to use the last characters of the syllable, as it was done in Estes and Hench (2016), we tried to be more agnostic about the language in question when developing these basic features, and chose the last characters of the word instead.
  - Word length (WLEN): We expected this to be an informative feature.
- Other features
  - Word: As the main basic units of the text, we used words as features.
  - Syllable: Some syllables are almost always stressed, which could help in the inference of stress patterns. For example, in Shakespeare's Sonnets, the syllable "sire" is used 10 times and in all of them it appears as stressed.
  - POS-tag: The part of speech is a key element to decide whether a word is a content word or function word, which affects the stress in many syllables, as in the following excerpt from *The voice* by Thomas Hardy: "*call to me call to me*", both the verb *call* and the pronoun *me* have lexical stress, but the pronoun loses the prominence when read aloud because it is not a content word. Previous works on poetry analysis, such as Groves (1998), rely on this information.
  - Lexical stress (LS): Knowing the lexical stress sequence in a phrase is an important hint for deducing the rhythmic pattern of a line of poetry. We include the lexical stress of the word that we are analyzing at the moment. This lexical stress is calculated by using the NETTalk dictionary (Sejnowski and Rosenberg, 1987) and when treating out-of-vocabulary words, we calculate their stress using an SVM implementation given in Agirrezabal et al. (2014).

These last four features are extended to include their context as well. For example, we take the current syllable ($syllable[t]$) into account but also additionally its previous and next 10 syllables (syllable[t$\pm$10]). In the case of words, part of speech tags, and lexical stresses we decided to include the $\pm$ 5 surrounding elements.

[11] In this example we use an underline to mark if a syllable is heavy or not.

5 Experiments

We first performed one experiment that only included basic features that could be inferred from each word language-agnostically, and another experiment which included all the features presented above. The simple feature configuration was composed of the first ten features above (SNOW, SNL, NSL, WLEN, SWEIGHT and LC1...LC5). Training greedy sequence predictors with these attributes shows us the basic capability of our predictors using little or (almost) no linguistic information. All these results are compared with the rule-based system ZeuScansion (Agirrezabal et al., 2016), our previous work which we use as our baseline. Results with this feature configuration can be seen in Table 1 and it seems that we could reach quite acceptable (although lower than our baseline) accuracies by simply extracting basic attributes from words. The results of the classifiers using all the features are reported in Table 2. Here, both the SVM and the Perceptron see their scores improve significantly. In the case of the Naive Bayes classifier results do not improve as much as in the other cases, probably because of the sensitivity to overlapping features in Naive Bayes. The difference between the linear SVM and the Perceptron, especially in per-line accuracy, is somewhat noteworthy. Normally, we would expect the SVM, which finds a maximum-margin classification boundary, to outperform the averaged Perceptron, but that is not the case here in both the basic feature set experiment and the full feature set one.

	Per syllable (%)	Per line (%)
Baseline	86.78	26.21
Naive Bayes	78.08	10.64
Linear SVM	83.12	23.40
Perceptron	**84.86**	**29.32**

Table 1: Accuracies of different classifiers using just the basic features (10 features) presented in section 4 using 10-fold Cross-Validation.

	Per syllable (%)	Per line (%)
Baseline	86.78	26.21
Naive Bayes	80.44	13.88
Linear SVM	87.47	35.69
Perceptron	**89.34**	**43.36**

Table 2: Accuracies of different classifiers using all the features (64 features) presented in section 4 using 10-fold Cross-Validation.

From single prediction to structured prediction

As single predictors do not optimize the resulting sequence labeling, they can make simple errors that propagate throughout the line—something that could be avoided by looking at the surrounding outputs. This is the main weakness of not using structured prediction systems.

Hidden Markov Models are simple models that have been successfully used in tasks like POS-tagging, reaching reasonably good results. Conditional Random Fields are often used as an alternative model for POS-tagging and also for Named Entity Recognition and other NLP tasks (McCallum and Li, 2003).

In our experiments, although the per-syllable accuracies do not vary too much, the per-line scores improve substantially by the use of structured predictors. In table 3 the per line and per syllable accuracy of structured prediction systems can be seen (HMM and linear-chain CRF). The HMM has been trained in the standard way, that is, using single syllables (emissions) and their corresponding classes (states). The CRF model is trained analogously, i.e. using only syllables as the features, and the previous label. As expected, training the CRFs using the richer feature configurations employed in the greedy sequence predictors above yields a much higher accuracy, especially in the per line measure. These results are shown in table 4.

	Per syllable (%)	Per line (%)
Baseline	86.78	26.21
Scandroid	89.78	42.95
HMM	**90.43**	**49.88**
CRF	88.13	43.93

Table 3: Accuracy of sequential systems using just syllables.

	CRFs		
	#Features	Per syllable (%)	Per line (%)
Basic features	10	89.66	50.16
All features	64	**91.41**	**55.30**

Table 4: Accuracies of CRFs using different (best) sets of features on 10-Fold Cross-Validation.

6 Discussion & Future work

After checking all the results of the systems, we extracted all the rhythmic pattern predictions of the systems, sorted and grouped them. We can observe that the sorted results of the greedy predictors are more scattered. This is obvious since the greedy predictors do not explicitly promote any holistic coherence at the line level. In the following we show the most common patterns and their frequencies in the same dataset (where roughly 900 lines were used for training and 100 lines were used for testing).

	CRF
26	x / x / x / x / x /
13	/ x x / x / x / x /
5	x / x / x / x / x / x
5	x / x / x / x /
5	x / x /

	Linear SVM
12	x / x / x / x / x /
7	/ x x / x / x / x /
6	x / x / x / x x x /
5	/ / x / x / x / x /
4	x / x /

In this example it can be seen that given the same dataset, the variance in outputs can be quite different. Both classifiers predict an iambic pentameter most frequently, but, in the case of the Linear Support Vector Machine there are approximately 50 analyses that only appear once (with slight differences between them). On the contrary, the number of unique analyses in the CRF results is around 30. This implicit bias toward regularity is probably helpful for highly regular poetry, but also detrimental for scansion of poetry with often recurring outlier lines. This raises an interesting question that could be tackled in the future: can we include the amount the variation of a single poet as a parameter in the model? Another related question is the amount domain adaptation that can be captured—in this case scanning poetry in a meter that has not been encountered previously.

In this work we have established a baseline for the analysis of rhythmic patterns in poetry using various supervised learning methods. As seen above, there are many cases in which the assignment of stresses is not straightforward which we plan to focus on in future work. We applied typical NLP tools directly and future efforts should focus on the improvement of these techniques, especially in the analysis of lines with syllable additions, removals, ambiguous stress assignments, etc. Additionally, we performed feature selection so as to improve accuracy—this, however, yielded a minimal improvement, but one which was not statistically significant.

The strongest results that we achieved were at around 91.4% per syllable accuracy, averaging 55.3% correctly scanned poetry lines on 10-fold cross-validation (CRF). Comparing with previous approaches to poetry scansion, we outperform rule-based systems such as *Scandroid*—which achieved a 89.78% per syllable and 42.95% per line accuracy—and *ZeuScansion*—which reaches 86.78% per syllable and a 26.21% per line accuracy (Agirrezabal et al., 2016).

Comparing this work with recent results presented in Estes and Hench (2016) on Middle High German poetry, the results that we get in 10-fold cross-validation are quite similar, as they achieve a F-score of .894 on 10-fold cross-validated data and .904 on held-out testing data.

In this article and mainly during our research, we treated the problem as a kind of binary classification task, marking the syllable either as stressed or unstressed. This binarization creates conflicts in some verses in which there is a slow increase of the stress level between syllables. In some works, e.g the above-mentioned Hayes et al. (2012), a four-level stress marking system is used. We believe that doing so can avoid some of the ambiguity problems in scansion. In this sense, the problem could be recast as either a multi-class problem, or a regression problem, calculating a non-binary level of stress for each syllable.

We also expect to improve these results using more advanced techniques. Our first intention is to use current advances in Deep Learning for the analysis of poetry, mostly sequence-based learning paradigms, such as the widely used Recurrent Neural Networks with Long Short Term Memory (LSTM). Our preliminary results with such models show that these frameworks can reach comparable (and sometimes even better) accuracies without extensive work on manual extraction of features.

We have mainly built analyzers for English poetry in this work, but our intention is to investigate if the basic features presented in this work are applicable to poetry written in other languages, and perhaps locate possible typological generalizations among different languages and poetic traditions.

As the corpus of annotated poetry we have used is not very large, we also want to explore the possibility of unsupervised learning of rhythmic patterns in poetry (in a manner similar to Greene et al. (2010)). In this context, the language-agnostic features we have developed should be especially useful. To this end, we plan to learn rhythmic patterns by extracting first the basic, and (nearly) language-universal features by performing basic syllabification according to general principles (Hayes, 2011) such as onset maximization and sonority sequencing.

Abstract

In order to apply computational linguistic analyses and pass information to downstream applications, transcriptions of speech obtained via automatic speech recognition (ASR) need to be divided into smaller meaningful units, in a task we refer to as 'speech-unit (SU) delimitation'. We closely recreate the automatic delimitation system described by Lee and Glass (2012), 'Sentence detection using multiple annotations', *Proceedings of INTERSPEECH*, which combines a prosodic model, language model and speech-unit length model in log-linear fashion. Since state-of-the-art natural language processing (NLP) tools have been developed to deal with written text and its characteristic sentence-like units, SU delimitation helps bridge the gap between ASR and NLP, by normalising spoken data into a more canonical format. Previous work has focused on native speaker recordings; we test the system of Lee and Glass (2012) on non-native speaker (or 'learner') data, achieving performance above the state-of-the-art. We also consider alternative evaluation metrics which move away from the idea of a single 'truth' in SU delimitation, and frame this work in the context of downstream NLP applications.

1 Introduction

By convention, texts written using the Latin alphabet are normally subdivided into smaller units – *sentences* – by capitalised initial characters and closing full-stops (periods), question marks and exclamation marks. The sentence has in turn become an orthodox unit of analysis for much linguistic research, from natural language processing to syntactic theory. Speech, meanwhile, is hardly ever so neatly portioned up. Pauses and turn-taking (in conversation) may at first appear to correspond to sentence-marking orthographic devices, and often they do delimit sensible language chunks, but not always. Speakers pause in strange places, make false starts, leave thoughts unfinished, and interrupt or overlap each other (Sacks et al., 1974; Dingemanse and Floyd, 2014; Carter and McCarthy, in press). These characteristic features of spontaneous speech pose a problem for researchers investigating monologues or dialogues in naturalistic scenarios: what is a sentence-like unit of spoken language?

This question has been addressed by conversation analysts, acquisition researchers assessing performance accuracy, and compilers of large corpora, among others. Common practice is to transform speech recordings into written transcripts in order to work further with the data, whether with manual or automated means. Now comes the dilemma of how to subdivide those transcripts, where appropriate, into chunks one can work with. For conversational data the first division is made by speakers' turns into what are known as 'utterances'. But then how should those utterances be further subdivided (if at all) into something akin to sentences?

The consensus, theoretically-speaking, has been to identify smaller, sentence-like units of speech on syntactic and/or semantic grounds (with more emphasis on the former), often with reference to prosody – *e.g.* intonation contour and pause duration. In terms of hand-annotated corpora, annotators are expected to have a 'feel' of where unit boundaries should go. For automated processing of large speech corpora,

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 782–793, Osaka, Japan, December 11-17 2016.

researchers have attempted to model this human intuition using supervised machine learning algorithms (Shriberg et al., 2000; Roark et al., 2006; Favre et al., 2008).

In engineering research, this is one task in 'metadata extraction' (MDE), along with the detection of disfluencies and orthographic conventions related to the readibility of transcripts (Walker et al., 2005). However, to the best of our knowledge, no open source software was released with these studies. Moreover, these systems have been trained and tested on corpora of telephone conversations and news broadcasts produced by native speakers of English. Our data are monologues and so we seek to replicate the set-up reported by Lee and Glass (2012), who combined multiple information sources to delimit boundaries in monologue restaurant reviews.

Our contribution is firstly one of terminology, asserting that we are searching for SPEECH-UNITS – with 'speech-unit delimitation' (SU delimitation) our preferred name for this task, thereby avoiding reference to the 'sentence'. Note that this is not a new term, but it is not always made clear what the unit of speech analysis is, or what is meant by 'speech-unit' where it is used. Secondly, we release an SU delimitation toolkit in a public repository[1]. Thirdly, we consider alternative evaluation metrics for SU delimitation, to move away slightly from the idea of a single 'ground-truth'. Finally, we report how well our system performs on monologues produced by native speakers and learners of English, achieving an F-measure of 0.674 with our best performing set-up.

2 The speech-unit

The sentence-like unit of speech has a varied history in the applied linguistic field. Foster et al. (2000) offer a thorough review of past proposals, identifying three types: 'mainly semantic', 'mainly intonational', and 'mainly syntactic' units. They settle on the last type in their 'analysis of speech unit' (AS-unit), allowing multiple clauses in one unit, based on evidence from pause studies that syntactically-coherent units play a central role in speech planning (Deschamps, 1980; Raupach, 1980). We do not dispute these findings, but note that this unit is again heavily reliant on syntax for its definition, though it is held to reflect a psychological reality.

Meanwhile, the *de facto* standard analysis unit in conversation analysis (CA) is the 'turn construction unit', types of which are identified as "sentential, clausal, phrasal, and lexical – i.e. syntactically" (Sacks et al., 1974). Reference is made to 'sound production' and the ways it can disambiguate, for example, statements and questions. But otherwise, for CA the object of analysis is the transcript, and as such, with speech in written form, syntax is king.

Researchers at the LDC adopted a deliberately less precisely specified approach in adding punctuation to transcripts of speech: their chosen unit, the 'SU', "functions to express a complete thought or idea on the part of a speaker" (Strassel, 2003). What 'SU' actually stands for is left open: "some possibilities include: Sentential Units, Syntactic Units, Semantic Units and Slash Units" (Strassel, 2003). The SU is defined on the basis of both syntax *and* semantics so we will not prioritise either *a priori*. Finally, the 'slash unit' refers to a transcription convention that may be obscure to some, and we avoid such overt esotericism. Instead we think of an SU as a 'speech unit': a generic and sufficiently transparent concept. We also note that it has been used before by Roberts and Kirsner (2000) in their study of 'temporal cycles' in speech, defining it as, "a segmented part of speech and the hesitation pause that preceded it".

Again, we see allusion to the planning process here, except in this case semantics are brought to the foreground. LDC annotators were instructed to "rely primarily on semantic and syntactic information, and secondarily on prosodic information" when listening to the speech recordings and deciding where to delimit SUs. We see the benefit of this flexible approach, drawing on multiple information sources rather than mainly syntax, and we adopt the SU as our sub-unit of choice for speech. Once we have a reliable system to automatically identify SU boundaries it is of benefit to downstream tasks of two broad types: natural language processing (NLP) and computer-assisted language learning (CALL). For NLP tasks we want to know whether the SUs are sensible and expected in some way, and for CALL we require chunks of language which are useful for automated learner assessment and feedback.

3 Speech-unit delimitation

Experiments in SU delimitation date back to work by Shriberg, Stolcke and colleagues (Stolcke and Shriberg, 1996; Stolcke et al., 1998; Shriberg et al., 2000). They initially developed a framework to bring together lexical, discourse and prosodic cues to tag transcripts with various kinds of hidden structural information, with some of these cues at first being hand-coded. They demonstrated that a combination of prosodic and language model features produced better tagging outputs than either feature type in isolation. Later, Shriberg et al. (2000) introduced fully automated extraction of the necessary cues. Since then, the systems have been extended with syntactic features to supplement *n*-gram models (Roark et al., 2006), alternative classifiers to the early decision tree (DT) models, such as the conditional random field (CRF) (Favre et al., 2008) and deep neural network (DNN) (Xu et al., 2014), ensemble models with multiple voting (Liu et al., 2005), and to languages other than English including Czech (Kolář et al., 2006) and Chinese (Tomalin et al., 2007). Xu et al. (2014) report leading results of 0.81 F-measure (harmonic mean of precision and recall) on SU boundaries with their DNN-CRF model, outperforming a DT-CRF baseline with 0.774 F-measure.

However, most of the above-mentioned systems have been trained and evaluated on native speaker telephone conversation and broadcast news dialogues: the Switchboard and Broadcast News datasets prepared for the RT-03/04 shared tasks in MDE by the National Institute of Standards and Technology, U.S. Department of Commerce. We work with monologues recorded in language tests, and so we more closely follow the work of Lee & Glass (2012; L&G) because they trained and tested a system on monologue restaurant reviews. We choose to mimic L&G's work because firstly the results are interpretable (as opposed to machine learning with neural networks, e.g. Xu et al. (2014)). Moreover we can work with the relatively small learner datasets we have, and make use of them in an optimal fashion – *i.e.* using different corpora to train the separate components of the system where this brings performance improvement (sections 3.1 & 4.1). The modular architecture is appealing as it allows different model types to be combined – that is, models other than the finite state transducers introduced below, even though we do not do so in this work.

3.1 System architecture

The design of L&G's system involves a combination of local constraints containing prosodic and language model information, and global constraints of SU-length. One insight from related work is that a tagging approach to the problem only considers local information: if the search space is constrained between a minimum and maximum SU-length we can instead compute the likelihood of an SU boundary, denoted <$break$>, at each inter-token interval (Matusov et al., 2006). The models are implemented with finite-state transducers and combined in a log-linear fashion, such that the problem becomes not one of tagging but instead of finding the best path through the internal SU structures of our transcripts. Figure 1 gives an overview of our system architecture which is in spirit inspired by L&G though it differs in the detail, as discussed below. It is a three-part system using several probability sources (prosodic, lexical and SU-length) modelled as finite state transducers.

3.1.1 Prosodic model

As is the norm in the SU delimitation task, we build a prosodic model (PM) to predict SU boundaries. This move, and the feature types collected, reflect the assumption that speakers tend to indicate SU boundaries in consistent ways – by pausing before starting a new SU, by producing lengthened sounds in advance of an SU end, or by tell-tale discontinuities in pitch and volume levels either side of a <$break$>. Thus our feature choices are largely conventional, following the lead of Huang et al. (2006) as well as L&G (Table 1). This gives us a feature-set whose evolution can be traced back to the work of Shriberg and colleagues, with the obvious exception of turn-taking which is not available to us in monologues, though turns have been found to be a highly informative feature in dialogues (Shriberg et al., 2000).

For each token w_i we have two measures of pause duration (before and after), three phone duration features (the final phone, the sum of its vowels, and the longest phone), nine features for fundamental frequency (f0), and nine for energy – a total of 23 features for each token in the prosodic model. In the

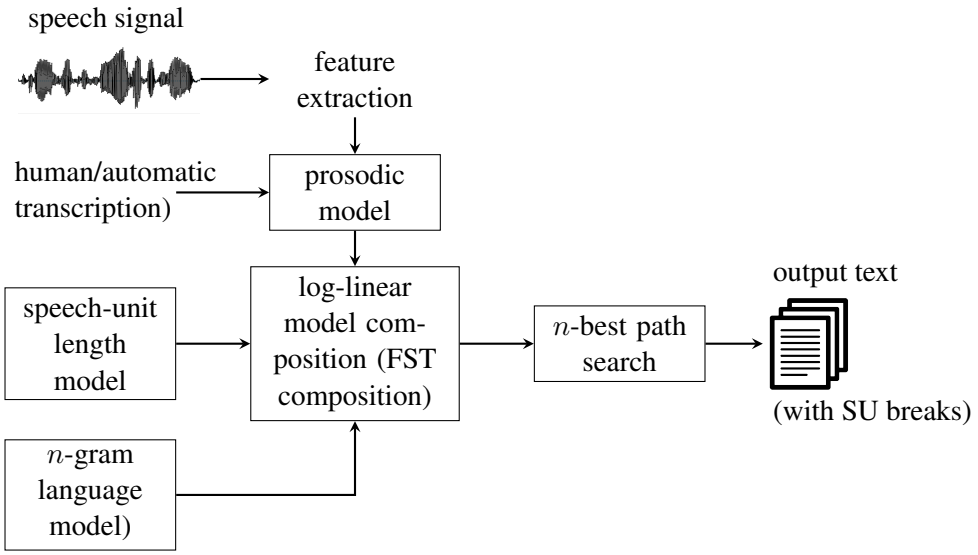

Figure 1: System diagram.

case of f0 and energy, the general task was to find maxima and minima in w_i and the following token w_{i+1}, or to calculate differences between the last frame in w_i and the first frame of w_{i+1}, or the minimum in the given recording, whilst also subtracting the speech-unit minimum from the mean across all frames in w_i, the start of w_{i+1}, and the mean of w_{i+1}.

All prosodic features were gathered automatically: transcriptions and sound files were force aligned using SPPAS (Bigi, 2012) before pause and phone durations were obtained with an R script (R Core Team, 2016), whilst fundamental frequency ('f0', measured in Hertz) and energy values (measured in decibels) were extracted in 10 millisecond frames using Praat's auto-correlated pitch and intensity tracking algorithms (Boersma and Weenink, 2016)[2]. As is conventional practice in signal processing – to normalise rapid, random changes in the signal – both f0 and energy values were smoothed using a five-point median filter and the 'robfilter' R package (Fried et al., 2014). Outlying phone durations were removed by filtering any tokens with a single phone posited to have been longer than two seconds, thereby excluding what were presumed to be gross alignment errors.

category	**features**	
pause duration	· pause before w_i · pause after w_i	
phone duration	· final phone in w_i · sum of vowel phones in w_i · longest phone in w_i	
f0	· max.f0 in w_i · min.f0 in w_i · max.f0 in w_{i+1} · min.f0 in w_{i+1}	· end of w_i − start of w_{i+1} · end of w_i − recording min.f0 · mean of w_i − recording min.f0 · start of w_{i+1} − recording min.f0 · mean of w_{i+1} − recording min.f0
energy	· per f0	

Table 1: List of prosodic features for the current word token (w_i).

This feature-set serves to capture the observed association between prosodic discontinuity and SU boundaries. That is, speakers tend to pause and lengthen SU-final tokens – hence the pause and phone duration features – and the pitch 'reset' between tokens either side of a boundary is likely to be more pronounced

[2]The Praat script was adapted from one written by Peggy Renwick, University of Georgia, for the BAAP workshop on 'methods for large-scale phonetic data analysis' held on 7 April 2014 in Oxford, U.K. We thank John Coleman, University of Oxford, for sharing it with us; `http://www.phon.ox.ac.uk/jcoleman/BAAP_workshop_info.html`.

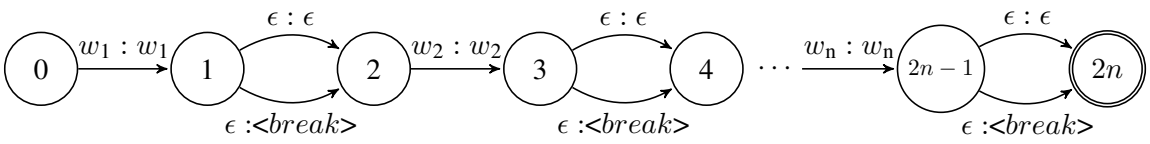

Figure 2: Prosodic model of an input string of length n.

than elsewhere: hence the focus on differences with the following token and the SU minimum (Shriberg et al., 2000). Energy features were not used by Shriberg et al. (2000) for reasons of data quality, but they were introduced by L&G on the basis of work by Huang and Zweig (2002) and so we use them here.

Per L&G, we trained a support vector machine (SVM) classifier with an RBF kernel trained on our twenty-three features, and used this to predict the probabilities of SU <$break$> tokens between word tokens. As a novel development we trained a logistic regression (LR) classifier using the six most significant features. Prosodic models can be modelled using an FST with a chain-like structure (Figure 2). Each odd-numbered node has a single arc to represent a word token, and each even-numbered node has a pair of arcs to represent what happens between those word tokens: one arc emits an empty string (modelled as an ϵ token), the other a <$break$> token, with the probabilities of these arcs being taken from the SVM or LR classifier based on the prosodic features of the given word token w_i.

3.1.2 Language model

To model the probability of local word ordering, we constructed an n-gram language model (LM). We used the OpenGRM library (Roark et al., 2012) to build models from native speaker and learner corpora. OpenGRM n-gram models are cyclic weighted FSTs, with a unigram state representing the empty string, and proper n-gram prefixes represented as their own states, so that an n-gram ($w_1..w_n$) is represented as a transition from its prefix state ($w_1..w_{n-1}$) via a word arc (w_n). Language models of this type take the same word for both input and output on each transition.

OpenGRM n-gram models use Witten-Bell smoothing by default (Witten and Bell, 1991) and back-offs are modelled using ϵ (empty string) arcs which allow the model to transition to a lower-order n-gram ($w_2..w_n$) should no state for ($w_1..w_n$) exist. To model SU delimiting <$break$> tokens we include them explicitly in the positions they occur in the training corpora. We also include an <unk> token to reserve some probability mass for out-of-vocabulary words. In all experimental settings we build 4-gram LMs.

3.1.3 Speech-unit length model

The third and final source of probabilities comes from the gold-standard length of speech-units gathered from our training corpora. Again following L&G we fit a gamma distribution to a histogram of gold-standard SU lengths. We then use this distribution to obtain the probability of a <$break$> token occurring at any given length of speech-unit, in an SU length model (SLM). These probabilities are used in the construction of a cyclic FST, where each node represents an SU of a given length (Figure 3). The transitions can accept any non-<$break$> symbol (represented here as <w>) and at each length a <$break$> is modelled by a backwards arc that restarts the 'counter' for the next SU.

Our model differs from that of L&G as we use a simple <$break$> or 'no break' probability at each length, whereas their model uses $P(length = n)$ or $P(length > n)$. As per their model we set a hard upper length L, which is corpus-dependent. We insert an SU delimiting <$break$> token when this length is reached.

3.1.4 Model composition

Across all models, probabilities are encoded as negative logs. When the models are composed, these weights, or penalties, are summed together. To find the most probable route through the combined FST we search for the combined path with the smallest weight. Since the non-<$break$> characters are accepted and emitted unchanged at each stage, it is the <$break$> tokens, or lack of them modelled as ϵ, that separate the various paths through the FST.

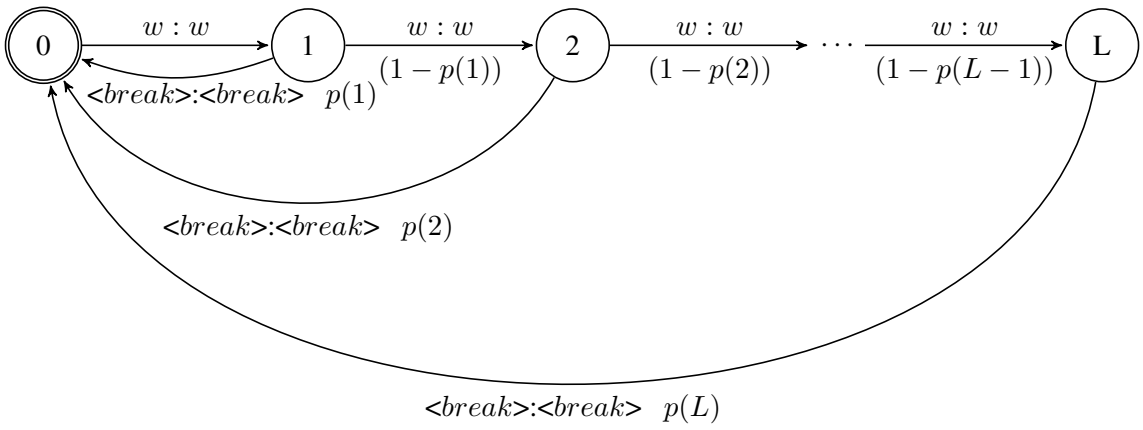

Figure 3: Speech-unit length model.

4 Experiments

The purpose of the system described above is to automatically assign SU-delimiting <$break$> tokens to transcripts of speech, based on a combination of prosodic features from the associated sound-file and probabilities from n-gram language and SU-length models.

4.1 Data

We work with a corpus of spoken learner English containing recordings of spontaneous speech from Business Language Testing Service (BULATS; `http://www.bulats.org`) oral exams. These feature 223 speakers whose first language (L1) is Gujarati – 96 male, 127 female, aged 14-50 (mean 25, median 24). Every recording has been graded by at least two expert assessors contracted by Cambridge English Language Assessment. This provides an average score for each learner which places them on the CEFR scale[3] from A1 ('beginner') to C2 ('mastery') via A2, B1, B2, C1 in increasing order of proficiency. Table 2 shows the distribution of learner CEFR levels in our BULATS corpus. It is apparent that the distribution of candidates and recordings is not equal, but there is no need for equivalence in this regard, as we seek only a representative sample of learners taking English exams. Note that there is only one candidate at the very highest C2 level, and therefore the corpus is very much a *learner* corpus mainly up to the C1 'advanced' level, rather than a corpus of Indian English learned as an L1.

CEFR level	Candidates	Recordings	Tokens
A1	33	209	6475
A2	44	288	10,597
B1	45	300	15,177
B2	44	304	17,921
C1	44	305	19,512
C2	1	6	383
Total	211	1412	70,065

Table 2: BULATS Spoken Learner Corpus.

Candidates were required to produce a monologue of twenty to sixty seconds on prompted business-related topics. Each recording was transcribed by two different crowdworkers via Amazon Mechanical Turk. Crowdworkers segmented the transcripts using punctuation, with full-stops (periods) indicating SU breaks. The two transcripts were then combined into a single version using the method described by van Dalen et al. (2015), which builds a network out of the two transcripts and uses an automatic speech

[3] 'Common European Framework of Reference for Languages' `http://www.cambridgeenglish.org/exams/cefr`

recogniser to identify an optimal path through it. Evaluating the quality of combined crowdsourced transcriptions, van Dalen et al. (2015) report a word error rate of 28.1% on another set of BULATS recordings. Inevitably, we pass word errors on through the pipeline described below, but as a method for the transcription of speech it at least gives us immediate access to large amounts of data. Phonetic transcriptions were then force-aligned with the recordings using the Hidden Markov Model Toolkit[4]. We found an error rate of 30% on phonetic alignments on a sample of the BULATS corpus, although such evaluation is not straightforward and a larger-scale exercise is needed in future work.

Transcribers indicated SU boundaries with full-stops and were asked to include all non-English words, partial words, filled pauses and repetition. The dataset features more than two hundred speakers, fourteen hundred recordings, and seventy thousand word tokens (Table 2). This is a small corpus by modern standards, and yet it is much larger than L&G's, which was 13.2k tokens. We trained a prosodic model as described in section 3.1.1 on a 90% set of 63k tokens and 2139 SUs identified by crowdworkers; the test set contains 7k tokens and 261 SUs.

We trained several 4-gram LMs (§3.1.2): firstly the learner English BULATS training set. This is only a small set of 63k tokens, and so we built a model of learner English based on a larger set of written exams from the Cambridge Learner Corpus (Nicholls, 2003), containing 766k tokens. Finally, we also trained a language model of native speaker transcripts, taken from the Switchboard Corpus of unscripted telephone conversations (Godfrey and Holliman, 1993), containing 217k tokens. Neither of the larger LMs are exactly apt for our learner monologues, in the sense that one is written language and the other is native speaker dialogue, but their greater size mitigates somewhat for the mismatch. We report in section 4.3 how all three LMs perform.

We experimented with different SLM models to little effect, and so for all experiments reported below we used an SLM model trained on our BULATS training set (§3.1.3). Maximum SU length was set to the longest SU found in the training corpus, which in this case was 185 tokens (*i.e.* if an SU reaches 185 tokens, the 186th token is a forced <$break$>). Figure 4 illustrates the distribution of SU lengths in our BULATS corpus.

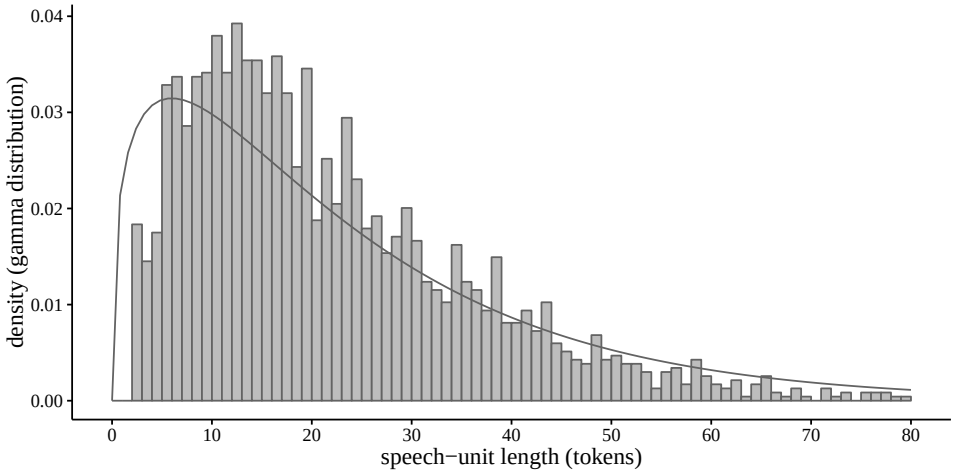

Figure 4: Density plot of speech-unit lengths in the BULATS learner corpus.

4.2 Evaluation

Lee and Glass (2012) report a BLEU-like score inspired by machine translation evaluation metrics (Papineni et al., 2002). L&G's modification is to only include n-grams consisting of hypothesised <$break$> tokens, which we have interpreted to mean any n-gram of size 1 to n with at least one <$break$> token within it. Their best performing system, with the PM weighted by 2.5, achieved a BLEU-like score of 0.56 on crowdsourced transcriptions. Unlike L&G we also report precision, recall and F-measure with

[4] `http://htk.eng.cam.ac.uk`

respect to the position of <$break$> tokens in the crowdsourced transcripts, because the BLEU-like score is a measure of *approximation* to the target inferred from the local context where <$break$> tokens occur, whereas F-measure with a single reference text is an exact score (although subject to the annotators' preferences).

These metrics very much rely on the idea of a 'gold-standard'. But as with so many language annotation tasks, the position of <$break$> tokens is highly subjective. Any downstream task requires that automatically identified SUs are useful in the sense that they can be passed to NLP tools for further inferential and processing tasks. Therefore we also report measures of SU quality, firstly with parse likelihoods from the RASP system (Briscoe et al., 2006), normalised by the number of nodes in the parse tree and averaged over each transcript. This gives us an idea of how useful the SUs are to downstream NLP tasks. Secondly we report perplexity scores for each transcript (with <$break$> tokens) obtained using the CMU-CAM toolkit (Clarkson and Rosenfeld, 1997) against a model of spoken learner English. This gives us an idea of how useful the SUs are for learner feedback in CALL systems.

Both of our new measures rely on language models and the idea of linguistic truth to some extent, but they are probabilistic, generalised over many SUs rather than the one-to-one comparison used in BLEU and precision/recall metrics. In both cases we can compare the scores for our hypothesised <$break$> tokens against the reference transcriptions and assess whether our SU delimitation system produces outputs we can work with in downstream CALL and NLP tasks. It is a matter for future work to investigate segmentation similarity metrics such as 'boundary edit distance' proposed by Fournier (2013)[5].

4.3 Results

We report modified-BLEU, precision and recall, parse likelihoods and perplexity scores (means and standard deviations) for our SU outputs in the BULATS test-set in various experimental configurations (Table 3). We tested several configurations of model type, weighting and combination, and evaluate our outputs from a held-out set of the BULATS corpus using a modified BLEU-score à la Lee and Glass (2012), information retrieval evaluation methods (IR, *i.e.* p, r, F), parse likelihoods, and perplexities.

The best performing set-up (f) features the BULATS-trained PM weighted by a factor of 5 and by recall, with a logistic regression classifier trained on the top six features. This is combined with the 4-gram Switchboard LM and BULATS SLM. Other configurations are shown for comparison. These include a baseline configuration with an unweighted SVM-based PM and learner LM/SLM (a), the same system with an LR-based PM trained on the top six features (b), and the uppermost weighting L&G apply to the PM of 2.5 (c). Both set-ups offer marked improvements on the baseline. Furthermore, a weighting of 5 on the PM offers an improved F-measure, though a reduced BLEU-like score (d). Finally, we show the performance of alternative LMs, constructed from the written learner Cambridge Learner Corpus (e) and native speaker Switchboard Corpus (f). The Switchboard LM offers a performance gain compared to the CLC, indicating that native speaker 4-grams model our test data more closely than learner writing, despite its smaller size.

We see in Table 3 that there are only small differences in BLEU-like scores, above the L&G-like baseline, in (b) to (f). This indicates that the systems are inserting <$break$> tokens in appropriate positions, given the training data, even if they are not precisely correct compared to the gold standard. Precision (p) and recall (r) confirm the differences in this regard, and show that adding weight to the PM greatly improves recall (*cf.* (b) and (c)..(f)). Increasing this weight from the 2.5 used by L&G to 5 again improves p and r (*cf.* (c) and (d)..(f)). Finally, using the larger LMs from other domains (CLC – the Cambridge Learner Corpus of written exams, and SWB – the Switchboard Corpus of telephone dialogues) leads to the most accurate SU delimitation compared to our gold standard annotations.

Our alternative measures – parse likelihood and perplexity – indicate that the hypothesised SUs score similarly across the configurations. That is, parse scores are slightly down on the gold-standard (these are negative logs, so closer to zero is more probable), whilst perplexity scores are more noticeably down

[5]We thank reviewer 1 for pointing us to this line of work. Having approached the topic from a speech engineering perspective, we were only aware of information retrieval metrics (precision, recall, *etc*) being used for evaluation, but there turns out to be a research literature in computational linguistics looking at more subtle evaluations to give credit for 'near misses' in light of the fact that annotators "frequently disagree upon the exact position of boundaries" (Artstein and Poesio, 2008).

BULATS PM	**LM**	**SLM**	**BLEU-like**	***p***	***r***	***F***	**parse likelihood mean (st.dev.)**	**perplexity mean (st.dev.)**
gold	.	.	.	.	.	.	-1.56 (0.52)	23.6 (39.9)
(a) PM_{SVM}	BULATS	BULATS	0.51	0.409	0.582	0.48	-1.58 (0.52)	35.9 (49.6)
(b) $PM_{r.6LR}$	BULATS	BULATS	0.75	0.64	0.5	0.56	-1.6 (0.53)	40.2 (60.7)
(c) 2.5*$PM_{r.6LR}$	BULATS	BULATS	0.75	0.639	0.617	0.628	-1.59 (0.54)	39.7 (60.8)
(d) 5*$PM_{r.6LR}$	BULATS	BULATS	0.74	0.653	0.686	0.669	-1.57 (0.54)	37.9 (58.7)
(e) 5*$PM_{r.6LR}$	CLC	BULATS	0.74	0.653	0.693	0.673	-1.59 (0.53)	39.2 (61.1)
(f) 5*$PM_{r.6LR}$	SWB	BULATS	0.74	0.656	0.693	0.674	-1.59 (0.54)	38.5 (60.4)

Table 3: Speech-unit delimiter output evaluation (PM: prosodic model; LM: language model; SLM: speech-unit model).

(the lower the score, the better the LM models the input) compared to gold, and the standard deviations indicate more variance within the output SU perplexities. This outcome reflects the error rate indicated by our F-measures – even though we outperform the state-of-the-art, we still have room for improvement before we can be sure that the SUs are entirely useful for downstream CALL tasks. However, the perplexity scores are low across the board and it does not seem therefore that the outputs are unfeasible. Since the parse likelihoods are similar to the gold standard, it seems that the outputs are syntactically feasible, which is promising for downstream NLP tasks – a matter we will fully evaluate in future work.

5 Discussion

Our best-performing configuration – 5*PM weighted by recall, with a logistic regression classifier trained on the top six features, and 4-gram Switchboard LM and SLM – compares favourably with the BLEU-like score of 0.56 reported by Lee and Glass (2012), and the state-of-the-art F-measure of 0.81 for SU delimitation in dialogues (Xu et al., 2014). L&G's optimal set up involves 2.5*PM based on an SVM classifier trained on their full set of twenty-three features (Table 1) and trigram LM/SLM.

It quickly became apparent to us that our prosodic model is strong (BLEU-like 0.728 alone), hence its greater weighting in our system. This was especially the case once we introduced a logistic regression (LR) classifier using the six most significant features to the PM, a refinement of L&G's method in this regard. For L&G the LM makes a huge improvement to the performance of the PM alone (from 0.13 to 0.53), while the SLM brings a more modest BLEU-like increase (to 0.56). In our case, the addition of the LM makes only a little difference (BLEU-like 0.735) with the SLM contributing another small increase (0.743). This outcome, so markedly unlike L&G's, requires several caveats. First, our LM is constructed from a relatively small corpus, with only 217k tokens in the Switchboard Corpus we use, compared to the 12m token web reviews corpus used by L&G. Secondly, it could be that native speakers of Gujarati transfer certain prosodic features that map well to speech-units when speaking English. To reinforce our results, we need to extend the system to learners with other L1s, a matter for future investigation. On the other hand, if the results stand up to further scrutiny, it suggests that the PM alone offers a good level of performance for SU delimitation, a possibility that would be beneficial resource-wise, as automatic extraction of prosodic features from the speech signal is a more straightforward exercise than subsequent combination with LM and SLM probabilities.

Moreover, we emphasise that the status of the 'gold-standard' in speech-unit annotation is uncertain. Both precision/recall and BLEU-like metrics rely on this idea, and hence we introduce other measures which relate to the 'likeliness' of the proposed SUs for downstream NLP and CALL tasks. Parse likelihoods and perplexity scores do not directly compare the hypothesised transcript to a gold-standard, but rather indicate the probability of such sequences, with <$break$> tokens positioned as they are. On these measures our outputs are syntactically feasible though more perplexing to a language model, reflecting the error rate implied by our F-measures in the range 0.4-0.7. Furthermore, as shown by the differences in BLEU-like and IR-type comparisons (Table 3) across SU delimiting systems, it is apparent that across the weighted-PM configurations, a similar performance is reported in terms of BLEU-like score, even where IR scoring varies. This suggests – because BLEU-like scores reward the prediction of n-grams commensurate with those found in the training data – that the proposed SUs in these cases may be 'good enough' even if they do not exactly correlate to the gold standard. Future work using segmentation similarity measures which explicitly reward near-misses will allow us to further investigate this matter (Fournier, 2013).

6 Conclusion

We have presented our work on speech-unit delimitation, firstly affirming that 'speech-unit' is the appropriate term for language chunks in spoken language, secondly releasing open-source software[6] to train and run an automatic SU delimiter constructed in a modular fashion per the work of Lee and Glass (2012). Thirdly, we considered alternative evaluation metrics for SU delimitation, ones which make use of the probabilities emitted by parsers and perplexity scores from statistical language models. We report the performance of our SU delimiter in various configurations on a spoken learner corpus, both with our new metrics and established BLEU-like and IR-type scores. Our best performing configuration makes use of a highly weighted LR-based PM and native speaker LM, demonstrating what we find most advantageous about this architecture: that its modular nature allows training on various sources, which is advantageous as the learner corpora we are interested in tend to be small resources.

ASR output transcripts are unpunctuated, and therefore an automated SU delimiter allows those transcripts to be subdivided and passed on to downstream applications in usable ways. In our case, we require SUs which are useful for automated learner assessment and feedback in CALL systems. In future we will continue to experiment with system configurations, data sources, and feature-sets for our SU delimiter. In addition, a further method to investigate how useful the outputs are would be extrinsic evaluation with users of a CALL system, to further consider what makes a meaningful speech-unit.

Abstract

Parallelism is an important rhetorical device. We propose a machine learning approach for automated sentence parallelism identification in student essays. We build an essay dataset with sentence level parallelism annotated. We derive features by combining generalized word alignment strategies and the alignment measures between word sequences. The experimental results show that sentence parallelism can be effectively identified with a F_1 score of 82% at pair-wise level and 72% at parallelism chunk level. Based on this approach, we automatically identify sentence parallelism in more than 2000 student essays and study the correlation between the use of sentence parallelism and the types and quality of essays.

1 Introduction

Parallelism is an important rhetorical device. It can be defined as *two or more coherent text spans (phrases or sentences), which have similar syntactic structures and related semantics, and express relevant content or emotion together.* Each text span is a parallelism unit and the parallel units form a parallelism chunk. The following two sentences segmented by the semicolon form an example of sentence parallelism.

The inherent vice of capitalism is the unequal sharing of blessing;

the inherent virtue of socialism is the equal sharing of miseries. by Churchill.

Parallelism adds balance and rhythm to make speeches and writings more vivid and powerful. Moreover, parallelism also adds clarity to the sentence or even the discourse. Several sentences are expressed similarly to show that the content in the sentences are equal in importance. Therefore, properly using parallelism may improve the quality of texts. On the other hand, identifying parallelism in essays would potentially help to evaluate the quality of writings and benefit applications like essay scoring and organization evaluation.

In this paper, we study the problem of identifying parallelism in student essays. We focus on identifying sentence parallelism. A parallelism unit is a sentence, and several *parallel sentences* form a *parallelism chunk*. Parallelism identification is a task to find the parallelism chunks within essays.

This task is nontrivial. There are several factors to be considered. Since the parallel sentences should have similar structures and related semantics, they can be seen as forming a certain kind of alignment between each other. However, such alignment can exist in various levels, from surface lexical patterns to syntactic structures, semantics and even emotions. Moreover, the alignment can occur at various granularity (words, phrases, clauses or sentences). Therefore, it is difficult to design manual rules to identify sentence parallelism.

We propose a learning based framework for sentence parallelism identification. We annotate a sentence parallelism dataset consisting of about 500 student essays. This dataset allows us to derive features to model sentence parallelism and utilize machine learning to learn a prediction model. Since parallelism can be seen as a kind of alignment, we study various alignment measures to quantify the alignment between sentences. Sentence alignment depends on word alignment so that we exploit several strategies to generalize word alignment based on semantic and syntactic properties. The interactions among alignment measures and word alignment strategies generate features to represent the alignment between sentences. The experimental results show that sentence parallelism can be effectively identified. The F_1 score can reach 82% at pair-wise level and 72% at parallelism chunk level. The features based on different alignment measures and different word alignment strategies complement each other. We further study the use of sentence parallelism in more than 2000 student essays based on automated sentence parallelism identification. We observe that the use of sentence parallelism varies in narrative and argumentative essays and has a positive correlation to the quality of writings especially in argumentative essays.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 794–803, Osaka, Japan, December 11-17 2016.

2 Data

We collected student essays written by Chinese students from a senior high school during mock examinations. The essay types include narrative and argumentative essays, covering multiple topics. Two labelers were asked to label parallelism in randomly sampled essays at sentence level. They were guided by the definition of parallelism. Sentences are obtained by the sentence splitter provided by the Chinese language processing toolkit — HIT-LTP (Che et al., 2010). If a sentence contains less than four words, it is not allowed to be labeled. A sentence parallelism chunk consists of multiple sentences. The labelers recognized the sentence parallelism chunks in essays and assigned a distinct number to all parallel sentences from the same chunk in order to distinguish different chunks.

Item	Number
#Essay	544
avg. #sentence per essay	28.47
avg.#parallelism chunk per essay	2.03
avg. #sentence per chunk	2.68

Table 1: Statistics of the annotated sentence parallelism dataset.

After annotation, we collected 544 student essays, each of which has at least one sentence parallelism chunk. 30 essays were annotated by both labelers, and the Kappa value between them is 0.71 (Carletta, 1996), which indicates a moderate consistence. The mainly disagreement lies in their different judgement standards in terms of the quality of parallelism between sentences. After discussion and reaching a consensus, they reviewed all the annotations. Table 1 shows the basic statistics of the dataset.

3 Sentence Parallelism Identification

We cast sentence parallelism identification as a classification problem. Given an essay, we conduct a binary classification for every pair of sentences to determine whether they are *parallel* or *non-parallel*. Further, we get parallelism chunks according to the results of pair-wise classification.

According to the definition of parallelism, parallel sentences are expected to have sorts of alignment. The alignment can be about words, syntactic structures and semantics. In this section, we would exploit a set of alignment measures to quantity sentence alignment for a pair of sentences. For all alignment measures, the basis is the alignment between single words. Therefore, we start by studying word alignment strategies and look forward to incorporate information from multiple aspects. Then we introduce the alignment measures that are adapted for this task. Combining alignment measures and word alignment strategies, we can derive rich features to represent sentence alignment.

We use the HIT-LTP toolkit (Che et al., 2010) to conduct word segmentation, part-of-speech (POS) tagging and dependency parsing. All alignment measures would be computed on word sequences.

3.1 Word Alignment Strategies

Without loss of generality, we define a matrix R, which measures the alignment between every pair of tokens in vocabulary $\mathcal{V}$. $R(w, v)$ represents the alignment score between a pair of tokens (w, v), $w, v \in \mathcal{V}$. According to different assumption, $R(w, v)$ may have different values. We consider the following word alignment strategies:

- **Exact Match**: $R(w, v) = 1$, if $str(w) == str(v)$, otherwise $R(w, v) = 0$. $str(w)$ is the surface string of w.
- **POS Match**: $R(w, v) = 1$, if $pos(w) == pos(v)$, otherwise $R(w, v) = 0$. $pos(w)$ is the POS tag of word w.
- **Syntactic Role Match**: $R(w, v) = 1$, if $syntacticrole(w) == syntacticrole(v)$, otherwise $R(w, v) = 0$. $syntacticrole(w)$ is the syntactic role of word w. Here, we use dependency parsing to get the dependency labels as the syntactic roles. Considering the example shown in Figure 1, $syntacticrole$(春风)=SBV, $syntacticrole$(摇曳)=HED and $syntacticrole$(大地)=VOB.
- **Semantic Match**. $R(w, v) = 1$, if $similarity(w, v) > threshold$, otherwise $R(w, v) = 0$. $similarity(w, v)$ is a semantic similarity measure for w and v. Here, we compute the similarity based on word embeddings. Word embeddings are distributed representations of words learned on large scale corpus using neural networks (Mikolov et al., 2013). Each word is represented by a dense real value vector. $similarity(w, v)$ computes the cosine similarity between the vectors of w and v. The threshold is empirically set to 0.75.

The above strategies generalize words to various levels. We expect such generalization could help find alignment between sentences. For example, consider the following parallel sentences:

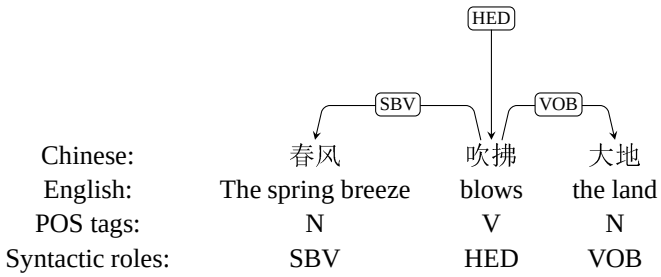

Figure 1: Dependency parsing tree for the sentence *春风吹拂大地(The spring breeze blows the land).*

春风吹拂大地, 万物复苏 (The spring breeze blows the land, reviving everything).

树根支撑枝叶,花繁叶茂 (The root supports the crown, growing the forrest).

The two parallel sentences don't share any word so that the exact match strategy fails to identify the alignment between them. However, the alignment can be captured based on POS, syntactic role and semantic matches.

3.2 Sequence Alignment Measures

We use the following algorithms to measure the alignment between sentences.

Longest Common Subsequence(LCSeq) Longest Common Subsequence algorithm is a commonly used approach to compare multiple sequences (Hirschberg, 1977). The subsequences are not required to occupy consecutive positions within the original sequences. Parallel sentences often contain longer common subsequences. The LCSeq algorithm can be effectively solved by using dynamic programming. Given two sequence $X = (x_1, x_2, ..., x_m)$ and $Y = (y_1, y_2, ..., y_n)$, the prefixes of X are X_i, i from 1 to m; the prefixes of Y are Y_j, j from 1 to n. Let $LCSeq(X_i, Y_j)$ represent the set of longest common subsequence of prefixes X_i and Y_j. This set of sequences can be got in the way below.

$$LCSeq(X_i, Y_j) = \begin{cases} \oslash & \text{if } i = 0 \text{ or } j = 0 \\ LCSeq(X_{i-1}, Y_{j-1}) \cup x_i & \text{if } R(x_i, y_j) = 1 \\ longest(LCSeq(X_i, Y_{j-1}), LCSeq(X_{i-1}, Y_j)) & \text{if } R(x_i, y_j) = 0 \end{cases}$$

$R(x_i, y_j)$ represents the condition of word alignment and can be realized using strategies in §3.1. We compute the LCSeq and the normalized length of LCSeq (NormLCSeq) for sentences s_i and s_j as features. NormLCSeq is computed as Equation 1.

$$NormLCSeq(s_i, s_j) = \frac{|LCSeq(s_i, s_j)|}{max(|s_i|, |s_j|)} \tag{1}$$

Longest Common Substrings (LCStr) Parallel sentences have a high chance to have common substrings. Therefore, we compute the longest common substrings of two sentences. Different from LCSeq, the common substrings are required to occupy consecutive positions. Therefore, high LCStr indicates a better local alignment. Different word alignment strategies can be applied. We use the length of the longest common substring as a feature.

Needleman-Wunsch Algorithm(NW) We adapt the Needleman-Wunsch algorithm (Needleman and Wunsch, 1970) for our task. This algorithm is widely used in computational biology for finding sequence alignment among genes. Compared with LCS, it looks for an alignment between whole sequences, which maximizes an overall score function as the sum of the scores over all aligned element pairs in two sequences.

Given two sequences $X \in \mathcal{V}^*$ and $Y \in \mathcal{V}^*$, an alignment can be represented as a two-dimensional array $Align_{2\times I}^{X,Y}$ that every word in one sequence is aligned to one word in the other sequence or to an indel which is caused by inserting a word into one sequence or deleting a word from the other sequence, where I is the number of aligned element pairs. The alignment score is computed as Equation 2.

$$AlignScore(X, Y) = \sum_{i=1}^{I} S(Align_{0,i}^{X,Y}, Align_{1,i}^{X,Y}) \tag{2}$$

where $S(x, y)$ assigns a score between a pair of aligned elements.

To compute $S(x, y)$, there are two types of parameters: a *gap penalty* and a *substitution matrix*. Gap penalty values are used to penalize the score when a word in one sequence is aligned to an indel in the other. Therefore,

NW algorithm would penalize the long distance matches. The substitution matrix is used to assign alignment scores between every pairs of words. A good pair alignment will be rewarded with a higher score. Obviously, the word alignment strategies we discuss in §3.1 can be used here to construct the substitution matrix.

The alignment algorithm runs based on dynamic programming. Please refer to the details in (Needleman and Wunsch, 1970). Once we get the best alignment, we can get a best $AlignScore$. This score is correlated to the length of sequences. To reduce this effect, we use the normalized score, as shown in Equation 3, to build features .

$$NormAlignScore(X, Y) = \frac{AlignScore(X, Y)}{I} \tag{3}$$

3.3 Tree Alignment Measures

We also exploit syntactic structures. Tree kernels are the natural way to exploit syntactic structural properties, which compute the similarities between parsed trees without enumerating the whole fragment space. In this work, we parse sentences with a dependency parser. We use the Partial Tree (PT) kernel (Moschitti, 2006) to measure the similarity between two trees, since it is suitable for dependency parsing. In addition, partial tree kernel considers the ordered child sequence, which makes it suitable for our task as well.

The PT kernel is defined as:

$$K(T_1, T_2) = \sum_{n_1 \in N_{T_1}} \sum_{n_2 \in N_{T_2}} \triangle(n_1, n_2) \tag{4}$$

where N_{T_1} and N_{T_2} are the sets of nodes in T_1 and T_2, respectively and $\triangle(n_1, n_2)$ indicates the number of common fragments rooted at the n_1 and n_2 nodes. The kernels can be effectively computed based on dynamic programming (Moschitti, 2006):

- if $R(n_1, n_2) = 0$, then $\triangle(n_1, n_2) = 0$
- else $\triangle(n_1, n_2)$ would be computed recursively on the sets of ordered child sequences of n_1 and n_2.

Again, we can utilize strategies introduced in §3.1 to compute $R(n_1, n_2)$. Figure 1 shows a dependency parsing tree of an example sentence. We use the normalized kernel values as features, $K^{norm}(T_1, T_2) = \frac{K(T_1,T_2)}{\sqrt{K(T_1,T_1)K(T_2,T_2)}}$.

3.4 Location and Length Features

We observe that parallel sentences also locate regularly in discourse. For example, they usually occupy consecutively within the same paragraph, or locate symmetrically in multiple paragraphs. In addition, they often have close length and close number of clauses. We use the following features to describe these observations.

- **Adjacency**: if two sentences in the same paragraph, and the absolute difference of sentence indexes is smaller than 3, the feature value is set to 1, otherwise it is set to 0.
- **Location Alignment**: This feature is based on the sentence positions. If two sentences are in different paragraphs and they are both the first sentence in the paragraphs, or both the last sentence in the paragraphs, the feature value is set to 1, otherwise it is set to 0.
- **Length difference**: The absolute length difference of two sentences.
- **Clause difference**: If the number of clauses is the same, the feature is set to 1, otherwise it is set to 0. The clauses are segmented by commas.

3.5 Summarization of Features

We summarize the used features in Table 2. Except for location and length features, we use various alignment measures together with different word alignment strategies to generate features. We use both the absolute and normalized length of LCSeq scores as features. LCStr focuses on local consecutive matches, therefore we only use the length of longest common substrings as features. The tree kernel method deals with syntactic structural properties, therefore we construct two trees for each sentence based on dependency parsing. We use POS tags and dependency tags respectively as the values of the tree nodes.

Feature Set	Feature	Word Alignment Strategy
LCSeq	$\|LCSeq_{exact}(s_i, s_j)\|$, $NormLCSeq_{exact}(s_i, s_j)$	Exact match
	$\|LCSeq_{pos}(s_i, s_j)\|$, $NormLCSeq_{pos}(s_i, s_j)$	POS match
	$\|LCSeq_{semantic}(s_i, s_j)\|$, $NormLCSeq_{semantic}(s_i, s_j)$	Semantic match
	$\|LCSeq_{syntacticrole}(s_i, s_j)\|$, $NormLCSeq_{syntacticrole}(s_i, s_j)$	Syntactic role match

	Clause Difference	—

Table 2: Summarization of the features for a sentence pair $< s_i, s_j >$.

3.6 Parallelism Chunk Identification

Given an essay, once every pair of sentences is classified as *parallel* or *non-parallel*, we construct parallelism chunks based on the classification results. We use an aggressive strategy based on transitivity: if two sentence pairs $< x, y >$ and $< x, z >$ are parallel, then $< x, y, z >$ forms a parallelism chunk, no matter whether pair $< y, z >$ is classified as parallel.

4 Evaluation

4.1 Experimental Settings

Data and Classifiers We split the essays in our dataset into 5 parts and run cross-validation. Each time, 4 parts are used for training and the remaining part is used for test. Sentences from the same parallelism chunks form a set of positive pairs, while sentences that are in the same essay but not parallel form negative pairs.

The word embeddings for semantic similarity computation are learned using the Word2Vec tool (Mikolov et al., 2013) on a dataset consisting of 85,000 student essays collected from the web. The dimension of word embeddings is 50. The size of vocabulary is about 490,000.

We adopt the Random Forests (Breiman, 2001) as the classifier and use the implementation in Scikit-learn toolkit (Pedregosa et al., 2011) with default parameters.

Evaluation Metrics We adopt precision, recall and F_1 score as evaluation metrics. The metrics can be computed at pair-wise level and parallelism chunk level respectively.

At pair-wise level, the precision and recall are computed as:

$$\textit{pair-precision} = \frac{\#\text{correctly identified parallelism sentence pairs}}{\#\text{identified parallelism sentence pairs}} \tag{5}$$

$$\textit{pair-recall} = \frac{\#\text{correctly identified parallelism sentence pairs}}{\#\text{true parallelism sentence pairs}} \tag{6}$$

At chunk level, the precision and recall are computed as:

$$\textit{chunk-precision} = \frac{\#\text{correctly identified parallelism chunks}}{\#\text{identified parallelism chunks}} \tag{7}$$

$$\textit{chunk-recall} = \frac{\#\text{correctly identified parallelism chunks}}{\#\text{true parallelism chunks}} \tag{8}$$

A correctly identified parallelism chunk means the identified chunk has the same sentences with a labeled chunk. In both cases, $F_1 = \frac{2 \times precision \times recall}{precision + recall}$.

Feature Set	pair-P	pair-R	pair-F_1	chunk-P	chunk-R	chunk-F_1
LocLen	0.71	0.41	0.52	0.38	0.32	0.35

Exact + Semantic + Syntactic role	0.82	0.72	0.77	0.64	0.65	0.64
Exact + Semantic + Syntactic role + POS	0.81	0.72	0.76	0.62	0.65	0.63

Table 4: Evaluation results of using different word alignment strategies.

4.2 Results

Table 3 shows the experimental results using different sequence alignment measures. All word alignment strategies are used in this experiment. The best alignment measure is the score computed using the Needleman-Wunsch algorithm. This is reasonable, since it captures the alignment on the whole sequence, considering the local alignments like LCStr and penalizing long distance matches, which LCSeq ignores.

Different from LCStr, LCSeq and NW, tree alignment exploits more complex structural information. So tree alignment based measures should complement sequence based measures. The best combination of tree based and sequence based measures are NW plus tree alignment.

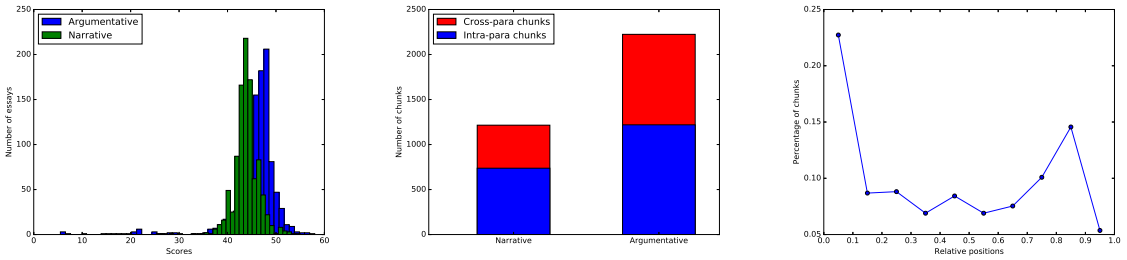
Using the location and length features (LocLen) alone leads to a low recall, but they can improve the performance when combining with other features. We can see that combining LocLen and NW achives good performance.

Combining all alignment measures achieves the best performance. The results demonstrate that pair-wise sentence parallelism can be effectively identified. The chunk-wise performance is moderate. The precision of pair-wise classification is shown to be more crucial to the chunk-wise performance.

Feature	Weight
$NormAlignScore_{semantic}$	0.161
$NormAlignScore_{exact}$	0.148
$NormAlignScore_{syntacticrole}$	0.117
$NormAlignScore_{pos}$	0.105
Location Alignment	0.078
$K^{norm}_{syntacticrole}$	0.062
$NormLCSeq_{exact}$	0.056
Length Difference	0.047
K^{norm}_{pos}	0.040
$LCStr_{exact}$	0.036

Table 5: Top ranked feature weights.

We are also interested in the contributions of various word alignment strategies. Table 4 shows the performance of using different word alignment strategies and their combinations. All alignment measures are used in this experiment. We can see that the semantic match strategy performs best. This indicates that semantic level information is important. We observe that the best combination of two strategies is the combination of exact match and syntactic role match, while the best combination of three strategies is the combination of exact match,



(a) Distribution of essays scores.

(b) Number of chunks in narrative and argumentative essays.

(c) Distribution of chunks' relative positions.

Figure 2: Basic statistics of the student essay dataset and the use of sentence parallelism in the dataset.

semantic match and syntactic role match. Different strategies complement each other except that the POS match doesn't provide extra gain in our experiments. Table 5 shows the feature weights learned by the Random Forests model. The trend is similar to the previous observations.

5 Sentence Parallelism and Essay Writing

The automated sentence parallelism identification makes it possible to study the use of sentence parallelism in student essays and its relation to essay quality on large datasets. We collected another dataset containing essays written by senior high school students in mock examinations. This dataset has 1036 narrative essays and 1064 argumentative essays, and it doesn't overlap with the dataset introduced in §2. All these essays had been scored by professional high school teachers. The scores ranges from 0 to 60. The distribution of essay scores is shown in Figure 2(a). We can see the distribution of either narrative or argumentative essays meets the normal distribution. The dataset should be representative to reflect the real situation.

5.1 How Students Use Sentence Parallelism

We use our system to process these essays and extract parallelism chunks. We extract 2224 and 1219 parallelism chunks in argumentative essays and narrative essays respectively. These parallelism chunks can be categorized into two types: *intra-para chunks* and *cross-para chunks*. Intra-para chunks contain parallel sentences within the same paragraph, while cross-para chunks have parallel sentences across multiple paragraphs.

The ratio of each type of chunks are shown in Figure 2(b). Parallelism chunks, especially the ones that cross paragraphs, are used more often in argumentative essays than in narrative essays. We examine some essays and find that in argumentative essays, students would use parallel sentences to express their main ideas that are used to support the thesis from different aspects. The parallelism can add the clarity in organization. Therefore, there are more cross-para chunks in argumentative essays.

We also examine the relative positions of parallelism chunks. We use the average sentence number of sentences in a chunk divided by the number of sentences in the essay as the relative position of the chunk. Figure 2(c) shows the distribution of relative positions, which are grouped into 10 zones. We can see the distribution is interesting that sentence parallelism is used much more often in the beginning or the ending of essays, while relatively less parallel sentences are used in the body part. We guess the reason is that since parallel sentences are used to impress the readers, the beginning and the ending parts are easier to draw readers' attentions. As a result, students tend to put impressive sentences at these important positions.

Essay type	#intra-para chunks	#cross-para chunks	#all chunks	Presence
Narrative	0.146	0.082	0.161	0.146
Argumentative	0.20	0.233	0.290	0.299

Table 6: Pearson coefficients between scores and the number of different types of parallelism chunks.

5.2 Sentence Parallelism and Essay Scores

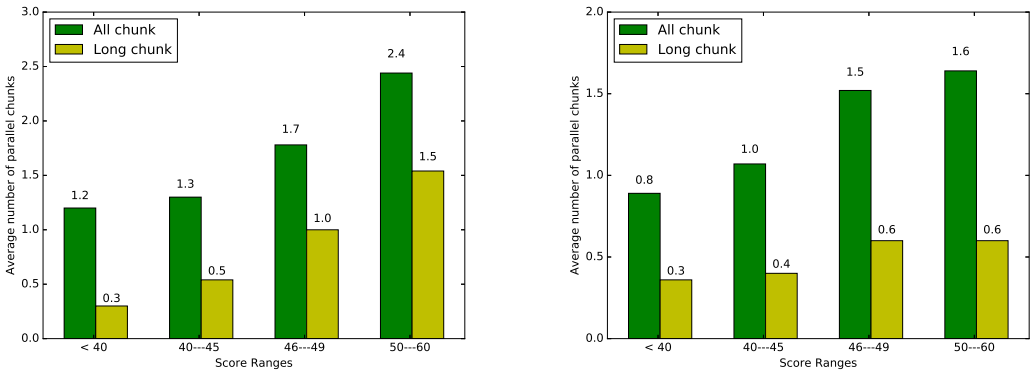
Does the use of sentence parallelism relate to the quality of essays? To answer this question, we analyze the relationship between sentence parallelism and essay scores. We first compute the pearson correlation coefficients between the number of different types of parallelism chunks and the scores of essays. Table 6 shows the results. The correlation coefficient with the number of chunks can reach 0.29 in argumentative essays. In contrast, the

Essay type	All essays	Presence	Absence
Narrative	43.74	44.09	43.13
Argumentative	45.65	46.35	42.13

Table 7: Average scores of essays in terms of the presence or absence of sentence parallelism.

correlation in narrative essays is much lower. The number of cross-para chunks has a higher correlation to essay scores in argumentative essays, but a lower correlation in narrative essays, compared with the number of intra-para chunks.

If we consider the presence or absence of parallelism, the correlations have the same trends as shown in the last column in Table 6. Table 7 shows the average scores of essays in terms of the presence or absence of sentence parallelism. In both narrative and argumentative essays, essays with sentence parallelism tend to have higher scores in average compared with the ones without sentence parallelism. Both differences are significant at 95% level (t-test, $p < 0.05$). The score difference is more obvious in argumentative essays.



(a) Argumentative essays.

(b) Narrative essays.

Figure 3: Average number of parallelism chunks in essays coming from different score ranges.

We further examine sentence parallelism in essays within 4 different score ranges, including 40 points below, 40 to 45, 46-49 and 50-60. We compute the average number of parallel sentence chunks in each score range. The result is shown in Figure 3 for argumentative and narrative essays respectively. We can see that the essays from higher score ranges have a larger average number of parallelism chunks. The trend holds for both argumentative and narrative essays.

We also want to consider the effect of the quality of sentence parallelism. Instead of dealing with the content, we consider *long chunks* whose chunk sizes are equal to or greater than 3. We simply view long chunks as high quality parallelism. The results are also shown in Figure 3. The differences among score ranges in argumentative essays are more obvious so that high quality sentence parallelism might be a useful indicator of well written argumentative essays. In contrast, long chunks appear much less in narrative essays across all score ranges.

5.3 Discussion

This section have studied the relationship between the use of sentence parallelism and the types and quality of student essays. The biggest observation is that the essay type—argumentative or narrative essay—is a key factor when we study sentence parallelism. First, the frequency and styles of using sentence parallelism are different. Parallelism is much more often used in argumentative essays. The ratio of cross-para chunks is also higher in argumentative essays. Second, the frequency or presence of using sentence parallelism has a positive correlation to the quality of essays. The correlation exists but is weak in narrative essays, while it is stronger in argumentative essays. According to the score distributions, recognizing high quality and low quality essays is crucial and challenging. High quality sentence parallelism may be useful to distinguish good and poor argumentative essays.

Notice that the ways of using parallelism may relate to how students are taught on writing, which might be different across countries and cultures. The observed statistics may also be affected by the topics of essays. Nonetheless, the observations should potentially help to design features for automated writing evaluation.

6 Related Work

6.1 Sequence Alignment

Finding the common parts among sequences have been a set of classic computer science problems. The typical problems include finding the longest common subsequence (Hirschberg, 1977), longest common substring and multiple sequence alignment (Carrillo and Lipman, 1988; Needleman and Wunsch, 1970). These techniques are commonly used in computational biology and also applied to natural language processing for constructing concept mapping dictionary (Barzilay and Lee, 2002), identifying sentence level paraphrases (Barzilay and Lee, 2003) and modeling the organization of student essays (Persing et al., 2010). In this work, we exploit these alignment measures for deriving features, since parallel sentences should have a kind of alignment.

6.2 Semantic Similarity of Texts

A large of body of previous work focuses on measuring the semantic similarity of texts. Semantic similarity of text usually depends on exploiting the semantic similarity of words and concepts (Corley and Mihalcea, 2005; Mitchell and Lapata, 2008). While the semantic similarity of words and concepts are learned based on distributional statistics (Lin, 1998; Padó and Lapata, 2007). Recently, neural networks based methods are proposed to learn the distributed representation of words on large scale of corpus (Mikolov et al., 2013). The learned word embeddings enable similar words to have a close distance in the vector space. There is also work on sentential paraphrase identification (Madnani and Dorr, 2010). Paraphrases are different expressions that convey the same meaning. Although it is similar to our task, the goals are different, since parallel sentences are not expected to have the same meaning and paraphrases are not required to have similar structures. Many researchers also exploit the structural properties of sentences to measure semantic similarity of texts, such as the tree kernel emthods (Moschitti, 2006; Mooney and Bunescu, 2005; Culotta and Sorensen, 2004).

6.3 Text Quality Analysis

Some work focuses on dealing with rhetorical device such as recognizing metaphor in texts (Shutova, 2010). Parallelism is also an important rhetorical device. Hobbs and Kehler (1997) study the clause level parallelism. However, little work has been done on sentence-level parallelism identification. These is work on predicting the quality of articles (Louis and Nenkova, 2013; Pitler and Nenkova, 2008), writing styles (Ashok et al., 2013) and student essays (Attali and Burstein, 2006). They mainly use simple shallow features, but seldomly use rhetorical device related features. Automated rhetorical device analysis should help to improve the above tasks.

7 Conclusion

We have investigated identifying sentence parallelism in student essays. We adopt machine learning to learn a prediction model based on an annotated dataset. We study various alignment measures and different word alignment strategies for deriving features. The evaluation demonstrates that our proposed method can effectively identify sentence parallelism, achieving a F_1 score of 82% at pair-wise level and 72% at parallelism chunk level. We also study the use of sentence parallelism in more than 2000 student essays based on automated parallelism identification. We find that students tend to use more sentence parallelism in argumentative essays compared with narrative essays. The essays with sentence parallelism have higher scores in average. The presence of high quality sentence parallelism shows to be an indicator of high quality argumentative essays.

Abstract

In this paper we analyze the effectiveness of using linguistic knowledge from coreference and anaphora resolution for improving the performance for supervised keyphrase extraction. In order to verify the impact of these features, we define a baseline keyphrase extraction system and evaluate its performance on a standard dataset using different machine learning algorithms. Then, we consider new sets of features by adding combinations of the linguistic features we propose and we evaluate the new performance of the system. We also use anaphora and coreference resolution to transform the documents, trying to simulate the cohesion process performed by the human mind. We found that our approach has a slightly positive impact on the performance of automatic keyphrase extraction, in particular when considering the ranking of the results.

1 Introduction

Automatic Keyphrase Extraction (henceforth AKE), i.e. the task of extracting a list of phrases of one or more words "that capture the main topics discussed in a given document" (Turney, 2000) is a natural language processing (herein NLP) task which received widespread attention in the last years, with applications, e.g., in the fields of digital libraries (Gutwin et al., 1999) or community modelling (De Nart et al., 2015).

Many AKE algorithms have been developed, which can be roughly divided into two categories (Hasan and Ng, 2014):

- *Supervised algorithms*: after the generation of candidate keyphrases (henceforth KPs) by means of linguistic knowledge, these candidates are associated to a set of *features* such as TF-IDF, position in the text, and so on; then, a supervised machine learning (herein ML) algorithm learns over a training set how to decide if a candidate is a suitable KP or not.

- *Unsupervised algorithms*: for example, the document is represented using a graph structure, whose nodes are candidate KPs. Then, the *popularity* of each candidate is evaluated using graph algorithms usually derived from the PageRank algorithm (Mihalcea and Tarau, 2004; Wan and Xiao, 2008). Other approaches include for example clustering-based algorithms, such as the one presented in (Liu et al., 2009), or techniques which rely on building a statistical language model to rank KPs, like the one presented in (Tomokiyo and Hurst, 2003).

However, the performance of the state of the art systems is still much lower than many other NLP tasks. An idea of the current top performing systems can be obtained by looking at the results of "SEMEVAL 2010 Task 5: Automatic Keyphrase Extraction from Scientific Articles" (Kim et al., 2010), where systems were ranked by F-score on the top 15 extracted keyphrases. The best system, presented by (Lopez and Romary, 2010), achieved a score of 27.5%.

After SEMEVAL 2010, many systems tried to improve this level of performance, with an increasing focus over supervised systems. A common strategy is to look for new features to be used by ML algorithms. As an example, in (Haddoud et al., 2015) the authors were able to overcome the best SEMEVAL

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 804–814, Osaka, Japan, December 11-17 2016.

performance achieving an F-Score of 28.6% on the top 15 KPs, by introducing a feature called Document Phrase Maximality, which they claim is able to better identify overlapping KPs, i.e. keyphrases that have a part in common, like for example "engineering" and "software engineering".

In this paper we follow the path of exploring new features and new ways of using linguistic knowledge from anaphora resolution to improve AKE. We started from the following hypotheses:

- If an n-gram is referenced many times inside a document, e.g. has many *anaphors*, its level of relevance as a KP may increase;
- If a pronoun can be replaced with the noun (or noun phrase) that it substitutes, we may detect information about said noun that otherwise would be lost; this information could be used to detect better KPs.

To check if these hypotheses hold we used the following approach. First, we set a baseline to compare our hypotheses against by choosing a minimal set of features that defined a system behaving like an average SEMEVAL 2010 contestant. Then, we designed two approaches, one based on the new linguistic features and the other based on a text preprocessing stage which applies anaphora-antecedent substitutions. Finally, we evaluated the performance of several ML algorithms using the SEMEVAL 2010 dataset and different feature sets combination which include the first hypothesis, the second one, or both.

2 Related work

The use of linguistic knowledge in AKE is not new. An interesting approach is the one presented in (Hulth, 2003), where the author wanted to demonstrate that the use of linguistic knowledge can lead to more compelling results than the ones obtained with the application of statistical features only. The AKE system proposed by Hulth exploits 4 features: three introduced in (Frank et al., 1999), which are within-document-frequency, collection-frequency and position of the first occurrence of the token, plus a new one that evaluates the POS-tag assigned to a term. The KPs extracted with the linguistic approach turned out to have lower recall but greater precision than the ones computed with the statistical one. In (Nguyen and Kan, 2007) the authors used a similar approach by taking into account also suffix sequences, acronym status and POS tag sequence as an hint for terminological status of the candidates. In (Pudota et al., 2010) instead the authors designed a system which weighted KPs based on the number of nouns contained in them. This system is the ancestor of the Distiller framework (Basaldella et al., 2015), which is the software we used in this work to perform our experiments.

Another way to improve AKE could be taking advantage of linguistic knowledge from anaphora and coreference resolution, which are the fields we are going to explore in this paper. Anaphora resolution is the problem of resolving what a pronoun or a noun phrase refers to. Lappin and Leass (1994) proposed "an algorithm for identifying both intrasentential and intersentential antecedents of pronouns in text": they use syntactical and morphological filters to find out dependencies between pronouns and possible related noun phrases (herein NPs), scoring the candidates by considering salience to select an adequate antecedent for each pronoun not flagged as pleonastic.[1]

A close field to anaphora resolution is *coreference resolution*. These two fields share similar information, so they overlap in a certain way: resolving anaphora is about finding the "cohesion"[2] which points back to some previous item" as stated in (Halliday and Hasan, 2014). So, the process of binding an antecedent to an anaphora is anaphora resolution; coreference resolution instead is the process of detecting when anaphors and their antecedent(s) have in common the same referent in the real world. Consider this the example from (Mitkov, 2014):

> This book is about anaphora resolution. The book is designed to help beginners in the field and its author hopes that it will be useful.

[1] A pleonastic pronoun is tipically used in phrasal verbs as subject or object but without an effective meaning (i.e. it seems, it is known, etc.)

[2] see section 3.1

Then the NP "the book" and both the pronouns "its" and "it" are anaphors referring to the antecedent "This book", and all three anaphors have the same real-word referent, which is "this book". So anaphors and their antecedent(s) are coreferential and form a chain, called *coreference chain*, in which all the anaphors are linked to their antecedent.

In our experiment we use the Stanford Coreference Resolution System `dcoref` (Manning et al., 2014) to retrieve anaphors and referents to implement our linguistics based features. We choose this software because of its good performance, since it is the direct descendant of the top ranked system at the CoNLL-2011 shared task. Moreover, both the Distiller and Stanford's system are Java-based, thus the integration of the two systems is easier. To resolve both anaphora and coreference, `dcoref` extracts the couples of anaphors and their relative referents, according to the matching of phrases' attributes, such as gender and number.

Other strategies to anaphora resolution, as the one introduced by Ge et al. (1998), use statistical information to resolve pronouns They use the distance between pronoun and the proposed antecedent to check the probability of the connection between them, information about gender, number, and animacity of the proposed antecedent as hints for the proposed referent, and head information to make selectional restrictions and mention count.

3 Anaphora in Keyphrase Extraction

3.1 Motivation

When we (humans) communicate, whether in a spoken or written form, generally we express a $coherent$ whole, i.e., a consistent and logical collection of words, phrases, and sentences. People often use abbreviated or alternative linguistic forms, such as pronouns, referring to or replacing some items that were previously mentioned in the discourse. Thus, to fully understand the discourse we need to interpret these elements, which *depend* on the elements they refer to. In linguistics, this process of interpretation is called *cohesion* (Mitkov, 2014).

On the other hand, when a document is processed for AKE, non influential words are usually removed. These words, commonly called *stop words*, are excluded from the text because they appear to be not significant, even if they are extremely frequent. Among them there are also pronouns such as *he*, *she*, *it*, *that*, *who*, and so on. The removal of such elements causes a loss of cohesion, both syntactically and semantically.

Moreover, pronouns have a relevant role in the sentences since they allow the author to enrich his writing using a richer vocabulary, composing more complex sentences, and so on. Pronouns are parts of the text which typically have the function of a substitute: depending on the case, they can replace a subject or an object, they can indicate possession, places, or refer back to people or things previously mentioned. Given these premises, disregarding all pronouns without replacing them with a valuable substitute could lead to a loss of a syntactical and/or semantical information. In fact, during the reading process we are able to decode the information conveyed by pronouns because we automatically replace them with the entity they refer to. In NLP a similar process is performed by anaphora resolution, thus our idea is to use this information, which would be otherwise lost, for AKE.

3.2 Definitions

We use the following definitions. Words are identified with the letter w and keyphrases with kp. Given a document d, $S(kp)$ is the set of sentences $s \in d$ in which kp appears. Given a sentence $s \in S(kp)$, we denote with $|s|$ the number of words in s, with $|kp|$ the number of words in kp, with $|S(kp)|$ the number of sentences in the set, and so on. Finally, $|C(d)|$ is the number of clauses in the document d, which are defined as a "simple sentences" or, more precisely, the smallest grammatical units which can express a complete proposition[3].

[3]Here we use *clause* and *proposition* as defined in (Kroeger, 2005).

3.3 First approach: Use of anaphora in Machine Learning features

As our first approach we decided to use linguistic knowledge to produce some new features. In detail, we designed a statistical feature that counts all the pronouns/pronominal anaphors which point to an entity (the *antecedent*), and a feature based on on lexical noun phrase anaphors, which are realized as definite noun phrases and proper names (Mitkov, 2014). We will call them *nominal anaphors* and *proper name anaphors* respectively.

For the first feature we follow this process: first, we use the Stanford CoreNLP Coreference Resolution System to find all the anaphors contained in a text and link them to their antecedent. Then, we select the pronominal anaphors, which are anaphors identified by personal pronouns *(he, she, ...)*, reflexive pronouns *(him, her, ...)*, possessive pronouns *(himself, itself, ...)*, demonstrative pronouns *(that, those, ...)*, and relative pronouns *(which, who, ...)*. Finally, we normalize the counted references for each antecedent dividing them by the number of clauses in the document.

Formally, we call $PA(kp)$ the set of pronominal anaphors for which kp is the antecedent. We define:

$$numOfReference(kp) = \frac{|PA(kp)|}{|C(d)|}$$

In our opinion, the use of sentences for normalization is not correct because within a sentence we could find more than one pronoun, skewing the normalization. If we choose the number of clauses to normalize the feature we are instead sure that $0 \leq numOfReference \leq 1$. For clarity, consider the "this book" example from (Mitkov, 2014) from in Section 2: by normalizing over sentences, the value of the feature would be $\frac{2}{1} = 2$, while by normalizing over clauses the value of the feature is $\frac{2}{5} = 0.4$.

The other linguistic feature we implemented is based on *nominal* and *proper name* anaphors. A nominal anaphora instead arises when the referring expression has a non-pronominal noun phrase as its antecedent: it is the case of clauses in which anaphora and antecedent are implicitly related, i.e., they do not stand in a structural or grammatical relationship, but they are linked by a strong semantic one. Consider this example from Wikipedia[4]:

> Margaret Heafield Hamilton (born August 17, 1936) is a computer scientist, systems engineer and business owner. She was Director of the Software Engineering Division of the MIT Instrumentation Laboratory, which developed on-board flight software for the Apollo space program. In 1986, she became the founder and CEO of Hamilton Technologies, Inc. in Cambridge, Massachusetts. The company was developed around the Universal Systems Language based on her paradigm of Development Before the Fact (DBTF) for systems and software design.

Here "Margaret H. Hamilton" is the $antecedent$ and the corresponding anaphors are the underlined words in the quote. "Computer scientist", "Director of the Software Engineering Division" are all examples of *nominal anaphors*.

The Wikipedia excerpt continues with this sentence:

> Hamilton has published over 130 papers, proceedings, and reports about the 60 projects and six major programs in which she has been involved.

Here, "Hamilton" is a proper name referring to "Margaret Heafiled Hamilton", and realizes a *proper name anaphora*.

When we read these sentences we automatically link for example the concept of being a "computer scientist" to a property of the subject of this sentence, while in AKE this information is lost. Hence, the basic idea behind this feature is to reward all the candidate KPs which appear in a nominal or proper name anaphora because they implicitly refer to the mentioned subject, highlighting important aspects of it.

[4] https://en.wikipedia.org/wiki/Margaret_Hamilton_(scientist)

In details, we process the document as previously defined. Then, for each candidate KP, we count all the times it appears in the set of the lexical noun phrases, i.e., the set of nominal and proper name anaphors. Finally we normalize the obtained score by the total number of appearances of the candidate in the document.

Formally, given a keyphrase $kp \in K$ and the set of the lexical noun phrase anaphors in the document NPA, the *inAnaphora* feature can be computed as follows:

$$inAnaphora(kp) = \frac{|\{a \in NPA | kp = a\}|}{|S(kp)|}$$

3.4 Second approach: Use of anaphora for preprocessing

While the previous approaches are able to capture some information about anaphora, they are not powerful enough to catch other knowledge that anaphora convey. For example, frequency-based features such as TF-IDF, which play an important role in several AKE algorithms since its first introduction in (Frank et al., 1999), may be recalculated using the anaphora in the frequency count as well.

This leads us to a different strategy: transforming the text into something that resembles the original human reading process as described in Section 3.1. To achieve this goal, we add to the our system a preprocessing stage that receives the original text from the dataset and substitutes in it all the non pleonastic pronouns with their antecedent. After this preprocessing phase, we perform AKE as usual and then we evaluate the results.

Consider the example we introduced in Section 3.3. If we apply the pre-processing, the sentence becomes:

> Margaret Heafield Hamilton (born August 17, 1936) is a computer scientist, systems engineer and business owner. Margaret Heafield Hamilton was Director of the Software Engineering Division of the MIT Instrumentation Laboratory, MIT Instrumentation Laboratory developed on-board flight software for the Apollo space program. In 1986, Margaret Heafield Hamilton became the founder and CEO of Hamilton Technologies, Inc. in Cambridge, Massachusetts. The company was developed around the Universal Systems Language based on Margaret Heafield Hamilton paradigm of Development Before the Fact (DBTF) for systems and software design.

Unfortunately, the original articles from the SEMEVAL 2010 Task 5 are transformed into plain text using the UNIX tool `pdftotext`. The output of this tool is a very unstructured text, where not only information about title, sections, etc., is lost, but also figures and tables may be placed inside content paragraphs, sentences may be badly split, and so on. This caused problems with the anaphora resolution and substitution algorithm, whose precision was undermined by these conversion errors. Moreover, these formatting problems may cause an erroneous coreference chain where the effects of an early bad resolution are amplified while going further in the text.

Thus, to improve anaphora resolution (and then substitution) in the original text, we segment the original text into sections. In this way, we improve the reliability of the parsing tree for the sentences and so we obtain more a correct performance in searching the antecedent. To perform this segmentation we use some heuristics to distinguish the title, the authors, and the email addresses, and to detect the boundaries of sections, paragraphs, figures, and so on. As a result, the text to process becomes more similar to the original graphical appearance in the PDF format, it is more structured, and it contains also less errors.

Then, by using this structure, we work on single sections, generating and using the coreference chain with the Stanford CoreNLP Coreference Resolution System to collect all the pronominal anaphors. Finally, we go back to the antecendent of each pronoun detected in the chain and we replace the former with the latter. The text turns out to be simpler but more informative for our AKE algorithm: by replacing the pronouns in the document we have no loss of information, while we are able to recover statistical and semantical information about the antecedents that would be otherwise lost.

The choice of substituting only pronominal anaphors is justified by the fact that nominal anaphors may not be just synonyms but also very different words, possibly with a different meaning. This happens because nominal anaphors have only the property of referring to the same entity in common thus substituting a nominal anaphora with its antecedent could change the meaning of the sentence. For example, from the text above, "Computer scientist", "system engineer", "Director of the Software Engineering Division", are all references to "Margaret Heafield Hamilton", but if we substitute them with the head of chain (i.e. "Margaret Heafield Hamilton"), the meaning of the sentence is completely different. Considering proper name anaphors is worthless as well: replacing a proper name anaphora with its antecedent could lead to a substitution that in our opinion could be useless or wrong. For example, in a biography there could be more people indicated by a common surname. Thus, an arbitrary substitution of all proper name anaphors could be wrong, because the anaphora resolution software may fail to identify the correct subject: in our example, if the head of the coreference chain is "Hamilton", we risk to replace "Margaret Heafield Hamilton" with her husband, whose surname is Hamilton too.

To summarize this approach, we follow this process: first, we parse the article from the dataset and use some heuristics to divide it into correctly formatted sections. Then, we process each section with the Stanford CoreNLP Coreference Resolution System, we collect all the pronominal anaphors, and we replace each anaphora with the correct antecendent. Finally, we submit the preprocessed text to the AKE process along with the value of the *InAnaphora* feature. Regarding to the *numOfReference* feature, which concerns only pronominal anaphors, its use has to be taken into consideration as well because when documents are preprocessed with substitution, different coreference chains could be discovered.

4 Methodology

4.1 Baseline algorithm

In order to evaluate the impact of the proposed features, we used the Distiller framework to implement a baseline keyphrase extraction algorithm with few basic features. In our baseline algorithm candidate KPs are n-grams selected from the text if they match a given set part-of-speech patterns, which is one of the most common way of generating candidates in literature (Hasan and Ng, 2014).

The baseline feature set for our experiment is a set of well-accepted features for AKE, i.e., given a candidate KP, we consider:

- TF-IDF;
- relative position of the first appearance of the candidate (*height*);
- difference between the position of the last and the first appearance (*lifespan*);
- number of appearances of the candidate in the text, normalized by number of sentences.

Then, we consider a new feature set, in which we add to the baseline a fifth feature called Document Phrase Maximality (DPM), introduced by Haddoud et al. (2015). We use this feature because it supposedly should help to discriminate between candidate keyphrases which often appear as substring of another candidate. We deem this feature as necessary because, by using our substitution algorithm, we usually substitute an anaphora with a longer antecedent, thus leading to an increase of frequency of all the words contained by the antecedent. In our example, we will substitute the anaphors with "Margaret Heafield Hamilton", thus increasing the frequency, e.g., of the word "Hamilton", but DPM allows us to assign a *low* score to the single words while assigning an *high* score to the full name of the scientist.

The Machine Learning algorithms we choose are logistic regression, neural networks, and boosted decision trees, since these algorithms have a reputation of being good algorithms in the AKE community (Hasan and Ng, 2014). We used their implementation with the R software, using the `glm`, `nnet` and `C5.0` libraries to train the respective models. We used no particular tweaking on the algorithms; the neural network used was a simple Multi Layer Perceptron (MLP) with one hidden layer. Then, we ranked KPs using the raw probability output by the algorithms.

																P	R	F1	MAP
A	✓	✓	✓	✓	✓	✗	✗	✗	✗	✗	✗	✗	✗	✗	✗	0.33	0.33	0.33	0.33
B	✗	✗	✗	✗	✗	✗	✗	✗	✗	✗	✓	✓	✓	✓	✓	0.33	0.33	0.33	0.02
C	✓	✓	✓	✗	✓	✗	✗	✗	✗	✓	✗	✗	✗	✗	✓	0.40	0.40	0.40	0.31

Table 1: Hypothetical Precision, Recall, F1-Score and MAP of three systems A, B and C over a document with 15 correct keyphrases. A tick mark (✓) indicates a system assigned correct keyphrase, while an x mark (✗) a wrong one.

We didn't choose a bigger feature set because there is no agreement on which are the "state of the art" features for AKE. The top performing systems use many different strategies: in (Lopez and Romary, 2010), the authors use few features, but a custom "post-machine learning" ranking algorithm; in (You et al., 2013) few features are used, but a different candidate generation algorithm; in (Haddoud et al., 2015), we can find more than 20 features.

Moreover, this simple feature set is enough to get an average performance on the SEMEVAL task. With the MLP, our baseline system showed an F-score of 19.69% on the best 15 keyphrases, which is good enough to be ranked 11^{th} out of 20 contestant in the SEMEVAL 2010 challenge. The same position would be achieved using logistic regression, with a score of 19.22%, while the use of decision trees causes a slip of one position down, with a score of 18.95%.

4.2 Metrics

The usual metrics used in AKE are Precision (P), Recall (R), and F1-Score, but these metrics are not the only ones that we will consider in evaluating our system. In fact, we believe that our proposed system may offer an interesting contribute even if we are just able to provide a *better ranking* of the keyphrases.

As pointed out in (Schluter, 2015), this better ranking could not be caught by the aforementioned metrics. For example, suppose we have two systems participating in SEMEVAL 2010, where algorithms are ranked by the F1-Score of the top 15 keyphrases returned by the algorithms. We call this systems A and B. Suppose that, looking at A's output, only the first 5 keyphrases are correct, while the other 10 are wrong. Then, suppose that B's output is the opposite: the first 10 keyphrases are wrong, then the next 5 are good. So, this system will have the same precision (33%), the same recall and the same F1-Score, but the ranking of the system A is arguably better than the ranking of the system B.

Therefore, to evaluate our system, we propose the use of the Mean Average Precision (MAP) metric, which is more suitable to evaluate a ranking than simple precision and recall. We borrow our definition of MAP for keyphrase extraction from (Manning et al., 2008), that is, if the set of correct keyphrases for a document D is $\{kp_{(D,1)}, \ldots, kp_{(D,n)}\}$ and $R_{D,k}$ is the set of retrieved keyphrases for the document D until you get to the k-th keyphrase,

$$MAP(D,R) = \frac{1}{n}\sum_{j=1}^{n}\frac{1}{j}\sum_{k=1}^{j} Precision(R_{D,k})$$

Where $Precision(R_{D,k})$ is the Precision@k score of the system over document D for the first k retrieved documents.

As an example, we see the systems A and B compared in Table 1, on a document with 15 gold keyphrases. The two systems share the same P, R and F1 scores, while MAP is radically different, being much higher for system A than for system B. If we suppose to have another system C, which gets the 1^{st},2^{nd},3^{rd},5^{th},10^{th} and 15^{th} keyphrases correct, we have that this system shows higher P, R and F1 scores than systems A and B but lower MAP than A. This happens because of A's better quality of the first results or, in other words, because of the higher *"weight"* of A's correct keyphrase in the fourth position than C's correct keyphrases in tenth and fifteenth position.

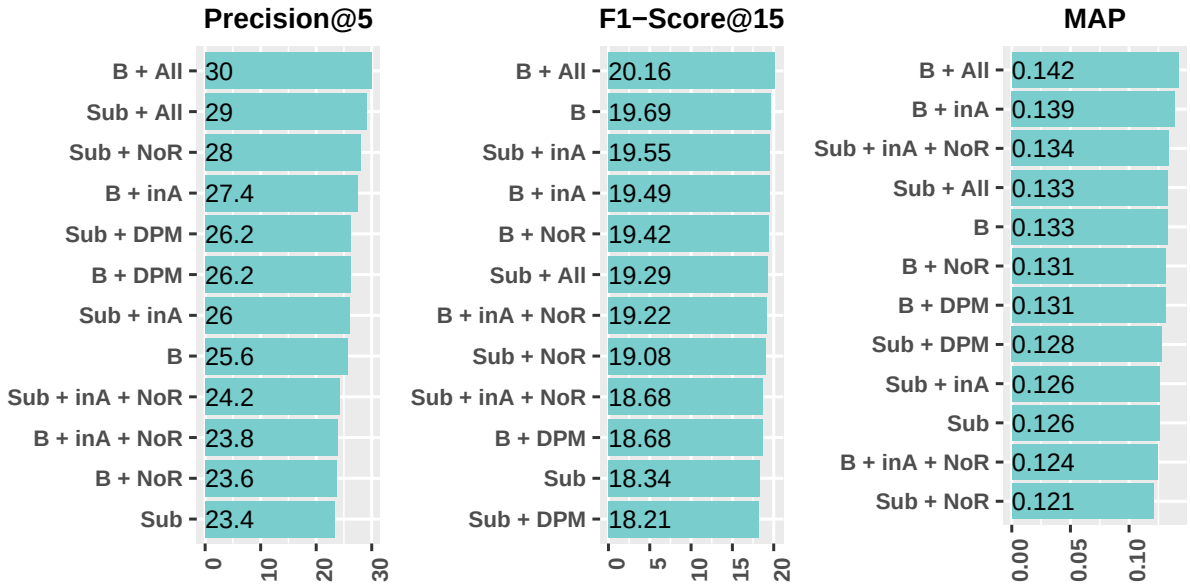

Figure 1: Scores obtained by running our keyphrase extraction algorithm over different feature sets. Note that "B" stands for "Baseline", "Sub" indicates the baseline features ran on the preprocessed documents, "inA" marks the $inAnaphora$ feature, "NoR" marks the $numberOfReference$ feature, "DPM" stands for the Document Phrase Maximality feature, and "All" indicates that the feature set contains all the aforementioned features.

5 Results

Combining the baseline features defined in Section 4.1 with our new features defined in Section 3.3 and the pre-processing technique we described in Section 3.4, we defined a total of 36 different AKE pipelines. These pipelines were built by running the three machine learning algorithms we choose on baseline feature set first, then adding DPM and our anaphora-based features, then combining the features together, both on the original SEMEVAL 2010 dataset and the text preprocessed with our technique.

The neural network was the best performing algorithm overall, and we can see its results in Figure 1. The first impression is that there is generally a little improvement in F1-Score, with the baseline algorithm on the original documents still being the second best feature set with this metric.

Nevertheless, looking at the Precision@5 score, we see that our approach has a significant impact: as shown in Figure 1 (left column), the combination of the linguistic features with the statistical ones, both in the original documents and in the ones with preprocessing, the precision score is greater than the one obtained for the baseline set. In particular, starting from the result of 25.60% for the baseline, we reach a score of 27.60% in precision just by using *inAnaphora* feature and 30.00% adding also *numOfReference* and *DPM*. A similar behavior can be observed in the results when considering that the substitution technique is performed in the preprocessing. In fact, while on the preprocessed text the baseline features show no improvement, a more interesting result can be seen using the linguistic features, for which precision score raises from the baseline's 23.40%, to 26.00% adding *inAnaphora*, and to 29.00% combining all the features together.

Looking at the scores of MAP, we can see that using all features on the original dataset offers the best ranking, as it would be expected by the high Precision@5 score; this confirms our idea of combining the anaphora-based features with DPM. Interestingly enough, most of the other feature sets show a slight decrease in the quality of the ranking, probably because the gain in precision is not high enough to balance the decrease in recall.

Taking into account just the second approach, the results provide evidence of our initial assumptions on the importance of using *inAnaphora* feature over preprocessed text. Precision and F1-Score show a more significant increment when using preprocessed documents, and the reason can be found in a second

parsing with more *coherent* coreference chains. In details, coreference resolution and so our features that depend from it improve because the substitution of pronouns with the common antecedent in the first chain produces a text with more noun phrases and less pronouns. This way, the parse tree of the preprocessed text is simpler, so the relationships between the "new" noun phrases are more clear. This allows the anaphora resolution library to find more anaphors and to better detect pleonastic pronouns, thus obtaining a more precise score for our feature.

The other ML algorithms (not shown in the figures) seem to prove the conclusions we obtain from the neural network: using either decision trees or logistic regression the behavior is similar to the one described for the neural network, with a relatively stable F1-Score on the top 15 extracted keyphrases, but a significant increase in Precision@5 and MAP score when adding linguistic features. It is interesting that for both algorithms, using all features on the original documents offers highest Precision@5 and MAP scores, confirming the results shown in Figure 1. In particular, with this features/dataset combination, with the `glm` library we see slight rises in Precision@5, F1-Score@15 and MAP from 24% to 24.4%, from 19.22% to 20.30% and from 0.127 o 0.136 respectively; for `C5.0`, while F1-Score rises from 18.95% to just 19.29%, Precision@5 and MAP shows a more significant improvement from 22.2% to 26.8% and from 0.123 to 0.137 respectively, thus supposedly showing a better ranking of the keyphrases found. On the other hand, using the same feature set over the preprocessed documents still shows an improvement from the baseline, but with slightly lower scores.

6 Conclusions

Our analysis shows that anaphora and coreference resolution can be used for AKE with significant results. Like in (Hulth, 2003), we see that by exploiting linguistic knowledge in a keyphrase extraction algorithm it is possible to increase the precision of the results. We think that it is important to analyze the relationships which could arise when linguistic features are combined together with statistical features. For example, it is clear that preprocessing the input text by substituting the pronouns with the entity they refer to could increase the frequency of certain terms, thus statistical features like DPM can be useful to gain a performance boost.

A better result could be obtained by improving anaphora resolution performance, since the software we used was not always able to find all the correct anaphors, even if it is (or it is close to) the state of the art system for anaphora and coreference resolution at the time of writing. For example, looking at the example we introduced in Section 3.3, the algorithm was not able to detect the anaphora *director* from the sentence "*She was Director of the Software Engineering Division*", which means that we would not able to detect and replace correctly all the pronouns in the coreference chains or compute the value of our features correctly. This is confirmed by the fact that the *numOfReference* feature, which is based on the count of pronominal anaphors, had a positive impact on performance even after the text preprocessing, which *should* have had replaced all the pronouns with their antecedents.

As a future work, we consider the idea of using the outcomes of our preprocessing stage for improving anaphora resolution specifically for the task of keyphrase extraction, developing an ad-hoc mining algorithm for the parsing trees, with the goal of producing a better pre-processing algorithm and finding for each valuable pronoun a good candidate antecedent. Moreover, another interesting approach would be looking for statistical features other than DPM which are able to better interact with the anaphora-related ones.

Retrieving Occurrences of Grammatical Constructions

Abstract

Finding authentic examples of *grammatical constructions* is central in constructionist approaches to linguistics, language processing, and second language learning. In this paper, we address this problem as an information retrieval (IR) task. To facilitate research in this area, we built a benchmark collection by annotating the occurrences of six constructions in a Swedish corpus. Furthermore, we implemented a simple and flexible retrieval system for finding construction occurrences, in which the user specifies a ranking function using lexical-semantic similarities (lexicon-based or distributional). The system was evaluated using standard IR metrics on the new benchmark, and we saw that lexical-semantical rerankers improve significantly over a purely surface-oriented system, but must be carefully tailored for each individual construction.

1 Introduction

Linguistic theories based on the notion of *constructions* are a recent development in linguistics, which has revitalized the discussion in fields such as syntax, lexicography, and argument structure theory. In particular, it is useful for describing *partially schematic* constructions: templatic patterns that exhibit lexical as well as syntactic properties, which are too specific to be referred to general grammar rules, but too general to be attributed to specific lexical units, which is a reason why they historically have been overlooked (Fillmore et al., 1988). These constructions are very frequent, and they are not only theoretically interesting but also important in language teaching (De Knoop and Gilquin, 2016), since they are challenging for second language learners (Prentice and Sköldberg, 2011).

So far, despite the importance of construction-based theory in linguistics and language pedagogy, it has seen limited adoption in natural language processing. A major impediment to their acceptance is probably the lack of resources of a nontrivial size. Efforts to build inventories of this kind – *constructicons* – are now underway for a number of languages. The emerging practice of constructicon development, or *constructicography*, can be seen as a combination of construction grammar and lexicography (Fillmore et al., 2012). A crucial requirement for constructicon building is access to corpus search tools allowing constructicographers to *search* for occurrences of constructions: either for finding prototypical examples (Gries, 2003), or for computing statistics such as word–construction cooccurrence (Stefanowitsch and Gries, 2003). Also, for the reasons mentioned above, finding authentic examples of uses of a particular construction is also useful in language teaching situations.

In this paper, we cast the task of searching for construction occurrences as an information retrieval (IR) problem. This is fruitful in construction-based research and constructicography for a number of reasons. First, while a partially schematic construction can have a surface form that is easy to describe as a structural pattern, its exact semantic properties and restrictions can be hard to capture as a clear-cut binary decision, or may not even be known *a priori*. This makes it natural to re-rank corpus hits according to a semantics-based scoring function. Such an approach allows a researcher to explore the spectrum of search hits, from the most prototypical – which a good retrieval system should place near the top – to the more unusual cases. Also, the IR perspective is natural in terms of interaction: a user

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 815–824, Osaka, Japan, December 11-17 2016.

can pose queries, rank and re-rank repeatedly according to different functions defined on the fly, to get a comprehensive overview of the various uses of a construction in a corpus.

To open up new opportunities for research in construction retrieval, we built a benchmark collection by annotating the occurrences of six different partially schematic constructions defined in the Swedish Constructicon (Sköldberg et al., 2013). This allows us to explore different retrieval systems and evaluate them according to standard IR evaluation protocols, and we developed a construction retrieval system that finds occurrences of partially schematic constructions in Swedish corpora, based on flexible user-defined ranking functions using lexicon-based and distributional similarities to describe the construction's slot fillers. These ranking functions are learned from a small number of seed examples. Our results show that ranking functions based on lexical-semantic properties are effective, outperforming a purely surface-based baseline for all six constructions. However, because the constructions are so structurally and semantically diverse, we cannot expect a single ranking function to be the best in all cases, and in practice we observed considerable difference among constructions as to which similarities are most useful. This shows that it is crucial for the ranking functions to be flexible and user-defined, which also makes most sense from a usability perspective.

2 Construction Grammar and the Swedish Constructicon

In terms of linguistic theory, the approach is couched in Construction Grammar, for which the aforementioned abundance of semi-general and partially schematic patterns is a key motivation, and where intermingling of linguistic levels is seen as the norm, not the exception. Rejecting the sharp distinction between lexicon and grammar, constructionists regard grammatical rules, lexical idiosyncrasies and "mixed" patterns alike as *constructions*: "conventional, learned form–function pairings at varying levels of complexity and abstraction" (Goldberg 2013, p17). A methodological benefit of assuming the same kind of unit across the board is that the machinery required to account for patterns with both grammatical and lexical properties can also handle those that are purely grammatical or purely lexical, another that the absence of distinct levels eliminates the problem of borderline cases (Fillmore et al., 1988).

Applying this view to descriptive practice, a constructicon is a collection of construction descriptions, a "dictionary of constructions." First introduced for English (Fillmore et al., 2012), there are now constructicon resources under development for a number of languages, including Swedish (Sköldberg et al., 2013; Lyngfelt et al., forthcoming), Brazilian Portuguese (Torrent et al., 2014), and Japanese (Ohara, 2013). The Swedish Constructicon currently covers around 400 constructions, many of which are partially schematic patterns of the kind that is hard to account for from a grammatical or lexical perspective alone. Hence, offering a wide and relevant selection of constructions, it provides a suitable testing ground for the study at hand.

To exemplify the organization of the Swedish Constructicon, Figure 1 shows the most important parts of its entry for V_REFL.RÖRELSE (REFLEXIVE_MOTION), a frequent construction in which motion is expressed using a verb with a reflexive pronoun. The entry contains a *definition* of the construction, that presents its structure and semantics textually, a *structure sketch* describing its surface structure in a semi-formal way, and a small number of annotated *examples* from corpora that show typical uses of the construction.

Name	V_REFL.RÖRELSE
Definition	[An actor]$_{\text{ACTOR}}$, expressed with a [reflexive]$_{\text{REFL}}$, [moves]$_{\text{V}}$ [in a direction, traverses a path, from a place or to a place]$_{\text{LOCATIVE}}$. The verb usually describes the manner of the motion. The construction also encompasses actions that indicate intended motion and non-motion.
Structure sketch	V PN$_{\text{REFL}}$ [PP | ADVP]
Example	[*Vi*]$_{\text{ACTOR}}$ *fick* [*armbåga*]$_{\text{V}}$ [*oss*]$_{\text{REFL}}$ [*fram*]$_{\text{LOCATIVE}}$ *i restaurangen*. [We]$_{\text{ACTOR}}$ had to [elbow]$_{\text{V}}$ [ourselves]$_{\text{REFL}}$ [forward]$_{\text{LOCATIVE}}$ in the restaurant.

Figure 1: Swedish Constructicon entry for V_REFL.RÖRELSE (REFLEXIVE_MOTION).

3 Related work

While we are aware of no previous work approaching the general problem of searching for construction occurrences from a retrieval perspective, quantitative and corpus-based methods have been a crucial part of the construction-linguistic toolbox from its early days (Gries, 2003; Stefanowitsch and Gries, 2003; Hilpert, 2013). In particular, a number of automatic methods have been presented that mine corpora for frequent patterns. For instance, Wible and Tsao (2010) collected generalized n-grams (that is, combinations of words, PoS tags and phrase labels) and applied standard measures of collocational strength to select n-grams that seem to be recurrent patterns. The Swedish constructicon project used similar methods (Forsberg et al., 2014), but also extended the approach by Wible and Tsao (2010) by considering patterns containing phrase labels (e.g. NP-*and*-NP, *as*-Adj-*as*-NP).

The only related work we found that treats the construction detection as a ranking task is by Dubremetz and Nivre (2015), who used a ranking approach to retrieve occurrences of the rare rhetorical *chiasmus* construction. They preferred ranking over classification since the complexity of this construction and the number of borderline cases made a hard classification infeasible, and similarly to our position, they argued that the existence of borderline cases should be embraced instead of ignored. However, since their work is limited to searching for just *chiasmi*, their system was completely tailored for this case.

4 A benchmark collection for evaluating construction retrieval systems

We built a new benchmark for evaluating construction retrieval systems based on six different constructions defined in the Swedish Constructicon. The selected constructions are nontrivial in the sense that their formal description cannot be translated into a standard corpus search query (based on surface features such as words or part-of-speech tags) that captures exactly their true instances – for instance, occurrences of the well-studied *let alone* construction (Fillmore et al., 1988) are easy to spot in corpora.

The initial pass of creating the benchmark was to extract a collection of potential instances for each of the six constructions. We extracted these instances by querying the *Korp* corpus search engine, hosted by the Swedish Language Bank (Borin et al., 2012). Korp stores a large collection of corpora, currently around 10 billion tokens, and allows structural queries based on surface strings but also several types of linguistic annotation; for this experiment, we used a corpus of contemporary fiction. The web service of Korp allows users to pose queries using the CQP language (Christ, 1994), and we selected the instances by translating the structure sketch (as in the example in Figure 1) of each construction into a corresponding CQP query. The corpus search engine then returns a (possibly very large) number of hits, and depending on the formal properties of the construction, fixed lexical content, variable tokens, or syntactic restrictions of particular slots, this list is 'contaminated' to some extent by unrelated hits.

Each collection of hits was then annotated manually as true or false instances of the construction in question. Table 1 shows the number of hits for each query, and the number of true hits among them.

Construction	Total hits	True hits
V_*av*_NP	501	169
PROPORTION_*i/om*	1703	205
REFLEXIVE_MOTION	1300	338
QUANTIFYING_GENITIVE:TIME	945	97
QUANTIFYING_GENITIVE:SCALE	945	166
BOUNDED_EVENT_*på*	2000	43

Table 1: Statistics for the benchmark.

In the following, we detail the six constructions used to create the benchmark.[1]

4.1 V *av* NP

V_*av*_NP is a causal VP construction where the event or state expressed by the verb is caused by the bare noun following the preposition *av* 'of'. It includes both literal and metaphorical causative relations such as *stinka av mögel* 'stink of mold' and *dö av skam* 'die of shame' but the formal surface description

[1]For clarity, we refer to the constructions by translating their Swedish names into English in the rest of this paper, except for construction-evoking keywords included in the names.

V *av* NP_{BARE} also catches phrasal verbs such as *dra av moms* 'subtract sales tax' and passive voice constructions like *läses av flickor* 'is read by girls'. The variable construction slots are not restricted to any obvious semantic classes, although emotions and physical states are clearly salient at first glance.

4.2 PROPORTION_*i/om*

PROPORTION_*i/om* is a rate construction that combines two entities, a numerator and a denominator, joined by the preposition *i* 'in' or *om* 'about', and is restricted to temporal relations such as frequency and speed, and salary rates also fit into this scheme. Its structure sketch NP_{INDEF} [*i* | *om*] N_{DEF} catches true instances such as *två gånger om dagen* 'two times a day' and *åttio pesos i månaden* 'eighty pesos a month', as well as false positives such as *tio dagar i fängelset* 'ten days in jail'.

4.3 REFLEXIVE_MOTION

As mentioned in Section 2, REFLEXIVE_MOTION is a self-motion construction where an actor expressed with a reflexive traverses a path in a direction from a place or towards a goal. The verb typically describes the means or manner of the motion, while the prepositional/adverbial phrase contributes the direction. The formal description V PN_{REFL} [PP | ADVP] captures prototypical occurrences like *sätta sig ned* 'sit down' and *ta sig fram* 'make one's way' as well as instances with verbs that do not usually indicate motion, like *svetta sig igenom* 'sweat one's way through' and *läsa sig bakåt* 'read one's way backwards'. False hits in the search result include common reflexive verbs that do not express motion, like *känna sig glad* 'feel happy' and *anförtro sig åt* 'confide in' as well as certain lexicalized multiword expressions like *tränga sig på* 'intrude' and *sätta sig på tvären* 'be obstinate'.

4.4 QUANTIFYING_GENITIVE:TIME

The QUANTIFYING_GENITIVE:TIME construction is defined as a genitive modifier that specifies the duration of an activity. The formal description DET N_{GEN} N_{INDEF} captures true instances of the construction such as *en stunds tystnad* 'a moment's silence', but also the related scale construction *fem meters djup* 'five meter's depth' (described below), as well as other genitives like *en människas skugga* 'the shadow of a human'.

4.5 QUANTIFYING_GENITIVE:SCALE

The scale construction QUANTIFYING_GENITIVE:SCALE is the sibling of the time construction described above. Here, the genitive modifier specifies the value on a scale expressed by the noun phrase. It shares the formal description DET N_{GEN} N_{INDEF} with QUANTIFYING_GENITIVE:TIME but is semantically restricted to scalable measures like height, depth, age, size and other things that can be quantified. Consequently, the query captures true instances of the scale construction like *tusen meters höjd* 'a thousand meter's height' and *elva månaders hyra* 'eleven month's rent', but also instances of the aforementioned time construction *tre timmars seglats* 'three hour's sailing trip'. Again, other genitive phrases like *en kvinnas fot* 'the foot of a woman' also end up in the search batch.

4.6 BOUNDED_EVENT_*på*

The BOUNDED_EVENT_*på* construction is a time expression that modifies the duration in time of a completed action, expressed using the preposition *på*, corresponding to the similar English construction using *in*. It is a specific and rather restricted instance of a more general pattern for prepositional time adverbials. The construction can only be used with events of bounded aspect, and thereby specifies the time required to complete the event. A related but separate construction is used for negated events, where time adverbials with *på* can be used to describe the duration that has passed since an event took place; this construction is called SPECIFIED_TIME:POLARITY. The structure sketch *på* NP naturally translates to a search query that captures all prepositional phrases with the preposition *på*, and even though the noun slot is strictly restricted to time expressions it is impossible to delimit it from related time constructions without taking the wider context into account. The search hits include true instances of the construction such as *rummet tömdes på några sekunder* 'the room was emptied in a few seconds' as well as false

instances like the negative construction *ingen hade samlat ved på ett år* 'nobody had been collecting firewood for a year'. However, most of the answer set consists of typical PPs like *på en stol* 'on a chair'.

5 Construction retrieval with lexical-semantic reranking

The new benchmark allows us to investigate and compare different systems for retrieving occurrences of constructions in corpora. We now describe the implementation of a retrieval system for finding occurrences of constructions: in particular, we discuss how the ranking function is defined, including the various lexical-semantic similarities the user can choose from, and how the ranking function is trained from a few user-selected seed examples.

The system is built on top of the corpus search service *Korp*, described in Section 4. This is the most comprehensive service of this kind for Swedish, but any similar search tool could be used if building a similar retrieval system for other languages. As when creating the benchmark, the first step of searching for occurrences is to call the underlying corpus search system with a query that describes the surface form of the construction (corresponding to the structure sketch in Figure 1). For instance, if we are looking for occurrences of the QUANTIFYING_GENITIVE:TIME construction (e.g. *an hour's rest*), we use a query corresponding to its structure sketch DET N_{GEN} N_{INDEF}. A number of hits are then returned, out of which some are instances of the construction we are looking for, while others are unrelated. For instance, the structural pattern mentioned above will match any genitive, such as *a dog's life*.

To address this problem, we apply a *reranking* function. The user is asked to provide the system with two additional types of information: (1) a number of positive seed examples of sentences containing true instances of the construction she is looking for and (2) what linguistic properties to consider for particular slots in the search string. For instance, a user could say that the ranking function should consider the distributional similarity function based on the second word in the hit, e.g. the time word in the example above, and then select a number of occurrences such as *an hour's rest, three years' study*. With a carefully designed ranking function and representative seed examples, the system can rank time/activity expressions above other expressions matching that surface pattern.

5.1 Training the reranking function

The reranker is a scoring function $R(x)$ applied to each hit x returned by the corpus search. Learning rankers is widely studied in IR (Liu, 2009); in this work, we assume that each hit x can be analyzed using m different similarity functions σ_j, selected by the user on the fly. Assuming there are labeled examples $x_1, \ldots, x_n$, we write the ranker as

$$R(x) = \sum_{i=1}^{n} \sum_{j=1}^{m} \alpha_{ij} \sigma_j(x, x_i)$$

where α_{ij} is a weight representing the contribution of similarity σ_j applied to the labeled example x_i. If the σ_j are valid kernels, this is the dual form of a linear scoring function, and the α_{ij} can be determined by training a kernelized learner such as the ranking SVM (Joachims, 2002). We prefer to use a simpler learning method that is efficient and that works with just a few examples. For these reasons, we set the weights by computing the *centroid* of the positively labeled instances: that is, by setting all α_{ij} to $1/n$. This method has trivial computation time and allows the use of any similarity function, not just kernels. More complex learners for this scenario, e.g. the one-class SVM (Manevitz and Yousef, 2001), may be considered in future work, and we could also imagine the weights being set manually by the users.

5.2 Similarity functions used in the reranker

The corpus search system takes care of basic surface-oriented features (word forms, morphology, grammatical functions and categories), so the central task of the reranker is to use representations of word meaning to go beyond the simple structural information. We investigate different measures: similarities based on hand-crafted lexicons, and distributional similarity computed from corpora.

5.2.1 Network-based similarity

SALDO (Borin et al., 2013) is a large lexical resource that connects senses of Swedish words into a hierarchical semantic network. To measure similarity between two SALDO entries, we use the measure

by Wu and Palmer (1994), based on proximity in the tree and the depth of the lowest common ancestor. This measure is a number between 1 and 0, where 1 is the score for two identical entries. A complication is that our corpora lacks sense annotation; however, since the first sense dominates overwhelmingly in corpora for most lemmas (Johansson et al., 2016), we use the first sense to compute the similarities.

5.2.2 Frame-based similarity

An alternative lexicon-based similarity function is based on the Swedish FrameNet (Friberg Heppin and Toporowska Gronostaj, 2012). This resource, similar to its English counterpart (Fillmore and Baker, 2009), maps lemmas to one or more *frames*, which for the current purposes can be seen as semantic classes. Intuitively, two words have a similar meaning if they belong to the same frame; for instance, *timme* 'hour' and *minut* 'minute' are related because they both belong to the frame CALENDRIC_UNIT. Again, we have to deal with the lack of word sense annotation in the corpora, so we define the similarity to be 1 if the two words share at least one frame, and 0 otherwise.

5.2.3 Distributional similarity

In a distributional model (Turney and Pantel, 2010), the meaning representation of a word is computed by observing the contexts in which it appears in a corpus. This is represented as a vector, which makes it possible to apply geometric operations – most importantly, to compute a word similarity by using a function such as the cosine. We trained `word2vec` (Mikolov et al., 2013) on a 1-billion mixed corpus, preprocessed by lemmatization and compound splitting. We used the default settings, except the dimensionality which was set to 512. To compute the similarity between two words, we applied the cosine to their lemma vectors.[2] Again, this similarity is at most 1, which happens if the vectors are identical.

6 Experiments

We first investigated the effect of the choice of lexical similarity. Table 2 shows the average precision scores for three different similarities: Wu–Palmer in SALDO, frame-based, and distributional. As a baseline we include a lemma-based similarity corresponding to a simple search with a number of specified lemmas in the variable construction slots (that is, we get exactly what we asked for and nothing else). As seed examples, the rerankers were trained on the first 15 positively labeled instances in the collection.

Construction	lemma	SALDO	frame	distributional
V_*av*_NP	0.69	0.73	0.63	**0.86**
PROPORTION_*i/om*	0.64	0.68	**0.95**	0.74
REFLEXIVE_MOTION	0.59	0.53	**0.61**	0.56
QUANTIFYING_GENITIVE:TIME	0.40	0.48	**0.60**	0.49
QUANTIFYING_GENITIVE:SCALE	0.64	0.63	0.52	**0.68**
BOUNDED_EVENT_*på*	0.43	0.51	0.36	**0.60**

Table 2: Effect of the choice of lexical similarity function.

The result clearly shows that reranking based on a lexical-semantic model can give very strong improvement over the lemma-based baseline. However, it should be noted that there is considerable variation in the result. For instance, for PROPORTION_*i/om* and QUANTIFYING_GENITIVE:TIME, the frame-based reranker outperforms the others significantly. As we will see in the detailed analysis, a likely explanation is that the slot fillers in these constructions have well-defined semantic restrictions that correspond cleanly to FrameNet frames, in particular time-related words (frames such as Calendric_unit and Measure_duration). In the case of V_*av*_NP, QUANTIFYING_GENITIVE:SCALE and BOUNDED_EVENT_på it is instead the distributional model that works best. The distributional model seems to work best when the slot fillers are not restricted to a narrowly defined semantic class (corresponding to a FrameNet frame), but instead belong to a broader semantic domain, like emotional states for V_*av*_NP.

The network-based lexicon similarity does better than the baseline in most cases, but never outperforms the other similarities. It is difficult to speculate about why, but we can at least conclude that FrameNet frames are better at capturing narrowly defined semantic classes and distributional models do better at generalizing beyond taxonomic similarity scores.

[2]We pick the first lemma if lemmatization is ambiguous.

6.1 Qualitative evaluation

We conducted a qualitative evaluation of the system by analyzing each construction search separately. The reranked instances were inspected with a particular focus on false positives, which are telling indicators of the shortcomings of our approach. We will also inspect the lower regions of the reranked list and say something about false negatives – true occurrences that end up near the bottom of the reranked search list. This qualitative evaluation is telling, since it may also exemplify how a constructicographer would describe delimiting characteristics of specific constructions.

6.1.1 V_*av*_NP

We expected the V_*av*_NP construction (e.g. *rodna av ilska* 'blush with anger') to be a hard nut to crack because of its great productivity and high lexical variation, but the distributional similarity performs beyond expectations. In particular, this model succeeds in generalizing beyond seen instances and gives high ranking scores to a wide array of new and creative occurrences of the V_*av*_NP construction.

Although there are no distinct semantic restrictions on the variable slots of the V_*av*_NP constructions, the state or event caused by the noun is typically physical or emotional. Representative verbs include *darra* 'shiver', *lida* 'suffer', *dö* 'die', *gråta* 'cry', *rodna* 'blush', *skälva* 'quiver', *kvida* 'whimper', *flåsa* 'pant' and *skaka* 'shake'. The noun slot is typically occupied by event nouns such as *raseri* 'rage', *smärta* 'pain', *ansträngning* 'exertion', *ängslan* 'anxiety', *migrän* 'migraine', *förälskelse* 'infatuation' and *upphetsning* 'excitement'. The distributional model excels in finding commonalities between these words, while the frame-based similarity is too restricted. The slot fillers display so much lexical variation that the frame-semantic lexicon manages to capture just a fraction of them.

6.1.2 PROPORTION_*i/om*

As mentioned above, it is hardly surprising that the search system is good at detecting the PROPORTION_*i/om* construction or that the best performing similarity feature in this case is frame-based. The rate construction (e.g. *tre gånger om dagen* 'three times a day') is strictly restricted to temporal relations, so the denominator will always be a time-related word belonging to a few well-defined frames.

6.1.3 REFLEXIVE_MOTION

The evaluation results for REFLEXIVE_MOTION (e.g. *pressa sig ut* 'press oneself out') are unimpressive. None of the rankers are particularly good at detecting this construction: the frame-based reranker just barely beats the baseline. When inspecting the results, it seems that there is too much diversity in this set, with creative metaphors frequently used, for the lexical models to be very effective.

On a lighter note, while this construction is diverse, we observed that some subsets of the occurrences can be handled nicely: if we are particularly interested in occurrences of the REFLEXIVE_MOTION construction where the verb has a more specific manner meaning, we can handpick seed examples of that kind. By doing so, sentences like (1) rise to the top of the answer set. This means that even if the overall score is low, the user can still use the search system productively to find a certain important subclass.

(1) Jag tror att han skulle ha [sovit sig igenom] hela eländet.
I think.PRS that he would.AUX have.AUX sleep.PRF REFL through hole misery.DEF
'I think that he would have slept through the whole ordeal.'

6.1.4 QUANTIFYING_GENITIVE:TIME

For the time construction QUANTIFYING_GENITIVE:TIME (e.g. *två timmars vila* 'two hours' rest'), the frame-based reranker clearly outperforms the other similarity functions in this case since the construction is restricted to time expressions, which we have already seen fit neatly into a few particular frames. Since time expressions are such a strong feature for detecting this construction, it comes as no surprise that false positives near the top of the ranked list contain time words as well. Example (2) is a false hit that is in fact an instance of the superficially similar QUANTIFYING_GENITIVE:SCALE construction.

(2) Det var [femton år-s åldersskillnad] mellan oss.
It is.PST fifteen year.PL-GEN age difference.INDEF between us.
'It was fifteen years of age difference between us.'

6.1.5 QUANTIFYING_GENITIVE:SCALE

The lexical similarities give a smaller improvement for the QUANTIFYING_GENITIVE:SCALE than for the related time construction. In particular, while the frame-based feature worked best for the time construction, it receives the lowest average precision in this case. The scalable measures that turn up here are diverse and do not seem to correspond neatly with FrameNet frames.

The distributional similarity does best at generalizing beyond seen examples, and quite impressively hands out high ranking scores to instances as diverse as *50 procents chans* '50 percent chance', *två veckors skäggstubb* 'two weeks' stubble' and *tre spalters bredd* 'three columns' width'. The precision starts to drop when false hits from the QUANTIFYING_GENITIVE:TIME construction and other constructions start to appear.

6.1.6 BOUNDED_EVENT_*på*

Even though this construction (e.g. *på två timmar* 'for two hours') is strictly restricted to time related words, the frame-based reranker performs worst in the evaluation. The explanation is quite straightforward; just spotting the time word is not enough to disambiguate BOUNDED_EVENT_*på* from related time constructions: most of the information that could be used to discriminate can be found outside of the hit. Recall that BOUNDED_EVENT_*på* only occurs with events of bounded lexical aspect.

Since we had little hope that the reranker would be effective for such a contextually dependent construction as BOUNDED_EVENT_*på*, it is a pleasant surprise to see that the distributional model is doing significantly better than the baseline. A possible explanation is that there are lexical preferences at play, beyond the more general time restriction. Short time spans like *på ett ögonblick* 'in an instant' seem more likely to be instances of this construction than cases such as *på en söndag* 'on a Sunday'. Among the top-ranked false positives, we find quite a few hits with the lexicalized phrase *på en gång* 'at once'.

Introducing more contextual information seems necessary for dealing successfully with a construction like this one. However, in this particular case it is not entirely clear how to determine the lexical aspect of the event in an automated fashion. A more straightforward feature to introduce would be negations that can be relatively easily spotted by using a list of negative polarity items.

7 Discussion

We considered the problem of searching for occurrences of a grammatical construction as a retrieval problem, and we created a new benchmark collection with annotated examples for six different constructions defined by the Swedish constructicon. This new resource allows us to investigate the effectiveness of different retrieval models. As a proof of concept, we presented a simple interactive architecture for searching for constructions, where a user provides a number of positive examples (occurrences of the construction) and tailors a ranking function based on a user-defined combination of features, and our benchmark enabled us to carry out detailed quantitative and qualitative investigations of the effect of different models of lexical representation on the retrieval performance of this system. All our experiments were carried out using Swedish, because of the availability of the Swedish Constructicon used to select the constructions in the benchmark, but our approach is general and could be ported to other languages, including English: similar corpus search tools and lexical resources are readily available.

As expected, grammatical constructions are diverse and the ranking function must be tailored for each construction. The most consistent result is that lexical-semantic models based on a constructions' slot fillers improve the reranker, but exactly which of them – lexicon-based or distributional – is most effective depends on the construction. It is important to note that the accuracy of the reranker depends on the construction definition and to which extent such semantic restrictions are in fact at play. The system should therefore be useful in the work of characterizing and defining constructions.

As we have already pointed out in the text, there are several ways to extend this work: more complex learning algorithms for the rankers could be considered, or we could make use of information beyond the slot fillers of the construction. Also, we have now studied the retrieval problem in isolation, but since our main motivation is that the system should be used in the practical work of linguists working with construction grammar, it would be interesting to investigate the usability and interaction aspect as well.

Acknowledgements

We are grateful for the availability of open lexicons, corpora, and technical infrastructures provided by *Språkbanken*, the Swedish Language Bank. The constructicon resource used in this research was developed during the project *A Swedish Constructicon*, which was funded by the Bank of Sweden Tercentenary Foundation (grant P12–0076:1). RJ was supported by the Swedish Research Council under grant 2013–4944, *Distributional methods to represent the meaning of frames and constructions*.

Automatic Extraction of Learner Errors in ESL Sentences Using Linguistically Enhanced Alignments

Mariano Felice **Christopher Bryant** **Ted Briscoe**

Abstract

We propose a new method of automatically extracting learner errors from parallel English as a Second Language (ESL) sentences in an effort to regularise annotation formats and reduce inconsistencies. Specifically, given an original and corrected sentence, our method first uses a linguistically enhanced alignment algorithm to determine the most likely mappings between tokens, and secondly employs a rule-based function to decide which alignments should be merged. Our method beats all previous approaches on the tested datasets, achieving state-of-the-art results for automatic error extraction.

1 Introduction

Within the field of Machine Translation (MT), one of the first steps of data processing is to align a source sentence with a target sentence. This is necessary because we want to determine which tokens and phrases in the source language map to which equivalent tokens or phrases in the target language. As this would be extremely time consuming to do manually, several tools, such as GIZA++ (Och and Ney, 2003), have been made available to do this automatically.

Within the related field of Grammatical Error Correction (GEC), we similarly want to align a source sentence with a target sentence to map errors to corrections (sometimes referred to as 'correction detection'; see example in Table 1). However, unlike in MT, the source and target sentences in GEC are in the *same* language and so a majority of tokens match. This means alignment is comparatively more straightforward and so it is more feasible to annotate texts manually, rather than automatically. In fact two of the largest publicly available GEC datasets, the First Certificate in English (FCE) corpus (Yannakoudakis et al., 2011) and the National University of Singapore Corpus of Learner English (NUCLE) (Dahlmeier and Ng, 2012), were aligned and annotated manually.

We	took	a	**guide**	tour	**on**		**center**	**city**	.
We	took	a	**guided**	tour	**of**	**the**	**city**	**center**	.

Table 1: A sample alignment between an original uncorrected sentence and its corrected version.

Nevertheless, automatic alignment of GEC data still has several advantages over manual alignment, not least because the latter is slow, laborious work. This is especially important for datasets that do not always contain explicit alignments, such as Lang-8 (Mizumoto et al., 2011), or GEC system output that needs to be aligned to the original uncorrected sentence.

Another important benefit of an automatic alignment is that it tends to be more consistent than a human alignment. For example, within both the FCE and NUCLE, strings such as *has eating* are inconsistently corrected as [*has* → *was*] or [*has eating* → *was eating*] even though they fundamentally equate to the same thing. In fact, the latter seems less desirable given the token *eating* does not actually change. A similar case is [*has eating* → *was eaten*], which is inconsistently realised either as one edit, as above,

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 825–835, Osaka, Japan, December 11-17 2016.

or two edits: [*has* → *was*] and [*eating* → *eaten*]. Ultimately, it seems desirable to regularise such edits and hence reduce ambiguity in the data. If all datasets are treated in the same way, this would also make them fully compatible with each other.

Finally, automatic alignment can also simplify the annotation of new data. For instance, Sakaguchi et al. (2016) recently claimed that forcing annotators to annotate grammatical errors within the confines of an error scheme often led to unnatural sounding sentences and that unconstrained editing correlated more with human judgements. As such, if we no longer ask humans to explicitly mark edit boundaries in new data, we would need to extract this information automatically. This is particularly useful for English as a Second Language (ESL) teaching, where teachers could edit text freely and then let a computer delimit the edits.

2 Background

There is very little previous work on automatic alignment of sentences for GEC. The first attempt was made by Swanson and Yamangil (2012), who built a system to align sentences and then classify the non-match tokens type for the purposes of ESL feedback. In particular, they used the well-known Levenshtein distance to align the sentences and then classified any non-matches according to the FCE error scheme (Nicholls, 2003) using a maximum entropy classifier.

One complication noted by Swanson and Yamangil is that edits do not necessarily consist of just a single token. For instance, reordering errors (e.g. [*only can* → *can only*]) or errors involving phrasal verbs (e.g. [*look at* → *watch*]) necessarily consist of more than one token on at least one side of the edit. The Levenshtein distance, however, only aligns individual tokens and so some alignments must be merged in order to obtain multi-token edits. Swanson and Yamangil hence experimented with some basic merging strategies and found that simply merging all adjacent non-match alignments most closely approximated human alignments.

Building on this foundation, Xue and Hwa (2014) carried out an analysis of Swanson and Yamangil's work and found that approximately 70% of all errors in their error type classifier were the result of bad alignments (merged or otherwise). In order to improve on the simple *all-merge* alignment strategy, they hence trained a binary maximum entropy classifier to determine whether edits should be merged or not. They tested this merging classifier on several datasets, including NUCLE and the FCE, and reported improvements of between 5-10% for both alignment and classification compared to Swanson and Yamangil.

Despite these improvements, however, there is still a considerable margin between automatic and human edit annotation. In addition, both approaches require training on existing annotations, which vary across datasets and can often be inconsistent. Ultimately, training on different datasets leads to different results and so undermines any effort towards data standardisation.

3 Automatic Alignment

A high-quality alignment between an original and corrected sentence is crucial for deriving meaningful edits. Unfortunately, however, the most common method of aligning sentences is to use the Levenshtein distance, which only optimises in terms of insertions, deletions and substitutions. This means that, while optimal in terms of edit operation, the alignments do not take linguistic information into account and are hence not optimal in terms of human intuition (see Table 2 (a)). Human alignments, on the other hand, do make use of linguistic information, so we propose automatic alignments should do the same.

3.1 Damerau-Levenshtein

First, however, as noted by Xue and Hwa (2014), another limitation of Levenshtein is that it is unable to handle word order errors. For example, [*only can* → *can only*] is realised as [*only* → ∅], [*can* → *can*] and [∅ → *only*]; in other words, reorderings are treated as deletions followed by insertions of identical tokens. Since we also need to preserve word order errors in the data, we argue that the Damerau-Levenshtein distance is better suited for the task than standard Levenshtein because it allows for token transpositions.

```
function DL_distance_extended(a, b):
  declare d[0..length(a), 0..length(b)]
  for i := 0 to length(a) inclusive do
    d[i, 0] := i
  for j := 0 to length(b) inclusive do
    d[0, j] := j

  for i := 1 to length(a) inclusive do
    for j := 1 to length(b) inclusive do
      if a[i] = b[j] then
        d[i, j] := 0
      else
        d[i, j] := min(d[i-1, j  ] + del_cost(a[i]),
                       d[i  , j-1] + ins_cost(b[j]),
                       d[i-1, j-1] + sub_cost(a[i], b[j]))

      // Damerau-Levenshtein extension for multi-token transpositions
      k = 1
      while i > 1 and j > 1 and (i - k) >= 1 and (j - k) >= 1 and
            d[i-k, j-k] - d[i-k-1, j-k-1] > 0 do
        if sorted(lowercase(a[i-k:i+1])) = sorted(lowercase(b[j-k:j+1])) then
          d[i, j] := min(d[i, j], d[i-k, j-k] + trans_cost(a[i-k:i+1], b[j-k:j+1])
          break
        k += 1

  return d[length(a), length(b)]
```

Listing 1: Damerau-Levenshtein distance allowing for transpositions of arbitrary length.

As the majority of word order errors in NUCLE and FCE data tend to only involve two tokens, this implies that the standard Damerau-Levenshtein distance, which is likewise only able to handle two-token transpositions, is generally sufficient for our purposes. Nevertheless, while it might seem acceptable to ignore the longer word order errors, this ultimately means they will be broken up into smaller and less meaningful edits which will increase the overall number of false positives and false negatives in the alignment.

To overcome this problem, we extend the Damerau-Levenshtein distance to allow for transpositions of arbitrary length, as shown in Listing 1. This is achieved by traversing a diagonal back from the current cell in the cost matrix and looking for a source sequence that would match the target sequence in any order. The cost of a transposition of length n is defined as $n - 1$, which is compatible with the original definition.

3.2 Linguistically Motivated Alignment

In an effort to incorporate linguistic information into the alignment, we replaced the substitution cost in Damerau-Levenshtein with the function shown in Listing 2. In this function, we set the cost to 0 if the original and corrected tokens differ only in case (e.g. [*the* → *The*]), otherwise, the substitution cost is the sum of sub-costs for lemma, part of speech and character differences. Each of these sub-costs is defined as follows:

lemma cost: 0 if tokens share the same lemma or derivationally related form (e.g. 'met' and 'meeting'), otherwise 0.499.

part-of-speech cost: 0 if tokens share the same part of speech, otherwise 0.25 if both tokens are content words (adjectives, adverbs, nouns or verbs) and 0.5 in all other cases.

character cost: the proportion of character mismatches between 0 and 1, computed as the character-level Damerau-Levenshtein distance between the tokens divided by the length of their alignment.

To increase the likelihood of aligning derivationally related forms, we lemmatise each token as if it were an adjective, adverb, noun and verb. We do this because if we only lemmatise for a single part of speech, then we might overlook certain derivationally related words. For example, while the lemma of

```
function substitution(a, b):
  if lowercase(a) = lowercase(b) then
    return 0
  else
    return lemma_cost(a, b) + pos_cost(a, b) + char_cost(a, b)
```

Listing 2: Our linguistically motivated token substitution function.

	This	widespread	publicity	only	benefits	their	companies			.
(b)	This	wide	spread	propaganda	benefits	only	to	the	companys	.
	This	widespread		publicity	only	benefits		their	companies	.

Table 2: Differences between (a) standard Levenshtein and (b) linguistically-enriched Damerau-Levenshtein alignment.

the verb 'met' is 'meet', the lemma of the noun 'meeting' is 'meeting', which suggests these words are not related. By also lemmatising 'meeting' as a verb however, we find that the two tokens do share a common lemma, 'meet', which instead correctly suggests they are related and should align. Ultimately, we consider two tokens to be derivationally related if their respective sets of lemmas intersect.

The sub-costs are also set in such a way that the overall substitution function always yields values in the $[0, 2)$ range. Keeping the cost asymptotic to 2 is important to enforce a preference for substitutions over insertions and deletions (both set to 1); this is why we use a lemma cost of 0.499 instead of 0.5. We tried different combinations of these costs, provided they met this condition, but did not find significant differences in the results.

By incorporating all this additional linguistic information into the cost, we improve the likelihood that tokens with a similar etymology, spelling or function will align. This is better than the simple surface matching used by the standard token-level Levenshtein distance and hence, we argue, results in more natural, human-like alignments (see Table 2 (b)). The final alignment is retrieved by collecting the operations that make up the optimal path in the cost matrix. Given that the cost is now dependent upon a variable function, it is often the case that there is just a single optimal alignment.

3.3 Data

We evaluated our improved alignment algorithm using the public FCE (Yannakoudakis et al., 2011), NUCLE corpus (Dahlmeier et al., 2013), and CoNLL test sets (Ng et al., 2013; Ng et al., 2014). While the CoNLL data is available in a pretokenised format, the FCE data is not, and so to keep things comparable, we only worked with the untokenized CoNLL data.

It should be noted that processing each of these datasets in a standard way is not at all straightforward. For example, unlike the CoNLL data, the FCE contains nested edits; e.g. [*entery* → *entry* → *entrance*] indicates a spelling error followed by a replacement noun error. Similarly, the NUCLE corpus can be quite noisy and it is not uncommon for annotators to select entire paragraphs or even essays as edits with comments such as "Rewrite in the 3rd person", which, in the context of edit extraction, should definitely be ignored.

In addition to these, a more general problem concerns converting character level edit spans into token level edit spans; there is no guarantee that a human-annotated character span will map exactly to a token span, which has consequences for token-based processing and evaluation. Similarly, some edits change sentence boundaries, which subsequently makes aligning original sentences with corrected sentences a lot more complicated, especially when there are multiple annotators. Ultimately, we refer the reader to Bryant and Felice (2016) for more information about the challenges involved in processing these datasets and for details about how we overcame them in our implementation.

Having preprocessed the data, we used spaCy[1] v0.101.0 to tokenize (words and sentences), part of

[1]https://spacy.io/

Dataset	Sents	Edits
CoNLL 2013	1,375	3,415
CoNLL 2014 (0)	1,314	2,397
CoNLL 2014 (1)	1,319	3,331
NUCLE	55,963	43,832
FCE-test	2,715	4,776
FCE-train	31,022	48,026

Table 3: Basic statistics of the datasets we use. CoNLL 2014 was annotated by two annotators who changed different sentence boundaries.

Alignment	*Lev*	*Lev*	*DL*
Reference	*Gold*	*Gold-Min*	*Gold-Min*
CoNLL 2013	49.17	62.29	70.51
CoNLL 2014 (0)	51.09	60.40	66.81
CoNLL 2014 (1)	48.41	62.98	69.16
FCE-test	58.52	63.30	72.45

Table 4: Table showing how minimised edits in the reference (Gold-Min) and our linguistically enriched Damerau-Levenshtein algorithm (DL) perform against standard Levenshtein (Lev) and unmodified references (Gold). All scores are F_1.

speech (POS) tag and lemmatise each sentence. The basic statistics of each processed dataset are shown in Table 3.

3.4 Alignment Experiments

To establish a baseline, we simply compared a standard Levenshtein alignment against the human alignments of the CoNLL 2013, CoNLL 2014 (each annotator individually) and FCE test sets (Table 4). The results show that Levenshtein alone does not perform particularly well at this task and is only able to achieve F_1 scores of about 50%.

In addition to improving alignment quality, another aim of our work is to attempt to standardise edit annotation. As mentioned previously, human annotations sometimes include tokens that do not change; e.g. [*has eating* → *was eating*]. Automatic alignments will never match these human edits, however, because any token that is common to both sides will be considered a match and hence not part of an edit. This is undesirable, so we also minimised the gold human reference edits by recursively removing tokens that were common to both sides of the edit from the right and left hand sides. This also removes edits that annotators detected, but were unable to correct. Results showing the effect of this minimisation, as well as of comparing Levenshtein against our linguistically enhanced Damerau-Levenshtein approach, are also shown in Table 4.

The first thing to notice about these results is that the scores for the minimised gold reference are typically substantially higher than for the unmodified gold reference. In the case of CoNLL 2014 (1), using the minimised gold reference even shows an improvement of almost 15% F_1. While the increase in score is less pronounced for FCE-test, at just under 5% F_1, this nevertheless demonstrates the high degree of variability in the way GEC data is annotated and that it is highly desirable to standardise annotations. In light of this result, we only use minimised edit spans in all subsequent experiments.

Comparing Levenshtein against our own approach, we again see a significant improvement, with scores greater than 70% F_1 on some datasets. This is significant, because these results are in spite of the fact that we fail to match all multi-token edits given that we do not yet merge any alignments.

4 Alignment Merging

The output of the automatic alignment is a list of individual token-level operations that map the original sentence to the corrected sentence in terms of insertions, deletions, substitutions and transpositions. An example of this is shown in Table 5. Each of these operations involves one token at most in either sentence, except in the case of transpositions, which involve 2 or more tokens in both sentences.

In most cases, these individual operations already represent a complete error: [*propaganda* → *publicity*] is a word choice error, [*benefits only* → *only benefits*] is a word order error and [*companys* → *companies*] is a noun inflection error. Other errors, however, may involve more than one single operation. For example, the correction [*wide spread* → *widespread*] in Table 5 involves two individual operations: a substitution ([*wide* → *widespread*]) and a deletion ([*spread* → ∅]).

The statistics in Table 6 show that most errors in NUCLE and FCE-train involve only a single token

M	S	D	S	T		D	S	S	M
This	wide	spread	propaganda	benefits	only	to	the	companys	.
This	widespread		publicity	only	benefits		their	companies	.

Table 5: Individual operations obtained from automatic alignment: (M)atch, (I)nsertion, (D)eletion, (S)ubstitution and (T)ransposition.

Orig:Corr Token Edit Size	**NUCLE**		**FCE-train**	
	Cum. Freq.	**%**	**Cum. Freq.**	**%**
1:1	17,580	41.23%	23,833	51.51%
0:1	24,823	58.22%	32,875	71.06%
1:0	30,599	71.77%	37,743	81.58%
0–2:0–2	36,868	86.47%	43,593	94.22%
0–3+:0–3+	42,636	100.00%	46,265	100.00%

Table 6: Distribution of edits in minimised gold NUCLE and FCE-train according to the number of tokens on either side of the edit; e.g. there are 17,580 instances of 1:1 token substitutions in NUCLE. Total edits are lower than in Table 3 because edit minimisation causes some edits to disappear.

on either side of an edit (i.e. 0:1, 1:0 or 1:1), and so a simple *all-split* strategy that merges nothing is likely to cover most of these edits. In fact this explains why the results in Table 4 are so high; just using Damerau-Levenshtein is equivalent to the *all-split* setting. Nevertheless, multi-token edits still form an important class of learner errors and so we should attempt to handle them.

4.1 Merging Rules

In order to improve performance and capture multi-token edits, we hence implemented a recursive rule-based merging function. First, we analysed the relationship between human annotations and how they mapped to alignment operations in NUCLE and FCE-train. For example, we found that the most common multi-token errors involved phrasal verbs, such as [*look at* → *watch*]; possessive nouns, such as [*friends* → *friend 's*]; or orthographic changes, such as [*wide spread* → *widespread*]. Second, we wrote rules to merge or separate alignments based on these observed patterns.

The complete list of rules and their priority is as follows:

1. Any match operation (M) breaks a sequence into sub-sequences that are processed individually, e.g. MDDSMMTMSI is split into DDS, T and SI.
2. Any operation that involves punctuation and is followed by a token that changes case is merged, e.g. [*,* → *.*] + [*we* → *We*] becomes [*, we* → *. We*].
3. Transpositions are returned as individual edits, e.g. [*only can* → *can only*].
4. Any operation that involves a possessive suffix is merged with any previous operations, e.g. [*freinds* → *friend*] + [∅ → *'s*] becomes [*freinds* → *friend 's*].
5. Operations that add or remove whitespace between tokens are merged, even if they have unmatched apostrophes, e.g. [*sub* → *subway*] + [*way* → ∅] = [*sub way* → *subway*].
6. Substitutions between very similar tokens ($> 70\%$ character matches) are returned as individual edits, e.g. [*writting* → *writing*], unless they have the same POS as the previous token, e.g. [*eated* → *have eaten*]; the verb phrase would be split without this exception.
7. Substitutions preceded by another substitution are returned as individual edits.
8. Any combination of operations that involves at least one content word is merged, e.g. [*On* → *In*] + [*the* → ∅] + [*other* → ∅] + [*hand* → *addition*] = [*On the other hand* → *In addition*].
9. Consecutive operations that involve tokens with the same part of speech are merged, e.g. [*because* → ∅] + [*of* → *for*] = [*because of* → *for*].
10. Any determiner at the end of a sequence is returned as an individual edit.

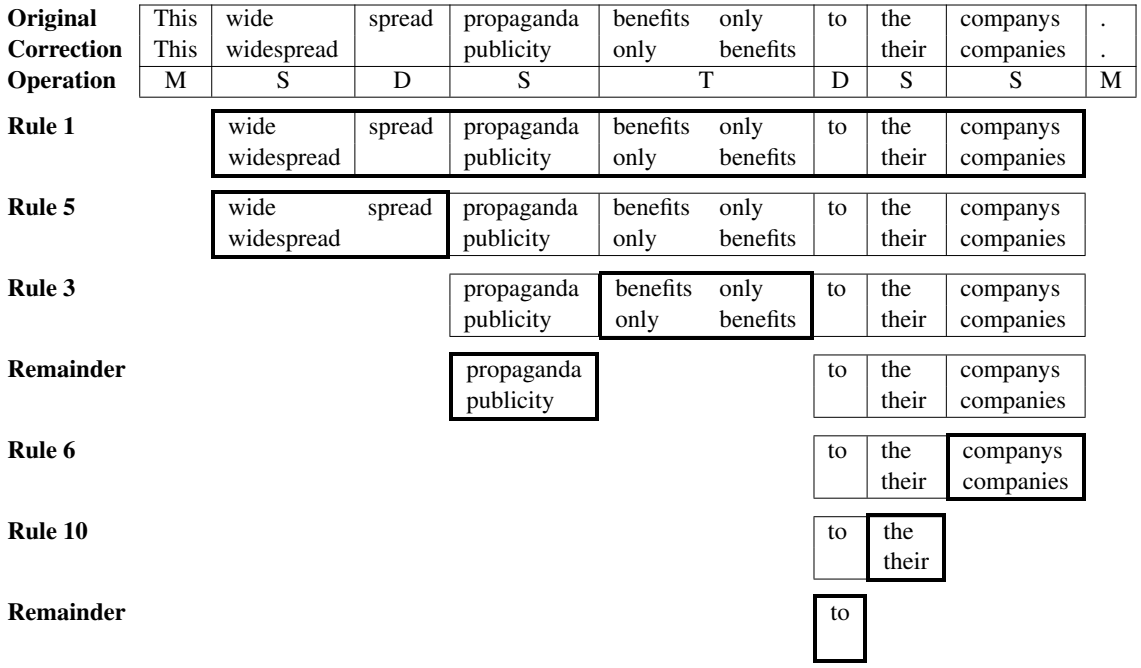

Figure 1: A step-by-step edit extraction example.

Each sequence of alignment operations between two sentences (e.g. MSDSTDSSM) is processed recursively using the above rules in a top-down fashion. Rules are applied in order, with priority relative to their position in the list. Every time an edit is returned by one of the rules, we process the remaining sub-sequences individually until they are exhausted or no more rules can be applied (see Figure 1). It should be noted that rules that iteratively grow the merge range of the alignment (e.g. #8) can be overridden by others with higher priority (e.g. #4), causing the remaining operations in the truncated subsequence to be reprocessed from scratch.

4.2 Merging Experiments

We evaluated our rule-based merging method on the CoNLL 2013, CoNLL 2014 (each annotator individually) and FCE test sets, and contrasted it against the following merging strategies:

all-split: All consecutive non-matches are split, e.g. DDSI → D, D, S, I.

all-merge: All consecutive non-matches are merged, e.g. DDSI → DDSI.

all-equal: All consecutive non-matches of the same operation are merged, e.g. DDSI → DD, S, I.

All of these methods were applied to the output of our enhanced Damerau-Levenshtein alignment described in the previous section. In addition to evaluating edit extraction against a minimised reference, we also evaluate error type classification on the merged output to replicate results for an end-to-end classification system. For this purpose, we retrained Xue and Hwa's publicly available implementation of their MaxEnt error type classifier[2] separately on NUCLE and FCE-train. This classifier was based on work by Swanson and Yamangil and is used in all classification experiments.

Results for both tasks are reported in Table 7 and reveal that our method achieves the best performance on all tasks and datasets. For edit extraction (i.e. merging), improvements in F_1 range between 4% and 12% over the second-best method (*all-merge*). We also observe that while *all-split* tends to have the highest number of TPs and lowest number of FNs, it also has the highest number of FPs, which shows how ignoring multi-token edits affects performance. In contrast, the *all-merge* strategy has the lowest number of FPs, but at the cost of also having the lowest number of TPs and highest number of FNs. This shows that each strategy has different strengths which our rule-based approach attempts to exploit.

Table 7: Performance of different merging methods on the edit extraction and full error classification task. TP: true positives, FP: false positives, FN: false negatives, P: precision, R: recall.

Table 7 also reports performance on error classification, given edit extraction, revealing how each merging strategy affects automatic error type prediction. Results are consistent with edit extraction, although they are (expectedly) lower by an average 21.1% F_1. Improvements in F_1 between our method and the second-best range between 3.9% and 9.0%. While CoNLL 2014 (1) achieved the best result for edit extraction, FCE-test achieved the best result for error classification. This might be because the two datasets are annotated according to different error classification frameworks and the FCE annotation is more consistent than NUCLE annotations.

5 Discussion

It is worth stating that many of our reported results are actually an underestimate of true performance. This is because, despite gold reference minimisation, there is a high degree of variability in the way humans annotate this sort of data. For instance, as shown by Bryant and Ng (2015), human annotators often have very different perceptions of grammaticality and it is linguistically plausible that, for example, [*has eaten* → *was eating*] is annotated either as one edit (as above) or two edits ([*has* → *was*] + [*eaten* → *eating*]) by different, or even the same, annotators. This means the *all-split* merging strategy will never match the former while the *all-merge* merging strategy will never match the latter, even though the annotations fundamentally equate to the same thing. Due to this inconsistency, system performance will be underestimated regardless of which merge strategy you choose.

In contrast, we consider merge consistency a strength of our rule-based approach. Even if our alignment does not agree with the gold standard in some cases, at least the decision to merge or split is consistent across all similar cases. Our approach could hence be used to standardise ambiguous annotations where splits or merges are equally plausible.

Another strength of a rule-based approach is that it is easier to diagnose which rules are responsible for producing a given output sequence. This is in contrast with machine learning techniques, which additionally require feature engineering and retraining, where it is much more difficult to determine why certain edits were merged in a certain way. Nevertheless, considering only about 30% of all edits (at most) in any dataset require merging anyway, a rule-based approach seemed a more cost-effective solution.

We also investigated how our approach compared against previous approaches in terms of single-token edits and multi-token edits (Table 8). To produce comparable results for Xue and Hwa (X&H), we retrained their publicly available implementation of their MaxEnt merging classifier separately on NUCLE and FCE-train. In general, while our method tends to score slightly lower precision than the

Table 8: Performance of our proposal vs. previous methods in terms of single and multi-token edits. S&Y used Levenshtein with an *all-merge* strategy while X&H used Levenshtein with a MaxEnt merging classifier.

others in the single-token setting, it makes up for this with a much higher recall. In contrast, our method achieves a higher precision in the multi-token setting, but at the cost of a lower recall. Ultimately, however, our method increases overall performance in almost all cases, the exception being multi-token edits in CoNLL 2014 (0), which is known to be an inconsistent dataset. These results hence confirm that our rule-based merging strategy is superior to previous approaches.

In addition to a quantitative analysis, we also carried out an informal qualitative analysis of the errors made by our system. One source of errors involves tokens that are affected by more than one mistake; e.g. [*wide spraed* → *widespread*]. While our system includes a rule to merge adjacent alignments where the only difference is white space, this rule does not activate in the above case since one of the tokens also contains a misspelling. This consequently means the alignments are not merged and do not match the gold standard; such cases are difficult to handle.

Another issue is that reference minimisation is unable to deal with edits where identical tokens occur in the middle of an edit; e.g. [*can easily been* → *could easily be*]. As an automatic alignment will always consider *easily* a matched token, the remaining non-matches will become isolated and hence never merged. In this case, however, we would argue that our automatic alignment is more informative than the human alignment which needlessly includes a redundant token in the edit.

Finally, we provide a comparison between our method and the previous approaches by Swanson and Yamangil (S&Y) and Xue and Hwa (X&H) (Table 9). Our method achieves state-of-the-art performance on all tasks and datasets, with an average improvement over X&H of 6.0% F_1 for edit extraction and 4.1% F_1 when adding error classification.

6 Conclusion

We have presented a new method for extracting edits from a parallel original and corrected sentence pair based on a linguistically enhanced token alignment and rule-based merging component. Results on a number of GEC test sets show that our method outperforms all previous work on edit extraction and can also boost error classification performance.

Since we only use a few hand-coded rules, we do away with the complexity of machine learning solutions and are hence also able to annotate data much more consistently. This is particularly useful for standardising GEC datasets, which are often annotated using different guidelines.

Abstract

Linguistic typology provides features that have a potential of uncovering deep phylogenetic relations among the world's languages. One of the key challenges in using typological features for phylogenetic inference is that horizontal (spatial) transmission obscures vertical (phylogenetic) signals. In this paper, we characterize typological features with respect to the relative strength of vertical and horizontal transmission. To do this, we first construct (1) a spatial neighbor graph of languages and (2) a phylogenetic neighbor graph by collapsing known language families. We then develop an autologistic model that predicts a feature's distribution from these two graphs. In the experiments, we managed to separate vertically and/or horizontally stable features from unstable ones, and the results are largely consistent with previous findings.

1 Introduction

Centuries of research in historical linguistics have identified groups of languages deriving from single common ancestors. Each of these groups, called a language family, is organized as a tree that reflects its evolutionary history. Such language families include Indo-European, Austronesian and Bantu languages.

Despite the huge success, historical linguistics fails to link some languages with others, and hence they are called language isolates. For example, Basque, Burushaski and Japanese have no established relatives. Although there are several attempts to uncover deep phylogenetic relations, in which the results are often represented as *macrofamilies*, they remain controversial (Dolgopolsky, 1998; Greenberg, 2000).

We argue that the limitation of the mainstream approach is that it relies on lexical traits. Language families are established by demonstrating that its member languages share *cognates*, or words that have a common etymological origin.[1] Lexical data are also the main target of modern statistical methods that are typically used to date the common ancestor (Swadesh, 1971; Gray and Atkinson, 2003). Language isolates are called so exactly because they lack reliable cognates.

For this reason, we follow a different line to research that makes use of typological data for phylogenetic inference (Tsunoda et al., 1995; Dunn et al., 2005; Teh et al., 2008; Longobardi and Guardiano, 2009; Murawaki, 2015). Linguistic typology is a cross-linguistic study that classifies the world's languages according to structural properties such as basic word order (SVO, SOV, etc.) and the presence or absence of tone. On the one hand, typological features, by definition, allow us to compare an arbitrary pair of languages including language isolates. On the other hand, they pose several new challenges to us. While the sharing of cognates is a direct indicator of shared ancestry, the sharing of the same basic word order SOV, for example, is only a weak signal because it occurred multiple times in multiple places. We believe that computer-intensive statistical methods can help taming the inherent uncertainty.

In this paper, we give a step forward toward typology-based phylogenetic inference. We specifically tackle the problem that horizontal (spatial) transmission obscures vertical (phylogenetic) signals. Like

[1] In historical linguistics, cognates are distinguished from loanwords. We broadly refer to both the traditional *comparative method* and modern statistical methods as lexicon-based approaches because they require cognate identification. Note that historical linguists often use regular sound changes, in addition to cognates themselves, as features to determine the relative order of multiple branching events (Pellard, 2009).

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 836–846, Osaka, Japan, December 11-17 2016.

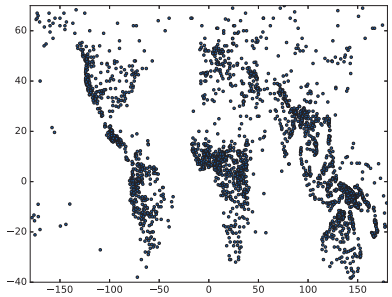

Figure 1: Map of languages in WALS.

loanwords, typological features can be borrowed from one language to another. In fact, non-tree-like evolution has been one of the central topics in linguistic typology (Trubetzkoy, 1928). Lexicon-based approaches, especially statistical ones, often address this problem by narrowing the scope to *basic vocabulary,* or a list of basic concepts. Words on the list are assumed to be resistant to borrowing (Swadesh, 1971), and some are even claimed to be extremely stable (Pagel et al., 2013). By contrast, typological features, in their original forms, are a mosaic with varying degrees of resistibility. We need to start with quantitatively characterizing each typological feature in this respect.

We present a probabilistic model that directly contrasts vertical and horizontal transmission of typological features. We begin by noting that anthropologists have worked on similar problems. From this field, we borrow a graph-based model (Towner et al., 2012) and extend it to model typological features. In this model, languages of the world are mapped to two neighbor graphs. One encodes vertical transmission and the other represents horizontal transmission. These two graphs are used to predict the distribution of a given feature, and the relative strength of the two modes of transmission is inferred. As a practical application, we use this model to impute missing values that are ubiquitous in the typological database.

In the experiments, we first evaluated the proposed model with missing value imputation and confirmed that the proposed model outperformed simple baselines for this task. We then used the model to estimate the relative strength of the two modes of transmission. Our model managed to separate vertically and/or horizontally stable features from unstable ones, and the results are largely consistent with previous findings. Our code is available online at `https://github.com/yustoris/autologistic-coling-2016`.

2 Data and Preprocessing

As the database of typological features, we used the online edition[2] of the World Atlas of Language Structures (WALS) (Haspelmath et al., 2005). As of 2016, it contained 2,679 languages and 192 features. The language–feature matrix was very sparse, however. Less than 15% of elements were present. We focused on 48 features, which covered at least 20% of languages. Some previous studies discarded languages with few observed features (Murawaki, 2015; Takamura et al., 2016). To avoid an unexpected bias, we used all but 72 languages in the database. The languages we excluded were sign languages, pidgins and creoles, which were all classified as *other* in WALS.

An item of the language–feature matrix was a categorical value. For example, Feature 81A "Order of Subject, Object and Verb" has 7 possible values, `SOV`, `SVO`, `VSO`, `VOS`, `OVS`, `OSV` and `No dominant order`, and every language took one of the 7 values. We used these categorical feature values as they were. Although the mergers of some fine-grained feature values seem desirable (Daumé III and Campbell, 2007; Greenhill et al., 2010; Dediu, 2010; Dunn et al., 2011), we leave them for future work.

Languages were associated with single-point geographical coordinates (longitude and latitude), as shown in Figure 1. We constructed a spatial neighbor graph by linking any pair of languages that were within the distance of R km.[3] We set R = 1,000 following da Silva and Tehrani (2016). The average

[2] `http://wals.info/`

[3] Grouping languages by distance is a very rough approximation. Ideally, the spatial neighbor graph should reflect geographic features such as mountains, rivers and oceans (Bouckaert et al., 2012).

number of spatial neighbors was 89.1.

We also constructed a weighted variant of the spatial neighbor graph such that spatially distant pairs of languages carried smaller weight. We set $1 - r/R$ to each edge where r was the distance between the neighboring languages.

Detailed phylogenetic trees were not provided by WALS, but each language is given two levels of groupings: family and genus.[4] We used genera to construct a phylogenetic neighbor graph in which every pair of languages within a genus was linked. The average number of linguistic neighbors was 30.8.

3 Background

3.1 Horizontal Transmission in Phylogenetic Inference

Although our ultimate goal is to infer past states of languages of the world, incorporating both vertical and horizontal transmission into a model is a notoriously difficult task due to excessive flexibility. Although the conventional tree model also requires a huge search space, it can be handled by computer-intensive statistical models (Felsenstein, 1981; Gray and Atkinson, 2003). Intuitively, the degree of uncertainty increases as we trace the states of languages back to the past, but at the same time, the tree model reduces the degree of freedom by repeatedly merging nodes into a parent. Horizontal transmission brings extra freedom that currently cannot be modeled without imposing some strong assumptions on it (Nelson-Sathi et al., 2010).

Most previous studies on phylogenetic inference employ the tree model even if they take horizontal transmission into account (Greenhill et al., 2010; Dediu, 2010; Dunn et al., 2011). Given typological features and a tree that is constructed by human experts or a lexicon-based phylogenetic model, they estimate the rate of change of each typological feature over time. We speculate that if a typological feature is prone to horizontal transmission, it is likely judged to be unstable by the exclusively vertical model. However, this cannot be confirmed in a straightforward manner.

Typologists have identified several geographical areas where the distribution of typological features suggests extensive horizontal transmission (Campbell, 2006). These areas are called linguistic areas, and features shared there are referred to as areal features. Daumé III (2009) incorporated linguistic areas into a phylogenetic tree and demonstrated that the use of linguistic areas improved phylogenetic reconstruction. In his Bayesian generative model, each feature of a language has a latent variable which determines whether it is derived from an areal cluster or the tree. As shown in Table 2 of his paper, summary statistics of this variable indicate how likely a feature is transmitted vertically or horizontally. Although linguistic areas are discussed in depth in linguistic typology, horizontal transmission does not necessarily result in areal clusters. For this reason, we make a weaker assumption as to the form of horizontal transmission. We use a single spatial neighbor graph of the world although not all pairs of languages are reachable in this graph.

3.2 Feature Stability Indices

Instead of reconstructing past states of languages, linguists often draw information from the current distribution of typological features. They claim that some features are more stable than others. In an extreme case, it is argued that some features reflect time depth of 10,000 years or more (Nichols, 1994).

With the notion of stability, some typologists try to quantitatively characterize typological features. They typically devise stability indices through series of deterministic arithmetic operations (Nichols, 1992; Nichols, 1995; Parkvall, 2008; Wichmann and Holman, 2009). This line of research was reviewed by Wichmann (2015) while Dediu and Cysouw (2013) conducted empirical comparison of several methods.

The intuition behind these methods is that if the same feature value is shared by a group of languages, defined vertically or horizontally, the feature in question must be stable. For a given feature, Nichols (1992) calculated the ratio of languages not taking the modal value in a given group and then computed

[4] Other resources such as Glottolog (Hammarström et al., 2016) and Ethnologue (Lewis et al., 2014) provide more detailed hierarchical classifications. However, there seems to be no way of selecting groups of languages at some specific level(s) of phylogenetic granularity.

the inter-group average. If groups are defined phylogenetically, the result implies vertical (in)stability and the same is true of areally defined groups. Parkvall (2008) also considered how often feature values were shared among a given group but designed a more complex formula to calculate *genealogical cohesiveness* C_{FAM} and *areal cohesiveness* C_{ARE}. Here per-group indices are simply averaged. The final stability index was defined as $S = C_{\mathrm{FAM}}/C_{\mathrm{ARE}}$. Wichmann and Holman (2009) presented a similar method but focused on vertical stability. Their stability index was adjusted for unrelated languages.

While we share the basic idea with these previous studies, our model is different from theirs. Instead of treating each group separately, we directly model the global distribution of a given feature with the hope that our model captures some universal tendencies. It is built upon a theoretical foundation of probability theory. Although computer intensive, the model itself is much simpler than series of arithmetic operations. Finally, we incorporate vertical and horizontal transmission into a single model. Since the two modes of transmission are directly contrasted, the outcome is more easily interpretable.

3.3 Autologistic Model for Cultural Traits

We find that a parallel can be drawn between anthropology and linguistics with respect to vertical and horizontal transmission. In anthropology, the two modes of transmission are known as phylogenesis and ethnogenesis, respectively (Collard and Shennan, 2000). Phylogenesis assumes the transmission of cultural traits primarily from ancestral to descendant populations while ethnogenesis assumes heavy influence from transmission between populations. Thus some models developed in the field of anthropology are applicable to linguistic data.

Towner et al. (2012) propose a variant of the autologistic model to contrast vertical and horizontal transmission. The autologistic model (Besag, 1974) is widely used to model the spatial distribution of a feature. It assumes that the value of a random variable depends probabilistically on the values of its neighbors. Towner et al. (2012)'s extension incorporates two neighbor graphs with associated weight parameters. Once these parameters are inferred from data, the relative strength of the dependency according to the graphs can be measured.

Towner et al. (2012) applied the autologistic model to cultural traits (features) of Western North American Indian societies, such as the presence or absence of agriculture, the tendency toward exogamy, and types of social structure. They constructed a spatial neighbor graph using longitude and latitude data of the societies while a phylogenetic neighbor graph was created by collapsing known language families. They empirically demonstrated that both transmission modes were non-negligible for the majority of traits. The same model was applied to folktales of Indo-European societies by da Silva and Tehrani (2016). At an intermediary step toward discovering folktales with deep historical roots, the model was used to filter out those with strong horizontal signals.

Our model is based on Towner et al. (2012)'s but differs mainly in three points. First, the latter only deals with binary features while we extend the model to handle categorical features. Although the original database of cultural traits was coded categorically, Towner et al. (2012) chose its small subset by dropping unsuitable features and by merging feature values. Second, the latter has four model variants that are compared using model selection criteria. Since the model comparison is performed for a fixed set of parameters, parameters are chosen by grid search. We omit model comparison for simplicity and directly optimize parameters with a gradient-based method. Third, since Towner et al. (2012) only use high-coverage features, they simply drop languages with missing values from the neighbor graphs. By contrast, the typological database is too sparse to ignore missing values. To cope with the inherent uncertainty, we resort to a sampling-based method.

3.4 Missing Value Imputation

The idea behind missing value imputation (MVI) of typological features in previous studies is that some features depends on others. Greenberg (1963) presents several rules that hold true for the world's languages, one of which is as follows: In languages with prepositions, the genitive almost always follows the governing noun, while in languages with postpositions it almost always precedes. In practical applications, we do not limit our scope to pairs of features but use a set of features to predict missing features.

At a preprocessing step, Murawaki (2015) used a variant of multiple correspondence analysis (Josse et al., 2012) for MVI. Takamura et al. (2016) chose a logistic model to investigate the predictive power of features. In their experiments, the discriminative classifier was given all but one feature of a given language and predicted the value of the remaining feature. They repeatedly selected one language for evaluation and trained the classifier using all other languages in the typological database.

Another idea, which we explore in this paper, is that phylogenetically or spatially close languages tend to share the same feature value. Note that proximity is implicitly utilized by the dependency-based approach because languages with similar feature combinations happen to be phylogenetically or spatially close ones. In fact, Takamura et al. (2016) conducted a type of ablation experiments in which they modified the training data (1) by removing languages sharing the same ancestor with the target language or (2) by excluding languages spatially close to the target. They demonstrated that accuracy dropped in either setting. This implies that vertical and horizontal clues are useful for MVI although they did not control for the tendency of smaller training data to decrease test accuracy.

In this paper, we exploit phylogenetic and areal proximity more directly for MVI. Note that the proximity-based approach is complementary to the dependency-based one. A combined model is expected to improve accuracy, but we leave it for future work.

4 Autologistic Model

4.1 Model

Like feature stability indices explained in Section 3.2, our model assumes that if the same feature value is shared by a group, the feature in question is stable. However, the collection of such groups is implicitly represented as a single neighbor graph. For each language, the model counts how many of its neighbors share the same feature value.

Our model incorporates both phylogenetic and spatial neighbor graphs. Given these graphs, our model predicts the distribution of each feature. If the same feature values are shared by many pairs of languages in the phylogenetic graph, it implies a strong vertical association, and the same holds for the spatial association.

Formally, let $\mathrm{x} = (x_1, x_2, \cdots, x_L)$ be the sequence of feature values, where x_i is the value of the i-th language and takes one of K categorical values (K differs according to feature types). Given a neighbor graph, the model checks if a language shares the feature value with its neighbors. For the unweighted spatial neighbor graph, let $S(\mathrm{x})$ be the number of pairs sharing the same value. For the weighted variant, the number of pairs is replaced with the sum of the edge weights. Analogously, let $T(\mathrm{x})$ be the number of pairs in the phylogenetic graph sharing the same value.[5] For each feature value k, $U_k(\mathrm{x})$ is the number of languages taking the value. Then the probability of x is given by

$$P(\mathrm{x}|\theta, \lambda, \beta) = \frac{\exp\left(\theta S(\mathrm{x}) + \lambda T(\mathrm{x}) + \sum_k \beta_k U_k(\mathrm{x})\right)}{\sum_{\mathrm{x}'} \exp\left(\theta S(\mathrm{x}') + \lambda T(\mathrm{x}') + \sum_k \beta_k U_k(\mathrm{x}')\right)}. \quad (1)$$

The denominator is the normalization term. β_k corresponds to the probability of taking the value k if the two neighbor graphs are not counted. θ and λ are parameters for spatial and phylogenetic associations, respectively. If θ (λ) is positive, spatial (phylogenetic) neighbors help predicting the value of the language in question. We estimate θ, λ, and β for each feature type while keeping the same spatial and phylogenetic neighbor graphs.

4.2 Inference

Given a feature distribution x, we want to infer θ, λ and β. If all languages are present, the objective function to maximize is $\log P(\mathrm{x}|\theta, \lambda, \beta)$. Unfortunately, the typological database is very sparse, and we have to deal with the inherent uncertainty. Suppose that x is decomposed into the observed portion $\mathrm{x}_{\mathrm{obs}}$ and the remaining missing portion $\mathrm{x}_{\mathrm{lat}}$. We use the notation $\mathrm{x}_{\mathrm{obs}} \oplus \mathrm{x}_{\mathrm{lat}}$ to recover x. Marginalizing $\mathrm{x}_{\mathrm{lat}}$,

[5] Up to this point, we placed vertical elements before horizontal ones. Hereafter we follow Towner et al. (2012) by reversing the order in the model description.

Model	Accuracy (%)	
	Macro	Micro
Global majority	55.30	54.22
Neighborhood	59.20	59.18
Proposed (Spatially unweighted)	61.98	61.97
Proposed (Spatially weighted)	61.84	61.82

Table 1: Results of missing value imputation.

we derive the modified log-likelihood function

$$L(\theta, \lambda, \beta; \mathrm{x}_{\mathrm{obs}}) = \log \sum_{\mathrm{x}'_{\mathrm{lat}}} P(\mathrm{x}_{\mathrm{obs}} \oplus \mathrm{x}'_{\mathrm{lat}} | \theta, \lambda, \beta). \tag{2}$$

We perform gradient-based training to maximize the objective. A simple gradient ascent algorithm would update λ as follows:

$$\lambda \leftarrow \lambda + \eta_t \frac{\partial L(\theta, \lambda, \beta; \mathrm{x}_{\mathrm{obs}})}{\partial \lambda}, \tag{3}$$

where η_t is a learning rate that decays according to time t. Instead of the simple gradient ascent algorithm, an adaptive extension of the optimization algorithm called Adam (Kingma and Ba, 2015) is used. θ and β are updated similarly.

The derivative of the log-likelihood function with respect to λ is

$$\frac{\partial L(\theta, \lambda, \beta; \mathrm{x}_{\mathrm{obs}})}{\partial \lambda} = \mathrm{E}_{\mathrm{x}'_{\mathrm{lat}} \sim P(\mathrm{x}'_{\mathrm{lat}} | \mathrm{x}_{\mathrm{obs}}, \theta, \lambda, \beta)} \left[S(\mathrm{x}_{\mathrm{obs}} \oplus \mathrm{x}'_{\mathrm{lat}}) \right] - \mathrm{E}_{\mathrm{x}' \sim P(\mathrm{x}' | \theta, \lambda, \beta)} \left[S(\mathrm{x}') \right]. \tag{4}$$

Both terms are computationally intractable due to the combinatorial explosion in the number of possible state x'. We approximate the expectation with samples. We collect samples of x' from the probability distribution and take the average of $S(\mathrm{x}')$ to estimate the expectation. We use Gibbs sampling to generate samples of x'. They are obtained by iteratively updating x'_i, one element of x' while keeping the remaining portion x'_{-i} fixed. The next value of x'_i is stochastically selected according to

$$P(x'_i = k | \mathrm{x}'_{-i}, \theta, \lambda, \beta) \propto \exp\left(\theta g_{i,k} + \lambda h_{i,k} + \beta_k\right), \tag{5}$$

where $g_{i,k}$ is the number of i's neighbors in the spatial neighbor graph taking the value k (or the sum of the edge weights for the weighted spatial neighbor graph). $h_{i,k}$ is defined analogously for the phylogenetic neighbor graph. For the first term of Eq. 4, we only update $\mathrm{x}'_{\mathrm{lat}}$ while keeping $\mathrm{x}_{\mathrm{obs}}$ unchanged. All elements are updated for the second term.

λ and θ are initialized with 0. β_k is set to the log-probability of taking the value k in $\mathrm{x}_{\mathrm{obs}}$. In this initial setting, Eq. 5 reduces to the empirical probability according to $\mathrm{x}_{\mathrm{obs}}$ and forces $\mathrm{x}_{\mathrm{lat}}$ to largely imitate $\mathrm{x}_{\mathrm{obs}}$.

5 Experimental Results

5.1 Missing Value Imputation

We indirectly evaluated the model performance with missing value imputation. If neighboring languages have some predictive power, our model must predict missing values better than chance. Although we have no ground truth for the missing portion of the original database, we can evaluate MVI by hiding some observed features and checking how well they were recovered. For each feature type, we conducted 10-fold cross validation.

We used the default settings for the hyperparameters of Adam (Kingma and Ba, 2015) (not to be confused with the parameters of the autologistic model): $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 10^{-8}$. We ran 100 iterations for parameter estimation. After that, we sampled $\mathrm{x}_{\mathrm{lat}}$ as follows. After 50 burn-in iterations, we collected 150 consecutive samples, one per iteration. For each language, we chose the most frequent feature value among the collected samples as the final output.

We compared the proposed model with two simple baselines.

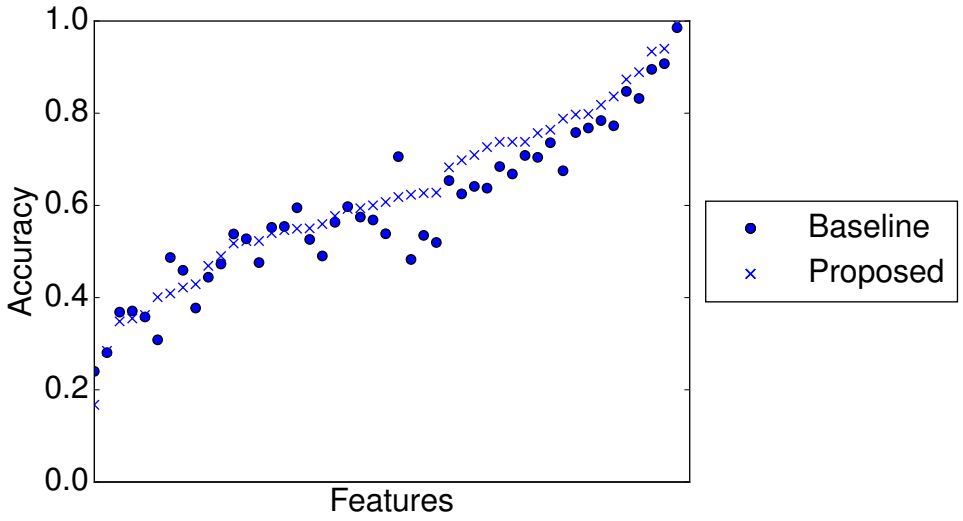

Figure 2: The MVI accuracy of the proposed model compared with that of the neighborhood baseline on a per-feature basis. Each cross denotes the accuracy of the proposed model with respect to a feature while the corresponding baseline accuracy is marked by a circle. Features are ordered in ascending order of the accuracy of the proposed model.

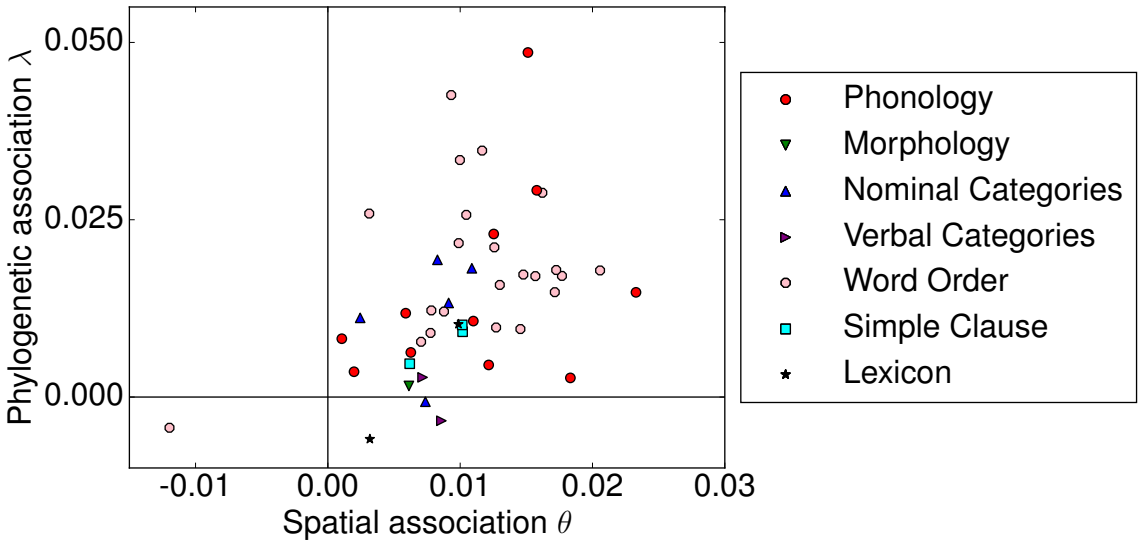

Figure 3: Estimates for phylogenetic (λ) and spatial (θ) associations. Each point denotes a feature. The shapes of the points represent broad categories of features (called *Area* in WALS).

	Feature type	Accuracy (%)
143G	Minor morphological means of signaling negation	99.31
11A	Front Rounded Vowels	93.99
90C	Postnominal relative clauses	93.39
130A	Finger and Hand	88.91
18A	Absence of Common Consonants	87.34
38A	Indefinite Articles	36.23
37A	Definite Articles	35.48
1A	Consonant Inventories	34.85
144A	Position of Negative Word With Respect to Subject, Object, and Verb	28.45
144L	The Position of Negative Morphemes in SOV Languages	16.75

(a) Features ranked by MVI accuracy of the proposed model.

	Feature type	Difference (%)
51A	Position of Case Affixes	+14.03
90A	Order of Relative Clause and Noun	+11.31
116A	Polar Questions	+10.81
3A	Consonant-Vowel Ratio	+9.25
69A	Position of Tense-Aspect Affixes	+9.17
26A	Prefixing vs. Suffixing in Inflectional Morphology	-3.72
144B	Position of negative words relative to beginning and end of clause and with respect to adjacency to verb	-4.55
144L	The Position of Negative Morphemes in SOV Languages	-7.26
4A	Voicing in Plosives and Fricatives	-7.79
129A	Hand and Arm	-8.75

(b) Features ordered by gain or loss. The proposed model is compared with the neighborhood baseline.

Table 2: Top 5 and bottom 5 features selected by two criteria.

Global majority Choose the most frequent value among $\mathrm{x}_{\mathrm{obs}}$ and always output the value.

Neighborhood For each language, collect neighbors in $\mathrm{x}_{\mathrm{obs}}$ and draw a value from the empirical distribution. If one of the two graphs has no observed neighbor, choose the other. If both are available, randomly choose one. If neither is available, draw from the empirical distribution according to the whole $\mathrm{x}_{\mathrm{obs}}$.

The proposed model itself had two variants: one with the unweighted spatial neighbor graph and the other with the weighted graph.

The results are shown in Tables 1 and 2(a). Our model outperformed the two baselines although the improvement was not so impressive as that of the dependency-based methods (Murawaki, 2015; Takamura et al., 2016). The edge weighting for the spatial neighbor graph had little effect on imputation performance.

Table 2(b) and Figure 2 compare the proposed model (spatially unweighted) with the neighborhood baseline in detail. As observed by Takamura et al. (2016), huge improvements were observed for Feature 81A "Order of Subject, Object and Verb" and some other word order related features. By contrast, the accuracy dropped sharply for Feature 144L "The Position of Negative Morphemes in SOV Languages," which might be explained by its mosaic-like distribution.

5.2 Parameter Estimation

In the next experiment, we used all observed features and estimated parameters θ, λ and β for each feature type. We chose the unweighted spatial neighbor graph for this experiment. We used the same hyperparameter settings for Adam and ran 100 iterations for parameter estimation.

	Feature type	θ
143G	Minor morphological means of signaling negation	0.0330
11A	Front Rounded Vowels	0.0233
144A	Position of Negative Word With Respect to Subject, Object, and Verb	0.0206
19A	Presence of Uncommon Consonants	0.0183
81A	Order of Subject, Object and Verb	0.0177
94A	Order of Adverbial Subordinator and Clause	0.0031
37A	Definite Articles	0.0024
8A	Lateral Consonants	0.0020
3A	Consonant-Vowel Ratio	0.0011
144L	The Position of Negative Morphemes in SOV Languages	-0.0120

(a) Features ranked by the spatial association θ.

	Feature type	λ
143G	Minor morphological means of signaling negation	0.0833
7A	Glottalized Consonants	0.0486
90A	Order of Relative Clause and Noun	0.0426
90C	Postnominal relative clauses	0.0347
87A	Order of Adjective and Noun	0.0334
26A	Prefixing vs. Suffixing in Inflectional Morphology	0.0016
38A	Indefinite Articles	-0.0007
69A	Position of Tense-Aspect Affixes	-0.0033
144L	The Position of Negative Morphemes in SOV Languages	-0.0043
129A	Hand and Arm	-0.0059

(b) Features ranked by the phylogenetic association λ.

Table 3: Features ranked by θ and λ. Top 5 and bottom 5 features are shown for each parameter.

Table 3 shows top- and bottom-ranked features for each parameter, and Figure 3 depicts the relations between the two parameters. 43 out of 47 features were in the top-right quadrant, meaning that they were both spatially and phylogenetically predictive. Nearly all word order-related features were given positive λ, which was consistent with previous findings (Daumé III, 2009). Wichmann and Holman (2009) also judged Feature 38A "Indefinite Articles" as "very unstable" although their result disagree with ours for Feature 69A "Position of Tense-Aspect Affixes" (stable) and Feature 129A "Hand and Arm" (stable).

In this study, we used genera to construct the phylogenetic neighbor graph, and thus λ can be seen as a genus-level global stability index. Although Feature 83A "Order of Object and Verb" is considered phylogenetically stable by the model, it is well known that the OV languages of India and predominantly VO languages of Europe constitute the Indo-European language family. Much work needs to be done to uncover deep phylogenetic relations. Despite the limitation, we argue that our present study presents a first necessary step toward typology-based phylogenetic inference.

6 Conclusion

In this paper, we quantitatively characterized features of linguistic typology with respect to vertical and horizontal transmission. We presented an autologistic model with which we can estimate the relative strength of transmission. Our model is simple and extensible, and the result are easy to interpret because the two modes of transmission are directly contrasted.

The high sparsity of the typological database remains a huge problem. Although our model recovers missing values better than simple baselines, the gain is not large. In the future, we would like to incorporate into the autologistic model a more effective imputation method that takes advantage of inter-feature dependencies.

How Regular is Japanese Loanword Adaptation? A Computational Study

Lingshuang Jack Mao and **Mans Hulden**
Department of Linguistics
University of Colorado
{lima4664,mans.hulden}@colorado.edu

Abstract

The modifications that foreign loanwords undergo when adapted into Japanese have been the subject of much study in linguistics. The scholarly interest of the topic can be attributed to the fact that Japanese loanwords undergo a complex series of phonological adaptations, something which has been puzzling scholars for decades. While previous studies of Japanese loanword accommodation have focused on specific phonological phenomena of limited scope, the current study leverages computational methods to provide a more complete description of all the sound changes that occur when adopting English words into Japanese. To investigate this, we have developed a parallel corpus of 250 English transcriptions and their respective Japanese equivalents. These words were then used to develop a wide-coverage finite state transducer based phonological grammar that mimics the behavior of the Japanese adaptation process, mapping e.g **cream** [kɹiːm] to [kɯ.ɾiː.mɯ]. By developing rules with the goal of accounting completely for a large number of borrowings, and analyzing forms mistakenly generated by the system, we discover an internal inconsistency within the loanword phonology of the Japanese language, something arguably underestimated by previous studies. The result of the investigation suggests that there are multiple **dimensions** that shape the output form of the current Japanese loanwords. These dimensions include orthography, phonetics, and historical changes.

1 Introduction

Borrowing lexical items from one language to another is a common linguistic phenomenon. For example, someone can wear a **beret** /bəˈreɪ/ while enjoying **sushi** /ˈsuʃi/ next to a pet **alpaca** /ælˈpækə/. Loanword adaptation refers to the process of how foreign sounds or phonological structures are made to conform to the sounds and structures of the recipient language (Goldsmith et al., 2011). Loanword phonology, as the study of the systematicity of such adaptation, attracts scholarly attention because it arguably 'pushes the limit' of the phonological system of the borrowing language in order to preserve the phonetic quality and phonological structure of the source language. This study aims to investigate how 'systematic' or 'unsystematic' a loanword phonology can be. We choose Japanese as our specific research context.

Loanwords in Japanese are ubiquitous. According to Tsunoda (1988), loanwords account for 10 to 25 percent of the lexicon in nationally circulated, news-oriented weeklies, and up to 70 percent in professional journals, medicine and science in particular. However, any attempt to provide a general account for the Japanese loanword adaptation mechanism is an ambitious enterprise because the loanword lexicon contains many phonological exceptions whose formation processes have become opaque. Furthermore, most earlier works in Japanese loanword phonology focus only on particulars or a handful of specific arguments revolving around a limited number of constraints, or assume that a set of rules or constraints discussed have covered all the phenomena; few works have actually given a complete overview of the process. Therefore, a need for a fuller description of the loanword system has motivated this study.

2 Related work

2.1 Lexical stratification of the Japanese language

It is well-known that the Japanese lexicon is stratified along the lines of etymology, and Itō and Mester (1993) formalizes such a stratification on a phonological level. That work claims that the Japanese lexicon can be categorized into the strata *Yamato* (native), *Sino-Japanese* (lexicon historically imported from China), *Mimetic* (various onomatopoeic expressions), and *Foreign* (modern loanwords, usually from western languages), based on how prototypical or peripheral the words are with respect to the phonological constraints of the language. The main argument is that each stratum has a different degree of strictness in applying certain phonological constraints. The following example illustrates this claim further with three well-known constraints on Japanese words:

1. ***P**: /p/ is only tolerated in geminates or partial geminates
2. ***NT**: post-nasal obstruents must be voiced
3. **CODACOND**: coda consonants may not have a place feature

The following table adapted from Itō and Mester (1993) shows how each constraint applies to each lexical stratum:

Lexical stratum	***P**	***NT**	**CODACOND**
Yamato	Yes	Yes	Yes
Sino-Japanese	Yes	No	Yes
Mimetic	No	Yes	Yes
Foreign	No	No	No

Table 1: Coverage of three constraints for each lexical stratum in stratified models of the Japanese lexicon.

In Table 1 we can see that in the *Yamato* stratum, all three constraints are all expected to be satisfied; in *Sino-Japanese* and *Mimetic*, only two are mandatory; while in *Foreign*, none are mandatory. Thus, Itō and Mester (1993) hypothesize that the *Yamato* stratum forms the core of the Japanese lexicon, because it violates the fewest constraints, while the *Foreign* stratum forms the outermost periphery of the lexicon because it violates the largest number of these constraints. Figure 1 shows a visual representation of the phonological stratification of Japanese lexicon.

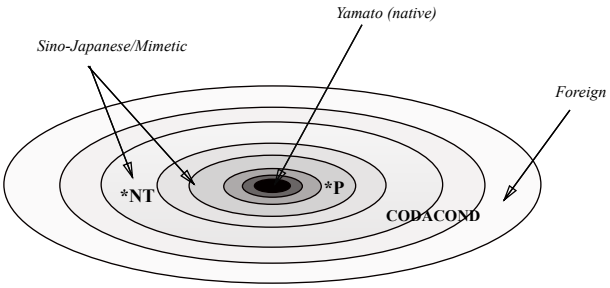

Figure 1: The core-periphery structure, adapted from Itō and Mester (1993)

This model of stratification of the Japanese lexicon has informed us that when approaching the periphery from the core, more and more forms are considered 'grammatical' because constraints becoming weaker and weaker until abolished altogether. Since the *Foreign* stratum sits on the periphery, we can assume that the loanword phonology actually **contains** the core phonology. Therefore, studying the loanword phonology matters to linguists who wish to study essential characteristics of the entire phonological system of a language and the tension between the native and foreign lexical strata.

2.2 Generative Phonology vs. Optimality Theory

As in most areas of phonology, the majority of previous work on Japanese loanword phonology has focused on analyzing its various aspects in the framework of rule-based Generative Phonology (Chomsky and Halle, 1968) and/or the newer and more fashionable constraint-based framework of Optimality Theory (OT) (Prince and Smolensky, 1993). Generative phonology regards a grammar as a set of phonological calculations (i.e. rules) that map an *underlying representation* (UR) into a *surface representation* (SR). OT on the other hand does not model the grammar of a language as a sequential algorithm; rather, a grammar is a set of defined structural limitations to be obeyed, each with a certain ranking of importance, known as *constraints*, and these constrains also interact with each other through their ranking. From a set of possible candidates of a certain form, the grammar chooses the candidate with the fewest violations of the constraints (i.e the 'optimal' one). Earlier works on Japanese loanwords are mainly based on generative phonology where the source language is the UR and the adapted Japanese loanword is the SR; with OT, a similar setup is assumed, but the SR is dictated by interaction of constraints.

2.3 Previous work and current study

Works on Japanese loanwords are substantial (e.g. Ichikawa (1929), Lovins (1975), Shirai (1999), Kubozono et al. (2013)) As a representative of earlier work in this field, Lovins (1975), in her dissertation *Loanwords and the phonological structure of Japanese*, takes a rule-based approach to investigate the loanword adaptation mechanisms from Western languages to Japanese. Her analysis is very detailed and the coverage of phenomena is also quite extensive, but, because the analysis and statistics are done manually, the whole endeavor is inevitably cumbersome. Some exceptions and corner cases are not clearly stated and explained, and the relations between loanwords and the rest of the Japanese language remains obscure. Such an effort of attempting to account for various linguistic forms has extended into recent work. For instance, Shoji and Shoji (2014) have proposed an OT account for vowel epenthesis and consonant deletion in Japanese loanwords adapted from English. However, such a framework predicts numerous Japanese outputs for an English word.

From those studies, not only did we see a limited scope of the investigation, but also a general underlying assumption that there exists a phonological system such that it can accurately transform the source language input into the borrowing language outputs, and that such a phonological system can potentially account for all the exceptions encountered in previous studies. In order to test the validity of this assumption, we decided to conduct a corpus-based computational study on Japanese loanword phonology. We decided to adopt a rewrite rule approach instead of OT because, as Karttunen (2005) points out, OT grammars are very difficult and tedious to debug; on the other hand, grammars based on rewrite rules built using finite-state transducer (FST) techniques are straightforward to construct and easily debugged.

What is different between our approach and previous ones is that we do not test or intuit the result of the rule compilation manually; rather, we utilize a more rigorous method: composing finite-state transducers to model phonological rules for mimicking the loanword adaptation processes, and automatically calculating coverage and adjusting the rules to maximize coverage. The benefit of the computational approach is obvious: we can immediately obtain the accuracy of the system output during each round of the rule development and modification process, which is nearly impossible when resorting to paper-and-pencil approaches.

3 Japanese loanword corpus compilation

We manually compiled a word list of 250 tokens of Japanese loanwords from a Japanese-Multilingual Dictionary—essentially a multilingual lexical database with Japanese as the pivot language (Breen, 2004). The word list contains parallel phonetic transcriptions of both English (source) and Japanese (borrowing) entries, and we designed it carefully in the following ways:

1. The word list includes all the phonemes in English and Japanese.
2. The word list reflects as many different phonological interactions as possible collected from previous studies.

3. The word list intentionally includes 'peculiar instances' discussed in previous studies (e.g. /pɪk.nɪk/ ↦ [pi.kɯ.nik.kɯ] in which the word-final /k/ is geminated while the word-medial /k/ is not.) (Kubozono et al., 2008).
4. We only included words with an English origin although some of them were often mistakenly attributed to other languages by some scholars. For example, Energie /ɛnɛʁgi/ ↦ [e.ne.rɯ.giː] (German) vs. energy /ɛnəʤi/ ↦ [e.na.jiː] (British English).

For majority of the words, we used standard British English transcription as the input instead of American English. The differences between the two varieties are largely irrelevant for the purpose of this study. But assuming British English to be the source is slightly preferred because it lacks the postvocalic /ɹ/ which is easier to adapt to Japanese as the language does not permit consonant codas except for the moraic nasal /N/ (e.g. /gɪtɑ(ɹ)/ ↦ [gitaː], and /fɔ(ɹ)k/ ↦ [foːkɯ]). However, some words were obviously borrowed from American English, and in such cases, American English transcription was used. For example, the Japanese SR for 'schedule' is [sɯ.ke.jɯɯ.rɯ] which is obviously derived from the American variant /skɛʤʊl/ as opposed to the British /ʃɛdjuːl/. In addition, the phonetic transcription is broad enough to reflect phonological processes rather than phonetic details. For instance, the Japanese adaptation of egg /ɛg/ was transcribed as [eg.gɯ] although voiced geminates are often devoiced in actual speech.

Some Japanese loanwords have two forms, as shown in the study of truncation/epenthesis loan doublets by Arakawa (1977):

	Truncation form	**Epenthesis form**	**English**
(1)	[pok.ke]	[po.ket.to]	pocket /pɒkɪt/
	[pɯ.ɾiN]	[pɯ.diŋ.gɯ]	pudding /pʊdɪŋ/
	[ɾa.mɯ.ne]	[ɾe.mo.neː.do]	lemonade /lɛməneɪd/

In these cases, only the epenthesis form was selected to be included in the corpus for the following reasons. First, the truncation form largely depends on the phonetics and phonology of the source language instead of the borrowing language. For example, because English phonology permits unreleased coda stops, such as /t/ in the source word pocket /pɒkɪt/, it provides a base for the Japanese loanword system to adapt the input also without the final consonant [t], namely [pok.ke]. Second, the epenthesis form usually keeps all the original consonants (or their adapted version) in the output, which contains more complete linguistic information. Third, the truncation form is not productive in the Japanese loanword system, and many loanwords do not have such forms. For example, gadget /gæʤɪt/ can only be adapted as [ga.jet.to] even though the English input ends with a /t/ that need not to be released.

We primarily relied on previous literature to decide which words to include in the corpus and how many instances to include for each process. Because we focused on compiling a computational grammar by composition of finite-state transducers, we believe that our corpus comprehensively reflects the Japanese loanword adaptation patterns gathered from previous literature. For a single segment, either a vowel or a consonant, previous literature and observations suggest that the adaptation is mostly predictable, so a few examples of each segment was considered sufficient. For instance, /θ/ ↦ [s] and /ð/ ↦ [z]. When dealing with unpredictable cases where a single input can be adapted into multiple output forms, more examples were included to ensure the generality of the rules. For example, /i/ is adapted as [iː] in comedy /kɒmɪdi/ ↦ [ko.me.d**iː**]; however, /i/ is adapted as [i] in celery /sɛləri/ ↦ [se.ro.r**i**]. In such cases, we included numerous examples of both adaptations and chose the rule that gave the better overall coverage. For more complex phonological phenomena such as gemination and vowel epenthesis, generally a large sample was included to ensure the coverage of all the phenomena described by previous literature.

In total, we discovered that the majority of the adaptation phenomena could be accounted for by a relatively small number of rules, the number of tokens included in the corpus was deemed sufficient for the purpose of this study.

4 Implementation

4.1 Finite-state phonology

The loanword adaptation grammar is implemented as a sequence of phonological rewrite rules in the Xerox finite-state calculus (Beesley and Karttunen, 2003). This is the standard mode of implementing complex hand-written phonological grammars computationally, capturing phenomena such as phonological alternations (Karttunen and Beesley, 2005), syllabification processes (Hulden, 2006), optimality-theoretic constraints (Karttunen, 1998), and nonconcatenative morphophonological processes (Beesley, 1998). The system relies on the ability to convert phonological replacement (or 'rewrite') rules into individual finite state transducers. A collection of such transducers can then be composed in a certain order, yielding one monolithic transducer, the end result essentially replicating the effect of applying multiple phonological rules in a sequence. This grammar transducer can also be applied in the inverse direction, mapping from a loanword phonological form to its possible sources. Although we don't explore this possibility here, the invertibility of a transducer is useful for debugging our rules. While finite-state tools have also been used to model other prominent approaches to describing loanword adaptation such as OT grammars (Karttunen, 1998; Gerdemann and van Noord, 2000; Gerdemann and Hulden, 2012), we restrict ourselves to the rewrite-rule model in this study.

The grammar itself is developed using the *foma*-toolkit (Hulden, 2009). A summary of the core formalism is given in Table 2. Although the formalism offers a vast number of operations, we essentially only make use of a standard context-conditioned rewrite rule, which has the following appearance

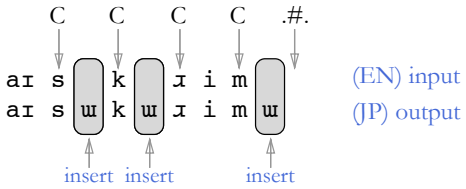
(2) `LHS -> RHS || LC _ RC`

which essentially reads as: replace all occurrences of the pattern `LHS` with the pattern `RHS`, whenever it occurs between the patterns `LC` and `RC`. The *patterns* in question can be expressed as *regular expressions*. Unlike the rewrite rules found in the phonological literature (Hayes, 2011), such a replacement rule is taken to operate simultaneously (and not iteratively in any directional manner) replacing all occurrences of `LHS` whenever warranted by the rule. For example, a rough approximation of accommodating the Japanese prohibition against complex consonant clusters, solved by epenthesis of [ɯ] between two adjacent consonants, or between a consonant and end-of-word, could be expressed as:

(3) `[..] -> ɯ || C _ [C|.#.]`

In effect, this says we insert a high unrounded back vowel [ɯ], whenever we have a consonant on the left-hand side and a consonant or end-of-word on the right. The rule itself compiles into an FST that gives rise to mappings such as the one below, translating the English phonetic representation of **ice cream** into a Japanese one (disregarding other relevant changes that also occur).

(4)



Note that this rule is simplified for the sake of exposition, and we will later provide a more accurate rule for the same phenomenon.

4.2 Developing and debugging rewrite rules

During development, we automatically checked the accuracy of our rules against the corpus, which contained not only the source forms (English) but also the attested output forms, i.e. the Japanese equivalents. This permitted us to gauge the coverage of each rule separately and iteratively address shortcomings of the adaptation grammar. Below is an example of three of our rules (here called R1, R2, and R3) that are active in transforming the English input **Christmas** /krɪsməs/ into the corresponding Japanese SR [kɯ.ri.sɯ.ma.sɯ].

`AB`	Concatenation
`A|B`	Union
`A & B`	Intersection
`A*`	Kleene Star
`~A`	Complement
`?`	Any symbol in alphabet
`0`	The empty string (epsilon)
`[` and `]`	Grouping brackets
`A -> B`	Change A to B
`[..] -> B`	Epenthesize B
`|| C _ D`	Context specifier
`.#.`	End or beginning of string
`def X ...`	Label a rewrite rule/regular expression

Table 2: An overview of the relevant regular expression and rewrite rule notation in *foma*.

R1: Epenthesize the vowel [ɯ][1] between two consonants or at the end of a word. The first consonant cannot be /n/, /t/, /d/, /tt/, or /dd/.

- `def insertu [..] -> u || C & ~[n|t|d|tt|dd] _ [C|.#.];`

R2: English input /ɪ/ becomes Japanese output /i/ in any phonological context.

- `def ichange ɪ -> i;`

R3: English input /ə/ becomes Japanese output /a/ in any phonological context.

- `def schwa ə -> a;`

Although they work, the context-free rule (R3) is too general. For example, for the input word, **violin** /vaɪəlɪn/ ↦ [bai.o.rin], it is necessary to apply another rule:

R4: English input /ə/ becomes Japanese output /o/ in any phonological context.

- `def schwa ə -> o;`

In order to reconcile the conflict between R3 and R4, new information has to be coded to differentiate versions of the input /ə/. We observed that the adaptation of /ə/ heavily depends on the original *orthographic* representation. Therefore, we coded each input /ə/ with the written orthographic symbol it originated from. For instance, 'əE' means that the input segment is /ə/ and it is represented as the letter **e** orthographically. After incorporating orthographic shape into the English transcription, we collapsed R3 and R4 into a single rule:

R5: The rule now can adapt /ə/ into different Japanese output forms.

- `def schwa əE -> e, əA -> a, əO -> o;`

Since the finite-state calculus allows us to view the input and output (domain and range) of a transducer as an automaton, we can compose our grammar with identity transducers that represent the source and target forms, respectively. This allows for quick identification of which rules fail and which overgenerate, which is helpful for rapid debugging and deployment—a standard technique in finite-state development (Beesley and Karttunen, 2003).

(5) `Sourcewords .o. Grammar .o. Targetwords`

After repeatedly refining our rules we arrive at the final Japanese loanword adaptation grammar.

5 Results

5.1 Phonological rules for adaptations from English to Japanese

By manual development of 34 phonological rules (3 insertion + 1 deletion + 30 alternation rules), the entire grammar correctly maps 215 out of 250 (86.0%) input forms to their Japanese counterparts.

[1]For convenience, we use [u] to represent [ɯ]—as there is no high back round vowel in Japanese, this cannot cause a conflict.

5.2 Error types

Before any rule is formally introduced into the system, we always test if the rule in question increases the overall coverage of the grammar. Although the final phonological system achieves high coverage for modeling loanword adaptation from English to Japanese, it is linguistically informative to analyze what kinds of mistakes the system makes. The mistakes arguably represent not only the shortcomings of this specific system, but also the characteristics of the Japanese loanword phonology as a whole.

Specifically, the Japanese SR forms which are mistakenly generated by the loanword adaptation grammar can be categorized into 3 types. Each type is presented in Table 3 with examples taken from the corpus for illustration.

English Input		System Output	Correct SR	Error Type	Percentage among mistaken outputs
diamond	/daɪəmənd/	dai.a.mon.do	dai.**y**a.mon.do		
steak	/steɪk/	sɯ.teː.kɯ	sɯ.teː.k**i**	Remainder of historical forms	28.6%
sport	/spɔːt/	sɯ.poː.to	sɯ.poː.**ts**ɯ		
gasoline	/gæsəlin/	gya.so.rin	**ga**.so.rin		
volunteer	/vɒlənˈtɪə/	bo.ran.chi.a	bo.ran.**t**i.a	Phonotactics relaxed	22.9%
teenager	/tineɪʤɜː/	chi.neː.jaː	**t**iː.neː.jaː		
bolt	/bəʊlt/	boː.rɯ.to	**bo**.rɯ.to		
tough	/tʌf/	taf.fɯ	ta.**f**ɯ	Unexpected segmental lengths	48.5%
sausage	/sɒsəʤ/	so.sej.ji	**soː.seː.**ji		

Table 3: Error types of the system output

From these mistaken forms, various types of linguistically useful information can be gleaned. First, historical forms, which comply more strictly with the native phonology of Japanese, and new adapted forms, which are more likely to be phonologically relaxed, exist simultaneously in the Japanese loanword lexicon. For example, the newer loanword **bike** /baɪk/ is adapted as [bai.k**ɯ**], while the older loanword **strike** /straɪk/ becomes [sɯ.to.rai.k**i]** due to a vowel harmony system in archaic Japanese (Shoji and Shoji, 2014). Secondly, some phonological processes, such as gemination, are unpredictable. It is difficult to explain why **bag** /bæg/ is adapted as /ba**g.g**ɯ/ but **bug** /bʌg/ becomes /ba.**gɯ**/ which forbids the gemination of the word-final voiced stop [g]. Therefore, the only way to model this type of ambiguous adaptation is to use segment-level statistics to help determine which adaptation has the highest probability to be the correct output form. This type of error also suggests that there might not be a single consistent way to generalize the loanword system of the Japanese language because the explanation for many corner cases and exceptions has been lost in history.

5.3 Rule modifications

According to these error types, we considered whether it was possible to modify the rules to eliminate these errors. Such a question can help us get closer to the ultimate goal: to construct a definitive phonological system which accurately produces adapted output forms. However, we noticed that when one rule is modified, it usually negatively affects the overall accuracy of the system output, because, although it 'fixes' a few current erroneous outputs, it also ruins previously correct forms. Table 4 shows how the number of mistaken outputs change when the current rules are modified according to various parameters.

Original number of erroneous forms	Parameter of modification	Current number of erroneous forms
35	Always inserting [y] between [i] and any vowel	35
35	No voiced geminates allowed	38
35	No velar stops allowed to be palatalized	38
35	No [t] allowed to be palatalized	38
35	First vowel of a trisyllabic word not allowed to be long	40
35	First vowel of any word not allowed to be long	71
35	No orthographic information coded into the lexicon	72-76 (depends one which uniform output is chosen, e.g. /ə/ ↦ [a], [o], or [e])
35	Only epenthesizing the default vowel [ɯ]	80

Table 4: Changes before and after rule modifications

As we see, none of the modifications given in Table 4 is really satisfactory since each of them increases the number of overall erroneous output forms of the system. This indicates that the essential 34 rules discussed in §5.1 have covered most of core phenomena in Japanese loanword phonology, and the remaining erroneous output forms are indeed exceptions outside of the set the core rules. This also means that there is clear limit to the predictability of the phonological system that drives the accommodation of loanwords in Japanese. In other words, after a certain point—corresponding to roughly 90% per type—there is a residue of internal inconsistency which is not capturable by any satisfactory phonological generalization.

6 Discussion

Because of such inconsistency within the system, if any analysis attempts to achieve a comprehensive account for Japanese loanword phonology, the model must involve external **dimensions** other than the one-to-one correspondence between the source tokens and borrowing language output. **Dimension** here refers to any domain which most significantly contributes to the nativization process of a certain group of loanwords. Based on the analysis, we incorporate four dimensions into our phonological system:

1. **Phonetic dimension**: phonetic characteristics of the source language heavily influences the form of output
   - Example: *pocket* /pɒkɪt/ ↦ [pok.ke] because English permits an unreleased /t/ at the end of the word, which is difficult for non-native speakers to perceive. As the result, Japanese adaptation also overlooks the final /t/ phoneme.
2. **Phonemic dimension**: The adapted form corresponds to all or almost all segments in the source language.
   - Examples: *pocket* /pɒkɪt/ ↦ [pok.ket.to] because all the segments in the source form are transformed into corresponding segments in the adapted form. In other words, the number of segments in the adapted form is no smaller than that in the source form.
3. **Orthographic dimension**: the orthography of the segment in the source language clearly determines or heavily influences the adaptation choice.
   - Example: *waffle* /wɒfəl/ ↦ [wa**f.f**ɯ.rɯ], where the gemination of [f] is clearly motivated by the orthography because the phonological environment where it occurs does not usually motivate gemination in Japanese. However, not every geminate reflects its original orthography. Compare *bottle* /bɒtəl/ ↦ [bo.**t**o.rɯ].
4. **Historical dimension**: For historical reasons, older forms survived diachronic changes and have become the only accepted adaptation in the current loanword system.
   - Example: The accepted Japanese loanword for the input *sport* /spɔːt/ is [sɯ.poː.**tsɯ**] with the affricate [ts] as the output instead of the newer adaptation mapping /t/ ↦ [t].

Notice that the orthographic and historical dimensions are not on the same hierarchical level as the phonetic and phonemic dimensions; rather, they exist as submembers of the phonemic dimension (see Figure 2 (a) and (b) for two examples). This hierarchical model successfully captures the fact that orthography and historical factors are only relevant when the phonemic dimension is chosen first.

7 Conclusion

Most previous studies on Japanese loanword phonology or on any phonology in general tend to take a 'paper-and-pencil' approach. Although doing phonology manually in fieldwork is considered traditional and long-standing, computational tools can arguably assist scholars to understand a new phonological system much more efficiently. In this study, we have investigated the phonological system of the Japanese loanwords using the finite-state tool, *foma*. By observing a carefully-compiled corpus and manually developing rewrite rules in *foma*, we obtained a holistic 'phonological grammar' of the adaptation process of Japanese. By analyzing the types of residual errors to which no good solution exists, modifying rules according to different linguistic parameters, we have discovered an internal inconsistency of the phonological system itself. This reveals linguistically important information about the phonological system:

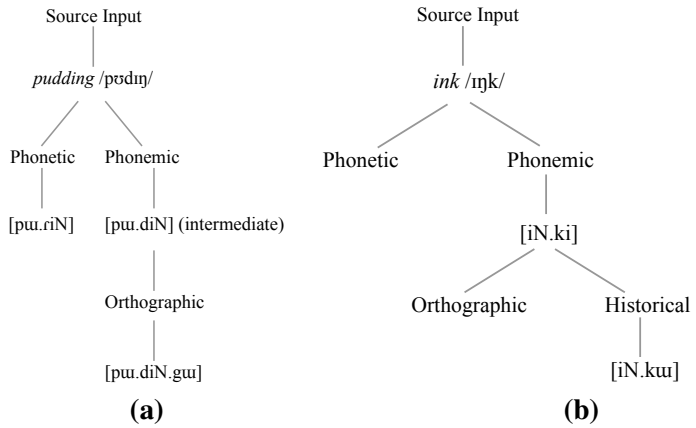


Figure 2: The hierarchical structure of phonetic, phonemic, and orthographic dimensions (a), and (b), the incorporation of a historical dimension into the hierarchical structure of dimensions.

multiple dimensions exist simultaneous within the Japanese loanword phonology that can represented in a tree-like hierarchical structure, and each foreign word has been adapted into Japanese through one specific dimension. All these discoveries would have been extremely difficult, if not impossible, to make without the computational tools available.

Abstract

We present a linguistic analysis of a set of English and Spanish verb+noun combinations (VNCs), and a method to use this information to improve VNC identification. Firstly, a sample of frequent VNCs are analysed in-depth and tagged along lexico-semantic and morphosyntactic dimensions, obtaining satisfactory inter-annotator agreement scores. Then, a VNC identification experiment is undertaken, where the analysed linguistic data is combined with chunking information and syntactic dependencies. A comparison between the results of the experiment and the results obtained by a basic detection method shows that VNC identification can be greatly improved by using linguistic information, as a large number of additional occurrences are detected with high precision.

1 Introduction

Multiword Expressions (MWEs) are recurrent combinations of two or more words expressing a single unit of meaning, this meaning not always derivable directly from the meanings of the component words (Sag et al., 2002). Therefore, Natural Language Processing (NLP) tasks that need to be sensitive to lexical meaning should treat MWEs as single units. However, this is a challenging problem since many MWEs can have multimple morphosyntactic variants, which makes them difficult to recognise or generate. Examples (1)-(3) below contain *take steps*; correct translation of this MWE into another language, for instance, requires it to be recognised as a single unit[1].

(1) The Government will *take* all the necessary *steps* to prepare.

(2) They set out five important *steps* the Minister needs to *take*.

(3) What were the *steps* that should have been *taken*?

Although the most straightforward method for recognising MWEs is to attempt to match word sequences against entries in a lexicon, this method does not work for combinations that can have multiple variants. This is often the situation for verb+noun combinations (VNCs), since this kind of MWE is usually morphosyntactically flexible.

In the case of Machine Translation (MT), there are two challenges that need to be addressed concerning VNCs: (1) the detection of a given combination in the source language, and (2) its translation into the target language. If the first part fails, the words that constitute the MWE will be translated separately,

[1]Google Translate English-French and English-Spanish https://translate.google.co.uk apparently detects *take steps* as an MWE in (1) but not in (2) or (3).

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 857–867, Osaka, Japan, December 11-17 2016.

which will usually result in an incorrect translation. Then, for the second part, it is vital to have the necessary information to know what translation should be given to each VNC. A further problem arises here, since the morphosyntax of this kind of MWE varies a great deal from one language to another, meaning that it is not necessarily translated by another VNC into the target language. This problem is especially acute when the source and target languages are typologically different, as with English, Spanish and Basque[2]. This is what happens in example (4).

(4) English (EN): *get married* (V+V)
Spanish (ES): *contraer matrimonio* (V+N)
'contract marriage'
Basque (EU): *ezkondu* (V)
'(to) marry'

In this paper, we present a linguistic analysis undertaken with the aim of improving the detection of VNCs in *Matxin* (Mayor et al., 2011), a rule-based MT system which translates English and Spanish into Basque. Although we ground our study in this particular MT system, our methodology, analysis and conclusions are relevant to any kind of NLP task that needs to be sensitive to lexical meaning.

The paper is structured as follows. After discussing related work (Section 2), we present our linguistic analysis (Section 3) including: our procedure for VNC tagging, how we classify the combinations, and levels of inter-annotator agreement. In Section 4 we present a VNC detection experiment, and give the results obtained by combining linguistic information with chunking and dependency parsing. Finally, in Section 5, we draw conclusions and propose directions for future work.

2 Related Work

It is widely acknowledged that good MWE processing strategies are necessary for NLP systems to work effectively (Sag et al., 2002), since these kinds of word combinations are very frequent in both text and speech. It is estimated that the number of MWEs in an English speaker's vocabulary is of the same order of magnitude as that of single words (Jackendoff, 1997), and that at least one MWE is used per sentence on average (Sinclair, 1991).

Various classifications of MWEs have been proposed, employing different criteria to match the requirements of a particular kind of target application. Some researchers propose a binary categorisation of literal and non-literal word combinations (Birke and Sarkar, 2006; Cook et al., 2008), whereas others propose a grading containing several MWE types based on semantic idiomaticity, considered as a continuum (Wulff, 2008). Within the Meaning-Text Theory, collocations are sorted according to the notion of lexical functions (Mel'ćuk, 1998), that is, taking into account how the component words are semantically related. Furthermore, some experiments have investigated automatic methods—such as distributional similarity or word embeddings—for the task of classification, leading to fairly good results (Baldwin et al., 2003; McCarthy et al., 2003; Fazly et al., 2007; Rodríguez-Fernández et al., 2016).

In addition to MWE classification, a great deal of work has been undertaken over the last two decades on MWE acquisition (Ramisch, 2015) and identification (Li et al., 2003; Seretan and Wehrli, 2009; Sporleder and Li, 2009). Precise and detailed syntactic information is crucial for both tasks, and, at the same time, MWE identification can also help parsers obtain better results (Seretan, 2013). Moreover, accurate MWE detection is crucial for MT, since MWEs vary greatly from one language to another, and are not usually translated word for word. In the context of MT systems, Wehrli (2014) states "the non-identification of collocations dramatically affects the quality of the output".

3 Linguistic Analysis

The linguistic analysis we present here aims at improving MWE processing in MT. More specifically, we base our study on Matxin (Mayor et al., 2011), a rule-based MT system for English-Basque and

[2]Whereas English (Germanic) and Spanish (Romance) are Indo-European languages, Basque is a non-Indo-European language which moreover belongs to no known language family.

Spanish-Basque translation. One of the problems Matxin has concerning MWEs is that it currently fails to detect many instances of morphologically flexible word combinations, since it only searches for word sequences against entries in a lexicon.

As mentioned in Section 1, our study foccusses on one particular kind of MWE: verb+noun combinations (VNCs). As well as the principal constituents of a verb and a noun, we also allow for combinations containing a preposition and/or a determiner in between. Candidate combinations were first gathered from machine-readable dictionaries and were then searched for in corpora, the most frequent combinations being selected for detailed analysis.

More details about the procedure for selecting the combinations are given in the following subsections, as well as explanations of a manual tagging process, the criteria used to classify the combinations, and the overall results and conclusions drawn from this analysis. How this information is used for VNC identification is explained in Section 4.

3.1 Selection of Verb+Noun Combinations

The Spanish combinations for this study were extracted from the Elhuyar Spanish-Basque dictionary[3], and the corpus used to obtain frequency information was made up of 491,853 sentences taken from a Spanish-Basque parallel corpus containing a range of text genres. A total of 150 distinct VNCs were selected, each of which occurred more than five times as a word sequence in the corpus.

For English, our original intention was to extract combinations from the Elhuyar *English*-Basque dictionary, in part because the Basque translations would be useful for the translation process in the MT system. However, the dictionary contained too few combinations for this study, so instead we decided to use the Oxford Collocations Dictionary (Deuter, 2008). After extracting the combinations matching our grammatical pattern, we searched for them in the British National Corpus (Burnard, 2007). If the verb and the noun (and the preposition, when necessary) were found as main elements in adjacent chunks more than 500 times, the combination was selected. The final set consisted of 173 combinations in all.

3.2 Tagging Process

The combinations were tagged manually and classified along lexico-semantic and morphosyntactic dimensions, as discussed in the next sections. Although annotators looked at corpora to take decisions, the tagging was not done on instances in a corpus but on combinations out of sentential context. Therefore, each annotator gave each combination a single tag per task.

The lexico-semantic classification was done for two reasons: to determine which combinations were worth detecting and which ones should not be treated as MWEs, and because making groups depending on the combinations' idiomaticity was considered relevant for the later translation process. The morphosyntactic data, on the other hand, was analysed to be used for VNC detection (Section 4).

The tagging was performed by five linguists, all of whom are Spanish native speakers and fluent in English. Firstly, a 'super-annotator' tagged all the data, comprising a total of 323 distinct combinations in Spanish and English. Then, the data were split in four parts, and a further four annotators each tagged one of these parts, following the guidelines created for this purpose.

3.3 Lexico-Semantic Classification

The tags assigned by the annotators separated the combinations into four lexico-semantic groups, from less to more idiomatic: (1) free expressions, (2) collocations and light verb constructions, (3) metaphoric expressions, and (4) idioms. This was not an easy task, as the boundaries between one group and another are not always clearly defined. Idiomaticity is rather understood as a continuum (Wulff, 2008), and some combinations are very difficult to classify (we return to this point in Section 3.5).

Idioms (also called **opaque expressions**) are combinations in which the whole meaning cannot be understood by looking at the meanings of the words separately. Two clear examples of these would be the sentences in examples (5) and (6), which are impossible to interpret correctly without knowledge of

[3] http://hiztegiak.elhuyar.eus/

the figurative meaning of the expressions in italics.

(5) Do not believe her, she is just *pulling your leg*.
= Do not believe her, she is just *joking*.

(6) Ese chico *no se corta un pelo*, es un descarado.
'That boy *does not cut a hair*, he is shameless.'
= That boy *is never intimidated*, he is shameless.

Metaphoric expressions are not used in their literal sense either, but it is possible to understand their meaning in terms of a metaphor, as in examples (7) and (8).

(7) He did not come to the meeting and the boss *had a word* with him.
= He did not come to the meeting and the boss *spoke* with him.

(8) Las experiencias de ese tipo *dejan huella*.
'These kinds of experiences *leave (a) mark*.'
= These kinds of experiences have a very significant effect (on people's life).

Unlike the combinations in examples (5)–(8), those in examples (9) and (10) are easily understandable on the basis of their component words; they belong to the group of **collocations and light verb constructions**. Collocations are defined as lexically constrained and recurrent combinations of words which are in a given syntactic relation (Evert, 2008; Bartsch, 2004). When they are VNCs, the verb is often a very common word which is semantically bleached—meaning that it loses its usual sense to a certain extent (Butt, 2010). These kinds of combinations are called light verb constructions (LVCs). Examples (9) and (10) would be classified in this group.

(9) Volunteers *gave support* to disadvantaged children.

(10) La educación *tiene* vital *importancia* para los niños desaventajados.
'Education *has* vital *importance* for disadvantaged children.'

Finally, **free expressions** are groups of words that can be combined freely, that is, following the standard lexical and grammatical rules of a given language. These kinds of expressions are not idiomatic, and are thus not considered MWEs, as in examples (11) and (12). Therefore, the combinations sorted in this group by the annotators were excluded for the later detection experiment (Section 4).

(11) They *are using a* new *technique* now.

(12) Este año *iremos a un lugar* diferente.
'This year *we will go to a* different *place*.'

As mentioned in Section 3.2, we consider that classifying the VNCs is relevant for translation. Our hypothesis is that the kind of translation a VNC should be given is often dependent on its lexico-semantic class. For instance, the combinations we have analysed so far suggest that, although idioms are usually translated by other (morphosyntactically equivalent or non-equivalent) idioms into the target language, they are unlikely to receive a word-for-word translation (see example (13)). On the other hand, in collocations, the noun is very likely to receive a direct translation, whereas the verb is often given a translation other than the one expected when it is not part of the collocation (see example (14)).

(13) EN: *pull* (somebody)*'s leg*
ES: *tomar el pelo* (a alguien)
'take (somebody)'s hair'
EU: (norbaiti) *adarra jo*

'play (somebody) the horn'

(14) EN: *take steps*
ES: *dar pasos*
'give steps'
EU: *pausoak eman*
'give steps'

We will not focus on the correlation between VNC classes and their translation in this paper. However, we do consider it an interesting topic for future investigation.

3.4 Morphosyntactic Classification

As well as the lexico-semantic tagging described above, we examined morphosyntactic features of combinations to classify them into three groups: (1) fixed combinations, (2) semi-fixed combinations, and (3) morphosyntactically free combinations. The annotators had to consider five questions to determine how fixed the combinations were:

- Does the noun phrase (NP) have a determiner? (always/never/optional)
- Is the NP singular or plural? (singular/plural/optional)
- Can there be a modifier (i.e. an adjective) inside the NP? (yes/no)
- Can the verb and the NP be separated by other words? (yes/no)
- Can the order of the elements be altered? (yes/no)

A given VNC needed to be classified as completely free when: the determiner and the number of the NP were marked as optional; there could be a modifier inside the NP; the verb and the NP could be separated by other words; and the order of the elements in the expression was judged to be alterable. When some of the answers were different to these, the combination had to be marked as semi-fixed, and as completely fixed if all the answers were different (that is, when the syntactic variability of the VNC was completely restricted).

None of the combinations was tagged as **fixed** by both the super-annotator and the second annotator, but this was not surprising, as VNCs which do not accept any kind of morphosyntactic variation are extremely rare. Usually, they can undergo some alterations (**semi-fixed expressions** as in examples (15) and (16)), or they can even be completely flexible (**morphosyntactically free expressions** as in examples (17) and (18)).

(15) be in love; be always in love; *be in the love; *be in loves.

(16) dar paso (a algo); dar siempre paso (a algo); *dar pasos (a algo)
'give way (to sth); always give way (to sth); *give ways (to sth)'

(17) cause a problem; cause two important problems; the problem was caused

(18) hacer un favor; hacer un gran favor; hacer dos favores; el favor que se hizo
'do a favour; do a big favour; do two favours; the favour that was done'

As these features have a direct impact on the detection of the combinations, the answers to the above-mentioned questions were also specified by the super-annotator one by one, so that this information could later be used to improve detection (see Section 4).

	Lexico-semantics	Morphosyntax
Agreement	70.52%	84.39%
κ	0.55	0.55

	Lexico-semantics	Morphosyntax
Agreement	76.00%	81.34%
κ	0.63	0.61

Table 2: IAA for Spanish VN combinations.

3.5 Inter-Annotator Agreement

Inter-annotator agreement (IAA) was measured in two ways: the percentage of combinations in which the annotators agreed, and Cohen's Kappa, κ (Cohen, 1960).

As shown in Tables 1 and 2, annotator agreement was 70% to 84% for all tagging tasks and for both languages. With κ scores between 0.55 and 0.63, we conclude that the task is coherent and that the tagging results are usable for further investigation. The lexico-semantic IAA for English is similar to the IAA obtained in previous related work (Fazly et al., 2007; Vincze, 2012), and for Spanish it is appreciably higher.

Consistent with previous work (Seretan, 2013), we found that in our selection of 323 of the most frequently occurring VNCs in Spanish and English, collocations and LVCs are the most common type of combination, and that opaque expressions (idioms) are very scarce.

We also found that the combinations that led to disagreements among annotators were not classified in random groups, but were almost always in classes lexico-semantically (and morphosyntactically) close to each other (see Tables 3 and 4). Indeed, only a few combinations were classified in two groups that were not directly adjacent on the idiomaticity continuum. This provides further evidence that MWEs form a continuum of idiomaticity with no clear boundaries between MWE types (McCarthy et al., 2003).

4 Identification Experiment

To test whether the analysed morphosyntactic data (see Section 3.3) could improve MWE detection, we undertook an experiment where three **identification methods** were combined and compared: (A)

the old one, used by Matxin, which searched only for word sequences; (B) a second one, based on the analysed linguistic data and automatically-produced chunking information; and (C) a third one, based on the analysed linguistic data and automatically-produced syntactic dependencies. Depending on how morphosyntactically fixed a given combination was, more or less linguistic restrictions were applied to identify them.

The **experimental set** was made of the combinations presented in Section 3, excluding the ones tagged as completely free by the super-annotator (Section 3.3). The final set consisted of 117 combinations in Spanish and 133 in English.

4.1 Results of the English Experiment

The corpus used for the experiment on English VNCs was the British National Corpus (Burnard, 2007), and chunking and dependency information was computed by the Stanford parser (Manning et al., 2014). A total of 152,051 occurrences of the 133 VNCs were identified by combining all three methods, 78.92% of which were not detected by method A, currently used for English-Basque translation in Matxin. Figure 1 shows the percentages of all the instances detected by each of the methods.

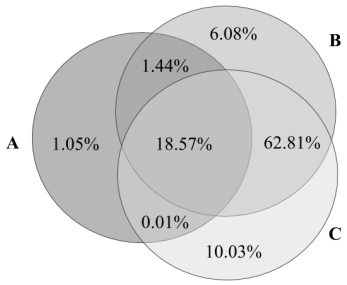

Figure 1: Percentages of English VNC occurrences identified by each method. (For clarity, areas are not drawn in scale with percentages)

We cannot calculate recall since our evaluation dataset contains only the occurrences identified collectively by the three methods, and it is almost certain that some occurrences of the VNCs under investigation were not detected. For future work, we would need to use MWE-tagged corpora to calculate recall, such as the Prague Czech-English Dependency Treebank (Uresova et al., 2013). In any case, the results obtained clearly show that the number of identified occurrences is increased considerably by using linguistic data specific to VNCs, as well as confirming that VNCs are commonly used in multiple morphosyntactic variations, as only 21.08% of the instances could be identified by searching for word sequences against entries in a lexicon.

To estimate the precision of VNC detection, we considered a representative sample of the full set, and evaluation was carried out manually by linguists. The precisions of methods B and C were not as good as that of method A. However, the evaluation on instances identified by both B and C methods reveals that detection quality is still very high when linguistic data specific to VNCs is combined with parsing (the second row of scores in Table 5).

	Additional VNCs %	**Precision**
Method A (in all)	21.08%	99%
Method B+C but not A	62.81%	96%
Method B only	6.08%	70%
Method C only	10.03%	79%

Table 5: Identification precision for the additional VNC occurrences detected in English

The least satisfactory results were those obtained by method B. When verifying the results, we noticed that the vast majority of false instances detected were light verb constructions (LVCs) containing verbs

that could also work as auxiliaries. In example (19), for instance, *have influences* is erroneously detected since *influence* is mis-analysed as the object of *have* rather than the subject of *have been likened*.

(19) These *influences have* also been likened to the forces effected by a millenarian journey to a new faith...

The overall improvement we obtained was substantial, as expected from previous work. Li et al. (2003) report an F-score improvement of 9 percentage points (86.9% to 95.6%) when using parsers and hand-crafted lexical patterns to identify phrasal verbs in English, as well as a precision improvement of 8 percentage points (90% to 98%). In our case, precision falls from 99% to 93% when combining all three methods, but the number of new instances detected suggests an appreciable increase in recall. As we already mentioned, MWE-annotated corpora would be needed to calculate recall and F-score and compare our results to those reported by other authors.

4.2 Results of the Spanish Experiment

For the experiment on Spanish, VNCs were searched in 15,182,385 sentences taken from the parallel English-Spanish corpus made public for the shared task in the ACL 2013 workshop on statistical MT[4], and the parser used was Freeling (Padró and Stanilovsky, 2012). A total of 433,092 occurrences were identified, 27.80% of which were not detected by method A (the percentages of the combinations identified by each method are shown in Figure 2). Consistent with the results obtained for English, this further reveals that the morphosyntactic data we took into account (Section 3.4) is very relevant for VNC identification.

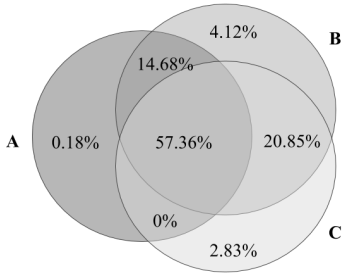

Figure 2: Percentages of Spanish VNC ocurrences identified by each method

Furthermore, as well as the quantity improving considerably, the manual evaluation reveals that the quality of our method is also very satisfactory. As is shown in Table 6, methods B and C, although not as precise as method A, got very good precision scores.

	Additional VNCs %	**Precision**
Method A (in all)	72.20%	99%
Method B+C but not A	20.85%	97%
Method B only	4.12%	93%
Method C only	2.83%	83%

Table 6: Identification precision for the additional VNCs detected in Spanish

As the corpora and parsers we used were different for English and Spanish, the experiments in both languages are not really comparable. However, it is evident that the improvement obtained for English was considerably higher than the one obtained for Spanish. Taking into account that the Freeling and Stanford parsers work in similar ways and that the manual tagging of the VNCs was done following the same criteria, this difference could suggest that syntactic variations of VNCs other than the canonical form are more common in English than in Spanish. One of the possible reasons for this could be the

[4] http://www.statmt.org/wmt13/translation-task.html

different word order inside NPs in both languages. In Spanish, adjectives can either precede or follow the head noun, whereas in English adjectives are almost never placed after the noun: *importantes pasos* or *pasos importantes* vs. *important steps* but not **steps important*. An exhaustive analysis would be needed to verify this hypothesis or identify other possible reasons.

5 Conclusions and Future Work

Morphosyntactically flexible MWEs constitute a problem for NLP systems, which often fail to process these kinds of word combinations correctly. In this paper, we presented a linguistic analysis undertaken with the aim of improving the identification of VNCs, as well as an experiment which shows how linguistic data can improve identification results greatly.

Firstly, we classified a selection of frequent VNCs in English and Spanish, following both lexico-semantic and morphosyntactic criteria. A total of 323 distinct combinations (173 in English and 150 in Spanish) were tagged by several annotators, with very reasonable inter-annotator agreement scores (κ 0.55 to 0.63). We noted moreover that the combinations that led to disagreements among annotators were always tagged in groups that were lexico-semantically and morphosyntactically close to each other, which gives further evidence that idiomaticity should be viewed as a continuum. More detailed morphosyntactic information was also specified for each combination, and this information was then used to improve VNC identification.

Our experiment confirmed that specific linguistic data about VNCs is useful for the identification of this kind of word combination, as it allows for the recognition of occurrences that do not match a combination's canonical form. Indeed, a large number of instances that were not identified by searching for fixed word sequences could be identified by combining linguistic data with chunking information and syntactic dependencies, with fairly good precision scores (79% to 97%).

Building on the satisfactory results obtained, we will test our methods in the context of MT, and we will keep analysing more VNCs. The next step will be to explore what kind of data is needed for an adequate translation of VNC combinations within MT systems. In addition, we intend to investigate how semantic information can be used within the translation process.

Abstract

University students in the United States are routinely asked to provide feedback on the quality of the instruction they have received. Such feedback is widely used by university administrators to evaluate teaching ability, despite growing evidence that students assign lower numerical scores to women and people of color, regardless of the actual quality of instruction. In this paper, we analyze students' written comments on faculty evaluation forms spanning eight years and five STEM disciplines in order to determine whether open-ended comments reflect these same biases. First, we apply sentiment analysis techniques to the corpus of comments to determine the overall affect of each comment. We then use this information, in combination with other features, to explore whether there is bias in how students describe their instructors. We show that while the gender of the evaluated instructor does not seem to affect students' expressed level of overall satisfaction with their instruction, it does strongly influence the language that they use to describe their instructors and their experience in class.

1 Introduction

Student evaluations of teachers (SETs), in which students are asked to provide their assessment of the quality of instruction they have received in a particular course, have been in use for over a century. At the end of a course, students are given forms, in paper or electronic format, containing a series of questions about the course and instructor, some requiring Likert-type scale responses and others seeking free text responses. SETs have increasingly become the de facto standard for evaluating university-level teaching performance (Centra and Gaubatz, 2000). The impact of these surveys on faculty is enormous, as they affect tenure, promotion, and compensation decisions.

Despite playing an outsized role in assessing teaching effectiveness, SETs have numerous shortcomings as tools for this task. Students, for example, are understandably often not well equipped to determine an instructor's knowledge of the subject matter, and they can be unreliable judges of how well they have mastered material, one important and generally accepted measure of teaching effectiveness. Perhaps more troublingly, several studies have demonstrated biases, whether conscious or unconscious, in students' evaluations of women instructors and instructors of color.

Most previous research in this area has focused on numerical (more precisely, *ordinal categorical*) ratings of various qualities related to teaching effectiveness. In this paper, we instead focus on computational analysis of the text responses to open-ended questions found in SETs. In the first part of this paper, we present a supervised instructor satisfaction classifier trained to identify the satisfaction polarity of SET comments. Next, we apply this model to a much larger dataset to examine how satisfaction varies across both genders. Finally, we analyze the patterns of word choice associated with each gender in order to explore how students' language changes according to the gender of the instructor they are evaluating.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 868–876, Osaka, Japan, December 11-17 2016.

2 Background

Several previous studies have found evidence for some sort of gender bias in SETs, although the results have been somewhat mixed and inconclusive. Female instructors reportedly receive lower overall numerical ratings than their male counterparts, particularly when male students evaluate them (Basow and Silberg, 1987; Basow, 1995; Young et al., 2009; Boring, 2015). At the same time, women whose personality and teaching style conform to expected gender stereotypes (e.g., warmth, helpfulness, accessibility) tend to receive higher marks overall, regardless of the gender of the evaluating students (Bennett, 1982; Kierstead et al., 1988). Gender bias also seems to vary according to the subject matter, level, and department of the course being taught (Basow, 1995; Centra and Gaubatz, 2000).

The rise of online instruction has provided a useful mechanism for identifying gender bias under more controlled conditions. MacNell et al. (2015) recently investigated the presence of gender bias in SETs of an online college-level social science class. In their experiment, two instructors, one male and one female, each taught two sections of the same course in an online setting: one in which the students were led to believe their instructor was a woman, the other in which they believed their instructor to be a man. Students in the sections with the *perceived* female instructors gave the instructors significantly lower scores in six areas, including the overall rating, than the students in the sections with the *perceived* male instructors. The differences in scores assigned to the instructors were not significantly different, however, across *actual* gender. Remarkably, it was noted that the instructor with the highest ratings was the female instructor who was perceived to be a man, while the instructor with the lowest ratings was the male instructor who was perceived to be a woman.

This previous work on gender bias in SETs has relied primarily on students' numerical ratings of their instructors for a variety of qualities related to their teaching effectiveness. In our research, we focus on the open-ended text comments that students are sometimes allowed to provide in order to elaborate on their numerical ratings. We rely on techniques and algorithms typically used for the NLP task of sentiment analysis, in which a variety of linguistic features are used to identify positive and negative tone expressed in natural language text (Mohammad, 2016; Liu, 2012). Our approaches to the task of identifying the degree of student satisfaction in their instructors, as expressed in their written comments, are inspired by, though distinct from, seminal work by Turney and colleagues (2002; 2003). Although our methods and features are not independently novel, the application of these methods in combination to the task of analyzing comments in SETs and the framing of the task itself constitute new and important contributions to the fields of NLP, gender studies, and education theory.

3 Data

SETs from a period of eight years were collected from a variety of undergraduate courses in math, physics, statistics, biology, and chemistry offered at a four-year, degree-granting institution in the United States. STEM courses were chosen because of national focus on gender disparities in physical sciences and the potential to eventually explore differences between scientific fields that do show such disparities (physics, mathematics) and those that do not (biology). Focusing on STEM also allows us to sample the majority of students, as the introductory courses in these fields are often service courses required for computing and engineering majors and can be used to meet distribution requirements for students in the humanities and social sciences.

We divide the SETs into three groups, which we call *small-labeled*, *medium-unlabeled*, and *large-unlabeled*. Each item in the first two sets contains one student response to the prompt: "*Comment on the instructor's strength and weaknesses*." The *large-unlabeled* set contains responses to multiple distinct prompts for comments on specific qualities associated with teaching effectiveness, including helpfulness, materials, organization, and presentation. Table 1 shows the the number of comments in the three groups.

The *small-labeled* dataset is the full set of "strengths and weaknesses" comments for two introductory statistics courses taught by multiple professors over several semesters, manually labeled by an undergraduate research assistant. We instructed this annotator to rate the level of satisfaction expressed in the comments. The options were *very satisfied*, *somewhat satisfied*, *neither satisfied nor dissatisfied*, *somewhat dissatisfied* and *very dissatisfied*. The comments in the remaining two datasets were not manually

Data set	Size
small-labeled	2,076
medium-unlabeled	15,896
large-unlabeled	107,855

Table 1: The three comment sets used in this study.

	Fleiss' Kappa	%Overlap
5 classes	0.49	0.61
3 classes	0.58	0.73

Table 2: Agreement scores for all annotators.

labeled. We trained and tested our classifier, discussed in detail below, on the *small-labeled* data, and then used it to predict the satisfaction level of the comments in the *medium-unlabeled* set. The *large-unlabeled* set was used for computing analytics and identifying terms strongly associated with either gender.

3.1 Inter-rater Agreement of Manual Annotations

Annotating the satisfaction level of a given text is an inherently subjective task. Since our classifier, described below, is trained on these annotations, it is important to estimate their reliability. Three individuals (co-authors), including the research assistant who rated the entire *small-labeled* set, annotated a subset of 100 comments using the previously described scheme. All of the annotations were performed after anonymizing the text and replacing all gendered titles, nouns, and pronouns with their equivalent gender neutral placeholders as explained below in Section 3.2. We then analyzed this newly annotated set by computing Fleiss' kappa (Randolph, 2009), using an online tool (Geertzen, 2012). Fleiss' kappa is a variant of Cohen's kappa (Byrt et al., 1993) that measures agreement among more than two raters.

The kappa scores were computed for two groupings. In the first grouping, each of the five satisfaction classes is considered independently. In the second, the two extreme classes on each side of the range were merged, yielding a 3-class rating scheme. The 3-class agreement scores exhibit less ambiguity, resulting in improved agreement.

Table 2 shows the Fleiss' kappa and overlap percentage of the results for both the 5-class and 3-class groupings. Both of these scores fall in the range of 0.4 to 0.6, which indicates moderate agreement under most interpretations of kappa in the psychology literature (Landis and Koch, 1977). It is also worth noting that inter-rater agreement scores such as the kappa score greatly depend on the level of subjectivity inherent in the task itself.

3.2 Data Preprocessing

Before extracting features for the satisfaction classifier, we anonymized the text by replacing all first and last names with a placeholder, merged all gendered pronouns (e.g., both *he* and *she* became *he/she*), replaced all words referring to a particular gender with a gender-neutral equivalent (e.g., *guy* and *lady* became *person*), downcased, and removed special characters. Another crucial step undertaken during preprocessing was the handling of negation terms. For instance, phrases such as *great at teaching* were differentiated from negative sentiments such as *not great at teaching*. This was achieved by applying the negation term *not* to each term that follows it until a special character or other negation term is encountered, using the method described by Narayanan et al. (2013).

The negation routine works by first detecting the negation markers *not* or *n't*. Whenever these markers are encountered, words that follow them are transformed into new terms prefixed with *not_*. After a negation marker is set, it negates every word that follows until a punctuation mark or another negation term is encountered. For instance, *not great at teaching* would be turned into *not not_great not_at not_teaching*. Term negation was responsible for an increase of about 4 percentage points in classification accuracy.

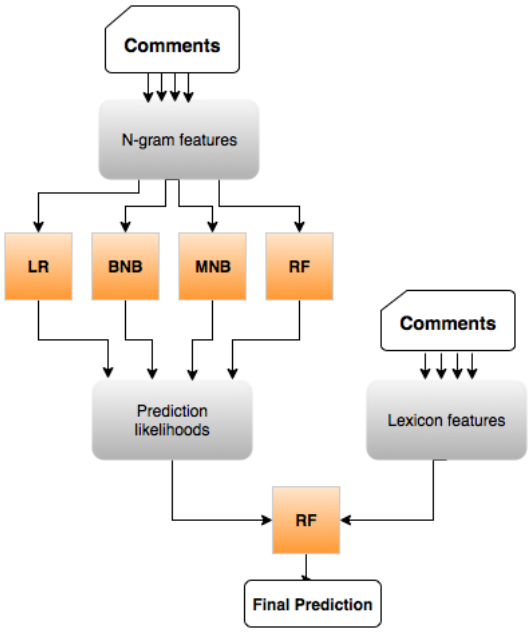

Figure 1: Architecture of the satisfaction classifier.

4 Method

4.1 Lexical Features

We extracted two types of lexical features from the data: n-gram features and sentiment term scores. Unigrams, bigrams, and trigrams served as features for the first tier of the classifier. Bigrams and trigrams can model useful local contextual features that unigrams are unable to model. For example, while unigrams features would be sufficient to capture single-word terms such as *intelligent* and *nice*, higher-order n-grams are required to capture the composite meaning found in phrases such as *extremely well* or *hardly ever available*. Over 30,000 n-grams were extracted from the dataset, resulting in a feature vector of this length for each comment.

Sentiment term scores were obtained by computing the aggregate positive and negative scores for each comment. To compute these aggregate scores, the prior polarities of the terms were determined using domain-independent lexicons. We relied on three general-purpose sentiment lexicons: the MPQA lexicon (Wilson et al., 2005), the NRC emotion lexicon (Mohammad and Turney, 2010; Mohammad and Turney, 2013), and Bing Liu's opinion lexicon (Liu, 2012). For each comment, the aggregate raw positive and negative term scores were computed from the scores from each of the three lexicons. Therefore, a 6-valued (i.e., 3 dictionaries x 2 sentiments) feature vector was computed for each comment.

4.2 Classifier Architecture

The classifier was designed as a two-tier system called *stacked generalization* (Wolpert, 1992), illustrated in Figure 1. The first tier comprises four classifiers: a random forest model, a multinomial naive Bayes model, a Bernoulli naive Bayes model, and a logistic regression model, each trained on unigram, bigram, and trigram features. The class likelihood predictions obtained from these four models, along with sentiment term scores, were then used to train a final classifier in the second tier. We used for this final classifier a random forest with parameters similar to those in the first tier.

Both the multinomial and the Bernoulli naive Bayes models have performed well in previous sentiment classification tasks (Pang et al., 2002) similar to ours. With both models we used Laplacian smoothing (i.e., $\alpha = 1.0$) with uniform priors. We trained and evaluated the random forest with 100 trees having a maximum depth of 80. The framework was implemented using the scikit-learn machine learning library (Pedregosa et al., 2011).

Total comments	2076
Total lexicon types	73802
Total tokens	80970
Type/token ratio	0.9
Avg. comment length	206 characters

Table 3: Descriptive statistics for the *small-unlabeled* data set.

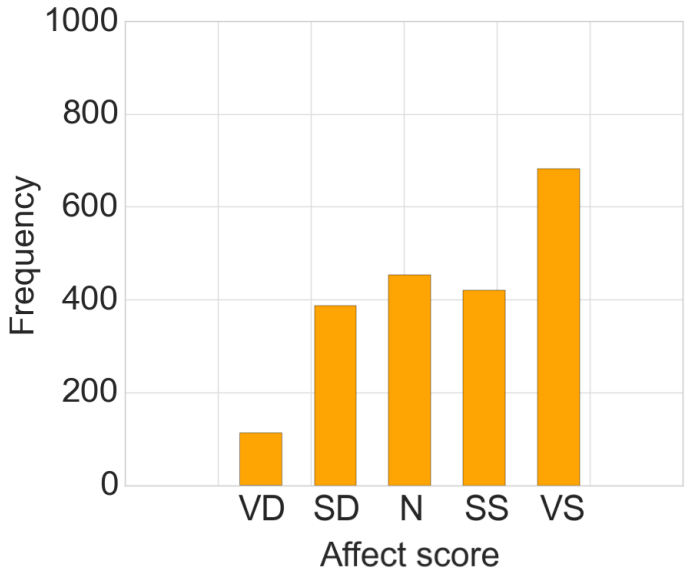

Figure 2: Distribution of 5 satisfaction levels in the *small-labeled* data set.

4.3 Results

We considered two classification tasks.

1. The *extremes* task: distinguishing *very dissatisfied* from *very satisfied*

2. The *merged* task: distinguishing (*very dissatisfied* or *somewhat dissatisfied*) from (*somewhat satisfied* or *very satisfied*)

In each case, we tested the classifier by running 10-fold cross validation on the *small-labeled* data. Table 3 presents statistics compiled from those tests. Figure 2 shows the distribution of satisfaction labels.

We evaluate a majority-class baseline and a Radial Basis Function (RBF) kernel-based SVM with penalty term $C = 2.0$, along with the main ensemble classifier. The SVM classifier utilized the same feature set as the ensemble one. However, instead of a two-tier architecture, the SVM directly combines the n-gram features with sentiment term score features. We report the classification accuracy and F1-scores in Table 4.

We see that our ensemble classifier yields large improvements over the majority-class baseline. This is especially true for the more challenging *merged* task. It also outperforms the SVM classifier by a notable margin for both tasks. Given that inter-annotator reliability on the 3-class task was just under $\kappa = .6$, achieving classification accuracy of 81% is impressive. Although there is room for improvement, these results demonstrate the efficacy of our framework.

	Baseline	SVM	RF Ensemble
Extremes task (n=795)			
Accuracy	86%	86%	**91%**
F1-score	80%	80%	**91%**
Merged task (n=1602)			
Accuracy	69%	79%	**81%**
F1-score	57%	77%	**81%**

Table 4: Classification accuracy and F1-score for both tasks. Boldfacing marks performance increases.

	Women	Men
small-labeled		
Satisfied	74%	62%
Dissatisfied	26%	38%
medium-unlabeled		
Satisfied	94%	94%
Dissatisfied	6%	6%

Table 5: Affect distribution broken down by gender. The top half shows breakdown of affect as annotated in the *small-labeled* set. The bottom half shows breakdown of affect in *medium-unlabeled* as predicted by the ensemble classifier.

5 Further Analysis

5.1 Satisfaction by Gender

For the *small-labeled* dataset, we computed the ratio of manually labeled *satisfied* to *dissatisfied* comments by gender. For the *medium-unlabeled* dataset, we computed this ratio using the satisfaction values from our classifier. Table 5 shows the results of these comparisons.

In the manually annotated dataset, male instructors receive slightly less favorable satisfaction ratings, in contrast to previous work reporting higher numerical ratings for male instructors. We note that this discrepancy is unlikely to be related to the gender of the students themselves since men were somewhat over-represented in the student body of the university from which the SETs were gathered. Rather, it seems that students were more satisfied with the instruction that they received from female instructors in the two introductory statistics courses from which these comments were drawn. We note, however, that satisfaction is a relatively subjective concept, and so may be influenced by the annotator's perception.

This difference in satisfaction disappears in the *medium-unlabeled* set, where the classifier predicts satisfaction levels to be equally distributed between genders. This could be an artifact of the larger size of the dataset, the broader range of course subject matter and level, the larger number of instructors, or simply the behavior of the classifier itself. In any case, our results do not seem to provide evidence for the presence of gender bias in students evaluations of teaching effectiveness. This does not preclude, however, the possibility of differences in students' language use according to the gender of the instructor being evaluated.

5.2 Gendered Language

In order to understand how word usage differs by the gender of the rated instructor, we first normalized and lemmatized the *large-unlabeled* set to account for morphological variation and abbreviation. We then ranked words based on their strength of co-occurrence, in terms of mutual information (MI) (Church and Hanks, 1990), with each gender. We selected the top 200 words from this ranking and sorted them into two groups based on their semantic functions. The first group contains terms used to *address* or *refer* to the instructor, and the second contains words *describing* an instructor or a student's experiences. We report the occurrence count of each term per 1000 comments after adjusting for the number of comments for each gender.

	F (per 1000)	M (per 1000)
Prof./professor	167	**209**
<Last name>	139	**151**
Dr.	75	**77**
teacher	**95**	79
instructor	172	172
<First name>	22	21

Table 6: Terms of address used to refer to faculty. Term frequency per 1000 comments adjusted by number of comments for both genders.

Word	F	M	Diff
amazing	**32**	18	128%
love(d)	**59**	32	84%
wonderful	**28**	12	57%
organized	**243**	178	37%
willing	**114**	88	30%
helpful	**454**	402	13%
tangent(s)	3	**16**	400%
funny	4	**14**	250%
knowledgeable	21	**33**	57%
interesting	68	**92**	35%
understanding	110	**126**	15%

Table 7: Gender differences in words used to describe men vs. women faculty. Values are per 1000 comments, adjusted by number of comments for each gender.

Table 6 shows that students are more likely to refer to their male instructors with the appropriate professional title (e.g., *Prof.*, *Dr.*) and by their last names. Conversely, female instructors are more likely to be referred to by their first names or descriptors that do not reflect their status as university professors (e.g., *the teacher* or *the instructor*). It is important to keep in mind that these comments were compiled from an institution having a faculty with roughly similar distributions of professional qualifications for both genders. These results therefore demonstrate an unwarranted bias toward more frequent use of prestigious titles and traditionally respectful forms of address for male instructors, regardless of their actual academic qualifications.

Table 7 shows the words with the most extreme differences in frequency according to instructor gender. Women were far more likely to be described with very positive but generic terms (*amazing, wonderful, loved*) than men. Perhaps more interestingly, students tended to describe women more often than men in terms of how the instructors impacted their learning experiences (*organized, willing, helpful*). Men, on the other hand, were recognized primarily for personal qualities (*funny, knowledgeable, interesting, understanding*) that may be independent of their ability to teach. The only negative term on this list, *tangent*, was also the term with the largest relative frequency difference between genders.

6 Conclusion

In this paper, we investigated the use of computational methods to analyze the language used in open-ended comments from student evaluations of teaching effectiveness in order to explore the possibility that gender bias exists in these evaluations. In contrast to previous research that relies on numerical ratings, our results fail to reveal differences by instructor gender in overall student satisfaction, as expressed in written comments. This results holds whether those satisfaction values are determined via direct human annotation or from machine learning models trained on the annotations. We do, however, observe real,

qualitative, gender-based differences in the language students use when providing written comments about their instructors.

Future work will follow several distinct but related paths. First, we will continue to develop our classifier using more complex features of language, such as those derived from semantic role labels or extracted from neural word embeddings or other vector space models. Secondly, we will explore the various student-assigned numerical ratings that accompany the text comments analyzed here. In particular, we hope to compare these ratings with our automatically generated satisfaction ratings in order to see the degree to which positive comments correlate strongly with high numerical ratings. As for gendered language, we plan expand our analysis by exploring whether certain syntactic structures are more strongly associated with either gender. Finally, we plan to investigate the various potential confounding factors in data, including subject matter, level, and instructor rank, as well as features of the students themselves, in order to shed light on the mixed and inconclusive evidence for gender bias described in the literature.

Acknowledgments

Many thanks to Ja'Nai Gray for providing manual annotations of the data used in this study and to the anonymous reviewers for their helpful feedback and suggestions.

Abstract

We study the problem of detecting sentences describing adverse drug reactions (ADRs) and frame the problem as binary classification. We investigate different neural network (NN) architectures for ADR classification. In particular, we propose two new neural network models, Convolutional Recurrent Neural Network (CRNN) by concatenating convolutional neural networks with recurrent neural networks, and Convolutional Neural Network with Attention (CNNA) by adding attention weights into convolutional neural networks. We evaluate various NN architectures on a Twitter dataset containing informal language and an Adverse Drug Effects (ADE) dataset constructed by sampling from MEDLINE case reports. Experimental results show that all the NN architectures outperform the traditional maximum entropy classifiers trained from n-grams with different weighting strategies considerably on both datasets. On the Twitter dataset, all the NN architectures perform similarly. But on the ADE dataset, CNN performs better than other more complex CNN variants. Nevertheless, CNNA allows the visualisation of attention weights of words when making classification decisions and hence is more appropriate for the extraction of word subsequences describing ADRs.

1 Introduction

Adverse Drug Reactions (ADRs) are potentially very dangerous to patients and are amongst the top causes of morbidity and mortality (Pirmohamed et al., 2004). Many ADRs are hard to discover as they happen to certain groups of people in certain conditions and they may take a long time to expose. Healthcare providers conduct clinical trials to discover ADRs before selling the products but normally are limited in numbers. Thus, post-market drug safety monitoring is required to help discover ADRs after the drugs are sold on the market. In the United States, Spontaneous Reporting Systems (SRSs) is the official channel supported by the Food and Drug Administration. However these system are typically under-reported and many ADRs are not recorded in the systems. Recently unstructured data such as medical reports (Gurulingappa et al., 2012b; Gurulingappa et al., 2012a) or social network data (Ginn et al., 2014; Nikfarjam et al., 2015) have been used to detect content that contains ADRs. Case reports published in the scientific biomedical literature are abundant and generated rapidly. Social networks are another source of redundant data with unstructured format. While an individual tweet or Facebook status that contains ADRs may not be clinically useful, a large volume of these data can expose serious or unknown consequences.

Common approaches to detect content with ADRs used Support Vector Machines (SVMs), Random Forest, Maximum Entropy classifiers with heavily hand-engineered features (Rastergar-Mojarad et al., 2016; Sarker et al., 2016; Zhang et al., 2016). These features normally include n-grams with different weighting schemes. When used with unigrams, these approaches suffer from the fact that their models do not take in account the interaction between terms and their orders. This problem can partially be solved by using bi-grams or trigrams. However this leads to the number of features exploding, and the models are thus easily overfitted. Meanwhile neural networks with pre-trained word representations have

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 877–887, Osaka, Japan, December 11-17 2016.

had some successes in other text classification tasks (Kalchbrenner et al., 2014; Kim, 2014; Zhou et al., 2015; Yang et al., 2016). Word representations that are typically pre-trained with unlabelled data are matrices that can be used to project words into a dense low-dimensional space (typically from 50 to 300 dimensions). These neural networks often contain convolutional filters or recurrent connections that compute weighted sums of words and their contexts.

In this paper, we train word embeddings and use them as parameters to different neural network architectures to classify documents to whether they contain ADR content. We show that even without engineered features our neural networks with word embeddings outperform maximum-entropy classifiers with different weighting schemes for n-gram features.

The rest of the paper is organised as follows. Section 2 discusses related work on ADR detection from text and briefly describes word embeddings. Various neural network architectures including two new models, Convolutional Recurrent Neural Networks (CRNN) and Convolutional Neural Network with Attention (CNNA), are presented in Section 3. Experimental setup and results are discussed in Section 4 and 5 respectively. Finally, Section 6 concludes the paper.

2 Related Work

2.1 ADR Detection from Text

Natural Language Processing (NLP) approaches have been used to detect ADRs and their relations from Electronic Health Records (EHR) (Wang et al., 2009; Friedman, 2009) and clinical reports (Aramaki et al., 2010; Gurulingappa and Fluck, 2011). Both EHRs and clinical reports have several advantages over plain text or social network data such as they contain more complete records of patients' medical history, treatments, conditions. Leaman and Wojtulewicz (2010) are ones of the first to attempt to extract ADRs from text and social networks. They generated a golden data set for DailyStrength[1], a social network where its users share health-related struggles and successes with each other, and lexicons created from UMLS Methathesaurus[2], SIDER (Kuhn et al., 2010) and The Canada Drug Adverse Reaction Database[3]. Their data set contains a total of $6,890$ comment records. Their approach is rather straightforward, which is to use direct matches of terms in their built lexicons against terms tokenised from the comments. They reported a precision of 78.3%, a recall of 69.9% and an F-score of 73.9%. Further work that focused on exploring existing or expanded lexicons to find ADRs can be found at (Benton et al., 2011; Harpaz et al., 2012; Gurulingappa et al., 2012b; Yates and Goharian, 2013; Liu and Chen, 2013). Lexicon-based approaches are limited in the number of drugs studied or the number of target ADRs. Nikfarjam and Gonzalez (2011) introduces a rule-based approach on the same DailyStrength data set. Though it does not perform as well as the lexicon-based approach, it can detect expressions not included in the lexicons.

With the emergence of annotated data, there have been more machine-learning based approaches to ADRs detection. Gurulingappa et al. (2011) used Decision Trees, Maximum Entropy and SVMs with many engineered features. They obtained an F-score of 77% for ADR class with ADE data set. Sarker and Gonzalez (2015) used SVMs with different feature sets from combined data sets (ADE, Twitter and DailyStrength). They observed that combining Twitter with ADE data sets or DailyStrength with Twitter data sets help improving their performances. Nikfarjam et al. (2015) used Conditional Random Fields to simultaneously detect ADRs and the condition for which the patient is taking the drug. In addition to traditional features, they introduced embedding clusters features trained with word2vec and k-means clustering. Rastergar-Mojarad et al. (2016) and Zhang et al. (2016) used ensemble models that combine decision trees (Random Forest) or different classifiers with various features.

Overall, approaches to ADR detection have been limited with shallow models and heavily engineered features. There has been a lack of an end-to-end approach that relies on redundancy of unannotated and annotated data.

2.2 Word Embeddings

Most of deep neural networks in NLP utilise an embedding that projects each unique word into a dense lower-dimensional space (typically from 50 to 300 dimensions) and use it as the input of the network. An *embedding* is a matrix $\mathbb{R}^{\mathrm{v}\times\mathrm{s}}$, where $\mathrm{v} \in \mathbb{R}$ is the size of vocabulary and $\mathrm{s} \in \mathbb{R}$ is the number of dimensions in the low dimensional space. These embeddings are normally trained from unlabelled text that are usually redundant in huge amounts from sources like Wikipedia or CommonCrawl[4]. The embeddings are usually trained in a fashion so that the dot product of vectors of a word and its neighbour word preserves the words' point-wise mutual information (PMI) (Mikolov et al., 2013; Pennington et al., 2014; Levy and Goldberg, 2014; Shazeer et al., 2016).

After being trained, these vectors can be used to look for word synonyms by looking for words with their vectors closest to the searched word's vector. They can also be used to answer certain types of questions like "what is to Italy like Paris to France?" by looking for words with vectors that is closest to vector $\overrightarrow{\mathrm{Paris}} - \overrightarrow{\mathrm{France}} + \overrightarrow{\mathrm{Italy}} = \overrightarrow{\mathrm{Rome}}$ (Mikolov et al., 2013). By representing words using these vectors, the model captures derived information from co-occurrences of the contained words from the unsupervised pre-training. Additionally using lower dimensional vector space also helps reduce overfitting. A tokenised sentence or document with their tokens projected by an embedding becomes a dense matrix that can then be fed as an input into a neural network.

3 Methods

In this section, we introduce a number of neural network architectures and propose two new models, Convolutional Recurrent Neural Networks (CRNN) and Convolutional Neural Network with Attention (CNNA)[5].

3.1 Convolutional Neural Network (CNN)

Deep Convolutional Neural Networks (CNN)s are recently extensively used in many computer vision (Alex Krizhevsky et al., 2012; Szegedy et al., 2014; Simonyan and Zisserman, 2014; He et al., 2015) and NLP tasks. In NLP, CNNs (Figure 1a) were previously used successfully in sentence classification and sentiment analysis (Collobert et al., 2011; Kim, 2014; Zhou et al., 2015). The network starts with a convolutional layer with Rectified Linear Units (RLUs) (Glorot et al., 2011). A RLU takes an input and returns the original input if it is larger than 0, otherwise, it returns 0. The convolutional filters normally have the same width as the word vectors, thus, produce feature maps with only 1 column. The network is then stacked by a max pooling layer that picks the maximum element from each column. The last layer is a feedforward layer to an output layer with either sigmoid (Equation 3) or softmax (Equation 4) activations depending on whether the classification is binary or multinomial. The mathematical formulations for different layers of the CNN are:

$$l^k_{1_{i1}} = \max\{(W^k_1 * \mathrm{X})_{i1}, 0\}, \tag{1}$$

$$l_{2_k} = \max_i\{l^k_{1_{i1}}\}. \tag{2}$$

If it is binary classification, we set

$$l_3 = \frac{1}{1 + \exp(-W_3^\top l_2 - b_3)}, \tag{3}$$

or, otherwise, if it is multinomial classification

$$l_{3_i} = \frac{\exp(W_3^\top l_2 + b_3)_i}{\sum_j \exp(W_3^\top l_2 + b_3)_j}. \tag{4}$$

Here, $\mathrm{X} \in \mathbb{R}^{\mathrm{d}\times\mathrm{s}}$ is the input matrix after the projection, $\mathrm{d} \in \mathbb{N}$ is the document length, $\mathrm{s} \in \mathbb{N}$ is the word vector length, $*$ denotes convolution, $W^i_1 \in \mathbb{R}^{\mathrm{h}\times\mathrm{e}}$, $W_3 \in \mathbb{R}^{\mathrm{k}\times 1}$ are the neural network weights, $b_3 \in \mathbb{R}$ is the bias term, $\mathrm{h} \in \mathbb{N}$ is the convolutional filter height and $\mathrm{k} \in \mathbb{M}$ is the number of convolutional filters.

(a) Convolutional Neural Network (CNN)

(b) Recurrent Convolutional Neural Network (RCNN)

(c) Convolution Recurrent Neural Network (CRNN)

(d) Convolutional Neural Network with Attention (CNNA)

Figure 1: Various neural network architectures.

3.2 Recurrent Convolutional Neural Network (RCNN)

Another architecture that has achieved comparable results in sentence classification task is Recurrent Convolutional Neural Network (RCNN) (Zhou et al., 2015). The RCNN (Figure 1b) also starts with a convolutional layer like the CNN but followed by a recurrent layer rather than a max pooling layer. The convolutional filters have the same width as the embedding and are applied in the manner that the outputs have the same number of rows as the input. We also use the Rectified Linear function as the activation function for the convolutional layer. For the recurrent layer, at time step t, the recurrent node takes the input from the outputs produced by all the convolutional filters at row t and previous values at time step $t-1$. For activation, we use Gated Recurrent Units (Cho et al., 2014). Finally the nodes at the last time step are fully connected to a single node with a sigmoid activation to produce binary classification:

$$l^k_{1_{t1}} = \max\{(W^k_1 * \mathrm{X})_{t1}, 0\}, \tag{5}$$

$$l_{2_{t_j}} = \mathrm{gru}(l^*_{1_{t1}}), \tag{6}$$

$$l_3 = \frac{1}{1+\exp(-W_3^\top l_{2_\mathrm{d}} - b_3)}, \tag{7}$$

where $\mathrm{gru}(\mathrm{X}): \mathbb{R}^{d\times k} \rightarrow \mathbb{R}^{d\times r}$ denotes Gated Recurrent Unit (GRU) with input X, $r \in \mathbb{R}$ is the size of the output of the RNN, $t \in \mathbb{R}$ denotes a time step that is equivalent to the order of the window that produces the values from convolutional filters.

GRUs are recurrent units which have additional gating units. The gating units modulate the flow of information inside the unit. The activation h^i_j of a GRU at time t is a linear interpolation between

previous activations:

$$\mathrm{h}_t^j = (1 - \mathrm{z}_t^j)\mathrm{h}_{t-1}^j + \mathrm{z}_t^j \tilde{h}_t^j,$$

where z_t^j acts as a gate which decides how much the unit updates its content and it is computed by $\mathrm{z}_t^j = \sigma(W_z \mathrm{x}_t + U_z \mathrm{h}_{t-1})^j$, while $\tilde{\mathrm{h}}_t^j$ is a candidate activation, computed similarly to traditional recurrent unit, $\tilde{h}_t^j = \tanh\left(W\mathrm{x}_t + U(\mathrm{r}_t \odot \mathrm{h}_{t-1})\right)^j$, where r_t is a reset gate and $\odot$ is an element-wise multiplication. These reset gates can be computed similarly to the update gate $r_t^j = \sigma(W_r \mathrm{x}_t + U_r \mathrm{h}_{t-1})^j$.

The idea behind gated flows is to enable information further in the past to be propagated to the current unit with fewer time steps. With fewer time steps, the error gradient is passed by back-propagation more efficiently due to the propagated gradient is less prone to vanishing or exploding. (Cho et al., 2014) show that GRUs have better performance than traditional $\tanh$ and comparable performance to Long Short-Term Memory (LSTM) units.

3.3 Convolutional Recurrent Neural Network (CRNN)

Inspired by RCNN, we introduce a new architecture called Convolutional Recurrent Neural Network (Figure 1c) that stacks a convolutional layer on top of a recurrent layer, which is opposite to a RCNN. The intuition behind this is that the recurrent layer can capture the global contexts before information passed to the convolutional layer. The convolution and max-pooling layers replace the traditional average over hidden features or only hidden features at the last word in the sentence. We use GRUs for the recurrent layers and RLUs for the convolutional layer:

$$l_{1_i} = \text{gru}(\mathrm{X}_{i*}), \tag{8}$$

$$l_{2_{i1}^k} = \max\{(W_2^k * l_1)_{i1}, 0\}, \tag{9}$$

$$l_3 = \frac{1}{1 + \exp(-W_3^\top l_2 - b_3)}. \tag{10}$$

3.4 Convolutional Neural Network with Attention (CNNA)

Inspired by the works from (Bahdanau et al., 2015; Hermann et al., 2015; Rush et al., 2015; Rocktäschel et al., 2016; Yang et al., 2016) which use the attention mechanism that the generation of outputs at each consecutive time step is conditioned on different subsets of the input, we introduce a new architecture built on top of the CNN with additional attention mechanism (Figure 1d). The addition is one-filter convolutional layer on top of the direct outputs from the first convolutional layer. The outputs of this convolutional layer are normalised with *softmax* function so that they can have a sum of 1, which we call *attention weights*. These *attention weights* are then multiplied with the outputs from the first convolution (*dot product*). The outputs of this dot product are forward connected to a perceptron for binary classification.

The advantage of introducing the attention mechanism is that we can use these attention weights to extract words that the model mainly uses for the prediction. In practice, we found it very interesting and helpful to see which words are more weighted in the model's decisions (see Figure 2 in Section 5).

Even though getting more popular, attention mechanism has been mostly applied with recurrent neural networks (Bahdanau et al., 2015; Hermann et al., 2015; Rush et al., 2015; Rocktäschel et al., 2016; Yang et al., 2016). There are recently some works that incorporate attention mechanism with CNNs (Yin et al., 2016; Yin et al. , 2016). In (Yin et al., 2016), attention weights are computed differently by taking the dot product between the representation of the input query and the sentences in question-answer tasks. In (Yin et al. , 2016), even though called attention, the attention layers behave more like feature maps than traditional attention weights (multiplied with features) and are computed by matching two feature maps.

4 Experimental Setup

4.1 Datasets

We use two datasets for the evaluation of various neural network architectures. The first one is a Twitter dataset (Sarker et al., 2016) published for a shared task in Pacific Symposium on Biocomputing, Hawaii,

2016. The tweets associated with the data were collected using generic and brand names of the drugs, and also their possible phonetic misspellings. The tweets were annotated for presence of ADRs. In the shared task, 70% $(7,575)$ of the original data set is shared for training and the rest of the data is used for evaluation. Owing to Twitter's data terms and conditions, only the tweet ids are contained in the original file. At the time of this experiment, we could download only $5,108$ tweets (with 557 tweets with ADR descriptions) as many tweets are no longer accessible. Due to the difference in the size of the experimental data set, we can not compare our results directly with the previously reported baselines. Thus we reuse the codes published by (Zhang et al., 2016) that perform classification with the various algorithms (see Section 4.2 for further details).

The second dataset, the ADE (adverse drug effect) corpus, was created by (Gurulingappa et al., 2012b) by sampling from MEDLINE case reports[6]. Each case report provides important information about symptoms, signs, diagnosis, treatment and follow-up of individual patients. The ADE corpus contains $2,972$ documents with $20,967$ sentences. Out of which, $4,272$ sentences are annotated with names and relationships between drugs, adverse effects and dosages.

For both datasets, we use 10-stratified-fold cross-validation and report precision, recall and F-scores of various methods.

4.2 Baselines

For the Twitter dataset, it was reported from the shared task that both the best (Rastergar-Mojarad et al., 2016) and the second best (Zhang et al., 2016) approaches are classifiers with engineered features. In order to directly compare our results with the existing approaches, we have reimplemented these classifiers based on the published code by (Zhang et al., 2016) including term-matching classifier based on an ADR lexicon, maximum entropy with n-grams and TFIDF weightings or NB log-count ratio, and maximum entropy with word embeddings. We describe each of these methods below:

- *Term-matching based on an ADR lexicon* (**TM**). An existing ADR lexicon[7] is directly used for ADR detection. The lexicon contains $13,699$ terms describing side effects from COSTART, SIDER, CHV and DIEGO_Lab. A document is classified as positive if it contains a term from the lexicon.

- *Maximum-Entropy classifier with n-grams and TFIDF weightings* (**ME-TFIDF**). For a document $d \in \mathcal{D}$, an n-gram i has a weight of

$$F_i(d) = \begin{cases} \big(1 + \log(n_i(d))\big) \times \log\big(1 + \frac{|\mathcal{D}|+1}{|\{d' \in \mathcal{D} | n_i(d') > 0\}|+1}\big) & \text{if } n_i(d) > 0 \\ 0 & \text{otherwise,} \end{cases}$$

  where $n_i(d)$ is the number of times a term i appears in document d.

- *Maximum-Entropy classifier with n-grams and NB log-count ratio* (**ME-NBLCR**). Each n-gram i has a weight of

$$f_i = \begin{cases} \log\big(\frac{1+\sum_{d:y(d)=1} n_i(d)}{\sum_{i' \in \mathcal{V}}(1+\sum_{d:y(d)=1} n_{i' \in \mathcal{V}}(d))} \times \frac{\sum_{i' \in \mathcal{V}}(1+\sum_{d:y(d)=-1} n_{i'}(d))}{1+\sum_{d:y(d)=-1} n_i(d)}\big) & \text{if } n_i(d) > 0 \\ 0 & \text{otherwise} \end{cases}$$

  where $\mathcal{V}$ is a set of all n-grams and $y(d) \in \{1, -1\}$ is the true label of each document.

- *Maximum-Entropy classifier with mean word embeddings* (**ME-WE**). This method simply uses the average of embeddings of words in each document as their input into a maximum-entropy classifier.

For the ADE dataset, the best performance published is 0.81 in F-score using SVMs trained from a rich set of features including n-grams, UMLS semantic types and concept IDs, synset expansions, polarity indicator features, ADR lexicon matches, and topics, etc. (Sarker and Gonzalez, 2015). However, since our ME-NBLCR outperforms SVMs on ADE, we don't report the results using SVMs here.

Table 1: Adverse drug reaction classification results on the Twitter and ADE datasets.

4.3 Training of Neural Networks

In all the described neural network architectures in Section 3, the training algorithm is Adadelta (Zeiler, 2012) with learning rate of 1.0, decay rate (ρ) of 0.95 using library Keras[8]. The embedding is trained together with other parameters. For each fold, we split the training dataset into training and validating sets. The training stops when there is no performance improvement on the validation set after 5 consecutive epochs. The batch size is set as 50. All convolutional window has a size of 5.

5 Results

We compare the precision, recall and F-scores of the positive class (instances labeled as containing the description of adverse drug reactions) of neural network architectures with the baselines in Table 1. Since both the Twitter and ADE datasets contain imbalanced class distribution, we also report the Area Under the ROC Curve (AUC) results. It can be observed that in general, results on the ADE dataset are better than those on the Twitter dataset. This is perhaps not surprising since tweets contain a lot of ill-grammatical sentences and short forms. Simply relying on an ADR lexicon for the detection of ADRs from text gives the worst results. Among the baselines, the best performing method is ME-TFIDF on the Twitter dataset where an F-score of 0.45 and an AUC value of 0.85 are obtained. But on the ADE dataset with more formal language, ME-NBLCR gives superior results compared to ME-TFIDF with an F-score of 0.84 and an AUC value of 0.95. Training MaxEnt from aggregated word embeddings (ME-WE) outperforms the term matching method (TM), but performs worse than both ME-TFIDF and ME-NBLCR.

All the neural network architectures perform similarly on the Twitter dataset and they improve upon the best baseline method ME-TFIDF by 4-6% in F-score and 2-3% in AUC. On the ADE dataset, CNN outperforms other neural network architectures and its performance gain over ME-NBLCR is 7% in F-score and 3% in AUC. Overall, CNN gives the best results although CRNN and CNNA are quite close to CNN in terms of AUC values. It is not very straightforward to explain why CNNs are better than the recurrent architectures in our experiments. Our hypothesis is that as ADR descriptions are composed of short fragments of texts, convolutions with small windows are enough to capture necessary information for ADR classification.

Since CNNA assigns a weight to each word when making classification decision, we show in Figure 2 a visualisation of attention weights of sampled tweets from the Twitter dataset. Words with higher attention weights are highlighted with darker blue colour. We can observe that most of the highlighted words are indeed related to descriptions of adverse drug effects. For example, "neck ache" and "lower back pain" in the fifth tweet and "dry eyed" in the seventh tweet. The above results suggest that although CNNA gives slightly worse results compared to CNN for ADR classification, it presents results in a more interpretable form and could be potentially used for the extraction of word subsequences actually

describing ADRs. As such, CNNA would be a better candidate than CNN for more fine-grained ADR extraction.

6 Conclusion

This paper has explored different neural network (NN) architectures for ADR classification. In particular, it has proposed two new neural network models, Convolutional Recurrent Neural Network (CRNN) and Convolutional Neural Network with Attention (CNNA). Experimental results show that all the NN architectures outperform the traditional Maximum Entropy classifiers trained from n-grams with different weighting strategies considerably on both the Twitter and the ADE datasets. Among NN architectures, no significant differences were observed on the Twitter dataset. But CNN appears to perform better compared to other more complex CNN variants on the ADE dataset. Nevertheless, CNNA allows the visualisation of attention weights of words when making classification decisions and hence is more appropriate for the extraction of word subsequences describing ADRs.

Abstract

Misuse of Chinese prepositions is one of common word usage errors in grammatical error diagnosis. In this paper, we adopt the Chinese Gigaword corpus and HSK corpus as L1 and L2 corpora, respectively. We explore gated recurrent neural network model (GRU), and an ensemble of GRU model and maximum entropy language model (GRU-ME) to select the best preposition from 43 candidates for each test sentence. The experimental results show the advantage of the GRU models over simple RNN and n-gram models. We further analyze the effectiveness of linguistic information such as word boundary and part-of-speech tag in this task.

1 Introduction

As learning Chinese has been popular world-wide, Chinese word spelling checking and grammatical error diagnosis for learners of Chinese language is recently advanced in the NLP community. In the NLP-TEA shared tasks (Yu et al., 2014; Lee et al., 2015a, Lee et al., 2015b), four types of grammatical errors including disorder, redundant, missing, and mis-selection are defined. These tasks focus on detecting and identifying grammatical errors, but not addressing error correction.

In English, selection of appropriate prepositions is a barrier to non-native language learners (Chodorow et al., 2007; Felica and Pulman, 2008). Many studies deal with the issue of preposition error detection and correction (Dale et al., 2012; Ng et al., 2013). The selection of Chinese prepositions is also challenging to non-native learners, especially for some common prepositions. (S1) and (S2) show a real case from the HSK corpus. The preposition 從 (cóng, "from") in (S2) is preferred to 在 (zài, "on/in/at") in (S1). In this paper, we investigate Chinese preposition selection.

(S1) **在** 公眾 利益 方面 來看 (**on** the view point of public interest)
(S2) **從** 公眾 利益 方面 來看 (**from** the view point of public interest)

A model trained on an error-annotated dataset benefits from learning the mapping between wrong instances and their corrected counterparts (Cahill et al., 2013). However, large error-annotated dataset for Chinese preposition error correction is still not available. In this paper, we utilize a large-scale corpus written by native Chinese speakers to deal with this problem. We adopt language models based on recurrent neural networks (RNNs) (Mikolov et al., 2011) to capture word dependencies in sentences. Cutting-edge methods like noise contrastive estimation (NCE) (Chen et al., 2015a) and gated recurrent unit (GRU) (Cho et al., 2014) are explored in RNNs. For the task of 43-way classification, i.e., to select the best preposition from 43 candidates, the gated recurrent neural network model (GRU) achieves an accuracy of 74.05% and an MRR of 83.08% on the Chinese Gigaword corpus (L1 corpus), and achieves an accuracy of 60.13% and an MRR of 72.54% on the HSK corpus (L2 corpus). An ensemble of gated

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers,
pages 888–899, Osaka, Japan, December 11-17 2016.

recurrent neural network model and maximum entropy language model (GRU-ME) further improves the accuracy and the MRR of the GRU model on the Gigaword corpus to 76.71% and 84.89%.

The contribution of this paper is two-fold. From technological point of view, to the best of our knowledge, this paper is the first attempt to deal with Chinese preposition selection based on gated recurrent neural network model and an ensemble of GRU and ME. From linguistic point of view, it discusses the unique phenomena of Chinese prepositions with empirical evidence. The rest of this paper is organized as follows. Section 2 introduces the related work of grammatical error diagnosis in English and Chinese. We further introduce Chinese prepositions in Section 3. Section 4 shows L1 and L2 corpora used in this study. Section 5 presents our approach to Chinese preposition selection. Section 6 shows the experimental results. We further analyze the results in Section 7. Finally, Section 8 concludes this work.

2 Related Work

English preposition error detection has attracted much attention for years. Felice and Pulman (2007) proposed a voted perceptron classifier for disambiguating the uses of five common prepositions including "in", "of", "on", "to", and "with". In the work of Felice and Pulman (2008), error detection of nine common prepositions is tackled with the maximum entropy classifier. Chodorow et al. (2007) deal with the detection of preposition errors of non-native learners. In addition to error detection, some studies address the task of English preposition selection. Bergsma et al. (2009) propose a supervised language model for preposition correction. Tetreault et al. (2010) introduce parse features for this task. Cahill et al. (2013) propose a preposition error correction model trained on error-annotated data, and treated the revision logs of Wikipedia as a large error-annotated corpus. Xiang et al. (2013) propose a hybrid approach to deal with preposition selection. Zhang and Wang (2014) introduce a framework for English grammatical error correction using the maximum entropy language model for the replacement errors. Ramisa et al. (2015) address the task of preposition prediction for image descriptions with multimodal features. Related evaluations are covered in the shared tasks of HOO 2011 (Dale and Kilgarriff, 2011), HOO 2012 (Dale et al., 2012), CoNLL 2013 (Ng et al., 2013) and CoNLL 2014 (Ng et al., 2014).

In addition to Chinese spelling checking (Lee et al., 2015b), grammatical error detection in Chinese has been investigated recently. Wang (2011) shows common Chinese grammatical errors like missing components and error word orderings. Lin (2011), Yu and Chen (2012), and Cheng et al. (2014) focus on the detection and correction of word ordering errors in Chinese written by foreign students in the HSK corpus. Shiue and Chen (2016) determine if a Chinese sentence contains word usage errors.

In the NLP-TEA shared tasks (Yu et al., 2014; Lee et al., 2015a), detection of four grammatical errors are targeted. Lin and Chan (2014) train SVM classifiers with various bigram features. Zampiperi and Tan (2014) propose a frequency-based approach based on a large general corpus. Zhao et al. (2014; 2015) model the task of correction as machine translation in such a way that the wrong sentences are translated to correct ones. The preposition error detection is one of error cases in NLP-TEA shared tasks. However, the preposition correction is beyond the scope of NLP-TEA.

Different from previous works, our work focuses on the correction of Chinese prepositions. We aim at selecting suitable prepositions from a set of 43 common prepositions. To overcome the limitation of error-annotated dataset, we propose an unsupervised approach based on language models, which can be trained on a large scale L1 corpus without the need of annotation.

3 Chinese Prepositions

A preposition is a function word that is followed by a noun phrase to introduce a preposition phrase (PP). It indicates a relation between the noun phrase and other words within the sentence. For example, "in", "on", "to", "with", and "of" are most common prepositions in English. In the Penn Treebank 3 corpus (Marcus et al., 1999), 186 distinct English words are tagged with the part-of-speech (POS) tag "P" (i.e. preposition). In the 186 prepositions, some of them are abbreviations such as "altho" (although) and "w." (with).

In the same manner, we found a total of 288 distinct Chinese prepositions in the Chinese Treebank 8.0 corpus (Xue et al., 2013). The total occurrences of them are 54,239 in 71,369 sentences. In the 288 prepositions, 199 of them appear more than once, and 44 of them appear more than 100 times. The top three most frequent prepositions are 在 (zài, "on/in/at"), 對 (duì, "to/at"), and 從 (cóng, "from").

The CKIP group (1993) categorized Chinese prepositions into 66 types of senses[1]. For example, these words 直到 (zhídào), 迄 (qì), 等到 (děng dào), 比及 (bǐ jí), 及至 (jízhì), and 待到 (dài dào) share the same meaning of "until" when they are used as preposition. Note that some prepositions have other usages. The words 與 (yǔ) and 和 (hàn) can be used as preposition with the meaning of "with", while they are also common conjunctions with the meaning of "and". The word 對 (duì) can be used as preposition (to/at), noun (a pair of), adjective (right/correct), adverb (yes), and verb (be opposite/reply) with various senses. Another highly ambiguous word 給 (gěi) can be used as preposition (to/for/with), verb (give/let), and emphatic particle. Both 對 (duì) and 給 (gěi) are common Chinese words, they have multiple senses by their own, and they are interchangeable in some situations.

Some preposition/noun pairs usually collocate. For example, the combination of the noun 辦公室 (office) and the preposition 在 (zài, "in") forms a common preposition phrase 在辦公室 (in the office). In a complicated sentence like (S3), there are eight words in-between 在 and 辦公室. Such a long distance dependency is challenging to language models.

(S3) 我 **在** 設於 上海 浦東 機場 西面 的 口岸 服務 **辦公室** (I am **in** the port service **office** located in the west of the Pudong airport, Shanghai)

In addition, the combination of the preposition and the noun varies according to semantics. For the noun 辦公室 (office) in (S4) and (S5), different prepositions are used. The ambiguity of preposition selection not only causes confusion to non-native learners, but also makes challenges in natural language processing.

(S4) 我 **在** 辦公室 上班 (I work **in** the office)
(S5) 我 **從** 辦公室 出發 (I depart **from** the office)

4 Datasets

We adopt the Tagged Chinese Gigaword (CGW) corpus 2.0[2] (Huang, 2009; Huang et al., 2008) as the L1 corpus. It contains 2,803,632 documents and 831,748,000 words with part-of-speech (POS) tags. By removing the sentences without prepositions, a total of 23,486,882 sentences covering 155 prepositions are collected from the Gigaword corpus. We randomly select 60% of sentences for training models due to the computation limitations. Additional 5,000 and 200,000 sentences are randomly selected as development data and test data, respectively. The development data is used for validation.

HSK dynamic composition corpus is adopted as the L2 corpus[3]. It collects articles written by students from foreign countries to study Chinese in Beijing Language and Culture University. Total 46 error categories range from character level, word level, sentence level, to discourse level are annotated and corrected in the HSK corpus. The CKIP segmentation system is used to perform Chinese word segmentation and POS tagging on the sentences in HSK because the POS tagging in the CGW corpus follows the CKIP style.

From the HSK corpus, total 745 sentences consisting of preposition errors are extracted from word-level grammatical error set. Limited to the small L2 dataset, these 745 sentences are used as test data only. The statistics of L1 and L2 datasets are listed in Table 1.

Dataset	Source	Number of Sentences
Training set (L1)	CGW	14,092,128
Development set (L1)	CGW	5,000
Test set (L1)	CGW	200,000
Test set (L2)	HSK	745

Table 1: Statistics of the L1 (CGW) and L2 (HSK) datasets used in experiments.

[3] http://202.112.195.192:8060/hsk/login.asp

Among the Chinese prepositions mentioned in Section 3, 43 prepositions, most of which are common words, appear in the HSK dataset. Note that 33 of them belong to the list of the top 50 prepositions in CGW. Furthermore, these 43 prepositions cover 88.61% of preposition uses in CGW. Figure 1 lists the 43 prepositions used in this work by the order of their occurrences.

在 (on/in/at) 對 (to/at) 從 (from) 用 (with/using) 以 (with/by) 跟 (with) 由 (by/from) 給 (to/for/with) 為 (for) 和 (to) 向 (to/toward) 與 (to) 像 (like) 對於 (for/regarding) 當 (at) 把 (owing to) 到 (to) 靠 (by) 於 (in/to/on/for/at/of) 被 (passive particle) 關於 (about/on) 隨著 (along) 比 (than) 根據 (according to/based on) 如 (as) 依 (according to/by) 就 (on) 針對 (against) 離 (from) 按照 (according to/by) 替 (for) 至於 (touching) 受 (passive particle) 至 (to/until) 等到 (until) 據 (according to) 按 (according to/by) 往 (to/toward) 經由 (via) 同 (with) 憑 (by) 趁 (at) 正當 (at)

5 Methods

This work deals with the preposition selection error. Given a set of Chinese prepositions, *PS*, and a sentence $S = (x_1, x_2, ..., x_{i-1}, x_i, x_{i+1}, ..., x_n)$, where x_i is a preposition, we try to substitute x_i for each preposition p in *PS*, and choose the most probable preposition $\hat{p}$.

$$\hat{p} = \underset{p \in PS}{\operatorname{argmax}} P(x_1, x_2, \ldots, x_{i-1}, p, x_{i+1}, \ldots, x_n)$$

Prepositions are a closed set of function words. Thus, it is feasible to substitute each of all prepositions for the location of a preposition. As listed in Section 4, *PS* contains 43 common prepositions which appear in both the CGW corpus and the HSK corpus. The probability of a sentence is estimated by a language model. The traditional n-gram language model is considered as the baseline in this work. The SRI language modeling toolkit (SRILM)[4], an implementation of n-gram language model, is adopted. The major disadvantage of n-gram is that the number of its parameters growths exponentially as the order of n-gram increases. As a result, the order of n-gram usually ranges between bigram and 5-gram. The n-gram model with high order is not impractical.

Recently, language models based on recurrent neural networks (RNNs) such as simple RNN, long short-term memory (LSTM), and gated recurrent unit (GRU) (Mikolov et al., 2011; Hochreiter and Jürgen Schmidhuber, 1997; Cho et al., 2014) have been shown to outperform traditional approaches in speech recognition and other applications. Figure 2 illustrates a basic recurrent neural network. The hidden state s_t is passed to the next step for the following update.

$$s_t = f(Wx_t + Us_{t-1})$$

where *f* is an activation function such as a sigmoid function or a tanh function, and *W* and *U* are parameters to be learned. In other words, the history information is kept.

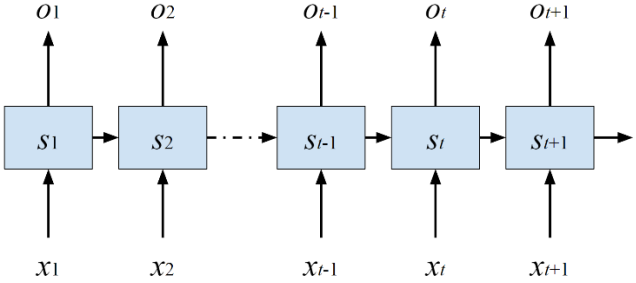

Figure 2: Recurrent neural network (RNN).

[4] http://www.speech.sri.com/projects/srilm/

Compared to n-gram, RNN based language model can capture longer distance dependencies with less parameters. As mentioned in Section 3, long distance dependency modelling is crucial to preposition selection. For this reason, we employ the simple RNN and the GRU language models to estimate the probability of a preposition in a given sentence. Instead of the single sigmoid or tanh function used by the simple RNN, GRU model, which is simplified from LSTM, uses a structure namely gated recurrent unit in the hidden layer.

$$s_t = (1 - z)h + zs_{t-1}$$
$$h = \tanh(W_h x_t + r_t(U_h s_{t-1}))$$
$$z = \sigma(W_z x_t + U_z s_{t-1})$$
$$r = \sigma(W_r x_t + U_r s_{t-1})$$

As shown in Figure 3, the update gate *z* decides how much the hidden state *s* is updated with the candidate hidden state $\tilde{s}$, while the reset gate *r* decides how much the memory to be forgotten. GRU is reported to be better for long-term dependency modeling (Chung et al., 2014; Chen et al., 2015b) than the simple RNN. Compared to LSTM, GRU requires few parameters for the same size of hidden layer.

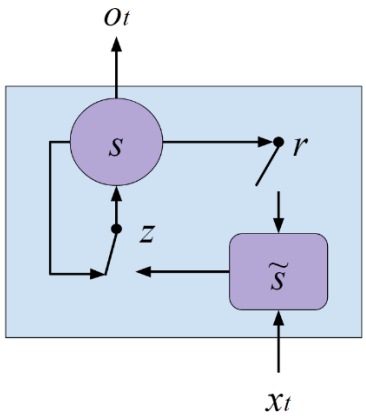

Figure 3: Gated recurrent unit (GRU).

In this work, we use the noise contrastive estimation (NCE) (Chen et al., 2015a) as the output layer for both simple RNN and GRU language models. The training performance of NCE is comparable to the class-based softmax, but NCE is faster in testing stage and can speed up together with GPU in training stage. The implementation of RNN models is based on faster-rnnlm, a toolkit for RNN language modelling[5].

6 Experiments

Three language models, n-gram, simple RNN, and GRU, are evaluated in the experiments with various configurations. The n-gram models are trained with the orders from 2 to 12. The simple RNN and the GRU models are trained with the hidden sizes of 128, 256, and 512. The number of noise samples of NCE is set to 20. Moreover, all language models are trained on three linguistic levels:

(1) Character level (**char**): each unit is a Chinese character.
(2) Word level (**word**): each unit is a Chinese word.
(3) Word level with POS tag (**w/p**): each unit is a combination of a word and its POS tag.

The performance is measured by accuracy and mean reciprocal rank (MRR). The accuracy is defined as number of correct selection versus number all test instances. The MRR is defined as $\frac{1}{N}\sum_{i=1}^{N}\frac{1}{\text{rank}_i}$ where *N* is number of instances, and rank_i is the rank of the correct preposition among *PS* according to its probability. In L1 testing, we check if the predicted preposition is the same as the original preposition in the sentence. In L2 testing, we check if the predicted preposition is the one corrected by annotators. McNemar test is used for significance testing at p=0.05.

[5] https://github.com/yandex/faster-rnnlm

Experimental results in L1 and L2 are shown in Table 2. For the n-gram models with different orders (from 2 to 12), we only show the highest performances due to the limited space. The subscripts of the simple RNN and the GRU models denote their hidden sizes. The best performing configuration for each of n-gram, simple RNN, and GRU models is highlighted in bold. In general, the larger the hidden layer, the better the performances of the simple RNN and the GRU language models. GRU model outperforms simple RNN and n-gram models in most cases. The best n-gram model is trained on word level with POS tags, the best simple RNN model is trained on word level using a hidden size of 512, and the best GRU model, which is also the best model of all, is trained on word-level with POS tag using a hidden size of 512. In both L1 and L2 testing, the best GRU model significantly outperforms the best simple RNN model.

The n-gram model and the GRU model perform better on the word level with POS tag, while the simple RNN model performs better on the word-level. On the other hand, all the n-gram, simple RNN, and GRU models trained on character level perform poorly. Grouping characters into words may help language models to capture long distance dependency. The neural networks are capable of learning feature representation from raw data. The linguistic information like POS tags still increases the performances of the GRU model.

The best performing model, GRU_{512} trained on word level with POS tag, achieves an accuracy of 74.05% and an MRR of 83.08% on L1, and an accuracy of 60.13% and an MRR of 72.54% on L2. The precision@3 is 91% in L1 testing, and 81% in L2 testing. For a task of 43-way classification, this result is promising.

Among the three best performing n-gram, simple RNN and GRU models, the smallest performance gap between L1 and L2 is found in the GRU model. Compared to the other two models, GRU model achieves better testing fitness and less overfitting. However, the performance gap between L1 and L2 is still an issue to be tackled in the future.

LM	CGW (L1)						HSK (L2)					
	Character		Word		Word/POS		Character		Word		Word/POS	
	ACC	MRR	ACC	MRR	ACC	MRR	ACC	MRR	ACC	MRR	ACC	MRR

7 Discussion

Table 3 shows the performances of most frequent prepositions by the best performing n-gram, simple RNN and GRU models in L2 testing. The last row represents the performances of all prepositions in micro average. In each row, the best precision (P), recall (R), and F-score (F) are highlighted. The confusion matrix of the best performing GRU model in L2 testing is shown in Table 4. Most frequent prepositions are listed. Each row represents the sample in an actual preposition, while each column of the matrix represents the samples in a predicted preposition.

The preposition 在 (zài), the most frequent Chinese preposition, covers the meanings of *on*, *in*, and *at* in English. The precision of the second preposition 對 (duì, "to/at") achieved by the GRU model is only 59.76%. As shown in Table 4, 18 instances of 在 (zài, "on/in/at") and 10 instances of 給 (gěi, "for/to") are misclassified to 對. As a result, the recall of 給 (gěi, "for/to/with") and the precision of 對 are poor. In fact, they are sometimes interchangeable. For instance, using 對 in place of 給 in (S6) is also correct. However, only one correct preposition is labeled in the HSK corpus. In other words, our models are under-estimated due to the one-answer evaluation. In English, prepositions are also reportedly more than one way to correct (Bryant and Ng, 2015).

(S6) 吸菸 **給** 人 們 的 健康 帶來 不好 的 影響 (smoking causes bad effect **to** human health)

The third frequent preposition 從 (cóng, "from") tends to confuse with 在 (zài, "on/in/at") and 以 (yǐ, "by/with"). The fourth and the fifth prepositions 用 (yòng, "by/with") and 以 (yǐ, "by/with") share similar meanings and tend to be confusing.

Preposition	N-Gram Word/POS			RNN_{512} Word			GRU_{512} Word/POS		
	P	R	F	P	R	F	P	R	F
在 (on/in/at)	52.22	69.86	59.77	68.66	**84.02**	75.56	**79.70**	73.52	**76.48**
對 (to/at)	50.66	61.11	55.40	**63.70**	73.81	68.38	59.76	**80.16**	**68.47**
從 (from)	70.59	26.09	38.10	**87.18**	36.96	51.91	74.70	**67.39**	**70.86**
用 (by/with)	63.16	32.43	42.86	71.43	27.03	39.22	**77.78**	**37.84**	**50.91**
以 (by/with)	27.59	25.00	26.23	34.55	59.38	43.68	**41.51**	**68.75**	**51.76**
跟 (with)	**60.00**	19.35	29.27	50.00	**38.71**	**43.64**	**60.00**	29.03	39.13
由 (by/from)	33.33	31.82	32.56	54.55	54.55	54.55	**72.22**	**59.09**	**65.00**
給 (for/to/with)	50.00	5.88	10.53	**100.00**	5.88	11.11	**100.00**	**17.65**	**30.00**
Average of all	46.14	43.62	41.71	60.15	56.78	55.88	**63.63**	**60.13**	**59.20**

Table 3: Performances of most frequent prepositions by the best performing n-gram, simple RNN and GRU models in L2 testing. All numbers are shown in percentage (%).

Actual	Predicted Prepositions							
	在 (on/in/at)	對 (to/at)	從 (from)	用 (by/with)	以 (by/with)	跟 (with)	由 (by/from)	給 (for/to/with)
在 (on/in/at)	161	18	7	1	1	1	0	0
對 (to/at)	8	101	3	0	4	1	1	0
從 (from)	10	3	62	1	9	1	0	0
用 (by/with)	2	3	2	14	9	0	0	0
以 (by/with)	0	4	2	0	22	1	0	0
跟 (with)	2	3	0	0	0	9	0	0
由 (by/from)	1	1	0	2	1	0	13	0
給 (for/to/with)	0	10	0	0	0	0	0	3

Table 4: Confusion matrix of the GRU_{512} on the word level with POS tag in L2 testing.

Figure 4 shows the accuracies of the n-gram, RNN_{512}, and GRU_{512} models on word level with and without POS tag with respect to difference sentence lengths. We divide the sentences in L2 test set into five groups according to their length. The average sentence length is 9.13 words, and the longest sentence consists of 32 words. The information of POS tag generally improves the performance for the cases of longer sentences. In particular, the GRU_{512} model on word-level with POS tag outperforms other models for the sentences of lengths ≥ 4 words. In the test set of L2, only 10 sentences (1.3%) are shorter than 4 words.

(S7) is an instance correctly predicted by the GRU_{512} model, while n-gram and RNN_{512} output a wrong outcome as (S8). In this case, the first word 在 (zài, "in") and the last word 裡 (lǐ, "inside") form a circumposition for the noun phrase 那些保守的家庭 (those conservative family). The pair of words 在... 裡 (inside) is a common usage in Chinese. The GRU_{512} model successfully captures their dependency although there are four words in-between.

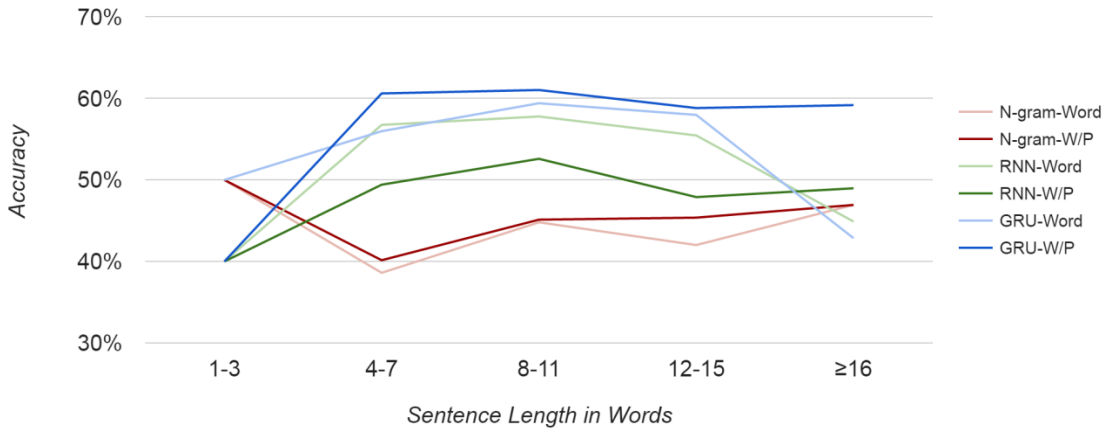

Figure 4: Accuracy versus sentence length in L2 testing.

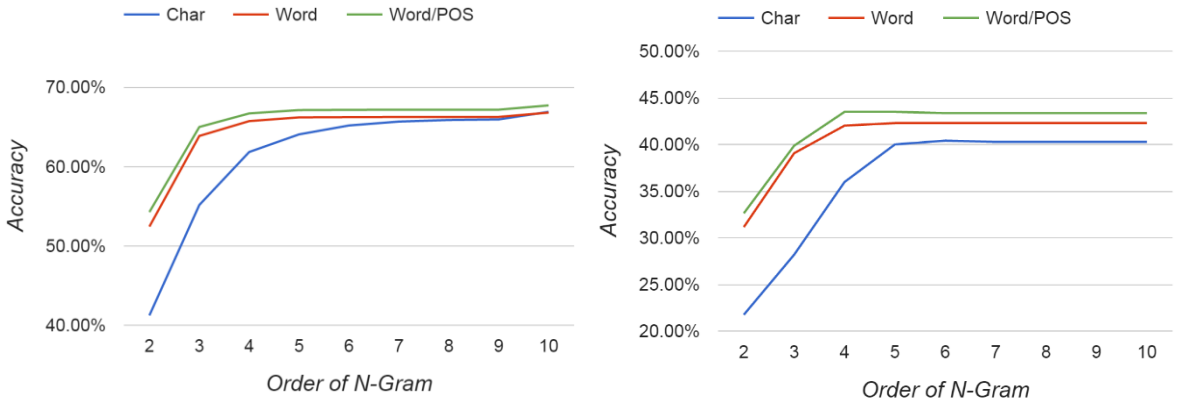
(S7) **在** 那些 保守 的 家庭 裡 (Inside those conservative family)
(S8) **對** 那些 保守 的 家庭 裡 (To those conservative family)

(S9) shows a much longer distance dependency successfully estimated by GRU_{512}. In this case, there are eight words in-between the word pair 以...為 (aim at ... as). The RNN_{512} selects 就 (jiù, "just/on") in the sentence (S10), which is not fluent. The n-gram model, even worse, selects 在 (zài, "in") and makes an incomprehensible sentence (S11).

(S9) 一些 家長 也 **以** 把 孩子 送入 純 女 或 純 男校 為 第一 選擇 (Some parents aim at sending their children into the pure female or pure male school as the first choice)
(S10) 一些 家長 也 **就** 把 孩子 送入 純 女 或 純 男校 為 第一 選擇
(S11) 一些 家長 也 **在** 把 孩子 送入 純 女 或 純 男校 為 第一 選擇

Figure 5 illustrates accuracies of varying order of the n-gram on character level, word level, and word level with POS tag. Results of L1 and L2 testing are shown in Figure 5(a) and Figure 5(b), respectively. As the order of n-gram increases, the models on word level and on word level with POS tag faster growth. In L1 testing, the n-gram model on character level finally achieves an accuracy close those of other two models on word level. In L2 testing, the performance gaps among the three models are more apparent. The information of Chinese word segmentation and POS tags not only speeds up training, but also improves the generalization.



(a) L1 Testing (b) L2 Testing

Figure 5: Accuracy versus order of n-gram in L1 and L2 testing.

Previous work suggests that the ensemble of RNN and traditional language model may improve the performance, especially for the RNN models with small hidden layer (Mikolov, 2012; Mikolov et al., 2011). We build an ensemble model GRU-ME by joint training the GRU model with a 4-gram maximum entropy language model (Berger et al., 1996). The input unit is word with POS tag (w/p), which has best performance in the experiments. The feature size of maximum entropy model is 1 billion. Figure 6 compares the performances between GRU and GRU-ME in L1 and L2. In L1 testing, ensembling the maximum entropy model with GRU significantly increases the performances of three GRU models, especially the ones with smaller hidden layer. In L2 testing, ensembling the maximum entropy model increases the performances of the GRU model with hidden sizes of 128. The results confirm that the RNN models with smaller hidden size gain from the combination of the traditional language model. The performances of the GRU models with larger hidden layer, however, are decreased with the combination of maximum entropy model and GRU. This phenomenon suggests that GRU-ME better fits the training data, but may suffer from overfitting. In contrast, the GRU model with a large hidden size is more robust when it is applied to another corpus.

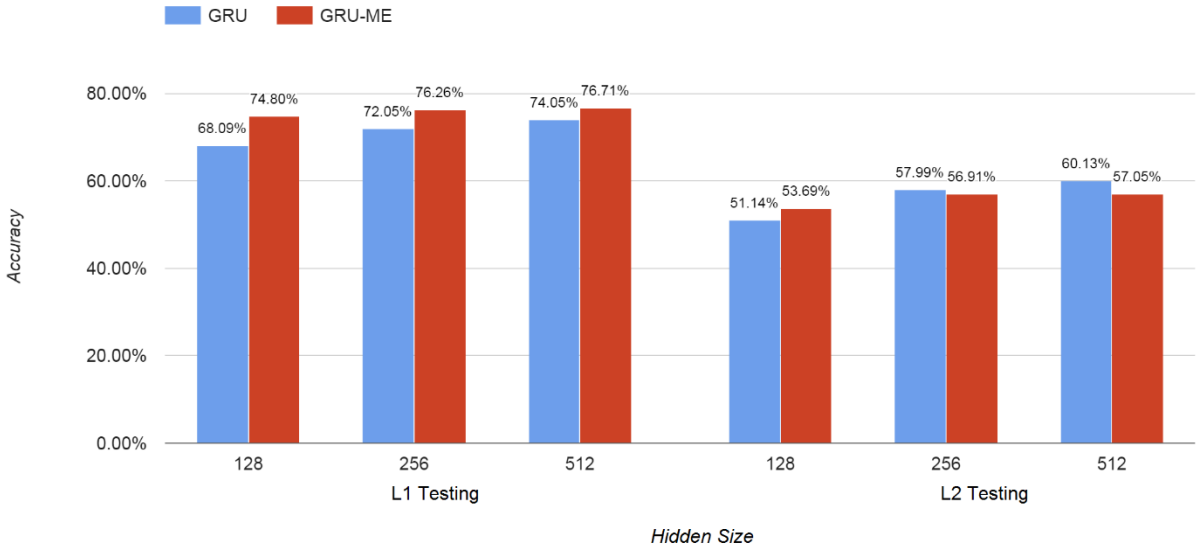


Figure 6: Performances of the GRU and the ensemble of GRU with Maxent (GRU-ME) models in L1 and L2 testing.

8 Conclusion

This work addresses the issue of Chinese preposition selection. We propose a method that uses language models to predict the most probable preposition in a given context. The classical n-gram models and the recurrent neural network models are explored. For the task of modelling Chinese prepositions, the experimental results show the advantage of the GRU models over simple RNN and n-gram models, especially for the cases involving longer distance dependency. In addition, linguistic information from Chinese word segmentation and the POS tagging improve the performances of n-gram and neural network language models. We will further adapt this approach to detection and correction for other grammatical errors in future work.

Abstract

We investigate using Adaptor Grammars for unsupervised morphological segmentation. Using six development languages, we investigate in detail different grammars, the use of morphological knowledge from outside sources, and the use of a cascaded architecture. Using cross-validation on our development languages, we propose a system which is language-independent. We show that it outperforms two state-of-the-art systems on 5 out of 6 languages.

1 Introduction

Morphological segmentation, the splitting of words into smaller units (morphs), is an important sub-task in several natural language processing (NLP) applications. With the increasing interest in NLP for low-resource languages, unsupervised morphological segmentation becomes a crucial pre-processing step to reduce data sparseness: instead of working on a large vocabulary of plausible words, a smaller set of smaller word units is processed.

A well-known toolkit used for unsupervised segmentation is Morfessor (Creutz and Lagus, 2007), which is a generative probabilistic model. In competition, Adaptor Grammars (AGs) (Johnson et al., 2007) represent a framework for specifying compositional nonparametric Bayesian models and are applied in unsupervised segmentation with notable success (Johnson, 2008).

AGs generalize probabilistic context-free grammars by allowing some nonterminals to be "adapted, which allows for dependencies between applications of these rules. Sirts and Goldwater (2013) present an in-depth investigation of the use of AGs. They make two important contributions. First, they discuss the effect of the underlying grammar on the results of unsupervised morphological segmentation. Second, they investigate two ways of using a small amount of annotated data during training. They show that while for English, Morfessor remains the top performing system, on three other languages their approach can beat the high Morfessor baseline.

A typical application for unsupervised morphological segmentation involves situations in which we are confronted with a low-resource language for which no prior NLP work exists, and for which we cannot annotate even a small corpus (either for lack of time, or because no annotators are available). Therefore, in this paper, we are interested in remaining language-independent and entirely unsupervised. We make the following contributions:

- We follow the insight of Sirts and Goldwater (2013) that the underlying grammar in an unsupervised AG approach matters. We explore a much larger set of grammars. We show that for most languages we develop on, the grammars we propose in this paper allow for the best AG results to date. The grammars are discussed in Section 4.

- We explore the use of "scholar-seeded knowledge". Here, instead of annotating even a small set with the desired result of the machine learning process (a segmentation), we search the web for easily accessible information about affixes in our language of interest, and explicitly include these in the grammar used in the AG approach (before learning happens). This can be done in a few hours by a scholar who has never studied the language. We show that generally scholar-seeded knowledge increases the performance. We discuss scholar-seeded knowledge in Section 5.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 900–910, Osaka, Japan, December 11-17 2016.

- We introduce an AG-based approach to approximate the effect of scholar-seeded knowledge: we use a high-precision AG to derive a set of affixes in a first round, and then we insert these into the AGs for the second round. We call this approach "cascaded adaptor grammars". We show that again, our approach generally improves performance. We discuss our cascaded architecture in Section 6.

- The best performing AG-based configuration differs from language to language. However, we would like to have a language-independent system which we can apply to unseen languages. Sirts and Goldwater (2013) solve this problem by using a hand-annotated tuning set to choose the best underlying grammar. We want to remain entirely unsupervised. Therefore, we perform a cross-validation on the six languages, using the five development languages of one fold to determine which grammar to apply to the held-out unseen language. We find that we always obtain the same cascade of the same two grammars for all languages if we do not consider scholar seeding. For the scholar-seeded approach we get a tie between two grammars. We use these cross-validation results to define our LIMS system, which is a language-independent morphological segmentation system, and show that it always outperforms Morfessor and on five out of six languages outperforms the best single AG of (Sirts and Goldwater, 2013). LIMS is our main contribution, and its performance on unseen languages in the cross-validation is our main result.

2 Related Work

Early research on unsupervised morphological segmentation was performed by extensive manual rule engineering, which was very expensive. With the advance of machine learning, minimum description length (MDL) based unsupervised approaches were applied for morphological segmentation in several languages (Goldsmith, 2001). However, this required extensive manual work, which was then replaced by maximum likelihood optimization (Creutz and Lagus, 2002).

Morfessor (Creutz and Lagus, 2007) is a commonly used system for unsupervised morphological segmentation. It is based on a generative probabilistic model. Because of its broad use, we use Morfessor as a reference system in this paper. Another system was developed by Poon et al. (2009), who apply classic log-linear models that use contextual and global features.

Nonparametric Bayesian methods with probabilistic grammars, such as Dirichlet process mixture models (see Antoniak (1974), Pitman (2002)) are widely used in unsupervised learning for NLP. Johnson et al. (2007) introduce nonparametric Bayesian models on whole tree structures, namely; Adaptor Grammars (AGs). AGs provide a flexible distribution over parse trees and are successfully applied in unsupervised segmentation (Johnson, 2008).

Sirts and Goldwater (2013) explore the use of AGs for minimally supervised morphological segmentation. They also compare the performance of different grammar trees. In this paper, we explore a much larger set of grammars, and simulate the performance of doing supervised morphological segmentation without the use of any annotated data or scholar-seeded knowledge.

Snyder and Barzilay (2008) propose a discriminative model for unsupervised morphological segmentation by using morphological chains to model the word formation process. A main drawback in their system is the slow learning curve, which requires a vast amount of data to learn from.

Wang et al. (2016) propose novel neural network architectures that learn the structure of input sequences directly from raw input words and are subsequently able to predict morphological boundaries. The architectures rely on Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997).

3 Problem Definition, Data, and Experimental Setup

The specific problem we are tackling is a segmentation of words in a language into a sequence of morphs. We do not rewrite or normalize morphs, we do not identify the stem, and we do not identify morphological features. For example, the English word *repayments* should be returned as *re pay ment s*.

We perform experiments on six languages, namely English, German, Finnish, Turkish, Zulu and Estonian. The data for English, German, Finnish, Turkish, and Estonian is the data from MorphoChallenge.[1]

[1] http://research.ics.aalto.fi/events/morphochallenge/

For Zulu, we used the Ukwabelana corpus (Spiegler et al., 2010). The sizes of our corpora are summarized in Table 1. Note that we reduced the German dev corpus to obtain only instances with true segmentation; therefore, our results are not comparable to other published results on this corpus. However, all comparisons we present in this paper are always based on the same train and dev corpora.

We use the Adaptor Grammar (AG) package available from Mark Johnson.[2] We run the experiments using nine grammars of different characteristics, which we present in detail in Section 4. All experiments are run using transductive learning, i.e., we include the evaluation data in the unsupervised learning along with the training data. The AG parameters are the same as the ones used by (Sirts and Goldwater, 2013) with 500 sampling iterations instead of 1,000 iterations; early experiments showed that the results of 500 iterations are nearly as good as 1,000 iterations, while fewer iterations decreased performance. We adapt all nonterminals except nontermials with recursive rules. For the AG results, we report the average of five different runs. We also run Morfessor2[3] as a baseline (Virpioja et al., 2013).

Language	Training	Dev
English	50,851	1,171
German	50,537	540
Finnish	51,305	1,031
Turkish	51,096	1,531
Zulu	50,597	1,000
Estonian	50,374	1,497

Table 1: Size of corpora (in types) of our development languages

We evaluate the segmentation against the DEV data from MorphoChallenge. Our evaluation metric is EMMA (Spiegler and Monson, 2010), which is based on morph recognition. EMMA has the advantage that it can return a meaningful result on unsegmented words (also see (Virpioja et al., 2011)).

4 Underlying Grammars

There are three fundamental dimensions in designing the grammars. The first dimension is how the grammar generates prefix, stem, and suffix. The first option is that a grammar does not explicitly model the division into prefix, stem, and suffix at all and only has morphs ("morph-only"); this is illustrated by Morph+SM in Figure 1. If we assume that we do want an explicit modeling of prefixes, stems, and suffixes, we have a "tripartite" grammar. The "tripartite" grammar is illustrated by PrStSu (tripartite, Figure 2). As an example, we give a schematic tree for the word *repayments*; we omit many details such as the handling of the beginning and end of word markers, the details of the recursion within nonterminals with plural names such as `PrefixMorphs` and `SuffixMorphs`, and the details of the generation of morphs through a recursive generation of characters. The plus signs in the trees are just for orientation, they are not actually generated.

A second dimension of modeling is the levels which are represented in the nonterminals. All grammars represent morphs. The tripartite grammars also explicitly model prefixes and suffixes. In addition, we follow Sirts and Goldwater (2013) in allowing morphs to be composed of submorphs; even when we distinguish prefix morphs from suffix morphs in a grammar, the submorphs are shared (as is the case in (Sirts and Goldwater, 2013)). A second option we take from Sirts and Goldwater (2013) is the possibility of having compounding, which is implemented as an iterated nonterminal immediately below the word level. It allows for the generation of compounds in which each compound element has its own prefix, stem and suffix (for example, German noun compounds such as *Ver+läng+er+ung+s+ge+such+e* 'requests for extension').

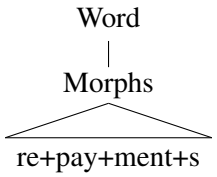

Figure 1: An analysis of *repayments* in Spine2+SM, a morph-only grammar. Submorphs are not shown.

A third dimension is the choice of the division into morphs for the output. If the grammar contains several levels of nonterminals (for example, compounds and morphs, or morphs and submorphs), then morph boundaries can be chosen at different levels (compound, morph, submorph). In the descriptions of our grammars below, we always list the level at which we define the morpheme boundary.

[2] `http://web.science.mq.edu.au/~mjohnson/Software.htm`
[3] `http://www.cis.hut.fi/projects/morpho/`

In developing our set of grammars, we started out with 44 grammars, which included the grammars used in (Sirts and Goldwater, 2013). Using EMMA F-measure as our criterion, we eliminated grammars which did not perform well across our languages, and we eliminated grammars which seemed to perform very similarly to other grammars. We ended up with nine grammars which we use for segmentation; one of these (PrStSu2b+Co+SM) was retained not because of its performance on F-measure, but on precision, which we only use for the first iteration in cascaded AG (which we will present in Section 6).[4] We now present our nine grammars.

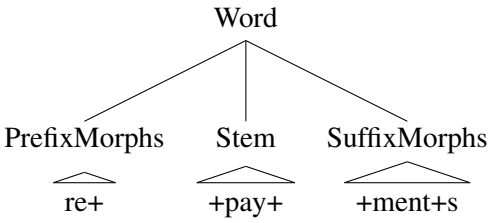

Figure 2: An analysis of *repayments* in PrStSu, a tripartite grammar. Submorphs are not shown.

We first have a morph-only grammar.

• Morph+SM: a word is recursively modeled as a sequence of morphs that consists of a lower level of submorphs, and the segmentation is based on the morph level. This grammar is grammar (2) (AG SubMorphs) from (Sirts and Goldwater, 2013), and we list it among our baselines.

We continue with tripartite grammars.

• Simple: a word is modeled as a sequence of an optional prefix, a stem, and an optional suffix, with no modeling of morphs beyond these three segments. The segmentation is based on the upper prefix, stem and suffix level.

• Simple+SM: the same as Simple with the introduction of a lower submorph level. The segmentation is still based on the prefix, stem and suffix level.

• PrStSu: a word is modeled as a prefix, stem and suffix sequence, where the prefix and suffix are sequences of zero or more morphs. The segmentation is based on the prefix, stem and suffix level. A sample analysis is shown in Figure 2. The segmentation is based on the prefix, stem and suffix level.

• PrStSu+SM: the same as PrStSu with the introduction of a lower submorph level shared by prefix and suffix morphs. The segmentation is based on the prefix morph, stem and suffix morph level.

• PrStSu+Co+SM: the same as PrStSu+SM with the introduction of an upper compound level. The segmentation is based on the prefix, stem and suffix level.

• PrStSu2a+SM: in contrast with PrStSu, where the prefix or suffix can simply be empty (but always exists in the derivation), we now allow the derivation to not have a prefix and/or a suffix. Specifically, a word is modeled as a stem-suffix sequence or a prefix and stem-suffix sequence, where the stem-suffix is a stem or a stem and a suffix. The prefix, stem and suffix are sequences of one or more morphs, with the introduction of a lower submorph level. The segmentation is based on the prefix, stem and suffix level. This grammar is an implementation of grammar (3) (AG Compounding) from (Sirts and Goldwater, 2013) without the compounding (since the compounding did not perform well for our languages), and we list it among our baselines in the result table.

• PrStSu2b+SM: this grammar is similar to PrStSu2a+SM but instead of modeling the the word as a prefix and stem-suffix sequence it is modeled reversely as a prefix-stem and suffix sequence.

• PrStSu2b+Co+SM: the same as PrStSu2b+SM but the upper compound level is added.

The results of the adaptor grammar experiments for our six development languages, English, German, Finnish, Turkish, Zulu and Estonian are in Table 2. Some observations:

- There is vast variation among languages in how grammars perform and which grammar is best.
- One of the grammars always beats the Morfessor baseline, and we always beat the AG baselines of Sirts and Goldwater (2013) except for Finnish. Some of the margins are small and probably not statistically significant.
- Grammar PrStSu2b+Co+SM, which has three levels of morphological representation (compounds, morphs, and submorphs) has very low recall across all languages, perhaps because the resulting morphs are too small (i.e., longer morphs are not predicted).

[4]The grammars are available at `http://www.cs.columbia.edu/~rambow/ag/ag.html` .

5 Scholar-Seeded Knowledge

The intuition behind the use of scholar-seeded knowledge is that for many languages, we have more or less extensive descriptions of their morphology. In fact, traditional descriptive grammars often concentrate on morphology. Today, a lot of information is available online. These resources provide lists of affixes, often in the form of paradigms or tables. Typically, only a very small number of lexemes are used to illustrate the morphology, or the affixes are simply listed without stems. Thus, the data is not a representative (type or token) sample of actual words in the language. We investigate the question of whether this data can be used in unsupervised segmentation. We note that this data is not "data" in the normal sense of machine learning: it is not in the same format as the desired output (i.e., segmented words). Therefore, this is not a case of semi-supervised machine learning, as Sirts and Goldwater (2013) explore.

Adaptor grammars is a framework that is particularly well suited for applying scholar-seeded knowledge as AG takes as input a hand-crafted grammar. Into this grammar, we can explicitly insert the affixes we have gleaned from the literature and from online sources. In Section 4, we investigated nine different grammars. We can insert the same affixes into all of these grammars in the position where morphs are generated. Of course, we continue to allow the grammars to generate new morphs, as we do not expect the sources to contain complete lists.

For these experiments, we consulted only online resources. We spent about two hours per language, and assembled between 30 and 120 affixes.

The results are shown in Table 3. We only show F-measure, and repeat the result for each grammar

Table 3: Adaptor-grammar results (percent Emma F-measure) for English, German, and Finnish (above) and Turkish, Zulu, and Estonian (below) for standard (Std; repeated from Table 2), scholar-seeded (Sch), and cascaded approaches (Casc). Boldface indicates best result by language for that grammar. The first three rows are baselines, and the next seven rows are tripartite grammars.

from Table 2 in the first column of each language. The second column shows the scholar-seeded result. (We discuss the third column in Section 6.) As we can see, the seeding of the grammars with some initial morphs does not, in general, improve our results. We provide a more detailed discussion at the end of the next section.

6 Cascaded Adaptor Grammars

In this approach, we investigate whether we can find the list of affixes which we use in scholar-seeded knowledge automatically, using AGs themselves. The basic approach is as follows:

1. We choose a grammar that has a high precision according to Emma across our development languages. The reason to choose a high precision (rather than a high F-measure) is that we want to be certain of having true affixes in the grammar, rather than having as many affixes as possible (even if some are not correct). We choose grammar PrStSu2b+Co+SM, which achieves the highest precision of all our grammars for English, Finnish, Turkish and Estonian, and close to highest for German. Only for Zulu is the precision mediocre. However, we want to choose a single grammar independently of the language, as we do not want to tune our approach to the language (we have no annotated tuning set).

2. We use this grammar to run AGs in a first iteration, and identify a list of prefixes and suffixes. We order the affixes by frequency.

English: +s, +ed, +ing, +e, +'s, re+, +es, +er, +y, a+, de+, +a, in+, co+, +ers, **ma+**, **ca+**, **se+**, **u+**, **e+**, **n+**, con+, **pa+**, +ly, **o+**, **ra+**, **+o**, **la+**, **ro+**, **ha+**, **ba+**, **mo+**, **ho+**, di+, +s', +ion, pro+, **sa+**, be+, **po+**
German: +en, +e, +er, +t, +s, ver+, be+, ge+, +ung, +es, +te, er+, +ten, +n, an+, ein+, aus+, ab+, +ungen, un+, vor+, zu+, +a, re+, ueber+, ent+, **s+**, +ischen, auf+, +et, +ern, +lich, +in, **+-**, unter+, +ische, **ma+**, +o, +ende, +enden

Figure 3: English and German affixes produced by our cascaded AG, shown in order of frequency in the corpus; incorrect affixes are in **boldface**.

3. We then include the top n affixes from our list in the grammars, in the same way we do for scholar-seeded knowledge. We run AG again, in a second iteration, using these modified grammars. We perform experiments on all our languages with $n = 10, 20, 30, 40, 50, 100$, which we refer to as Cascade$n$.

For example, grammar PrStSu2b+Co+SM finds the prefixes and suffixes for English and German shown in Figure 3; we list the 40 most common affixes (not including the empty prefix and the empty suffix, which are also generated). We show incorrect affixes in boldface. As we can see, the 15 most frequent affixes found for English are indeed correct affixes of English, but among the subsequent 25 most frequent affixes, only seven are correct.[5] In contrast, for German, a language with much richer inflectional and derivational morphology, all but three affixes are correct among the top 40 (and the top 25 are all correct).

The results for Cascade40 (i.e., using the top 40 affixes from the first iteration in the second iteration) are shown in the third column for each language in Table 3. We chose $n = 40$ since it has the best performance across all languages.

We now jointly discuss the results for the scholar-seeded approach (column 2 in Table 3, Section 5) and the cascaded approach (column 3, this section).

- If we simply look for the language-specific best performance, we see that the best score is achieved by a Standard AG for English and Turkish; by a scholar-seeded AG for German, Zulu, and Estonian; and by a cascaded AG for Finnish.

- The cascaded approach in general achieves results that are comparable to the scholar-seeded approach, i.e., we have shown that we can use AGs to provide information that is equivalent for the AG to what we can obtain from scholarly sources and the Internet.

- The scholar-seeded and cascaded approaches outperform the basic AG approach for some languages and some of our grammars. However, many grammars do not profit from scholar seeding or cascading. For example, for grammars PrStSu+SM and PrStSu+Co+SM, for all six languages the best configuration is the simple AG.

- Only for German and Zulu is the best performing configuration exactly the same; each of the other languages has a different configuration as its best performing. We thus do not see a cross-linguistic generalization emerge readily from Table 3.

If we were interested in optimizing performance for each language separately (i.e., by using the development set on which we are reporting results as a tuning set), then we would be done now. However, if we want to optimize our result across languages (as we do in this paper), we need to look more closely at the results, which we do in the next section.

[5]We consulted the Wiktionary pages for English affixes (`https://en.wiktionary.org/wiki/Category:English_prefixes` and `https://en.wiktionary.org/wiki/Category:English_suffixes`), but discarded some affixes which we did not feel were relevant (such and $n+$ as a typographical variant of μ). For German, we used our native speaker knowledge, as the corresponding Wiktionary pages do not contain all inflected affixes.

7 Finding the Optimal Language-Independent System

So far, we have discussed different approaches and presented results only on the development sets. In this paper, we are not interested in maximizing a single language-specific system; instead, we are interested in finding a single system which will perform well on an entirely unseen language (for which we have no annotation at all). To do this, we perform leave-one-out cross validation *on languages*. In each of the six folds of the cross validation, we choose one language in turn as the test language. We average the results for the other five languages (which become our development languages in this fold) for all grammars, for Standard, Cascaded, and Scholar-Seeded. We are interested in two configurations: no use of scholar-seeded knowledge (Standard or Cascaded), and inclusion of scholar-seeded knowledge (Scholar-Seeded). For each of these two configurations, we determine which grammar performs best on average across the five development languages of the fold. We then apply this grammar to the held-out test language. This means that for the held-out language, the choice of grammar was not in any way influenced by any observation from that language.[6] We first describe which grammars we choose in this manner.

- For the configuration without scholar-seeded knowledge, the cross-validation results are shown in table 4. We find that the best performing system for all six averages across five development languages (with the sixth language being held out) is a cascade, starting with PrStSu2b+Co+SM, and then inserting the obtained affixes into PrStSu+SM and running this modified PrStSu+SM. We will call this cascade of AGs LIMS, for Language-Independent Morphological Segmenter.

- For the configuration with scholar-seeded knowledge, the cross-validation results are shown in table 5. We find that the best performing system is split. For three held-out languages (Finnish, Turkish, and Estonian), the best performing grammar for the average of the other five languages is PrStSu+SM (augmented with scholar-seeded affixes), while for the other three held-out languages (English, German, and Zulu), it is PrStSu2a+SM, as shown in table 5. Since we need to choose a single configuration, we (arbitrarily) choose the grammar which we have already chosen for the configuration without scholar-seeded knowledge, namely PrStSu+SM, and we call this system LIMS-Scholar.

Held-out Language (HL)	**Best Grammar for {All - HL} (=G)**	**Ave. F-Score of G on {All - HL}**	**F-Score of G on HL**	**Oracle**
English	PrStSu+SM	70.2%	80.9%	82.6%
German	PrStSu+SM	70.8%	77.7%	79.0%
Finnish	PrStSu+SM	71.9%	72.7%	73.2%
Turkish	PrStSu+SM	74.6%	59.1%	64.7%
Zulu	PrStSu+SM	74.2%	61.1%	61.1%
Estonian	PrStSu+SM	70.3%	80.5%	84.3%

Table 4: Leave-one-out cross-validation results with no use of scholar-seeded knowledge. The Oracle result is the best performing configuration not using scholar-seeded knowledge on the held-out language, as shown in Table 3.

We now have two segmentation systems. LIMS is a black box system which can be applied to any language. LIMS-Scholar is a system which requires input in the form of a list of affixes. Clearly, its performance depends on the list of affixes provided. We present experimental results for these two systems in Table 6. The top two rows are baselines: the Morfessor system used out of the box (Morfessor2[7]), and grammar Morph+SM, which is the same as the AG SubMorphs grammar of Sirts and Goldwater (2013),

[6] We acknowledge that early elimination of additional grammars, not discussed in this paper, was in fact done by considering all languages.

[7] http://www.cis.hut.fi/projects/morpho/

Held-out Language (HL)	Best Grammar for {All - HL} (=G)	Ave. F-Score of G on {All - HL}	F-Score of G on HL	Oracle
English	PrStSu2a+SM	70.4%	77.8%	81.8%
German	PrStSu+SM	70.5%	77.3%	79.3%
Finnish	PrStSu2a+SM	71.7%	72.9%	72.9%
Turkish	PrStSu+SM	76.0%	51.2%	63.4%
Zulu	PrStSu2a+SM	74.6%	56.5%	65.7%
Estonian	PrStSu+SM	70.2%	84.4%	84.4%

Table 5: Leave-one-out cross-validation results with scholar-seeded knowledge. The Oracle result is the best performing configuration using scholar-seeded knowledge on the held-out language, as shown in Table 3.

which obtains the best average across their five development languages (our six development languages but not Zulu). We use our reimplementation of the grammar, and the results we obtain with this grammar are somewhat better than the results published in (Sirts and Goldwater, 2013), probably because of slightly different parameter settings. (Recall that our German data is different from the German data used in (Sirts and Goldwater, 2013).) The following two rows are our two systems. Since LIMS is always the same system, this row is the same as the penultimate column in Table!4. And the last two rows are the best results we obtained for that language across all of our grammars, without and with scholar seeded knowledge. We note that these last two rows are oracle experiments in the sense that we observe all of our results and choose the best configuration. However, if (for some odd reason) we wanted to perform unsupervised segmentation of words in one of our development languages, we would use these systems in the bottom two rows, though we have not demonstrated their performance on unseen test data in those languages (because that is not the goal of this paper).

System	English	German	Finnish	Turkish	Zulu	Estonian	Avg.
Morfessor	80.5%	74.0%	67.5%	55.1%	41.4%	77.9%	66.1%
Morph+SM	80.8%	72.6%	67.2%	53.2%	45.0%	**82.6%**	66.9%
LIMS	80.9%	77.7%	72.7%	**59.1%**	61.1%	80.5%	**72.0%**
LIMS-Scholar	**81.8%**	**79.3%**	**72.9%**	51.2%	**65.7%**	80.4%	71.9%
Best Standard/Cascaded	82.6%	79.0%	73.3%	64.7%	61.1%	84.7%	74.2%
Best Scholar-Seeded	82.1%	79.3%	72.9%	63.4%	65.7%	84.4%	74.6%

Table 6: A comparison between our systems and two baselines: Morfessor and Morph+SM (= AG SubMorphs of (Sirts and Goldwater, 2013)). The two best performing grammars from our experiments are also shown as an oracle result. The best result among the baselines and our systems is boldfaced.

Table 6 shows that for all of our held-out development languages except Turkish and Estonian, LIMS and LIMS-Scholar both outperforms both Morfessor and AG SubMorphs. For Turkish, LIMS outperforms both baselines, but LIMS-scholar outperforms neither. For Estonian, both LIMS and LIMS-scholar outperform Morfessor, while AG SubMorphs performs better than either of our systems. Furthermore, we see that in four of the six held-out languages, LIMS-Scholar outperforms LIMS, but on average LIMS slightly outperforms LIMS-Scholar because of the poor performance on Turkish. We note again that the performance of LIMS-Scholar depends on the quality of the scholar-seeded knowledge, so that one should be cautious with drawing conclusions. However, it appears overall that the cascaded approach of LIMS is a perfectly adequate alternative to using the scholar-seeded knowledge required for LIMS-Scholar.

8 Conclusion and Future Work

We have investigated the issue of unsupervised segmentation using Adaptor Grammars. Unlike recent work, we remain entirely unsupervised, i.e., we do not assume that we have some data which has been annotated by hand. We have experimented with different forms of grammars, the notion of seeding the grammar with knowledge obtained from scholarly publications and the web, and an architecture in which we obtain an equivalent amount of information using an AG, resulting in a cascaded architecture.

In this paper, we are not interested in maximizing performance on our development languages individually, and therefore we have not presented results on held-out test sets for the development languages. Instead, we have performed a cross-validation experiment on languages. We determine the best configuration to apply to the unseen language using only the other development languages, not the unseen language itself. We obtain two systems, which we call LIMS and LIMS-Scholar, with the latter using scholar-seeded knowledge. We show that LIMS outperforms Morfessor on all languages (LIMS-scholar on all but one language), and LIMS outperforms the previous best Adaptor Grammar results on all but one language (LIMS-scholar on all but two languages).

In future work, we intend to perform an extrinsic evaluation, in which an outside task, which requires morphological segmentation in its input, will be used to compare different settings. We will also investigate whether we can estimate the number of affixes to use in the cascaded approach; Figure 3 shows that choosing the top 40 affixes for all languages is not a good choice. Furthermore, we would like to determine in an entirely unsupervised manner the best underlying grammar for a language. This is an appealing goal as the best performance for a language is often superior to that obtained by LIMS or LIMS-Scholar.

Acknowledgments

We thank Kairit Sirts for her insights and for sharing her grammar trees, which we used as a baseline, and some of the data. We also thank three anonymous reviewers for their helpful comments. Abstract

We describe and evaluate a character-level tagger for language-independent Named Entity Recognition (NER). Instead of words, a sentence is represented as a sequence of characters. The model consists of stacked bidirectional LSTMs which inputs characters and outputs tag probabilities for each character. These probabilities are then converted to consistent word level named entity tags using a Viterbi decoder. We are able to achieve close to state-of-the-art NER performance in seven languages with the same basic model using only labeled NER data and no hand-engineered features or other external resources like syntactic taggers or Gazetteers.

1 Introduction

Named Entity Recognition is commonly formulated as a word-level tagging problem where each word in the sentence is mapped to a named entity tag. A typical approach is to slide a window over each word position to extract features for a classifier that produces tags. Moreover, one can allow the classifications at adjacent positions to interact by chaining local classifiers together and perform joint inference. To achieve good performance, one has to overcome the data sparsity problem in the labeled training data. This is achieved by handcrafting good word-level features by exploiting affix, capitalization, or punctuation (Zhang and Johnson, 2003), using the output of syntactic analyzers (part-of-speech taggers, chunkers) and external resources such as gazetteers, word embeddings, word cluster ids to improve performance further (Turian et al., 2010; Ratinov and Roth, 2009). These solutions require significant engineering effort or language specific resources that are not readily available in all languages of interest.

It is even harder to design a multilingual model with handcrafted features considering each language offers different challenges. A distinguishing feature for one language may not be informative for another. For example, capitalization (a typical feature for English NER) is not a distinguishing orthographic feature for the Arabic script. Models for languages with agglutinative or inflectional morphologies may need to utilize the output of a language specific morphological analyzer. In some morphologically rich languages, production of hundreds of words from a given root is common, which makes models even more susceptible to the data sparsity problem.

This work is motivated by the desire to eliminate the tedious work of feature engineering, language specific syntactic and morphological analyzers, and language specific lexical or named-entity resources which are considered necessary to accomplish good performance on Named Entity Recognition. We accomplish this by combining the following ideas: First, instead of considering entire words as the basic input features, we take the characters as the primary representation as in (Klein et al., 2003; Gillick et al., 2016). Second, we use a stacked bidirectional Long Short Term Memory (LSTM) model (Hochreiter and Schmidhuber, 1997) which is able to operate on sequential data of arbitrary length and encode observed patterns in its memory at different scales. Finally, we use a Viterbi decoder to convert the character level tag probabilities produced by the LSTM into consistent word level tags.

Considering characters as the primary representation proves fruitful in several ways. Characters provide sub-word-level syntactic, morphological, and orthographic information that can be directly exploited by our model, whereas word-based models have to incorporate this information using feature

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 911–921, Osaka, Japan, December 11-17 2016.

engineering. Furthermore, useful sub-word features may vary from language to language, which our model can automatically learn but word-based models would have to incorporate using language-specific resources and features. Finally, character-based models reduce the size of the input vocabulary compared to word-level models, using fewer parameters, increasing computational and statistical efficiency.

We report results similar to or better than the state-of-the-art in resource-free Named Entity Recognition in seven languages. Moreover, our proposed model is not limited to Named Entity Recognition in particular and can be applied to other tagging tasks such as part-of-speech tagging.

In the rest of the paper we discuss related work in Section 2, detail our model and describe the input/output representation, stacked bidirectional LSTMs and inference details in Section 3. In section 4, we describe evaluation datasets in detail and present our experiments and results. Section 5 summarizes our contributions.

2 Related Work

In this section, we first outline the previous work on NER with word-level inputs then move onto character-based NER models. Next, we summarize the applications of character-based models in NLP in general.

2.1 Word based NER

Early successful studies on NER use hand-crafted features and language specific name lists with word-level classifiers. Both of the first place submissions in CoNLL-2002 (Spanish & Dutch), CoNLL-2003 (English & German) NER shared tasks (Carreras et al., 2002; Florian et al., 2003) use a rich set of handcrafted features along with gazetteers to achieve top performance. Subsequently, semi-supervised approaches (Ando and Zhang, 2005; Suzuki and Isozaki, 2008; Turian et al., 2010) have reported better results by utilizing large unlabeled corpora. Demir and Ozgur (2014) employs a semi-supervised learning approach to achieve best result for Czech. Darwish (2013) exploits cross-lingual features and knowledge bases from English data sources to achieve the top performance on Arabic. The current state-of-the-art system for Turkish (Seker and Eryigit, 2012) is based on Conditional Random Field (CRF) and utilizes language dependent features along with gazetteers.

2.2 Character based NER

Klein et al. (2003) introduce a Hidden Markov Model (HMM) with character-level inputs to alleviate the data sparsity problem inherent in word-level inputs. Their character-level HMM achieves a 30% error reduction over an HMM with word-level inputs. However, the character-level HMM suffers from unrealistic independence assumptions and it is not able to compete with their best system where they utilize a maximum-entropy conditional Markov model using richer set of features (word, all substrings of the word, part-of-speech and chunk tags). Ma and Hovy (2016) utilize pretrained word embeddings and character-level representation of a word by using a combination of Convolutional Neural Network (CNN), bidirectional LSTM and CRF. They report the best published result for English. Lample et al. (2016) also utilize characters to construct word representations with LSTM-CRF model and relies on unsupervised word representations extracted from unannotated corpora. They announce the best results for German and Spanish. Gillick et al. (2016) adapt the sequence-to-sequence model used for machine translation (Sutskever et al., 2014) to part-of-speech tagging and NER. The model inputs the text as sequence of bytes and outputs span annotations of the form (phrase start byte, length of the phrase in bytes, type of the phrase). Our model CharNER has a similar input/output representation with the character-based HMM of (Klein et al., 2003) and employs a much more compact network than (Gillick et al., 2016).

2.3 Other character-based models

Character-based models have been used successfully for NLP tasks other than NER as well. Depending on the nature of the task, characters are utilized in two different ways. One line of work uses characters to form a word representation for each token in a sentence (Kim et al., 2015; Ling et al., 2015a; Ballesteros

et al., 2015). Alternatively character representations are used without mapping to words first (Klein et al., 2003; Zhang and LeCun, 2015; Ling et al., 2015b; Dhingra et al., 2016).

Ling et al. (2015a) construct vector representations of words by composing characters using bidirectional LSTMs and Kim et al. (2015) employs a convolutional neural network (CNN) over characters to form word representations. Ling et al. (2015a) achieve state-of-the-art results in language modeling and part-of-speech tagging by utilizing these word representations. Kim et al. (2015) use word representations constructed by CNN with recurrent neural network for language modeling. They show that taking characters as the primary representation is sufficient to encode both semantic and orthographic information and their model is on par with the existing state-of-the-art despite having significantly fewer parameters. Ballesteros et al. (2015) employs the same strategy with (Ling et al., 2015a) to represent each token for a continuous-state dependency parsing model. They show that the parsing model benefits from incorporating the character-based encodings of words for morphologically rich languages.

Zhang and LeCun (2015) demonstrate that convolutional neural networks are successful at mapping characters directly to ontology/sentiment classes and text categories. Ling et al. (2015b) introduce a neural machine translation model that views the input and output sentences as sequences of characters rather than words. They show that the model is capable of interpreting and generating unseen word forms. They achieve translation results that are on par with conventional word-based models. Dhingra et al. (2016) proposes a model which finds vector space representations of whole tweets by utilizing character sequences rather than words. Their model performs significantly better compared to word-based counterpart when the input contains many out-of-vocabulary words or unusual character sequences.

3 Model

In this section we outline the architecture of our model, CharNER. We first define the input/output representation. Next we provide preliminary background on LSTMs and bidirectional LSTMs. Then we explain the deep stacked bidirectional LSTM network used in CharNER. Finally, we detail the decoding process.

3.1 Input/Output Representation

Since Named Entity Recognition is proposed as a word-level tagging problem, all of the proposed data sets use word-level tags to denote named entity phrases. A named entity (NE) phrase may span multiple words, hence a NE tag is composed of concatenation of a position indicator (B- Beginning, I- Inside) and a NE type (PER, ORG, LOC, ...). In addition, an O tag indicates that a token is not inside a NE phrase. A named entity phrase starts with a B- tag and if it consists of multiple words, the following word tags are prefixed with I-.

Our model, however, examines a sentence as a sequence of characters and outputs a tag distribution for each character. Therefore, we convert word-level tags to character-level tags. We abandon the position indicator prefixes (B-, I-) and use phrase types (PER, ORG, ...) directly as character tags. If a character subsequence in a sentence constitutes a NE phrase, all of the characters in that subsequence (including spaces) receive the same NE phrase tag. Otherwise, characters get the outside tag (O). Figure 1 shows word-level and character-level tags for an example sentence.

Figure 1: An example sentence with word level and character level NER tags.

3.2 Long Short-Term Memory

Recurrent Neural Networks (RNN) have recently achieved state of the art results in natural language processing tasks such as language modeling (Mikolov et al., 2010), parsing (Dyer et al., 2015), and machine translation (Sutskever et al., 2014). One major problem with simple RNNs is that they are difficult to train for long term dependencies due to the vanishing and the exploding gradient problems (Bengio et al., 1994). Hochreiter and Schmidhuber (1997) developed Long Short-Term Memory (LSTM) to overcome the long term dependency problem. They introduced a special memory cell which is controlled by input, output and forget gates. The input gate controls how much new information should be added to current cell, the forget gate controls what old information should be deleted. The output gate controls the information flow from the cell to the output. Many variants of the LSTM have been developed, in this study we use the LSTM architecture with peephole connections which was proposed by Gers et al. (2000). The LSTM memory cell is defined by the following equations[1]:

$$
\begin{aligned}
f_t &= \sigma(\boldsymbol{W_{fx}} x_t + \boldsymbol{W_{fh}} h_{t-1} + w_{fc} * c_{t-1} + b_f) \\
i_t &= \sigma(\boldsymbol{W_{ix}} x_t + \boldsymbol{W_{ih}} h_{t-1} + w_{ic} * c_{t-1} + b_i) \\
c_t &= f_t * c_{t-1} + i_t * \tanh(\boldsymbol{W_{cx}} x_t + \boldsymbol{W_{ch}} h_{t-1} + b_c) \\
o_t &= \sigma(\boldsymbol{W_{ox}} x_t + \boldsymbol{W_{oh}} h_{t-1} + w_{oc} * c_t + b_o) \\
h_t &= o_t * \tanh(c_t)
\end{aligned}
$$

where σ is the logistic sigmoid function, $\tanh$ is the hyperbolic tangent function and $*$ is element wise multiplication. f, i and o are the forget, input and output gates respectively, c denotes the cell vector, and h is the hidden state vector. All gate vectors and the cell vector have the same dimensionality as the hidden state vector. Bold upper case letters stand for matrices, lowercase variables are vectors, and subscripts indicate the connection (e.g. $\boldsymbol{W_{fx}}$: input to forget gate weight matrix).

3.3 Bidirectional LSTMs

It is a common approach to use both preceding and following tokens to derive features for the current token in natural language processing tasks. If we look at the LSTM equations, the current output depends only on previous inputs, the initial cell value and hidden state. Graves and Schmidhuber (2005) proposed bidirectional LSTM (BLSTM) to gain information from future inputs. In a BLSTM, two LSTM components are present, namely the forward LSTM and the backward LSTM. The forward LSTM traverses the sequence in the forward direction and the backward LSTM traverses same sequence in the reverse order using h_{t+1} and c_{t+1} are used instead of h_{t-1} and c_{t-1} for the gate calculations. For example, input gate at time t is calculated using the following:

$$
i_t = \sigma(\boldsymbol{W_{ix}} x_t + \boldsymbol{W_{ih}} h_{t+1} + w_{ic} * c_{t+1} + b_i)
$$

In a bidirectional model the output at time t depends on both the forward hidden state $\overrightarrow{h_t}$ and the backward hidden state $\overleftarrow{h_t}$.

3.4 Deep BLSTMs

The CharNER model uses bidirectional stacked LSTMs (Graves et al., 2013) to map character sequences to tag sequences. Figure 2 demonstrates the model overview. The network takes characters as the input sequence and each character is fed into the first forward and backward LSTM layers as one-hot vectors. The output of the first forward and backward layers are concatenated and fed into the next layer. The same process is carried on for the additional BLSTM layers. To obtain the distribution over the tag at position t, an affine transformation followed by a softmax is applied to the hidden representation of the final BLSTM.

[1] We denote matrices with bold upper case letters and vectors with lower case letters.

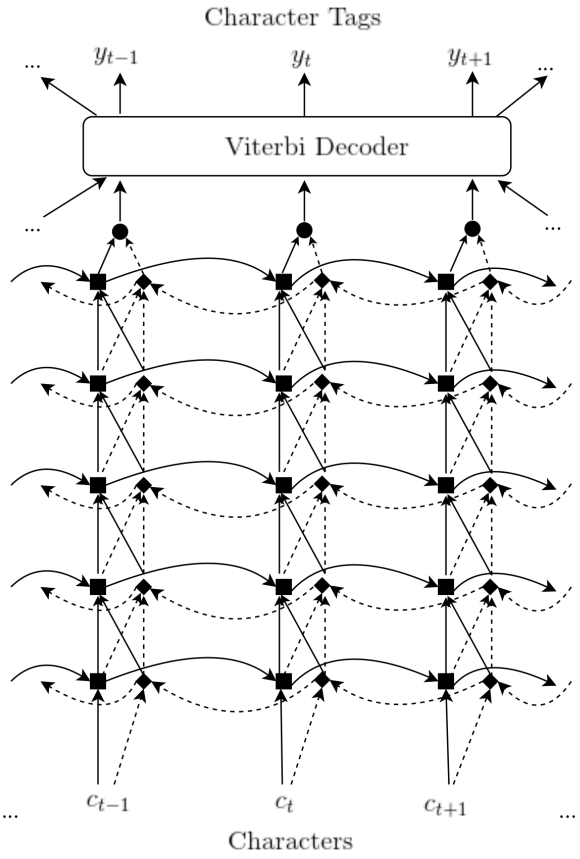

Figure 2: CharNER model: 5-layer Bidirectional LSTM Network with a Viterbi decoder. Each square and diamond node represents a forward and backward hidden LSTM layer, respectively. Circles denote the output layer (i.e. softmax layer). Solid lines show forward connections and dashed lines show backward connections. The model takes characters as an input sequence and each character is represented with a one-hot vector (c_t). A Viterbi decoder takes the sequence of character tag probabilities that is produced by the softmax layer and produces most likely character tag sequence (y) that is consistent at the word level.

3.5 Decoder

The deep BLSTM gives us a tag distribution for each character position. In this section we discuss the final step of turning these character level tag distributions into word level tags.

In early experiments, we observed that the most probable character tags within a word were not always consistent. For example, the model may assign higher probability to person (P) tags in the beginning of a word and organization (G) tags at the end of the same word. Even though the deep BLSTM has access to both left and right input contexts, it is unable to learn word level consistency for output tags. To remedy this, we use a decoder similar to (Wang et al., 2015).

Given a character sequence $c_1, c_2, ..., c_n$ (henceforth denoted with $[c]_1^n$), and a tag set $y \in \mathcal{Y}$, the decoder takes output tag probabilities from the LSTM, $o(c_i)_{y_i} = p(y_i \mid [c]_1^i, [c]_i^n)$, as emission probabilities and exploits transition matrices, A_{ij}, that only allow tags consistent within a word. Three types of transitions can occur between consecutive character tags (y_{i-1}, y_i) according to the position of the character at hand. A character is either followed by a fellow character in the same word ($c \rightarrow c$) or it can be the last character of a word followed by space ($c \rightarrow s$) where c denotes a character inside word boundaries and s denotes the delimiter space. Finally, it can be a space character followed by the first character of the next word ($s \rightarrow c$). The entries in Table 1 show transition matrices A_{ij} for these three states.

	PER	ORG	O	PER	ORG	O	PER	ORG	O
PER	1	0	0	1	0	1	1	0	0
ORG	0	1	0	0	1	1	0	1	0
O	0	0	1	0	0	1	1	1	1
	$c \rightarrow c$			$c \rightarrow s$			$s \rightarrow c$		

Table 1: Example transition matrices for two phrase types (PER, ORG) and Outside (O). c denotes a character inside word boundaries and s denotes the delimiter space.

The score of a sentence $[c]_1^n$ along a path of tags $[y]_1^n$ is computed by the product of transition scores

and model output probabilities:

$$s([c]_1^n, [y]_1^n) = \prod_{i=1}^{n} A_{y_{i-1}y_i} o(c_i)_{y_i} \quad (1)$$

The path of tags with the highest sentence score is computed by:

$$[y^*]_1^n = \arg\max_{[y]_1^n} s([c]_1^n, [y]_1^n) \quad (2)$$

To find the path of tags with the highest sentence score we use the Viterbi algorithm (Viterbi, 1967). Once a character tag sequence is decoded without violating word boundaries, it is trivial to convert these tags to word-level tags.

4 Experiments

This section presents our experiments and results. We start by describing the evaluation datasets with their properties. We detail our network training and demonstrate how changing the shape of the network effects performance. We present the results of our model on a variety of languages and compare with related work.

4.1 Datasets

In order to evaluate our system, we applied our model to NER datasets in various languages. The shared tasks of CoNLL-2002 and CoNLL-2003 provide NER data for four languages, Spanish, Dutch, English and German. In addition to these datasets, we evaluated our model on languages with rich morphologies: Arabic, Czech and Turkish. The Turkish NER dataset was prepared by (Tür et al., 2003). For Czech, Konkol and Konopík (2013) make the dataset prepared by (Ševčíková et al., 2007) CoNLL compatible. Benajiba et al. (2007) prepared ANERCorp for Arabic Named Entitiy Recognition. All of the datasets except Turkish and Arabic have conventional training, development and test splits. The Turkish dataset is provided with training and test sets. We separated a small fraction of the training set for development. Since the Arabic dataset (ANERCorp) do not have training and test splits, we applied Monte Carlo cross validation (Arlot et al., 2010) with 3 random runs. All of the datasets are in CoNLL format and we used the CoNLL evaluation script to report phrase-level F1 scores. Table 2 gives the number of sentences.

	Arabic	Czech	Dutch	English	German	Spanish	Turkish
Train	3988	4644	15806	14041	12152	8323	30000
Dev.	-	572	2895	3250	2867	1915	2237
Test	797[2]	577	5195	3453	3005	1517	3336

Table 2: Number of Sentences for Training, Development and Test sets.

In some morphologically rich languages production of hundreds of words from a given root is common, which increases data sparsity. We present unique, phrase-wide and corpus-wide unknown word percentages in Table 3 where a word is considered unknown if test set contains it but the word is absent in training. The Unique row counts an unknown word only once while the Phrase and Corpus rows consider all the occurrences of an unknown word in NE phrases and the whole test set, respectively.

	Arabic	Czech	Dutch	English	German	Spanish	Turkish
Unique	34.88	43.18	43.42	38.92	47.46	26.85	30.08
Phrase	18.82	35.54	39.28	31.27	42.20	18.39	13.82
Corpus	15.52	21.33	10.08	12.18	14.28	6.25	11.22

Table 3: Unknown Word Percentages.

[2]Randomly sampled with replacement for each run.

We give a brief comparison word-level and character-level views in Table 4. The number of unique tokens and average sequence length are indicated for each language. Switching from word-level to character-level view reduces the number of unique tokens drastically while making the input sequences longer. For direct comparison we trained and evaluated the same CharNER architecture (5 layer BLSTM with hidden size of 128) on both word-level and character-level data. The character-level model yields improved results for all datasets.

		Arabic	Czech	Dutch	English	German	Spanish	Turkish
Char	X	136	136	101	85	96	92	100
	μ_l	149	142	70	76	105	173	90
	F1	75.12	76.87	79.03	90.75	71.64	79.02	93.58
Word	X	27050	34869	27803	23623	32932	26099	63703
	μ_l	27	25	12	14	17	31	13
	F1	74.50	56.77	61.72	84.12	50.68	68.09	91.82

Table 4: Comparison of word-level and character-level views. X denotes the number of unique input tokens and μ_l denotes the average sequence length. F1 gives the best scores achieved on development sets when the same architecture is used on both word-level and character-level data.

4.2 Network Training

We use Adam (Kingma and Ba, 2014) for the gradient based training of the network[3] and we find that the default parameters given in the original study work well for this task. We update our network parameters after each mini-batch of 32 sentences. Before mini-batching, we sorted sentences according to character length to group sentences with similar lengths to speed up training. Also, we shuffle the order of mini-batches prior to each epoch. We use 5 BLSTM layers of size 128 (both forward and backward) stacked on top of each other and apply dropout (Srivastava et al., 2014) to outputs of each layer including the input layer. When no dropout is used, the network overfits the training data quickly and loses the generalization power. Notice that dropout at the input layer turns off bits of characters at random positions in the sequence. Applying dropout to character sequences yields +2 F1 score (absolute). To stabilize the network training, we use gradient norm clipping to prevent gradients from diverging (Pascanu et al., 2012). We set the maximum total norm of the gradients as 1. We tested several configurations of hyperparameters of the network and picked parameters that work well across the all seven languages. Although one may obtain further improvements by tuning hyperparameters as well as depth and width of the network for each dataset individually, we kept the hyperparameters and model configuration same for each language to demonstrate that one can achieve adequate results with the same model across many languages.

	Hidden Size		
Depth	64	128	256
1	52.06	56.27	57.98
2	60.31	68.72	70.77
3	67.22	71.09	70.84
4	70.16	71.70	71.60
5	70.79	72.19	70.53

Table 5: F1 scores on Czech test set for networks with different depths and hidden sizes. Depth denotes the number of layers the network has and Hidden Size denotes the number of hidden units for each layer.

4.3 Network Shape

We experimented with different configurations by varying the number of layers the network has (depth) and number of hidden units in each layer (width). We evaluated different volumed networks on Czech dataset which is modest in size and have conventional training, development and test splits. We summarized the results in Table 5.

Table 5 shows that increasing the depth of the model is more beneficial than increasing the width of the model. Although the wider model (width=256) yields better results when the network is shallow, its advantage disappears as the network gets deeper. Nevertheless, performance of narrow model (width=64) is limited compared to the model with medium width (width=128).

4.4 Need for a Decoder

As discussed in Section 3.5, the deep BLSTM does not output probabilities that always favor a single tag within a word. Character level NER is a structured learning problem, i.e. there are dependencies between the outputs that are difficult to capture by the deep BLSTM which only has access to the input sequence. To quantify the effect of capturing these dependencies, we ran a simpler baseline model for comparison. We did not apply Viterbi decoding to the output probability distributions of the network and picked the most probable tag for each character. Then, we used majority voting between characters of the same word to assign single tag to a word. With this scheme, we observed 2 F1 (absolute) performance drop on Czech dataset.

4.5 Results and Discussion

Here we present the performance of our model on languages with diverse characteristics. Since our model only uses the labeled training data, and no external resources such as gazetteers, we selected previous works which report the top scores without use of any additional data to make a fair comparison. We also included the best results which do make use of arbitrary external resources for each language. We summarized all the comparisons in Table 6.

The results highlight that our model attains good performance and it is robust across variety of languages. We achieve similar to or better than the state-of-the-art in Named Entity Recognition that use no external resources. Abdul-Hamid and Darwish (2010) employ a CRF sequence labeling model which is trained on features that primarily use character n-gram of leading and trailing letters in words and word n-grams. They assert that the proposed features help overcome some of the morphological and orthographic complexities of Arabic. Although they do not utilize any external resource, they apply Arabic specific input preprocessing before training which may be the reason for better performance. Demir and Ozgur (2014) employs a window-based classifier approach with language independent features for

	Arabic	Czech	Dutch	English	German	Spanish	Turkish
Best	84.30 [1]	75.61 [2]	82.84 [3]	91.21 [4]	78.76 [5]	85.75 [5]	91.94 [6]
	79.90	68.38	78.08	80.79	-	-	82.28
Best w/o External	81.00 [7]	68.38 [2]	78.08 [3]	84.57 [3]	72.08 [3]	81.83 [3]	89.73 [2]
CharNER	78.72	72.19	79.36	84.52	70.12	82.18	91.30

Table 6: Phrase-level F1 scores. The bottom row presents our model's results across seven languages. The middle row consists of models that report the top scores while not using any external resources, comparable to our model. The top row presents state-of-the-art models that achieve the best results in each language utilizing external resources like word embeddings or Gazetteers. The top row also reports the scores of best models when they only use NER training data, if available. Works are numbered in the order of appearance: [1] (Darwish, 2013), [2] (Demir and Ozgur, 2014), [3] (Gillick et al., 2016), [4] (Ma and Hovy, 2016), [5] (Lample et al., 2016), [6] (Seker and Eryigit, 2012), [7] (Abdul-Hamid and Darwish, 2010)

[3]Code repository: https://github.com/ozanarkancan/char-ner

Czech and Turkish. We outperform their results by a considerable margin for both languages. Gillick et al. (2016) reports the top scores with no external resources for Dutch, English, German and Spanish. They achieve higher F1 score for German dataset, however, our model performs better for Dutch and Spanish despite having 50% less parameters. Our result is on par with (Gillick et al., 2016) for English dataset.

Most state-of-the-art NER models are obtained by handcrafting good word-level features and generally utilizing external information sources. Models usually resort to additional training resources: (1) when training and test set are not from the same data generating distribution (English) or (2) training set is small (Arabic and Czech). Ma and Hovy (2016) report the best published F1 score (91.21%) for CoNLL-2003 English dataset. Without pretrained word embeddings however, their model loses approximately 10 F1 score (absolute). Lample et al. (2016) also relies on unsupervised word representations extracted from unannotated corpora. They announce the best results for German and Spanish datasets. On the other hand, Demir and Ozgur (2014) utilize pretrained word embeddings along with their corresponding word cluster ids to achieve top performance on Czech dataset. Darwish (2013) outperforms (Abdul-Hamid and Darwish, 2010) by 3.4 F1 score by exploiting cross-lingual features and knowledge bases from English data sources. Moreover, language specific expertise can be incorporated to improve the performance. The current state-of-the-art system for Turkish (Seker and Eryigit, 2012) achieves 91.94% F1 score by using language dependent features along with gazetteers. Finally, Gillick et al. (2016) achieves the best result for Dutch by using concatenated Dutch, English, German, Spanish training sets as one. Even though we do not use any additional training source, the performance of our model is competitive for Czech, Dutch, Spanish and Turkish.

5 Contributions

We describe a character-level tagger employing a deep bidirectional LSTM architecture and evaluate it on the Named Entity Recognition task. We showed that taking characters as the primary representation is superior to considering words as the basic input unit. Our main contribution is to show that the same deep character level model is able to achieve good performance on multiple languages without hand engineered features or language specific external resources.

In our current research, we are exploring ways to boost the performance of our model using semi-supervised and transfer learning. Moreover, our method may be promising for languages written without space characters such as Chinese and Japanese since word segmentation error affects the score of NER. Also, there is nothing specific to NER in our model, we are planning to evaluate it on other tasks such as part-of-speech tagging and shallow parsing.

A Neural Model for Part-of-Speech Tagging in Historical Texts

Christian Hardmeier
Uppsala University
Dept. of Linguistics and Philology

first.last@lingfil.uu.se

Abstract

Historical texts are challenging for natural language processing because they differ linguistically from modern texts and because of their lack of orthographical and grammatical standardisation. We use a character-level neural network to build a part-of-speech (POS) tagger that can process historical data directly without requiring a separate spelling normalisation stage. Its performance in a Swedish verb identification and a German POS tagging task is similar to that of a two-stage model. We analyse the performance of this tagger and a more traditional baseline system, discuss some of the remaining problems for tagging historical data and suggest how the flexibility of our neural tagger could be exploited to address diachronic divergences in morphology and syntax in early modern Swedish with the help of data from closely related languages.

1 Introduction

Most tools for automatic linguistic text annotation are based on supervised learning and trained on manually annotated text samples such as treebanks. This approach works best when the texts to be annotated are very similar to the language in the training corpora. The greater the differences, the more difficult it becomes to do automatic annotation with high accuracy. One application that poses particular challenges is automatic processing of historical texts. Language records from a few centuries ago are often still intelligible to modern readers, but they can nonetheless exhibit substantial divergence from later language use in terms of orthography, morphology, syntax, etc. Moreover, the languages we speak and write have undergone relatively recent processes of standardisation. Historically, there was much more variety in spelling and grammar both across and within texts, making the data sparseness problems we know from modern language processing even more acute. Standard approaches to deal with this challenge include manual or semi-automatic annotation of historical data sets to train language processing tools or automatic spelling normalisation to convert historical into modern spellings for the purpose of applying standard tools for modern language.[1] In this work, we present a neural network model to do part-of-speech (POS) tagging in historical texts. Our model uses a modern POS-tagged data set and a historical corpus with original and normalised spellings for training, but reads historical data without specific preprocessing at test time. We test the model on a Swedish verb identification and a German POS tagging task and analyse the output of the model to identify some remaining challenges to be addressed in future work.

2 Model Architecture

The core of our neural network is a POS tagger. The network takes as input a sentence in the form of a sequence of characters. For each character, it computes a representation in the form of a dense, approximately 50-dimensional vector that captures information about the character and its preceding and following context. The vector representations occurring at word boundaries are then used to predict a POS tag for each of the words in the sentence. At training time only, the model contains additional components

[1] For an overview of the relevant literature, we refer the reader to the recent PhD thesis by Pettersson (2016).

to ensure that the context-dependent vector-space representations created by the model are similar for historical data in original and normalised form.

Our character-level POS tagging model is shown in Figure 1. It is inspired by the work of Ling et al. (2015). The input of the model is a sentence split into characters. No normalisation or preprocessing is done at this point, and the input vocabulary consists of all Unicode code points encountered in the historical training set or its normalised form. In addition to the uppercase and lowercase letters of the modern alphabet, this also includes various forms of punctuation and letters with different diacritics, some of which are specific to the transcriptions of historical texts. The input characters are first transformed into dense character embeddings using a lookup table with trainable weights (**1**). Then, the entire sequence is scanned with a bidirectional recurrent neural network (Schuster and Paliwal, 1997) composed of gated recurrent units (GRUs; **2**) (Cho et al., 2014). The output states of the GRUs are passed through a linear layer and fed as inputs into another GRU layer (**4**). Up to this point, we are still processing the data at the character level and taking into consideration the context of the entire sentence. Unlike the model by Ling et al. (2015), our tagger never creates cacheable word embeddings that are independent of the surrounding words. We expect that this optimisation, which is used to speed up tagging in the Ling et al. model, would be less effective for historical than for modern text because of the greater spelling variability.

The transition to the word level, a prerequisite for predicting word-level POS tags, is done in the next step by combining, for each word, the final state reached by the forward and backward part of the bidirectional layer **4** after processing the word in question. These states are combined linearly (**5**), fed into a hidden layer using the hyperbolic tangent activation function (**6**) and passed on to a final softmax layer that outputs a probability distribution over the POS tagset (**7**).

The layer sizes of our network are shown in Table 1. Owing to memory limitations of the hardware we trained our systems on (Nvidia K20 GPUs with 5 GB of RAM), we could not test larger layer sizes systematically. Increasing the size of the hidden layer **6** from 100 to 300 brought a consistent improvement of 1–2 percentage points in F-score or accuracy for all experiments on Swedish. For German, the results were less conclusive, and the overall best model has a hidden layer of size 100.

3 Model Training

The situation we consider in our experiments is one in which we have access to a POS-tagged training corpus of modern language as well as an unrelated corpus of historical texts in original and modern spelling, but not a POS-tagged training corpus of historical text. This corresponds to the actual situation for Swedish. Our historical training corpus for German does in fact contain a small amount of gold-standard POS annotations. In this paper, these are not used other than for comparison and evaluation.

The training objective we optimise our models for is to *maximise POS tagging performance on the tagged corpus* whilst *ensuring that the RNN states generated from historical texts in original spelling are similar to those arising from the corresponding normalised forms.* To achieve this, we compute two types of training error at every training step. The first is obtained by feeding a training example from the modern POS-tagged training set into the neural network shown in Figure 1. The *POS training error* E_{POS} of the training example is defined as the cross-entropy of the predicted tag distribution with respect to the gold-standard solution. For the second, we take a training example from the historical corpus and separately calculate the context-dependent word representations of the original historical text and its normalised form using layers **1** to **5** of the neural network, but omitting the hidden layer **6** and the final softmax layer. The *normalisation training error* E_{norm} of the training example is the squared error between the representation generated from the historical spellings and the representation of the normalised forms. The training examples used for the calculation of the two error types are independent from each other and paired randomly. The overall training objective is a weighted combination of the two error types:

$$E_{\text{total}} = \lambda E_{\text{POS}} + (1-\lambda) E_{\text{norm}} \tag{1}$$

To train our model, we apply minibatch stochastic gradient descent with a learning rate of 0.01, together with gradient clipping (Pascanu et al., 2013) to a maximum ℓ_2 norm of 10. The minibatch size was set to 30. We found that this batch size tended to give better results than smaller batches. Larger values could not be tested because of memory restrictions of our computer systems. The input sentences from both the POS-tagged corpus and the historical training corpus are cut at word boundaries into segments of approximately 25 words. To improve training efficiency, minibatches are formed from segments of similar length. The systems are trained on 100,000 to 200,000 minibatches, which corresponds to a wall-time limit of approximately 48 hours per training run. The error on the validation set is checked after every 3,000 batches. The set of parameters selected for evaluation purposes is the one that achieved the lowest validation error during training.

4 Tasks, Data Sets and Baseline System

We apply our model to two different tasks known from the literature. For Swedish, we address the problem of verb identification in historical texts. This task was introduced by Pettersson and Nivre (2011). It is motivated by its use in a historical research project named *Gender and Work* (Fiebranz et al., 2011). The goal of the *Gender and Work* project is to study the activities that men and women, respectively, carried out for a living in early modern Sweden (1550–1800). One of the core methods used in this project

was the systematic identification of verb phrases describing such activities in historical documents. In the course of the project, Pettersson and her colleagues developed data sets and methods to support the automatic annotation of such verb phrases (Pettersson, 2016). For German, the availability of a corpus of historical texts with gold-standard POS annotations allows us to tackle the more general task of POS tagging for historical texts.

For each language, we need a modern corpus annotated with POS tags and a corpus of historical texts in original and normalised spelling. Additionally, we need historical data with verb annotations or POS tags to evaluate our systems. Table 2 shows an overview of the corpora used in our experiments. For Swedish, we closely follow the setup of the experiments of Pettersson (2016). As a modern resource annotated with POS tags, we use version 2.0 of the Stockholm-Umeå corpus (SUC), a fairly large balanced collection of Swedish texts from the 1990's (Gustafson-Capková and Hartmann, 2006). We removed the last 1,000 sentences of the corpus to be used, in equal parts, as validation and test sets. As a historical training corpus, we have the *Gender and Work* corpus (Fiebranz et al., 2011; Pettersson, 2016). The split of this corpus into different data sets corresponds to the experiments of Pettersson (2016). The *training* and *validation* sets (corresponding to the training and tuning sets of Pettersson's spelling normalisation experiments) are used for neural network training and validation. The *development* set (corresponding to Pettersson's spelling normalisation evaluation set, which she subsequently used as a development set for verb phrase identification) was used as a test set during development. Finally, the *test* set (corresponding to Pettersson's verb phrase evaluation set) was used as a held-out set for the final evaluation of our model.

For German, our modern POS-tagged resource is the NEGRA corpus (Skut et al., 1997). As for SUC, we removed the last 1,000 sentences for validation and testing. Our historical data for German comes from the gold-standard portion of the GerManC corpus (Scheible et al., 2011), a corpus of early modern German (1650–1800) annotated with normalised spelling, lemmas and POS tags. The manually annotated gold standard part of this corpus consists of 24 documents. We set aside two of the more recent documents each for validation ("Ursprung", 1772; "Wolfenbüttel 1", 1786) and testing ("Gottesdienst", 1770; "Anton Reiser", 1790) and use the rest as training data.

Our baseline systems are modelled on the best-performing approach of Pettersson (2016) and consist of a pipeline that first normalises the spelling of the historical texts to be as similar as possible to modern orthography and then applies standard natural language processing tools trained on modern resources. The spelling normalisation component is a character-based statistical machine translation (SMT) system (Pettersson et al., 2013) implemented with the Moses toolkit (Koehn et al., 2007). It is a phrase-based SMT model with phrase length 10, disabled reordering and a 10-gram language model with modified Kneser-Ney smoothing (Chen and Goodman, 1998). The feature weights are tuned with minimum error-rate training (Och, 2003) to optimise the character error rate of the output. The default values of the Moses training pipeline and decoder are used for all other settings. After spelling normalisation, we run the HunPos tagger (Halácsy et al., 2007) for verb identification and POS tagging. Our HunPos models for Swedish and German are trained on exactly the same modern data sets as our own neural network tagger. For German, we also have the possibility to train HunPos on historical text with gold-standard POS tags from the GerManC corpus as another point of comparison.

5 Results

Table 3 shows the results of our two best-performing neural network taggers together with some comparative figures. The POS weight λ refers to the parameter in the error function in Equation 1. With equal weights for the POS tagging error and the normalisation error, our system reaches an F-score of 0.8668 on the development set and 0.8427 on the test set. Precision is higher than recall on the development set, but on the test set they are fairly balanced. Increasing the POS weight to 0.8 leads to an improvement to 0.8695 on the development set, which also carries over to the test set and gives us an F-score of 0.8529, about one percentage point over the result with equal weights. Decreasing the POS weight to 0.2 gives lower scores (not reported here).

The most interesting point of comparison is, of course, the HunPos system with SMT normalisation that emerged as the best model from the study of Pettersson (2016). Our own implementation of this

	SUC tagging	Historical verb identification

Table 4: Results for German POS tagging and verb identification

system achieves an F-score of 0.8601 on the test set, about half a percentage point better than the result of 0.855 reported by Pettersson for her corresponding system. The difference could be due to the feature weight settings of the SMT normalisation model or to some other minor difference in training parameters. Compared with those results, the scores achieved by our neural network tagger are very close, but still slightly lower. This corroborates Pettersson's finding that SMT normalisation is a very strong method for processing Swedish historical texts.

The other two contrastive systems reported in Table 3 are trained towards tagging modern Swedish without specific accommodations for historical text. Our character-based neural network tagger trained with a λ weight of 1.0 (at an F-score of 0.7055) seems to be slightly more robust to the unexpected historical spellings than HunPos (at 0.6632), but as expected, both models perform substantially worse in this setting.

The results of our experiments with German are in Table 4. The table includes POS tagging accuracies for the modern (NEGRA) and historical (GerManC) corpora. For better comparison with Swedish, it also includes precision, recall and F-score values for a historical verb identification task. These results were derived from the POS tagging results by considering only those word classes that would be tagged as verbs in the Swedish verb identification setup (i. e., finite, infinite and imperative forms of main, auxiliary and modal verbs, but not participles since they have a separate tag in the SUC tag set).

Unlike for Swedish, we do not see a consistent advantage from enlarging the final hidden layer **6** in the German experiments, and indeed the best overall score on the GerManC corpus is achieved with a layer **6** size of 100 in combination with a λ weight of 0.8. The development score of our best system is 2.8 percentage points above the HunPos baseline without normalisation, which already performs quite well on this task, but still 1.9 points below the baseline with SMT normalisation. On the test set, the neural system performs almost on a par with the SMT normalisation baseline; the small remaining difference corresponds to only 5 additional mistagged tokens out of 4,845. Increasing the size of layer **6** to 300 without additional regularisation results in development accuracy scores on the order of the HunPos baseline without normalisation. On the test set, these systems still outperform the unnormalised system and achieve scores that are only 0.4–1 percentage points lower than those of the comparison systems.

When we evaluate the experiments as a verb identification task, we see mixed results. Spelling normalisation, either in the form of a normalisation error term during neural network training or as a separate preprocessing step, has a clear advantage, but all normalisation-aware systems achieve fairly similar F-scores around or just under 90 %. Pitting our best-performing system against the baseline with SMT normalisation, we find that the latter has an advantage on the development set, but the former wins on the test set. Compared to the results on Swedish, the performance on German is even more similar. On the whole, we can conclude that both system types are clearly viable approaches to this task.

It is interesting to observe that the additional constraint we impose on the neural network tagger by requiring that its internal representation of historical spellings should be similar to that of modern text does not have a negative effect on its tagging performance for modern text. Indeed, both of the adapted Swedish systems in Table 3, while still about 1.5–2.5 percentage points below the performance of HunPos, achieve higher scores on the SUC test set than the tagger trained without the additional constraint. For German, tagging performance on modern text lags more behind the HunPos benchmark and the effect of adding the normalisation error is smaller, but still slightly positive. We have not studied this result in detail, but one could speculate that the normalisation error term adds a form of regularisation to the model that improves its performance on the original domain.

6 Qualitative Observations and Discussion

To gain a clearer picture of the strengths and weaknesses of our tagging models, we subjected the output of the models on the final test sets to a manual qualitative study. The study was done informally by looking through the original text, the spelling produced by the SMT normalisation step, the gold-standard annotations and the annotations generated by our own best system and by the HunPos baseline with SMT normalisation in parallel. For each language, we checked approximately 20 % of the test set data. For German, we additionally consulted the confusion matrices for the test set annotations generated by the baseline with SMT normalisation and by our best neural network tagger.

6.1 Swedish

For Swedish, we find very few qualitative differences between the baseline tagger and our neural system. By and large, both systems seem to struggle with the same difficulties, and they often make the same errors in parallel. In the Swedish verb identification task, by far the most common source of errors was a confusion between the tags for common nouns, NN, and verbs, VB. We encountered both nouns marked as verbs and vice versa, and both errors were frequent in both systems, making it difficult to draw conclusions about the properties of a specific system from these observations. Another type of error that occurred frequently in both systems was a confusion between verbs (VB) and participles (PC), which is understandable since participles are inflected verb forms and the tested systems are explicitly designed to be tolerant towards orthographical details. Other frequent sources of errors included confusions of verbs with adverbs (AB), adjectives (JJ) and proper nouns (PM). These occurred a bit more frequently in the output of the neural tagger, but they were well attested in the HunPos output as well.

One peculiarity that is specific to our neural network tagger is that it is much more likely to output the tag UO (foreign word) than HunPos (262 instances versus 11 in the test set). In general, it does this in quite reasonable ways, for instance for tagging the Latin words *pastor in* in a list of parish priests. However, since the foreign words in the SUC training corpus are mostly in English, a language scarcely attested in our early modern corpus, it sometimes overgenerates the UO tag in incorrect contexts, for instance for the word *tree* ‘three’ (modern spelling *tre*). More seriously, it occasionally seems to interpret the presence of the letter *w*, which is frequent in early modern Swedish, but missing in the modern Swedish alphabet except for its occurrence in foreign-language words, as a cue for generating the tag UO. To address these problems, we might consider augmenting the training data with sentences from relevant foreign languages, to familiarise the model with foreign words it might encounter, or with artifically generated historical spelling, to make it more robust to the expected spelling variance.

Our clear impression from the inspection of the tagging output for the historical Swedish found in the *Gender and Work* corpus is that the most important potential gains for this type of text and task are

unlikely to be realised by tweaking the implementation of the tagger, but require a more targeted approach to handle the specific differences between historical and modern language. The work in this paper, as well as the baselines we compare with, primarily addresses orthographical differences between historical and modern text. It is well known and acknowledged in the literature, however, that the diachronic differences in language development affect all parts of language, including not only orthography but also morphology, syntax, the lexicon and so forth. Pettersson (2016) provides a good overview of different linguistic properties that are relevant for historical language processing. In the case of verb identification in historical Swedish, the errors made by our systems suggest that least morphology and syntax should be considered for better results.

In terms of Swedish morphology, a very significant development that has taken place between the early modern period and now is the decline of verb inflection. In contemporary Swedish, verbs are not inflected for person. However, the complete disappearance of person inflection is relatively recent; until the first half of the 20th century, Swedish verbs had different forms for singular and plural, and in the early modern texts in our test set, we find a separate form for first person plural (as opposed to third person, second person not being attested in the sample we inspected). The tense forms of the first person plural have an ending in *-om*, which is easily confused with similar endings of other word classes by a purely orthographical approach:

> . . . och *worom* [VB, JJ] begiärandes / at klara Gudz ord måtte blifwa predikat kring om alt Riket.
> . . . and *were* desirous / that the clear word of God should be preached in all the country.

> . . . och *hördom* [NN, NN] thesligest theras predikan och disputatien som samma nya tro sagdes predika / och *funnom* [PP, VB] doch i sanningen thet rykte oredeliga fört wara. . .
> . . . and *heard* also the sermons and teachings of those who were said to preach that new faith / and *found* in reality that this rumour was spread dishonestly. . .

The three words in italics are all first person plural verbs; the POS tags in brackets were assigned to them by the neural tagger and the SMT-normalised baseline, respectively. In the first case, the HunPos tagger assigns the tag JJ because the word *worom* is incorrectly normalised to the adjective *varm* 'warm' by the spelling normaliser. In the second example, both taggers select an incorrect noun tag, presumably because they recognise *-dom* as a derivational suffix for abstract nouns (as in *visdom* 'wisdom'). The third example is incorrectly tagged as a preposition by the neural tagger, possibly because of the similarity of its ending with Swedish prepositions like *inom* 'within' or *förutom* 'except'. HunPos tagged it correctly even though it did not get transformed into a correct modern word form by the spelling normaliser and must therefore have been treated as an unknown word by the tagger.

Another morphological phenomenon that occurs very frequently in our texts is the derivational suffix *-liga* that is used to form adverbs, as in the word *oredeliga* 'dishonestly' in the previous example. In modern Swedish, the corresponding suffix is *-ligen*. In principle, this transformation is accessible to spelling normalisation, but the problem is that *-liga* could also plausibly be a plural ending of an adjective or a common noun derived from an adjective. Moreover, *-a* is the ending of the infinitive or third person plural of a verb. Accordingly, both taggers frequently assign adjective, noun or verb tags to these adverbs.

The syntax of early modern Swedish is strongly influenced by German. In particular, it is very common for subordinate clauses to have verb-final word order, as in both clauses of the second example above. In this particular example, the verbs were tagged correctly by HunPos, but the neural tagger failed to parse the clause *som samma nya tro sagdes predika* 'who were said to preach that new faith' correctly. In this indirect speech construction, the noun phrase *samma nya tro* 'the same new faith' is the object of the verb *predika* 'to preach', which in turn is governed by the passive verb *sagdes* 'were said to'. The clause could be rendered in modern Swedish as *som sades predika denna nya tro*. The neural tagger chooses to interpret the verb *predika* as the homonymous noun *predika* 'sermon', an interpretation that makes perfect sense in the light of contemporary Swedish grammar, which does not allow a direct object to precede the governing verb as early modern Swedish did.

While the two tagging approaches sometimes make different choices for individual examples, both of them are clearly affected by the problems outlined above. An interesting fact about early modern Swedish is that many of its historical features, despite having disappeared completely from the modern form of the language, are still attested in other, closely related contemporary languages. In particular, morphological features similar to those of early forms of Swedish can be found in present-day Icelandic, and modern German still exhibits some of the syntactic patterns that were common in early modern Swedish. We believe that the versatility of vector-space embeddings will make it possible to exploit resources from those languages to train models for historical forms of Swedish by integrating them in a similar way as we integrated the historical and modern data resources in this work. In this sense, the neural method has a clear advantage of flexibility over a pipeline approach with an explicit spelling normalisation stage.

6.2 German

The German test data is rather different from the Swedish test set, mostly because it is from a later period. The two texts we selected for testing in German are from the late 18th century. This is the age of authors like Goethe and Schiller, whose works had a lasting influence on the German language. While the writing style of that epoch may seem a bit archaic to a speaker of modern German, it is still perfectly readable and much closer to present-day German in terms of syntax and morphology than the texts of the *Gender and Work* corpus are to present-day Swedish.

In the German data, we can find some distinctive tagger-specific patterns. A recurring problem in the HunPos output is the incorrect assignment of an adjective tag ADJA to an attributive possessive pronoun that should be tagged PPOSAT. This invariably concerns the pronoun *unser* 'our', which historically and dialectally can have oblique forms with elided *e* such as *unsrem* (dative). These forms do not get translated into their modern standard spellings like *unserem* and are therefore not recognised by the modern tagger. The neural tagger handles these forms without any problems. HunPos also has a tendency to mix up common nouns (NN) with adjectives (ADJA or ADJD), whereas the neural tagger is more prone to confuse common nouns with proper nouns (NE).

A large class of errors that we find in the output of both taggers is the confusion of finite verbs (VVFIN, VAFIN and VMFIN) with infinite verbs (VVINF and corresponding tags for auxiliaries and modals) and, to a lesser extent, participles (VVPP etc.). The underlying problem for most of these examples is the homonymy of first and third person plural forms and infinitives. One of the texts in the test set is a homily that extensively mixes general exhortations in the form of infinitives with first person plural verbs, as in the following example:

> Es heißt nicht Werke der Barmherzigkeit deswegen *thun*, weil wir begangne Bosheiten, die wir nicht aufrichtig *bereuen*, dadurch auszulöschen … *glauben*.
>
> It does not mean to *do* acts of charity because we *believe* we can thus eliminate sins that we have committed … and do not sincerely *regret*.

Here, *thun* is an infinitive, while the following verbs are first person plural forms, but both taggers frequently confuse the two. Unfortunately, it is difficult to evaluate these examples correctly because the gold standard itself is inconsistent. The GerManC gold standard was produced semi-automatically with automatic annotation followed by manual error correction (Scheible et al., 2011). Since the infinitives and first person plural forms are homonymous and freely mixed in the text, disambiguating them is difficult for a tagger and not entirely trivial even for a human. Looking through the homily mentioned above, we quickly found more than 25 instances of incorrectly tagged verb forms that had probably escaped the manual correction pass. It is therefore unclear to what extent the gold standard can be trusted for this specific distinction in this specific text type.

7 Conclusion

In this paper, we have presented a new method for POS tagging historical texts with a character-based recurrent neural network. Our neural tagger can be trained on a combination of a modern tagged corpus and a historical corpus in original and normalised spelling. At training time, we use a two-part error

function that combines optimisation for POS tagging performance with a criterion to ensure that historical and modern spellings are represented similarly by the neural network. The trained model can then be used to process historical data directly, without explicit spelling normalisation and achieves a level of performance that is very close to that of a state-of-the-art solution with explicit SMT-based normalisation. In a manual study of the output of our own tagger and that of a baseline with explicit spelling normalisation, we have identified the most important remaining problems for the tasks under consideration. While the 18th century German texts exhibited general tagging problems that were more reminiscent of domain adaptation than peculiar to the historical nature of the texts, the older Swedish texts clearly suffer from specific problems due to language development. We suggest that our neural tagging approach opens up new ways for tackling these problems with the help of data from other, closely related languages. This is an approach that we plan to explore further in future work.

Acknowledgements

The author would like to thank Eva Pettersson for providing the data sets used in the experiments. This work was supported by the Swedish Research Council under grant 2012-916. The computations were performed on resources provided by the Swedish National Infrastructure for Computing (SNIC) at the Lunarc centre under project SNIC 2016/1-238.

Abstract

The goal of keyphrase extraction is to automatically identify the most salient phrases from documents. The technique has a wide range of applications such as rendering a quick glimpse of a document, or extracting key content for further use. While previous work often assumes keyphrases are a *static* property of a given documents, in many applications, the appropriate set of *keyphrases* that should be extracted depends on the set of *documents* that are being considered together. In particular, good keyphrases should not only accurately describe the content of a document, but also reveal what discriminates it from the other documents. In this paper, we study this problem of extracting *discriminative* keyphrases. In particularly, we propose to use the hierarchical semantic structure between candidate keyphrases to promote keyphrases that have the right level of specificity to clearly distinguish the target document from others. We show that such knowledge can be used to construct better discriminative keyphrase extraction systems that do not assume a static, fixed set of keyphrases for a document. We show how this helps identify key expertise of authors from their papers, as well as competencies covered by online courses within different domains.

1 Introduction

The purpose of keyphrase extraction is to automatically identify the most salient phrases from documents. Keyphrases (of which keywords are a special case) are widely used for providing a quick glimpse of various types of documents, such as news, technical documents, etc. Automatically extracting the relevant keyphrases therefore has a wide range of applications and accordingly has attracted much attention from the scientific community.

Previous work, however, often assumes that keyphrases are a *static* property of documents, that is, a given document would always produce a fixed set of keyphrases. Many approaches were developped for that purpose. For example, the Keyphrase Extraction Algorithm, or KEA (Witten et al., 1998), uses a supervised learning method (Naïve Bayes) to predict keyphrases based on their lexical features. Turney (2000) developed a genetic algorithm (GenEx) to extract keyphrases, and showed that this outperformed the well-known C4.5 algorithm. More recent work on supervised keyphrase extraction used, e.g., a combination of lexical and syntactic features (Hulth, 2003) or other statistical classifiers such as support vector machine (SVM) (Zhang et al., 2006) or conditional random fields (CRF) (Zhang et al., 2008). Unsupervised methods were also proposed, based on a graph-based ranking model (Mihalcea and Tarau, 2004), or using co-occurrences (Matsuo and Ishizuka, 2004), enriched with WordNet (Martinez-Romo et al., 2016). Unsupervised keyphrase extraction was also applied to shorter texts from twitter, using multiple random walks to topic context (Zhao et al., 2011) or unsupervised feature extraction (Marujo et al., 2015). The use of hierarchical information to extract keyphrases was explored in (Smatana and Butka, 2016; Berend, 2016). Although these supervised and unsupervised methods achieve improved performance, little work has been done to generate discriminative keyphrases based on other documents in the group.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 932–942, Osaka, Japan, December 11-17 2016.

In many applications, the appropriate set of keyphrases that should be generated depends on the context in which the document is considered, and particularly the *group* of documents being considered. For example, the keyphrases that represent the competencies of a researcher or a job hunter could depend on the groups of researchers or resumes that are being considered. Similarly, the keyphrases describing an online course depend on the set of courses under consideration: *Machine Learning* may be the appropriate descriptive keyphrase to describe a course within a set of Computer Science courses, but it is not very useful to a student considering a set of Machine Learning courses. Note that we differentiate the *collection* of documents, e.g. the online course descriptions, and the *group* of documents considered within the collection. For example, the subset of Machine Learning courses we use later is a *group* of 25 documents within the 1132 courses in the entire Coursera collection. Although previous work takes into account the specificity of terms within the *collection* (for example using inverse document frequency), they do not target discriminative keyphrases within a *group*. Restricting the collection and the extraction to the subset of documents in the group in order to use existing approaches has the important downside that it degrades the estimates of term/phrase frequency the extraction relies on. This is especially problematic for supervised approaches that require annotated documents.

In this paper, we study the problem of extracting *discriminative* keyphrases, that depend on the group of documents under consideration within a larger collection. We embed keyphrases in a semantic hierarchical structure using a *Deep Belief Network* (DBN) to characterize the relationship between pairs of phrases. We show that such knowledge can be used to build a discriminative keyphrase extraction system that adapts to the set of documents considered instead of returning a fixed set of keyphrases for a document. We test our approach on two tasks. First, using scientific articles, we extract keyphrases that identify authors expertise from the articles they published. Using a hierarchy of concepts learned from a scientific book, we show that this allows us to contrast researchers within different but related domains. The set of expertise keyphrases differs, for the same researcher, depending on the domain and the set of peers. In our second collection, we explore the problem of extracting keyphrases describing competencies taught by online courses. A semantic hierarchical structure of course phrases guides the extraction towards keyphrases that distinguish one course from the set of courses it is compared to. This is illustrated on two overlapping domains, showing that descriptive keyphrases for the same course may differ depending on the other courses within the domain.

2 Method

The discriminative keyphrase extraction relies on a keyphrase similarity decribed in Section 2.1, used to compute a similarity-based score (Section 2.2). We then extend that score with a semantic hierarchy learned using a Deep Belief Network, as described in Section 2.3.

2.1 Embedding-based Keyphrase Similarity

In order to measure the semantic similarity between two keyphrases p and q, we employ the widely used cosine similarity. This requires some kind of vector representation for both phrases. Learning representations for words, phrases or documents is central to natural language understanding. Vector representations learned using neural networks, a.k.a. embeddings, have recently shown to be effective in a wide range of tasks (Collobert et al., 2011; Mikolov et al., 2013). In our work, we use these low-dimensional vector representations to encode the meaning of each keyphrase.

Starting from word representations obtained from `word2vec`[1], we follow a standard approach to obtain a phrase representation, by averaging the vectors of each component word:

$$\mathbf{p} = \frac{1}{|p|} \sum_{w \in p} \mathbf{w}, \tag{1}$$

where p, w are the phrase and words respectively, $\mathbf{p}$ and $\mathbf{w}$ are their vector representations and $|p|$ is the number of words in p. For example, the embedding for *Machine Learning* is the average of the vector

[1] `https://code.google.com/archive/p/word2vec/`

representations for *Machine* and for *Learning*. The similarity between two phrases p and q is:

$$\text{cosine}(\mathbf{p}, \mathbf{q}) = \frac{\langle \mathbf{p}, \mathbf{q} \rangle}{\sqrt{\langle \mathbf{p}, \mathbf{p} \rangle \langle \mathbf{q}, \mathbf{q} \rangle}} = \frac{\sum_i p_i q_i}{\sqrt{(\sum_i p_i^2)(\sum_i q_i^2)}} \tag{2}$$

where i runs over the dimensions of the chosen embedding space, and $\langle \cdot, \cdot \rangle$ is the scalar product notation. Note that despite its simplicity, arithmetic average has been found to be very effective among many alternatives when combining word vectors to represent phrases (Mitchell and Lapata, 2008).

2.2 Similarity-based Discriminative Keyphrase Extraction

Now equipped with a similarity between keyphrases, we turn to extracting *discriminative* keyphrases for a document. In the similarity-based approach, we consider every candidate keyphrase p, and compare it to all other keyphrases from the group of document by computing the average similarity score between p and all other keyphrases q from all documents in the group. In our example, this would be all expertise keyphrases extracted for all researchers in the group considered:

$$sScore(p) = \frac{1}{C} \sum_{q \in \mathcal{K}} \text{cosine}(\mathbf{p}, \mathbf{q}), \tag{3}$$

where $\mathcal{K}$ is the set of keyphrases extracted from all documents, and $C = |\mathcal{K}|$ is the total number of keyphrases extracted in the group. We use $sScore(p)$ to rank all candidate keyphrases for the document (or researcher) under concern. We consider various ways to select the best discriminative keyphrases below and compare these different strategies in the experimental section.

Top: Pick the top N keyphrases, i.e. most similar with other candidates on average. These should be "safe bets" but not too specific;

Bottom: Pick the bottom N keyphrases, i.e. most dissimilar with other candidates on average. These should be very specific but also noisy;

Middle: Pick the middle N keyphrases, These may strike the right balance: some similarity with the rest, i.e. not noisy, but not too similar, i.e. specific to a document.

This separation is somewhat crude, but further investigation in Section 4.2 show that further refinements do not yield better performance.

2.3 Hierarchy-based Discrimintive Keyphrase Extraction

In order to use hierarchical semantic information to extract discriminative keyphrases, we first need to model the hierarchical information between keyphrases. We generalize the linear projection for hierarchical relations proposed by Fu et al. (2014), by using a Deep Belief Network (DBN) to model this relationship on keyphrase embeddings. A d-dimensional vector for each keyphrase is obtained using again `word2vec`, as in Section 2.1. The hierarchical information between two keyphrases p and q is then modeled as a binary classification problem: From a $2 \times d$ dimensional input containing the embeddings $\mathbf{p}$ and $\mathbf{q}$, the model predicts whether q is a child of p (positive class) or not (negative class).

DBNs are deep learning models consisting of multiple layers of hidden variables, often used to obtain abstract representations (e.g., features) for raw inputs. They were shown to be effective in many problems (Bengio, 2009). We use a typical DBN architecture composed of two hidden layers between one input and one output layer. Pairs of adjacent layers in the DBN are trained in a greedy layer-wise fashion as described in (Hinton et al., 2006). The principle of greedy layer-wise unsupervised training is widely applied to train DBNs with Restricted Boltzmann Machines (RBMs) as the building blocks for each layer. It mainly consists of two steps: (1) train each RBM in an unsupervised way to obtain the initial weights; and (2) starting from these initial weights, train the network in a supervised way using backpropagation. A RBM is a type of undirected graphical model (Hinton, 2010). Given a vector of visible (input) binary units $\mathbf{v} \in \{0, 1\}^{|\mathbf{v}|}$ and a vector of binary hidden units $\mathbf{h} \in \{0, 1\}^{|\mathbf{h}|}$, connections

between the visible and hidden units are weighted by the $|\mathbf{h}| \times |\mathbf{v}|$ matrix $\mathbf{W}$. Given bias terms $\mathbf{a}$ and $\mathbf{b}$ for the visible and hidden units, respectively, the energy function is given by:

$$E(\mathbf{v}, \mathbf{h}) = -\mathbf{a}^T\mathbf{v} - \mathbf{b}^T\mathbf{h} - \mathbf{h}^T\mathbf{W}\mathbf{v} \tag{4}$$

The joint probability distribution over visible and hidden units $P(\mathbf{v}, \mathbf{h})$, and the marginal distribution $P(\mathbf{v})$ over the visible units are defined as:

$$P(\mathbf{v}, \mathbf{h}) = \frac{1}{Z}e^{-E(\mathbf{v},\mathbf{h})} \quad \text{and} \quad P(\mathbf{v}) = \frac{1}{Z}\sum\nolimits_{\mathbf{h}} e^{-E(\mathbf{v},\mathbf{h})} \tag{5}$$

with $Z = \sum_{\mathbf{v}}\sum_{\mathbf{h}} e^{-E(\mathbf{v},\mathbf{h})}$ the partition function. The RBM is trained using Gibbs sampling, alternatively sampling $\mathbf{h}$ given $\mathbf{v}$, and $\mathbf{v}$ given $\mathbf{h}$ from the conditional probabilities:

$$P(h_j = 1|\mathbf{v}) = \sigma(b_j + \mathbf{W}_{j\cdot}\mathbf{v}), \quad \text{and} \quad P(v_i = 1|\mathbf{h}) = \sigma(a_i + \mathbf{W}_{\cdot i}^T\mathbf{h}) \tag{6}$$

where $\sigma(x) = 1/(1 + \exp(-x))$ is the sigmoid function, $\mathbf{W}_{j\cdot}$ the j-th row and $\mathbf{W}_{\cdot i}$ the i-th column of weight matrix $\mathbf{W}$. Gibbs sampling allows us to get unbiased samples of the expectation of $v_i h_j$ under the distribution specified by the model, from which the RBM can be learned using contrastive divergence (Hinton et al., 2006).

Once the DBM model has been trained, we use it to predict the hierarchical relationship between pairs of candidate keyphrases. Specifically, given a candidate keyphrase, we form pairs with all the other keyphrases from the considered group of documents. For each pair, a prediction is made using the trained DBN model, indicating the hierarchical relationship between the two keyphrases in the pair. From these predictions, we estimate the number of children M of the candidate keyphrase in the group. This hierarchical information allows us to estimate the position of the candidate keyphrase in the semantic hierarchy. A large M indicates that the keyphrase is relatively high in the tree. Otherwise, the keyphrase is likely located at a lower level in the hierarchy. We incorporate this information in a hierarchy-based score by combining it with the discriminative score from Eq. 3 and modulating the trade-off through an exponent α:

$$hScore^{\alpha}(p) = sScore \times \left(\frac{1}{M}\right)^{\alpha} \tag{7}$$

3 Experiments

Two collections were used in this study: NIPS (Neural Information Processing Systems) conference papers and Coursera courses. The collections are described below and summarized in Table 1.

3.1 The NIPS Data

The NIPS data was obtained from `http://www.cs.nyu.edu/~roweis/data.html`. The dataset contains papers published at the NIPS conference from 1987 to 1999. All texts from volumes 0 to 12 were combined as one corpus to train the word embeddings using the `word2vec` tool. We set the window size to 8 and vector dimension to 200 so that each word is represented by a 200-dimensional numerical vector.

The DBN classifier modelling the hierarchical semantic information was trained from the table of content (TOC) of a machine learning book (Bishop, 2006). All words were converted to lowercase and unrelated keyphrases (e.g., from introduction and exercises) were removed. A phrase pair (p, q) was marked as positive if p was the ancestor of q in the TOC tree. Negative pairs were sampled from keyphrases without hierarchical relationship (e.g., from different chapter titles). The labeled training data includes 424 positive and 576 negative examples, used to train the DBN.

We selected two groups of researchers from the NIPS authors: one for deep learning (DL) and one for machine learning (ML). We selected ten researchers in each group, and collected reference expertise keyphrases from the following resources: homepages, resumes, Google Scholar webpages, LinkedIn profiles, as well as other related webpages. From the extracted list of keyphrases, four human annotators manually selected the gold standard expertise keyphrases from candidate keyphrases for each researcher and each group. Note that researchers who appear in both groups can have two distinct sets of reference discriminitive keyphrases, depending on which researcher group is considered.

3.2 The Coursera Data

Coursera is one of largest online education platforms, providing thousands of massive open online courses. One purpose of extracting discriminative keyphrases from course descriptions is to help students choose courses according to their interests. Discriminitive keyphrases among similar courses are more useful and meaningful than general keyphrases. We collected the course information of 1132 courses using the Coursera API[2] (Coursera, 2016).

To obtain the semantic keyphrase hierarchy from the Coursera data, word vectors were trained using `word2vec` based on the whole Coursera corpus, and the DBN model was built based on the hierarchical pairs of phrases from courses. Phrases extracted from the course titles and course descriptions formed positive example pairs, while pairs of keyphrases occurring in the course description of the same course were negative examples. In total, 1945 positive and 455 negative keyphrase pairs were used to train a DBN model on the Coursera data.

Groups of similar courses were identified by clustering courses based on their textual descriptions. We removed punctuation, stop words and numbers and used tf-idf to generate document profiles. Thirty clusters were generated using k-means. The second largest cluster was identified as grouping a computer science and data science (CSDS) courses. We selected 31 courses with more than 30 candidate keyphrases from that CSDS cluster. We also selected 25 courses in the Machine Learning (MLC) subdomain under Data Science. Courses in MLC are more homogeneous than in CSDS, but may have fewer keyphrases (Table 1). In both groups (CSDS and MLC), candidate keyphrases were extracted from the course names and course descriptions. Part-of-speech patterns based on Brill's part-of-speech tagger (Turney, 1997) were used to extract candidate keyphrases. Two researchers picked the reference discriminative keyphrases from the set of candidates, for each course in CSDS and MLC (Summary in Table 1). Note again that the same course can have different reference discriminative keyphrases, depending on whether it is considered in the MLC or CSDS groups.

3.3 NIPS Data Results

Similarity- and hierarchy-based scores were used to extract the discriminative keyphrases from all articles of each researcher. Eight keyphrases in the DL group and seven keyphrases in the ML group were extracted for each researcher. The experimental results for both groups are illustrated in Figure 1. We measure performance using the F_1 score (Van Rijsbergen, 1979). The baseline method corresponds to randomly selecting keyphrases within the set of candidates. Its performance is the expected F_1 score under a uniform probability of extraction. For similarity- and hierarchy-based methods, the $sScore$ and $hScore$ were computed for each candidate expertise keyphrase for each researcher, and ranked in descending order of score. We measure the performance when selecting the top, middle or bottom keyphrases from the ranked list. Results from Figure 1 show that the hierarchy-based method ($hScore$) always outperforms both the baseline and the similarity-based approach ($sScore$). The similarity-based

(a) DL

(b) ML

Figure 1: Performance of discriminative keyphrase extraction using similarity-based ($sScore$) and hierarchy-based ($hScore$) methods from the top ($\alpha = 0$), middle ($\alpha = 0.25$), and bottom ($\alpha = -2$) keyphrases in the NIPS DL (a) and top ($\alpha = -1$), middle ($\alpha = 3$), and bottom ($\alpha = 0$) in ML (b) groups of researchers. Baseline is a random choice among candidate keyphrases.

method sometimes performs worse than the baseline, which performs quite well as the candidate lists are small. These results show that the hierarchical information is clearly beneficial for discriminative keyphrase extraction. The best performance is achieved by mid-level keyphrases in the ML dataset and top level keyphrases in the DL dataset. This suggests that the hierarchy-based method does a good job pushing the relevant discriminative keyphrases towards the top in the narrower DL domain.

3.4 Coursera Data Results

The same setup was used to extract keyphrases that represent the concepts covered in Coursera courses. Ten keyphrases were extracted from the CSDS group, since each course has at least 30 keyphrases. For the MLC group, we extracted only 5 keyphrases as there are fewer candidates. Examples are given below for 2 course:

Course #1—Machine Learning: Clustering & Retrieval

1. MLC: mixed membership, expectation maximization, dirichlet allocation, other documents, latent dirichlet

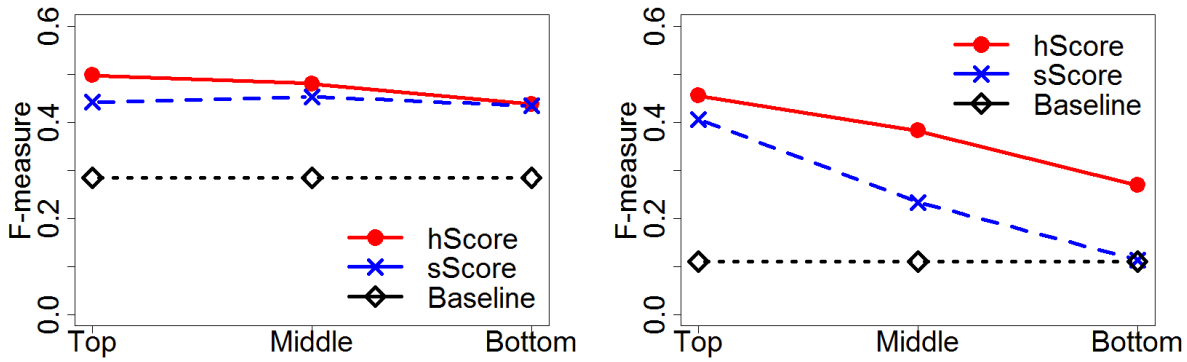
2. CSDS: document retrieval, similar documents, membership modeling, mapreduce learning, case study

Course #2—Machine Learning Capstone : An Intelligent Application with Deep Learning

1. MLC: product recommender, deep features, deep learning, intelligent application, pretrained models

2. CSDS: product recommender, learning classifiers, neural network, activation functions, pre-trained models

Results are presented in Figure 2, using the F_1 score for the top, middle, and bottom keyphrases. They show that both the similarity- and hierarchy-based methods outperform the baseline by a large margin in most situations. This is in part due to the fact that there are many more candidate keyphrases than in the NIPS data, so that the baseline's expected performance is much lower. The middle keyphrases yield the best performance for $sScore$ on the MLC group, otherwise the top keywords reach the best performance. This suggests again that both scores generally do a good job pushing the most discriminative



(a) MLC

(b) CSDS

Figure 2: Performance of discriminative keyphrase extraction using similarity-based ($sScore$) and hierarchy-based ($hScore$) methods from the top ($\alpha = -7$), middle ($\alpha = 0.5$), and bottom ($\alpha = 5$) keyphrases in the Coursera MLC (a) and the top ($\alpha = -7$), middle ($\alpha = 0.25$), and bottom ($\alpha = 10$) CSDS (b) groups of courses. Baseline is a random choice among candidate keyphrases.

competency keyphrases to the top of the list. The hierarchy-based method again consistently outperforms the similarity-based method. This suggests that the semantic hierarchy brings an important information that is useful for extracting discriminative keyphrases and provides a clear boost in performance.

4 Discussion

We analyze and discuss below two additional issues on the Coursera datasets: the effect of the hierarchical information on the hierarchy-based score, and the optimal selection of the discriminative keyphrases.

Note also that in this study, we used DBN to learn the hierarchical relationship between keyphrase pairs. Other classifiers could be used to model this relationship. However, DBN are expected to perform well on high dimensional word-embedding and are able to model non linear relationships between word pairs.

4.1 Effect of Hierarchical Information on the Hierarchy-based Scores

We saw that the hierarchy-based method outperforms the similarity-based method in all experiments. The $hScore$ is a trade-off between the number of children M and the $sScore$, to which it reduces when $\alpha = 0$ (Eq. 7). To further investigate the role of the hierarchical information in the $hScore$, we vary the value of α and compare it to the $sScore$, the baseline, and a new score using only the number of children, $nChildren = M^{-\alpha}$. We show their performance on the top, middle, and bottom level keyphrases in Figure 3. Note that negative α promote keyphrases with more children (more general keyphrases), while positive α push these keyphrases down the ranked list and favours more specific (less children) keyphrases. When $\alpha = 0$, $hScore = sScore$ and $nChildren$ is constant and performs the same as the random selection baseline.

On both course groups (MLC and CSDS), the best performance is achieved by the $hScore$ using negative α, on the top level keyphrases. Although the number of children behaves similarly in that regime, its performance is slightly lower, indicating that the keyphrase similarity still plays a key role. The difference in behaviour between $hScore$ and $nChildren$ is more pronounced on the bottom and middle level keyphrases. In particular, the $nChildren$ clearly outperforms the $hScore$ for positive α, but the resulting performance is still lower than what $hScore$ achieves on the top level keyphrases. Note also that the flexibility provided by the α parameter allows $hScore$ and $nChildren$ to always outperform the other two scores ($sScore$ and random baseline) for at least some value of α, again confirming the positive role of the hierarchical semantic information. In conclusion, this confirms that the best performance is usually obtained using the combination of similarity and hierarchy information implemented in the

$hScore$, and that picking the keyphrases with the top scores works best.

4.2 Selection of Discriminative Keyphrases

We previously selected the discriminative keyphrases from the top, middle and bottom of the ranked candidate keyphrases. Although picking the top keyphrases usually works best, in the NIPS ML group, the middle level performed better. We investigate the influence of the location of the keyphrases in the list by computing the F_1 score of keyphrases in a sliding window on the MLC and CSDS course groups. Results are shown in Figure 4. Discriminative keyphrases were selected using five windows of five keyphrases (from top to bottom)[3] for the MLC group, and ten windows of ten keyphrases (from top to bottom) for the CSDS group. Results show that candidate keyphrases with high similarities and more children (top on the list when $\alpha = 0$ and $\alpha = -1$) perform very well for both groups. When $\alpha = 1$, keyphrases with more children were pushed down to the end of the ranked list, and they were selected as "lower intermediate" level keyphrases and performed better in both groups. There is a balance between the similarity with other keyphrases and number of children in the hierarchy in these two datasets, and $hScore$ is able to find the optimal parameter for extracting discriminative keyphrases.

We also compared the performance of our method to KEA using the R package RKEA, in Figure 5. Whereas our method extracts discriminative keyphrases from the candidate keyphrases in a totally unsupervised manner (once the hierarchy is estimated), KEA uses a supervised learning methods to directly extract keyphrases from the text. In order to estimate the performance, we therefore average F_1 over 50 random choices of (labelled) training examples. As KEA does not use the same candidate keyphrases as our method, any partial match between keyphrases extracted by KEA and the gold standard is counted as a positive. We see from Figure 5 that the performance of KEA improves as the number of training cases increases, for both MLC and CSDS. However, on MLC is does worse than the random baseline, likely because it picks keyphrases that are not even among the candidate keyphrases. This is due to the fact that MLC contains courses with very short course description (sometimes as short as a

[3]For example, for a ranked list of 25 candidates, Figure 4(a) would show the performance of picking keyphrases in ranks 1–5 (top), ranks 6–10, ranks 11–15 (middle), ranks 16–20 and ranks 21–25 (bottom).

couple sentences). KEA performed relatively better on CSDS, as that group contains courses with longe descriptions. Overall, our methods performed better than KEA on both datasets.

5 Conclusions

We propose a novel approach to keyphrase extraction, with a goal of finding phrases that both describe a document and differentiate it from a set of texts it is compared with. Previous work often assumes keyphrases are a *static* property of a document, while this work allows us to go beyond most state-of-the-art algorithms and generate keyphrases that depend on the set of documents under consideration, to generate discriminative descriptions of documents. This is done by learning the hierarchical semantic relation between concepts, and using this hierarchy to inform the keyphrase extraction process. We illustrate this on two datasets: a collection of scientific articles from which we extract keyphrases describing the expertise of authors in two related fields, and a collection of on-line courses from which we extract keyphrases describing the competencies covered by the courses, within two domains. Our experiments show that our method can extract domain-specific keyphrases, and that the hierarchical semantic information is useful for extracting the discriminative keyphrases from a group of similar articles or courses.

Abstract

On microblogging services, people usually use hashtags to mark microblogs, which have a specific theme or content, making them easier for users to find. Hence, how to automatically recommend hashtags for microblogs has received much attention in recent years. Previous deep neural network-based hashtag recommendation approaches converted the task into a multi-class classification problem. However, most of these methods only took the microblog itself into consideration. Motivated by the intuition that the history of users should impact the recommendation procedure, in this work, we extend end-to-end memory networks to perform this task. We incorporate the histories of users into the external memory and introduce a hierarchical attention mechanism to select more appropriate histories. To train and evaluate the proposed method, we also construct a dataset based on microblogs collected from Twitter. Experimental results demonstrate that the proposed methods can significantly outperform state-of-the-art methods. By incorporating the hierarchical attention mechanism, the relative improvement in the proposed method over the state-of-the-art method is around 67.9% in the F1-score.

1 Introduction

Along with the rapid development of social media, many people write brief text updates about their life on the go. Among these thousands of millions of microblogs posted every day, some contain # in front of words or unspaced phrases. The # symbol, called a *hashtag*, is usually used to mark keywords or topics in a microblog. Social media users originally created it to categorize messages. Now, hashtags have been widely used in a variety of circumstances. Hashtagged words that become very popular are often trending topics. Various works have also shown that hashtags can provide valuable information about different problems such as twitter spammer detection (Benevenuto et al., 2010), popularity prediction (Tsur and Rappoport, 2012), and sentiment analysis (Wang et al., 2011).

With the increasing requirements, the hashtag recommendation task has received considerable attention in recent years. Discriminative models have been proposed from different aspects using various kinds of features and models (Heymann et al., 2008; Liu et al., 2011), collaborative filtering (Kywe et al., 2012), generative models (Ding et al., 2013; Godin et al., 2013; She and Chen, 2014), and convolutional neural networks (CNN) (Gong and Zhang, 2016). Some of the previous works treated this task as a multi-class classification problem and used word-level features and exquisitely designed patterns to perform the task. Numerous existing studies utilized the word trigger assumption (Liu et al., 2011; Ding et al., 2013) and introduced topical machine translation models to achieve the task.

Due to the advantages of deep neural networks and the effectiveness of these methods in various NLP tasks, convolutional neural networks have also been applied to the hashtag recommendation task (Gong and Zhang, 2016). Some have also treated the hashtag recommendation task as a multi-class classification problem and incorporated an attention mechanism to handle the trigger words. This method only used a microblog as input. It did not take the history information of the user into account. However,

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 943–952, Osaka, Japan, December 11-17 2016.

the microblogs a user posted in recent history can represent their interests to some degree. Previous works (Zhang et al., 2014) also studied this issue using generative models, and the experimental results demonstrated the usefulness of the histories of users.

In this work, to incorporate the histories of users, we propose a novel end-to-end memory network architecture to combine the microblog textual information and corresponding user history to perform the task. We regard the user history as an external memory for the microblog. The memory networks can help to extract the useful features from the external memory, which are relevant to the microblog and hashtag, to construct user interest representations. With the underlying intuition that not all microblogs in the user history are equally relevant for recommending hashtags, and not all of the words in a microblog are equally important, we introduce a novel hierarchical attention mechanism and integrate it with a memory network to capture two insights about the posting histories of users. Experimental results demonstrate that the performance of the method incorporating the hierarchical attention mechanism is also better than the method without it.

The main contributions of this work can be summarized as follows:

- To incorporate the user history information, we propose to extend the end-to-end memory networks to perform the hashtag recommendation task.
- Since not all of the microblogs and words in a microblog are equivalent in importance, we introduce a novel hierarchical attention mechanism and integrate it with the end-to-end memory networks.
- Experimental results using a dataset collected from a real microblogging service demonstrated that the proposed method can achieve significantly better performance than the state-of-the-art methods.

2 Related Work

2.1 Hashtag Recommendation

In recent years, various studies have been conducted on this task(Kywe et al., 2012; Ding et al., 2013; Godin et al., 2013; Sedhai and Sun, 2014; Wang et al., 2014; Gong and Zhang, 2016; Shi et al., 2016).

Kywe et al.(2012) used a similarity based method to solve this problem. They recommends hashtag by combining hashtags from the similar tweets as well as hashtags from the similar users. Many other approaches focus on the topic modelling(Ding et al., 2013; Godin et al., 2013; She and Chen, 2014). Based on the assumption that the hashtag and the trigger words of the tweets are two different language and have the same meaning, Ding et al.(2013) proposed to use translation process to model this task. In contrast to the methods that focuses on topic modelling, Shi et al.(2016) proposed a learning-to-rank approach for modelling hashtag relevance. Due to advantages of deep neural netowrks, CNN has been applied on this task(Gong and Zhang, 2016). Most of the works are based on textual information of tweets. However, some other works found there were different types of information which are helpful. Zhang et al.(2014) proposed a topical model based method to incorporate the temporal and personal information. Sedhai and Sun(2014) combined the textual information and hyperlinked information to recommend hashtags.

In this work, we propose a novel networks architecture to combine the textual information and the corresponding user history to perform the task.

2.2 Attention and Memory

The second relevant line of work is the research on attention mechanisms and memory networks. Attention mechanisms have been widely used in many studies and have shown to achieve promising result on several tasks, such as generating handwriting (Graves, 2013), machine translation (Bahdanau et al., 2014), speech recognition (Chorowski et al., 2014), action recognition (Sharma et al., 2015), caption generation (Xu et al., 2015) and so on. In recent months, memory networks(Weston et al., 2014) have been proposed and applied on natural language question answering, which have four component: input (I), generalization (G), output (O) and response (R) component. After then, Sukhbaatar et al.(2015) proposed a end-to-end memory networks and applied it on question answering and language modeling.

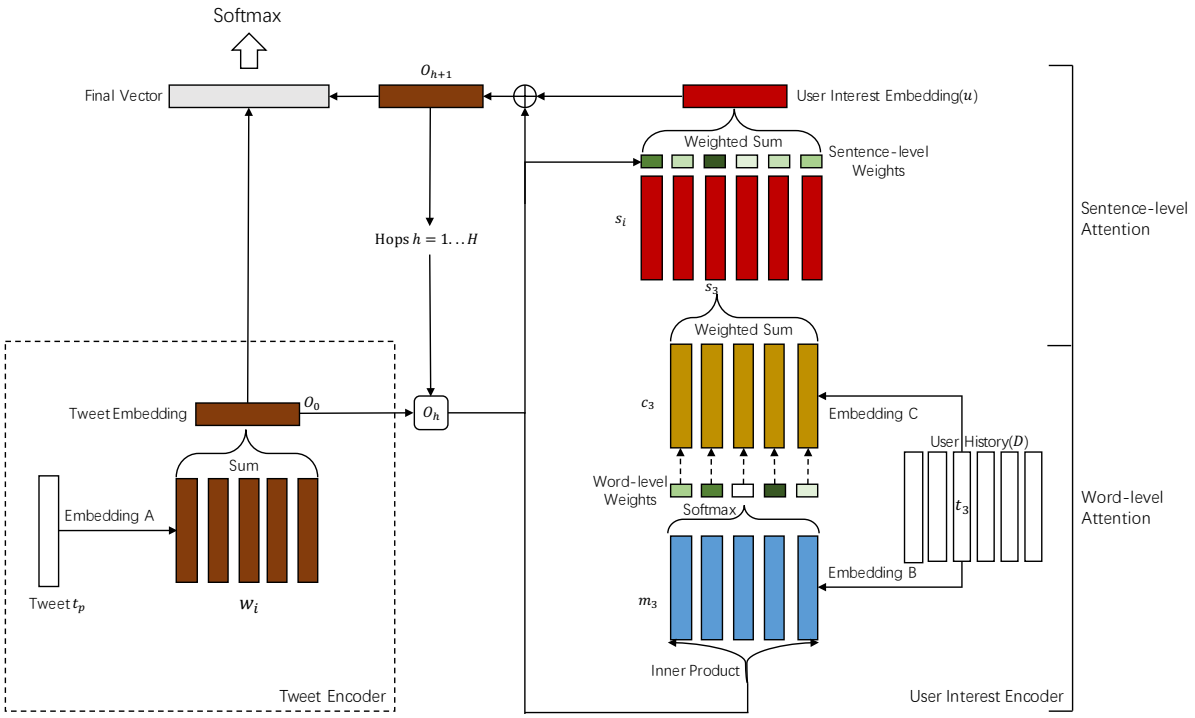

Figure 1: End-To-End Memory Networks with Hierarchical Attention

The memory networks architecture has been adopted in dialog systems(Dodge et al., 2015; Bordes and Weston, 2016; Weston, 2016) and query answering(Kumar et al., 2015; Weston et al., 2015).

In this work, we treat user history as the external memory and use a memory networks architecture with hierarchical attention to encode the user interest.

3 Approach

3.1 Preliminary

Given a tweet t_p, our task is to recommend a hashtag that is most relevant to the tweet. Based on this definition, we formulate the hashtag recommendation task as a multi-class classification problem. From the above description, we can see that the user information is also very important because each user always focuses on several aspects that may relate to the hashtag. Meanwhile, the interests of users can in most cases be represented by the tweets that they post. Hence, we use the tweet set D to represent the interests of users. Each tweet is a word sequence denoted by $t = \{w_1, w_2, ..., w_N\}$, where N is the length of the tweet. The user history contains many tweets denoted by $D = \{t_1, t_2, ..., t_M\}$, where M is the size of the history document. Let $H_p = \{H_{p1}, H_{p2}, ..., H_{p|H_p|}\}$ be the set of candidate hashtags.

3.2 The Proposed Methods

To solve this classification problem, we propose a novel end-to-end memory network architecture (HMemN2N) to combine the tweet textual information and corresponding user history, which is shown in Figure 1.

In our proposed models, we first use a tweet encoder to embed the tweet t_p. Then, the user interest encoder can extract the interest information of the user from the user history D with the help of t_p. Finally, we combine the information from two encoders and use a softmax layer to score and recommend a hashtag list. In this work, we regard the user history as an external memory for the tweet t_p. The introduction of the memory networks can help to extract the useful features from the external memory to build the user interest representations. With a underlying intuition that not all tweets in the user history are equally relevant for recommending the hashtag, not all words in each tweet are equally important,

and the tweets in the history document are relatively independent and focus on different aspects, we introduce a hierarchical attention mechanism into memory networks to capture two insights about the user history document and obtain a high-quality user interest representation.

We describe the details of different parts of Figure 1 in the following sections.

3.2.1 Tweet Encoder

As shown, the first part of the original input is the tweet t_p, and it is treated as a bag-of-words (BoW) representation. Then, we embed each word w in t_p in a continuous space and sum the embedding vectors to obtain an embedding representation. Specifically, the embedding matrix A(of size $dim \times |V|$, where V is the vocabulary and dim is the embedding dimension) is used to look up the vectors for words w, and the representation can be calculated as follows: $o_0 = \sum_i^N Aw_i$. The embedding o_0 is also treated as an initial input of the user interest encoder.

3.2.2 User Interest Encoder

The second part of the input is the user history, which is stored in the memory. We use a memory with a two-tier architecture: sentence and word. Based on the previously provided notations, the document is a tweet set: $D = \{t_1, t_2, ..., t_M\}$, which is a sentence-level structure. Then, each tweet $t_i \in D$ is divided into a bag-of-words representation: $t_i = \{w_{i1}, w_{i2}, ..., w_{iN}\}$.

To obtain the user interest representation, we propose a two-level encoder architecture, which can then be stacked in what is called multiple hops, denoted as $h = 0, 1, 2, ..., H$.

Now, we first introduce a word-level attention mechanism for embedding the tweets t_i. There are two components: input memory and output memory. In the input memory component, given an input set $\{t_1, t_2, ..., t_i\}$, each word $w_{ij} \in t_i$ is embedded using a matrix B of size $dim \times |V|$ into memory vectors $\{m_{ij}\}$ of dimension d, giving $m_{ij} = Bw_{ij}$. The input memory representation m_i of tweet t_i is a matrix of size $N \times dim$, where N is the length of the tweet. However, because not all words contribute equally to the tweets meaning, and the importance degree of the word w_{ij} should be considered in our models, we propose a probability layer to achieve the goal. The match between o_h and memory vectors m_{ij} is then computed by taking the inner product followed by a softmax:

$$p_{ij} = \frac{exp(o_h^{\mathrm{T}} m_{ij})}{\sum_n^N exp(o_h^{\mathrm{T}} m_{in})}, \tag{1}$$

where o_h is the internal input state in hop h, and p_{ij} is a probability vector over the input memory.

In the output memory component, each word $w_{ij} \in t_i$ has a corresponding output vector c_{ij}, which is obtained using an embedding matrix C with the same size. Then, the output representation s_i of tweet t_i is constructed by summing the output vector c_{ij}, weighted by the probability p_{ij}, and the equation of this operation is as follows:

$$s_i = \sum_j^N p_{ij} c_{ij}, \tag{2}$$

From the above procedure, the memory is converted into a matrix s that contains M tweet embedding vectors of size dim. Next, we propose a sentence-level method to extract sentences that are important to the user and aggregate the representation of this information to form the user interest representation. The weight p_{s_i} of sentence s_i is calculated, and the user interest vector u is formed by the weighted sum of the tweet embeddings:

$$m_{s_i} = tanh(W_o o_h + W_s s_i), \tag{3}$$

$$p_{s_i} = \frac{exp(W_{ms}^{\mathrm{T}} m_{s_i})}{\sum_j^{|M|} exp(W_{ms}^{\mathrm{T}} m_{s_j})}, \tag{4}$$

$$u = \sum_i^{|M|} p_{s_i} s_i, \tag{5}$$

where $|M|$ is the number of tweets in the users history document, and the parameters in these equations are W_o, W_s, and W_{ms}.

By implementing the hops operator, the memory can be read and write iteratively using the state o_h. At the last step of each hops h, a new output state o_{h+1} is updated with $o_{h+1} = o_h + u$, where u is the user interest embedding obtained in this hop. The last output state o_H is regarded as a high-level representation of user insterest.

3.2.3 Final Prediction

Finally, the tweet embedding o_0 and the user interest output o_H can also be concatenated into the final vector f, giving $f = o_0||o_H$. Then, we can use the final vector to predict the recommended hashtag through a softmax layer:

$$p(y = h_{pi}|f; \theta_s) = \frac{exp({\theta_s^{h_{pi}}}^{\mathrm{T}}(W_f f + b_f))}{\sum_j^{|H_p|} exp({\theta_s^{h_{pj}}}^{\mathrm{T}}(W_f f + b_f))}, \tag{6}$$

where W_f, b_f and θ_s are parameters, H_p is the candidate hashtag set and h_{pi} is the i-th hashtag in H_p.

According to the scores from the last softmax layer, we can list a top-ranked recommended hashtags for each tweet.

3.3 Training

The training objective function in this work is:

$$J = \sum_{(t_p, D, h_p) \in S} -logp(h_p|t_p; D), \tag{7}$$

where h_p is the hashtag for tweet t_p and S is the training set.

The parameter list of our model is:

$$\theta = \{A, B, C, W_o, W_s, W_{ms}, W_f, b_f, \theta_s\}, \tag{8}$$

where A, B and C are three embedding matrix. W_o, W_s and W_{ms} are the parameters of attention layer in user interest encoder. W_f, b_f and θ_s are the parameters of the final predict layer.

In this study, we use stochastic gradient descent (SGD) with the adagrad update rule to optimise our model. Dropout regularization has proved to be an effective method for reducing the overfitting in deep neural networks with millions of parameters. In this work, we use it and add $l2$-norm regularization terms for the parameters of the network to augment the cost function.

Table 1: Statistics of the evalution dataset

#Tweets	#Users	#Hashtags	#Avg.Hashtag/Tweet
288,545	36,003	3,883	1.28

4 Experiment

In this section, we first introduce the data collection. Then, we describe the experiment configurations and baseline methods. Finally, the evaluation results and analyses are given.

4.1 Dataset and Setup

We started by using Twitter's API to collect public tweets from randomly selected users. In a first step, we randomly selected 40,000 users and crawled their tweets. In this step, we obtained 77,995,265 tweets. In the second step, we selected users with more than 50 tweets and filtered out the tweets whose language was not English. Then, we filtered out the hashtags whose frequencies were very low. Third, we extracted the tweets in the original corpus that contained hashtags.

Based on the statistics, there were 281,345 tweets in our evaluation collection, which belonged to 36,003 different users. The unique number of hashtags in the corpus was 3,883, and the average number of hashtags in each tweet was 1.28. The list of hashtags annotated by their users were treated as the ground truth. The detailed statistics are listed in Table 1. All of the tweets were processed by removing stopwords and special characters. In our experiment, we split the dataset into a training set, validation set, and test set. There were 232,378 tweets in the training set and 28,092 in the validation set. The remaining 20,875 tweets were in the test set.

In this work, the poster of each tweet had a history. For the user history, we assumed that the latest tweets posted could represent the user's current interests and could be stored in the memory. In this work, the memory capacity was restricted to the most recent 5 tweets posted by the users, the maximum length of the tweets was 52, any tokens out of this range were discarded and any hashtags occuring in the history had been removed. The embedding dimension of our model was set to 300, and the number of hops was set to 2 unless noted otherwise. This configuration was also used in the other methods described in the following paragraphs. The network was used for training for 60 epochs with early stopping. The learning rate was set to l = 0.01, and the dropout rate was 0.2.

The three metrics used in this experiment to evaluate the quality of our model were the precision, recall, and F1-score (denoted as P, R, and $F1$, respectively). The number of recommended hashtags for each tweet are denoted as k, where $k = \{1, 2, 3, 4, 5\}$ and the precision, Recall, and F1-score at the k result are denoted as $P@k$, $R@k$, and $F1@k$, respectively.

4.2 Baseline

In this section, to compare with our model, we select some effective methods as a baseline and introduce a degeneration model, described as follows:

- **NB**: To achieve the task, we convert the hashtag recommendation problem into a classification problem. We apply Naive Bayes to model the posterior probability of each hashtag using only the textual information of the tweets.

- **NB+H**: To assess the usefulness of the user interest information, the textual information and user history are given to Naive Bayes to recommend hashtags.

- **SVM**: We use the pre-trained word vector [1], which was trained using a portion of a Google News dataset containing 300-dimensional vectors for 3 million words using the continuous bag-of-words model, and sum them as the feature vector of the tweet as features, which are used to implement the support vector machine for the recommendation.

- **SVM+H**: The information of the user interest history is added to the features and the support vector machine is used to achieve the task.

- **TTM**: TTM was proposed by (Ding et al., 2013) for hashtag recommendation. The authors proposed a topical translation model to recommend hashtags, which only used the tweet content.

- **CNN-Attention**: CNN-Attention was proposed by (Gong and Zhang, 2016). It was a convolutional neural network architecture with an attention mechanism, and it was the state-of- the-art method for this task. In this paper, we compare our method with it.

- **MemN2N**: The user interest encoder in our model is a memory network architecture with a hierarchical attention mechanism. Now, we replace it with the end-to-end memory network method proposed by (Sukhbaatar et al., 2015) and compare it with our proposed model.

Table 2: Result of different methods on the evaluation collection

Method	Precision	Recall	F1
NB	0.123	0.098	0.109
NB+H	0.198	0.156	0.175
SVM	0.232	0.181	0.203
SVM+H	0.312	0.241	0.272
TTM	0.234	0.190	0.210
CNN-Attention	0.328	0.255	0.287
MemN2N	0.501	0.403	0.446
HMemN2N	0.538	0.436	0.482

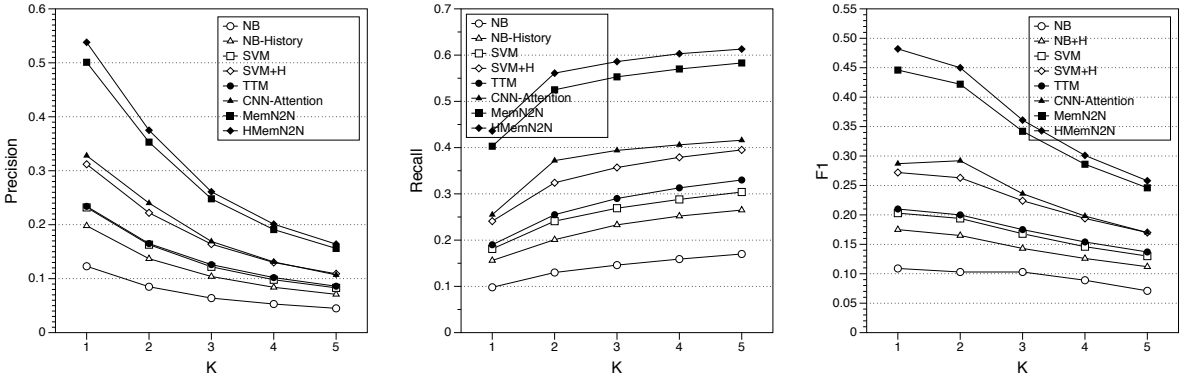

Figure 2: Precision, Recall, and F1-Score with different number of recommendation hashtags

4.3 Result and Discussion

In Table 2, we list the trend recommendation performances on our dataset using the different methods. The three metric results listed in Table 2 were obtained when we recommended the top hashtag for each tweet, i.e., $k = 1$.

In Table 2, we can see that the proposed method HMemN2N is better than all the other methods because it obtains the best result on all these metrics. Our approach provides improvements of 0.21 in precision, 0.181 in recall, and 0.195 in the F1-score over CNN-Attention, which is by far the state-of-the-art method for this task. Compared with the degeneration model MemN2N, our approach also shows a significant improvement. HMemN2N achieves a relative improvement of 7.4% in precision, 8.2% in recall, and 8.1% in the F1-score over MemN2N. The results show the practical applicability of our model, which can be used to provide users with good recommendations.

Observing the comparisons of the "NB" and the "NB+H", and the "SVM" and the "SVM+H", it is clear that the user interest history is a key ingredient in the recommendation, which is the strongest confirmation that much important information in the user history can be used to recommend hashtags in social media. This strongly suggests that we should find an effective method to extract useful information from the user history. In this paper, we provide a memory network architecture to solve this problem. The history is treated as an external memory, and a hierarchical attention mechanism is provided to help the model to extract the information, where the attention operation can be performed repeatedly and iteratively. The properties of this aspect of our proposed model have been proven to be effective by observing the results shown in Table 2.

CNN-Attention is the latest method used for this task, and it showed a good performance in this work. However, CNN-Attention only considers the content of the tweets and uses an attention mechanism to find important words in tweets. With a intuition that users will tend to repeatedly use the same hashtag, the performances of CNN-Attention and HMemN2N have a huge gap, which is mainly caused by not considering the user information. The results of the topical translation model (TTM) were obviously worse than those of our method, because it also only uses the textual information of the tweets.

Table 3: Parameter Influence on the evaluation collection

Model	embedding dim	# of hops	Precision	Recall	F1
CNN-Attention	300	-	0.328	0.255	0.287
MemN2N	300	2	0.501	0.403	0.446
	300	3	0.481	0.385	0.428
HMemN2N	300	1	0.521	0.421	0.466
	50	2	0.462	0.370	0.411
	100	2	0.508	0.410	0.454
	200	2	0.530	0.430	0.475
	300	2	0.538	0.436	0.482
	400	2	0.536	0.437	0.481
	500	2	0.538	0.437	0.482
	300	3	0.534	0.433	0.478
	300	4	0.528	0.428	0.473
	300	5	0.521	0.421	0.466

Considering the comparison between MemN2N and HMemN2N, the results show that it is necessary to introduce a hierarchical structure to store and select information. Each tweet has its own degree of importance in different recommendations, and each word in each tweet should also be given individual attention. Our model further utilizes an attention mechanism with a hierarchical structure to improve the information extraction. Compared to MemN2N, HMemN2N had superior performances across the board, which clearly demonstrated the effectiveness of the hierarchical mechanism.

In Figure 2, we list the result of models with different numbers of recommendation hashtags. The number of hashtags recommended k ranges from 1 to 5. From Figure 2, we can see that HMemN2N outperforms all of the baseline methods in all three metric curves with varying k. Clearly, the precision result decreases as k increases, and the recall result increases as k increases. The highest F1-score is obtained when we recommend the top 1 hashtag for each tweet. By analyzing the result, we can see that our model achieves the best performance in this task because all of the curves for HMemN2N are the highest in the graphs.

4.4 Parameter Influence

To evaluate the influence of the parameters used in our model, we changed the critical parameters to those in our dataset and list the results in Table 3. The effects of different hop numbers are shown, and the performances with different embedding dimensions are investigated.

From Table 3, we observe that changing the number of hops has some impact on the overall performance. However, the results disprove that more hops are better, because when the number of hops is larger than 2, the performances of HMemN2N and MemN2N are both decreasing.

The results listed in Table 3 also show the contribution of the embedding dimension to the performance. We fix the number of hops to 2 and vary the embedding dimension. A higher embedding dimension results in a better performance. When the dimension is low such as $dim = 50$ or $dim = 100$, the result is very poor. Our proposed model performs very well with a high embedding dimension. When the dimension is equal to 300, 400 or 500, we all can obtain the good performance. The size of the embedding dimension represents the expression ability of each word, and a higher dimension can enhance the text feature expression ability. To recommend a more appropriate hashtag, it is suggested to choose a high embedding dimension.

5 Conclusion

In this paper, we proposed a novel end-to-end memory network architecture that combines a tweets textual information and the corresponding user interest information for the hashtag recommendation task. The user interest history was a key ingredient of the recommendation and was adopted in this work. We

treated the user history as an external memory and proposed a novel memory network with a hierarchical attention mechanism to encode the user interest. To evaluate the proposed method, we collected data from real word twitter services. The experimental results on the evaluation dataset demonstrated that the proposed method could achieve better results than the current state-of-the-art methods for this task because they do not consider the user information.

Abstract

Topics generated by topic models are typically represented as list of terms. To reduce the cognitive overhead of interpreting these topics for end-users, we propose labelling a topic with a succinct phrase that summarises its theme or idea. Using Wikipedia document titles as label candidates, we compute neural embeddings for documents and words to select the most relevant labels for topics. Compared to a state-of-the-art topic labelling system, our methodology is simpler, more efficient, and finds better topic labels.

1 Introduction

Topic models are a popular approach to detecting trends and traits in document collections, e.g. in tracing the evolution of a scientific field through its publications (Hall et al., 2008), enabling visual navigation over search results (Newman et al., 2010a), interactively labelling document collections (Poursabzi-Sangdeh et al., 2016), or detecting trends in text streams (Wang and McCallum, 2006; AlSumait et al., 2008). They are typically unsupervised, and generate "topics" t_i in the form of multinominal distributions over the terms w_j of the document collection ($\Pr(w_j|t_i)$), and topic distributions for each document d_k in the collection, in the form of a multinomial distribution over topics ($\Pr(t_i|d_k)$). Traditionally, this has been carried out based on latent Dirichlet allocation (LDA: Blei et al. (2003)) or extensions thereof, but more recently there has been interest in deep learning approaches to topic modelling (Cao et al., 2015; Larochelle and Lauly, 2012).

In contexts where the output of the topic model is presented to a human user, a fundamental concern is the best way of presenting the rich information generated by the topic model, in particular, the topics themselves, which provide the primary insights into the document collection. The de facto topic representation has been a simple term list, in the form of the top-10 terms in a given topic, ranked in descending order of $\Pr(w_j|t_i)$. The cognitive overhead in interpreting the topic presented as a list of terms can be high, and has led to interest in the task of generating labels for topics, e.g. in the form of textual descriptions (Mei et al., 2007; Lau et al., 2011; Kou et al., 2015), visual representations of the topic words (Smith et al., to appear), or images (Aletras and Stevenson, 2013). In the former case, for example, rather than the top-10 terms of ⟨*school, student, university, college, teacher, class, education, learn, high, program* ⟩, a possible textual label could be simply EDUCATION. Recent work has shown that, in the context of a timed information retrieval (IR) task, automatically-generated textual labels are easier for humans to interpret than the top-10 terms, and lead to equivalent-quality relevance judgements (Aletras et al., 2014). Despite this, the accuracy of state-of-the-art topic generation methods is far from perfect, providing the motivation for this work.

In this paper, we propose an approach to topic labelling based on word and document embeddings, which both automatically generates label candidates given a topic input, and ranks the candidates in either an unsupervised or supervised manner, to produce the final topic label. Our contributions in this work are: (1) a label generation approach based on combined word and document embeddings, which is both considerably simpler than and empirically superior to the state-of-the-art generation method; (2) a

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 953–963, Osaka, Japan, December 11-17 2016.

simple label ranking approach that exploits character and lexical information, which is also superior to the state-of-the-art ranking approach; and (3) release of an open source implementation of our method, including a new dataset for topic label ranking evaluation.[1]

2 Related Work

Mei et al. (2007) introduced the task of generating labels for LDA topics, based on first extracting bigram collocations from the topic-modelled document collection using a lexical association measure, and then ranking them based on KL divergence with each topic. The approach is completely unsupervised.

Lau et al. (2011) proposed using English Wikipedia to automatically label topics. First, they map the topic to a set of concepts by querying Wikipedia using the top-10 topic terms based on: (a) Wikipedia's native search API; and (b) Google's search API, with site restriction. The top-8 article titles from each of these two sources are pooled to generate the primary candidate topic labels. Secondary labels are generated from component n-grams contained within the primary candidates, and filtering out incoherent and unrelated titles using the `RACO` measure (Grieser et al., 2011) to measure similarity with the primary labels, based on Wikipedia document categories. The combined set of primary and secondary label candidates is then ranked using a number of lexical association features, either directly in an unsupervised manner, or indirectly based on training a support vector regression model. The authors provide an extensive analysis of their method with that of Mei et al. (2007), and find their label generation and ranking methodology to be empirically superior (in both an unsupervised and supervised setting). In this paper, we seek to improve upon the topic labelling benchmark set by Lau et al. (2011).

Hulpus et al. (2013) developed a graph-based method for topic labelling, leveraging the structure of DBpedia concepts. Their approach is styled around graph-based word sense disambiguation, and extracts a set of DBpedia concepts corresponding to the top-N terms of a topic. They then construct a graph centred around DBpedia concepts and filter noise based on graph connectivity (the hypothesis being that sense graphs of words from a topic should be connected). To find the best label for a topic, they experiment with a variety of graph centrality measures.

In work slightly further afield, Zhao et al. (2011) proposed topical keyphrase extraction for Twitter. Although the work focuses mainly on Twitter, the methodology can be applied to other domains and to label topics. Zhao et al. (2011) follow a three-step process for keyphrase extraction: (1) keyword ranking; (2) candidate keyphrase generation (based on the individual keywords); and (3) keyphrase ranking. They use a novel topic context-sensitive *PageRank* method to regularise topic scores for keyword ranking, and a probabilistic scoring method that takes into account relevance, interestingness and keyphrase length for keyphrase ranking.

Not directly for the purposes of topic labelling but as a relevant pretraining method, Mikolov et al. (2013) proposed `word2vec` to learn word embeddings, which they found to perform strongly over a range of word similarity tasks, and also to be useful for initialising deep learning models. Two approaches are proposed in the paper: `cbow` and `skip-gram`. `cbow` combines neighbouring words to predict a target word, while `skip-gram` uses the target word to predict neighbouring words. Both approaches use a feedforward neural network with a non-linear hidden layer to maximize the objective function; to improve computational efficiency, the authors propose using negative sampling. In this paper, we will use `word2vec` as a means of generating topic term and label representations.

As an extension of `word2vec`, Le and Mikolov (2014) introduced `doc2vec` to learn embeddings for word sequences (e.g. paragraphs or documents). By treating each document as a word token, the same `word2vec` methodology can be used to learn document embeddings. The authors propose two implementations: `dbow`, which uses the document vector to predict its document words, and is the `doc2vec` equivalent of `skip-gram`; and `dmpv`, which uses a small window of words and concatenates them with the document vector to predict a document word, and is the `doc2vec` equivalent of `cbow`.[2] Compared to `dbow`, `dmpv` takes into account the local word ordering, and has a higher number of parameters, since the input is a

[1] `https://github.com/sb1992/NETL-Automatic-Topic-Labelling-`

[2] Strictly speaking, `cbow` combines word vectors by summing them, while `dmpv` combine word vectors and document vector by concatenating them.

concatenation of vectors. As with word2vec, we will use doc2vec as an alternative means of generating topic term and label representations.

Building on word2vec, Kou et al. (2015) experimented with neural embeddings in the context of topic labelling. In addition to skip-gram and cbow word vectors, the authors also included letter trigram vectors of a word, with the rationale that it generalises over morphologically-related forms of the same word. Their methodology consists of first generating candidate labels for topics from topic-related documents using a chunk parser. By representing both topic words and topic labels using word embeddings and letter trigrams, they rank the labels using cosine similarity to obtain the best label for a topic. In their evaluation, they find that simple letter trigrams are ultimately the most reliable means of label ranking.

3 Methodology

Following Lau et al. (2011), our method is made up of two steps: (1) topic label generation based on English Wikipedia; and (2) topic label ranking, based on a supervised learn-to-rank model. We detail each of these steps below.

3.1 Candidate Generation

To match topics to Wikipedia articles,[3] Lau et al. (2011) used an IR approach, by querying English Wikipedia with the top-N topic terms. However, in order to do this, they required external resources (two search APIs, one of which is no longer publicly available), limiting the general-purpose utility of the method. We propose an alternative approach: precomputing distributed representations of the topic terms and article titles using word2vec and doc2vec.

To this end, we train a doc2vec model on the English Wikipedia articles, and represent the embedding of a Wikipedia title by its document embedding. As doc2vec runs word2vec internally, word embeddings are also learnt during the training. Given the top-N topic terms, the topic embedding is represented by these terms' word embeddings. Based on the findings of Lau and Baldwin (2016) that the simpler dbow has less parameters, trains faster, and performs better than dmpv in several extrinsic tasks, we experiment only with dbow.[4] In terms of hyper-parameter settings, we follow the recommendations of Lau and Baldwin (2016).[5]

In addition to doc2vec, we also experiment with word2vec to generate embeddings for Wikipedia titles. By treating titles as a single token (e.g. concatenating *financial crisis* into *financial_crisis*) and greedily tokenising the text of all of the Wikipedia articles, we can then generate word embeddings for the titles. For word2vec, we use the skip-gram implementation exclusively.[6]

For both doc2vec and word2vec, we first pre-process English Wikipedia,[7] using Wiki Extractor to clean and extract Wikipedia articles from the original dump.[8] We then tokenise words with the Stanford CoreNLP Parser (Klein and Manning, 2003), and lowercase all words. We additionally filter out articles where the article body is made up of less than 40 words, and also disambiguation pages. We also remove titles whose length is longer than 4 words, as they are often too specific or inappropriate as topic labels (e.g. *List of Presidents of the United States*). For word2vec, we remove any parenthesised sub-component of an article title — e.g. in the case of *Democratic Party (United States)*, we remove *(United States)* to generate *Democratic Party* — as we would not expect to find verbatim usages of the full title. This has the potential side-effect of mapping multiple articles onto a single ambiguous title, resulting in multiple representations for *Democratic Party*. While acknowledging that there are instances where the more specific title may be appropriate as a label, the generalised version is always going to be a hypernym of the original, and thus appropriate as a label candidate.

[3] As of 2016 there are over 5 million documents in English Wikipedia.

[4] We use Gensim's implementation of both doc2vec and word2vec for all experiments: https://radimrehurek.com/gensim/.

[5] doc2vec hyper-parameters: sub-sampling threshold $= 10^{-5}$, vector size $= 300$, window size $= 15$, negative sample size $= 5$, and training epochs $= 20$.

[6] word2vec hyper-parameters: sub-sampling threshold $= 10^{-5}$, vector size $= 300$, window size $= 5$, negative sample size $= 5$, and training epochs $= 100$.

[7] The English Wikipedia dump used in all experiments is dated 2015-12-01.

Table 1: The top-5 labels generated using doc2vec and word2vec title embeddings for the topic provided

Given a topic, we measure the relevance of each title embedding (generated by either doc2vec or word2vec) based on the pairwise cosine similarity with each of the word embeddings for the top-10 topic terms, and aggregate by taking the arithmetic mean. Formally, the doc2vec relevance (rel_{d2v}) and word2vec relevance (rel_{w2v}) of a title a and a topic T is given as follows:

$$rel_{d2v}(a,T) = \frac{1}{|T|}\sum_{v\in T}\cos\left(E^{d}_{d2v}(a), E^{w}_{d2v}(v)\right) \quad (1)$$

$$rel_{w2v}(a,T) = \frac{1}{|T|}\sum_{v\in T}\cos\left(E^{w}_{w2v}(a), E^{w}_{w2v}(v)\right) \quad (2)$$

where $E^{d}_{d2v}(x)$ is the document embedding of title x generated by doc2vec; $E^{w}_{d2v}(y)$ is the word embedding of word y generated by doc2vec; $E^{w}_{w2v}(z)$ is the word embedding of word z generated by word2vec; $v \in T$ is a topic term; $|T|$ is the number of topic terms (10 in our experiments); and $\cos(\vec{x},\vec{y})$ is the cosine similarity function.

The idea behind using both doc2vec and word2vec to generate title embeddings is that we observe that the two models favour different types of labels: doc2vec tends to favour fine-grained concepts, while word2vec favours more generic or abstract labels. As an illustration of this, in Table 1 we present one of the actual topics used later in our evaluation, and the top-5 article titles based on doc2vec and word2vec. This dichotomy is rooted in the differences in the modelling of context in the two models. In doc2vec, the title embedding is determined by the words that belong to the title, each of which is in turn determined by its context of use; it thus directly captures the compositional semantics of the title. With our word2vec method, on the other hand, the title embedding is determined directly by the neighbouring words of the title token in text, oblivious to the composition of words in the title.

To combine the strengths of doc2vec and word2vec, for each topic we generate a combined candidate ranking by summing the relevance scores using top-100 candidates from doc2vec and word2vec:[9]

$$rel_{d2v+w2v}(a,T) = rel_{d2v}(a,T) + rel_{w2v}(a,T) \quad (3)$$

3.2 Candidate Ranking

The next step after candidate generation is to re-rank them based on a supervised learn-to-rank model, in an attempt to improve the quality of the top-ranking candidates.

The first feature used in the supervised reranker is *LetterTrigram*, and based on the finding of Kou et al. (2015) that letter trigram vectors are an effective means of ranking topic labels. Our implementation of their method is based on measuring the overlap of letter trigrams between a given topic label and the topic words. For each topic, we first convert each topic label and topic words into multinomial distributions over letter trigrams, based on simple maximum likelihood estimation.[10] We then rank the

[9] From preliminary experiments we found that summing only the top-100 candidates from doc2vec and word2vec is better than summing all candidates. As we remove the parenthesised sub-component of an article title for word2vec (*Democratic Party (United States)* $\longrightarrow$ *Democratic Party*) , we observe that these titles tend to be very general and can ocassionally produce very high cosine similarity and skew the combined score for a number of similar labels (e.g. causing *Democratic Party* from a host of countries (*Democratic Party (United States)*, *Democratic Party (Australia)*, etc) to appear in the top ranking).

[10] For topic words, the letter trigrams are generated by parsing each of the topic words as separate strings rather than one concatenated string.

labels based on their cosine similarity with the topic words. The rank value constitutes the first feature of the supervised learn-to-rank model. Additionally, this ranking by letter trigram method also forms our unsupervised baseline, as we found that it to have the best unsupervised ranking performance of all our features, consistent with the findings of Kou et al. (2015).[11]

The second feature is *PageRank* (Page et al., 1998), in an attempt to prefer labels which represent more "core" concepts in Wikipedia. *PageRank* uses directed links to estimate the significance of a document, based on the probability of a random web surfer visiting a web page by either following hyperlinks or randomly transporting to a new page. We construct a directed graph from Wikipedia based on hyperlinks within the article text, and from this, compute a *PageRank* value for each Wikipedia article (and hence, title).[12]

Our last two features are lexical features proposed by Lau et al. (2011): (1) *NumWords*, which is simply the number of words in the candidate label (e.g. *operating system* has 2 words); and (2) *TopicOverlap*, which is the lexical overlap between the candidate label and the top-10 topic terms (e.g. *desktop virtualization* has a *TopicOverlap* score of 1 in our example from Table 1).

Given these features and a gold standard order of candidates (detailed in Section 4.1), we train a support vector regression model (SVR: Joachims (2006)) over these four features.

4 Datasets

For direct comparison with Lau et al. (2011), we use the same set of topics they used in their experiments. These were generated from 4 different domains: BLOGS, BOOKS, NEWS and PUBMED. In general, BLOGS, BOOKS and NEWS cover wide-ranging topics from product reviews to religion to finance and entertainment, whereas PubMed is medical-domain specific.

BLOGS is made up of 120k blog articles from the Spinn3r blog dataset; BOOKS is made up of 1k English language books from the Internet Archive American Libraries collection; NEWS is made up of 29k New York Times articles from English Gigaword; and PUBMED is made up of 77k PubMed biomedical abstracts. Lau et al. (2011) ran LDA on these documents and generated 100 topics for each domain. They filtered incoherent topics using an automated approach (Newman et al., 2010b), resulting in 45, 38, 60, 85 topics for BLOGS, BOOKS, NEWS and PUBMED, respectively.

4.1 Gold Standard Judgements

To evaluate our method and train the supervised model, gold-standard ratings of the candidates are required. To this end, we used CrowdFlower to collect human judgements.[13] We follow the approach of Lau et al. (2011), presenting 10 pairings of topic and candidate label, and asking human judges to rate the label on an ordinal scale of 0–3 where 0 indicates a completely inappropriate label, and 3 indicates a very good label for the given topic.

To control for annotation quality, we make use of the original annotations released by Lau et al. (2011). We select labels with a mean rating ≥ 2.5 (good labels) and ≤ 0.5 (bad labels) to serve as controls in our tasks. We include an additional topic–label control pair in addition to the 10 topic–label pairs in a HIT. Control pairs are selected randomly without replacement, and randomly injected into the HIT. To pass quality control, a worker is required to rate bad labels ≤ 1.0 and good labels ≥ 2.0. A worker is filtered out if his/her overall pass rate over all control pairs is < 0.75.

Each candidate label was rated by 10 annotators. Post-filtered, we have an average of 6.4 annotations for each candidate label.[14] To aggregate the ratings for a candidate label, we compute its mean rating, and rank the candidate labels based on the mean ratings to produce the gold standard ranking for each topic.

[11] Note that we do not make use of the noun chunk-based label generation methodology of Kou et al. (2015), in line with the findings of Lau et al. (2011) that Wikipedia titles give rise to better label candidates than n-grams extracted from the topic-modelled documents.

[12] We use the following implementation for *PageRank*: `https://www.nayuki.io/page/computing-wikipedias-internal-pageranks/`

[13] `https://www.crowdflower.com/`

[14] Post-filering, some candidates ended up with less than 3 annotations; these candidates were posted for another annotation round to gather more annotations.

Table 2: Results across the four domains. Boldface indicates the better system between NETL and LGNB (with an absolute difference > 0.01).

We collect judgements for the top-19 candidates from the unsupervised ranking.[15] For candidate ranking (Section 3.2), we are therefore re-ranking the top-19 candidates.

5 Experiments

In this section we present the results of our topic labelling experiments, and compare our method with that of Lau et al. (2011). Henceforth we refer to our method as "NETL" (neural embedding topic labelling), and Lau et al. (2011) as "LGNB".

Following LGNB, we use **top-1 average rating** and **normalized discounted cumulative gain (nDCG)** (Järvelin and Kekäläinen, 2002; Croft et al., 2009) as our evaluation metrics. Top-1 average computes the mean rating of the top-ranked labels, and provides an evaluation of the absolute utility of the preferred labels. nDCG, on the other hand, measures the relative quality of the ranking, calibrated relative to the ratings of the gold-standard ranking. Similarly to LGNB, we compute nDCG for the top-1 (nDCG-1), top-3 (nDCG-3), and top-5 (nDCG-5) ranked labels.

5.1 Results

Following LGNB, we present results for: (a) the unsupervised ranker (based on letter trigrams); (b) the supervised re-ranker in-domain, based on 10-fold cross validation, averaged over 10 runs with different

[15] Ideally we would have liked to have collected judgements for as many candidates as possible, but due to budget constraints we were only able to have the top-19 annotated.

Domain	Topic Terms	Label Candidate
BLOGS	vmware server virtual oracle update virtualisation application infrastructure management microsoft	virtualisation
BOOKS	church archway building window gothic nave side value tower	church architecture
NEWS	investigation fbi official department federal agent investigator charge attorney evidence	criminal investigation
PUBMED	rate population prevalence study incidence datum increase mortality age death	mortality rate

Table 3: A sample of topics and their topic labels generated by NETL.

partitionings; (c) the supervised re-ranker cross-domain; and (d) the upper bound, based on a perfect ranking of the candidates. For cross-domain learning, we train our model using one domain and test it on a different domain, or alternatively combine data from three domains and test on the remaining fourth domain, e.g. training on BOOKS +NEWS +PUBMED and testing on BLOGS. Cross-domain results give us a more accurate picture of the performance of our methodology in real-world applications (where it would be unrealistic to expect that there would be manual annotations of label candidates for that domain). We primarily use the in-domain results to gauge the relative quality of the cross-domain results.

We present the results in Table 2, displaying the performance of NETL and LGNB side by side for ease of comparison.[16] For each domain, the unsupervised baseline of NETL is based on the overlap of letter trigrams of the generated candidates with topic words (see Section 3.2). The unsupervised baseline of LGNB ranks the labels using a lexical association measure (Pearson's χ^2).

Looking at the performance of our method, we can see that the supervised system improves over the unsupervised baseline across all domains with the exception of a small drop observed in NEWS. Surprisingly, there is relatively little difference between the in-domain and cross-domain results for our method (but greater disparity for LGNB, especially over BOOKS; for NEWS, our cross-domain models actually outperform the in-domain model). The most consistent cross-domain results are generated when we combine all 3 domains, an unsurprising result given that it has access to the most training data, but encouraging in terms of having a single model which performs consistently across a range of domains.

We next compare NETL to LGNB, first focusing on the top-1 average rating metric. The most striking difference is the large improvement over PUBMED. LGNB attributed the poor performance over PUBMED to it being more domain-specific (and a poorer fit to Wikipedia) than the other domains, and suggested the need of biomedical experts for annotation. Our experiments found, however, that the performance of PUBMED is comparable to other domains. Additionally, the improvement in BOOKS is also quite substantial. Overall, NETL is more consistent across different domains and outperforms LGNB over 2 domains (BOOKS and PUBMED), and the difference between NETL and LGNB is small for NEWS and BLOGS. The other observation is the upper bound performance of NETL is uniformly better than that of LGNB, implying we are also generating better label candidates (we revisit this in detail in Section 5.2.1).

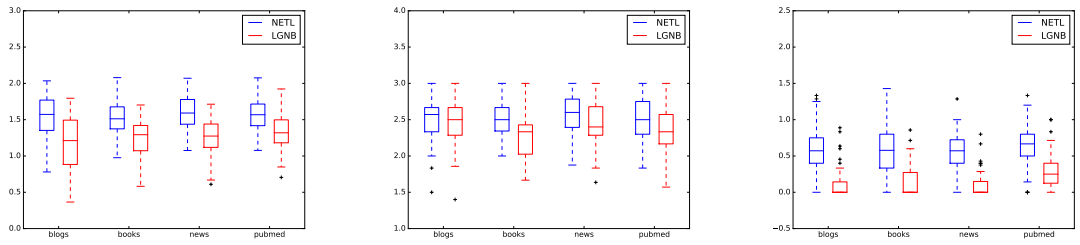
Moving to nDCG, the performance difference for nDCG-3/5 is largely indistinguishable for the two systems. LGNB, however, outperforms NETL in NEWS for nDCG-1 whereas NETL does better inPUBMED for nDCG-1 .

To give a sense of the sort of labels generated by NETL, we present a few topics and their top-ranked labels in Table 3.

5.2 Breaking Down NETL vs. LGNB

The results for NETL and LGNB in Table 2 conflate the candidate label selection and ranking steps, making it hard to get a sense of the relative impact of the different design choices implicit in the two sub-tasks. To provide a better comparison between the two methodologies, we present experiments

[16]LGNB results are taken directly from the original paper.



(a) Mean Ratings (b) Maximum Ratings (c) Minimum Ratings

Figure 1: Boxplots of ratings of candidates generated by NETL and LGNB.

evaluating the candidate generation and ranking method of the two systems separately.

5.2.1 Candidate Generation

In Table 2 we saw that NETL has a higher upper bound than that of LGNB, suggesting that the generated candidate labels were on average better. This is despite the average number of topic label candidates actually being higher for LGNB (25 vs. 19). Here, we present a more rigorous evaluation of the candidate generation method of both systems.

For each topic, we determine the mean, maximum and minimum label ratings for a given topic, and plot them in boxplots in Figure 1, aggregated per domain. The mean rating boxplot shows the average quality of candidates, while the maximum (minimum) rating boxplot reveals the average best (worst) quality of candidates that are generated by the two systems.

Looking at the boxplots, we see very clearly that NETL generates on average higher-quality candidates. Across all domains for mean, maximum and minimum ratings, the difference is substantial.

To provide a quantitative evaluation, we conduct one-sided paired t-tests to test the difference for all pairs in the boxplots. Except for the maximum ratings on BLOGS, all tests are significant ($p < 0.05$). These results demonstrate that NETL generates better candidates than LGNB (in all of the best-case, average-case and worst-case scenarios).

5.2.2 Candidate Ranking

Next, we directly compare the ranking method of NETL and LGNB. Using candidates generated by NETL, we re-rank the candidates using the ranking method of each of LGNB and NETL, and compare the results.

Both LGNB and NETL train an SVR re-ranker, using a partially-overlapping set of features. For LGNB, the ranking methodology uses 7 lexical association measures (PMI, Student's t-test, Dice's coefficient, Pearson's χ^2 test, log likelihood ratio, conditional and reverse conditional probability), 2 lexical features (the same 2 features that NETL uses: *NumWords* and *TopicOverlap*), and a search engine score based on Zettair. NETL, on the other hand, uses only 4 features: *LetterTrigram*, *PageRank*, *TopicOverlap* and *NumWords*.

For LGNB, we exclude the Zettair search engine score feature (as it was found to be an unimportant feature), and generate the lexical association features by parsing English Wikipedia. We train 2 SVR models using LGNB and NETL features. Results are presented in Table 4.

Using the same candidates, we see that NETL's features produce better rankings, outperforming LGNB's features across all domains. This shows that not only does NETL generate better candidates, but also ranks them better than LGNB.

6 Discussion

To better understand the contribution of each feature in NETL, we perform feature ablation tests (Table 5). An interesting observation is that different features appear to have different impact depending on the

Test Domain	Features	Top-1 Avg.	nDCG-1	nDCG-3	nDCG-5
BLOGS	LGNB	1.92	0.79	0.81	0.82
	NETL	**2.00**	**0.81**	**0.85**	**0.84**
BOOKS	LGNB	1.86	0.77	0.79	0.80
	NETL	**1.99**	**0.82**	**0.82**	**0.84**
NEWS	LGNB	1.87	0.75	0.79	0.81
	NETL	**2.02**	**0.80**	**0.84**	**0.85**
PUBMED	LGNB	1.89	0.77	0.79	0.81
	NETL	**1.99**	**0.81**	**0.81**	0.82

Table 4: Comparison of ranking performance with NETL features and LGNB features. Boldface indicates the better system between NETL and LGNB (with an absolute difference > 0.01).

Test Domain	BLOGS	BOOKS	NEWS	PUBMED
All Features	2.00	1.99	2.02	1.99
−*LetterTrigram*	1.99 (−.01)	1.96 (−.03)	2.02 (±.00)	1.93 (−.06)
−*PageRank*	1.93 (−.07)	1.980 (−.01)	2.00 (−.02)	2.00 (+.01)
−*TopicOverlap*	2.00 (±.00)	2.03 (+.04)	2.04 (+.02)	1.95 (−.04)
−*NumWords*	1.97 (−.03)	2.02 (+.03)	2.02 (±.00)	2.00 (+.01)

Table 5: Feature ablation results based on in-domain top-1 average ratings.

domain. Looking at BLOGS, we find that there is a considerable drop in top-1 average rating when we remove the *PageRank* feature. Similarly, ablating *LetterTrigram* appears to have a significant impact on PUBMED as well as some influence on BOOKS. As far as NEWS is concerned, we observe feature ablation does not play a big role. These observations indicate there is some degree of complementarity between these features, and that combining them produces robust and consistent performance across different domains.

Additionally, we explored using different numbers of topic terms when computing topic and title relevance for candidate ranking (we tested using top-5/10/15/20 topic terms). In general, we find that performance drops with the increase in topic terms. We also experiment with weighting each topic term with its word probability. We observed an improvement, although the difference is so marginal that we omit the results from the paper. Lastly, we tried computing relevance by first computing the centroid of topic terms before computing the cosine similarity with a candidate title. Again, we found little gain with this approach.

One feature type that we expect would have high utility is graph connectivity over the graphical structure of the Wikipedia categories or similar, along the lines of Hulpus et al. (2013). We leave this to future work. Methods based on keyphrase extraction such as Zhao et al. (2011) are also potentially worth exploring, although it remains to be seen whether notions such as "interestingness" benefit topic label selection.

7 Conclusion

We propose a neural embedding approach to automatically label topics using Wikipedia titles. Our methodology combines document and word embeddings to select the most relevant labels for topics. Compare to a state-of-the-art competitor system, our model is simpler, more efficient, and achieves better results across a range of domains.

Abstract

This paper presents a new memory-bounded left-corner parsing model for unsupervised raw-text syntax induction, using unsupervised hierarchical hidden Markov models (UHHMM). We deploy this algorithm to shed light on the extent to which human language learners can discover hierarchical syntax through distributional statistics alone, by modeling two widely-accepted features of human language acquisition and sentence processing that have not been simultaneously modeled by any existing grammar induction algorithm: (1) a left-corner parsing strategy and (2) limited working memory capacity. To model realistic input to human language learners, we evaluate our system on a corpus of child-directed speech rather than typical newswire corpora. Results beat or closely match those of three competing systems.

1 Introduction

The success of statistical grammar induction systems (Klein and Manning, 2002; Seginer, 2007; Ponvert et al., 2011; Christodoulopoulos et al., 2012) seems to suggest that sufficient statistical information is available in language to allow grammar acquisition on this basis alone, as has been argued for word segmentation (Saffran et al., 1999). But existing grammar induction systems make unrealistic assumptions about human learners, such as the availability of part-of-speech information and access to an index-addressable parser chart, which are not independently cognitively motivated. This paper explores the possibility that a memory-limited incremental left-corner parser, of the sort independently motivated in sentence processing theories (Gibson, 1991; Lewis and Vasishth, 2005), can still acquire grammar by exploiting statistical information in child-directed speech.

2 Related Work

This paper bridges work on human sentence processing and syntax acquisition on the one hand and unsupervised grammar induction (raw-text parsing) on the other. We discuss relevant literature from each of these areas in the remainder of this section.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 964–975, Osaka, Japan, December 11-17 2016.

2.1 Human sentence processing and syntax acquisition

Related work in psycholinguistics and cognitive psychology has provided evidence that humans have a limited ability to store and retrieve structures from working memory (Miller, 1956; Cowan, 2001; McElree, 2001), and may therefore employ a left-corner-like strategy during incremental sentence processing (Johnson-Laird, 1983; Abney and Johnson, 1991; Gibson, 1991; Resnik, 1992; Stabler, 1994; Lewis and Vasishth, 2005). Schuler et al. (2010) show that nearly all naturally-occurring sentences can be parsed using no more than four disjoint derivation fragments in a left-corner parser, suggesting that general-purpose working memory resources are all that is needed to account for information storage and retrieval during online sentence processing. These findings motivate our left-corner parsing strategy and depth-bounded memory store.

An extensive literature indicates that memory abilities develop with age (see e.g. Gathercole, 1998 for a review). Newport (1990) proposed that limited processing abilities actually facilitate language acquisition by constraining the hypothesis space (the 'less-is-more' hypothesis). This theory has been supported by a number of subsequent computational and laboratory studies (e.g, Elman, 1993; Goldowski & Newport, 1993; Kareev et al., 1997) and parallels similar developments in the 'curriculum learning' training regimen for machine learning (Bengio et al., 2009).[1] Research on the acquisition of syntax has shown that infants are sensitive to syntactic structure (Newport et al., 1977; Seidl et al., 2003) and that memory limitations constrain the learning of syntactic dependencies (Santelman and Jusczyk, 1998). Together, these results suggest both (1) that the memory constraints in infants and young children are even more extreme than those attested for adults and (2) that these constraints impact – and may even facilitate – learning. By implementing these constraints in a domain-general computational model, we can explore the extent to which human learners might exploit distributional statistics during syntax acquisition (Lappin and Shieber, 2007).

2.2 Unsupervised grammar induction

The process of grammar induction learns the syntactic structure of a language from a sample of unlabeled text, rather than a gold-standard treebank. The constituent context model (CCM) (Klein and Manning, 2002) uses expectation-maximization (EM) to learn differences between observed and unobserved bracketings, and the dependency model with valence (DMV) (Klein and Manning, 2004) uses EM to learn distributions that generate child dependencies, conditioned on valence (left or right direction) in addition to the lexical head. Both of these algorithms induce on gold part-of-speech tag sequences.

A number of successful unsupervised raw-text syntax induction systems also exist. Seginer (2007) (CCL) uses a non-probabilistic scoring system and a dependency-like syntactic representation to bracket raw-text input. Ponvert et al. (2011) (UPPARSE) use a cascade of hidden Markov model (HMM) chunkers for unsupervised raw-text parsing. Christodoulopoulos et al. (2012) (BMMM+DMV) induce part-of-speech (PoS) tags from raw text using the Bayesian multinomial mixture model (BMMM) of Christodoulopoulos et al. (2011), induce dependencies from those tags using DMV, and iteratively re-tag and reparse using the induced dependencies as features in the tagging process. In contrast to ours, none of these systems employ a left-corner parsing strategy or model working memory limitations.

3 Methods

Experiments described in this paper use a memory-bounded probabilistic sequence model implementation of a left-corner parser (Aho and Ullman, 1972; van Schijndel et al., 2013) to determine whether natural language grammar can be acquired on the basis of statistics in transcribed speech within human-like memory constraints. The model assumes access to episodic memories of training sentences, but imposes constraints on working memory usage during sentence processing. The core innovation of this paper is the adaptation of this processing model to Bayesian unsupervised induction using constrained priors.

[1] The 'less-is-more' hypothesis has been a subject of controversy, however. See e.g. Rohde and Plaut (2003) for a critical review.

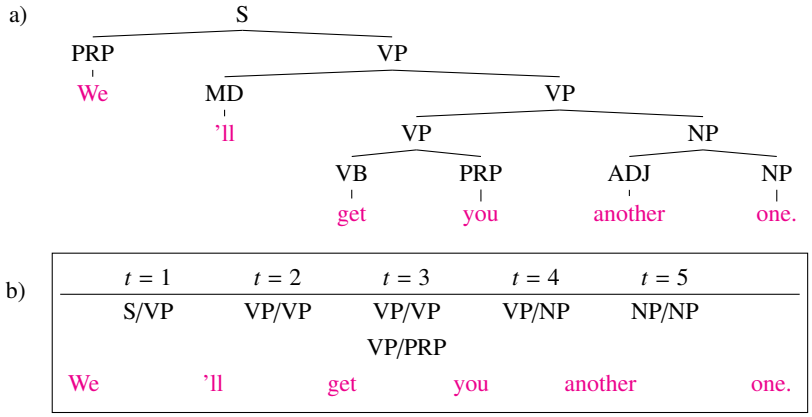

Figure 1: Trees and partial analyses for the sentence '*We'll get you another one*', taken from the training corpus. Derivation fragments are shown vertically stacked between words, using '/' to delimit top and bottom signs.

3.1 Left-corner parsing

Left-corner parsing is attractive as a sentence processing model because it maintains a very small number of disjoint derivation fragments during processing (Schuler et al., 2010), in keeping with human working memory limitations (Miller, 1956; Cowan, 2001; McElree, 2001), and correctly predicts difficulty in recognizing center-embedded, but not left- or right-embedded structures (Chomsky and Miller, 1963; Miller and Isard, 1964; Karlsson, 2007). A left-corner parser maintains a sequence of derivation fragments $a/b, a'/b', \ldots$, each consisting of an active category a lacking an awaited category b yet to come. It incrementally assembles trees by forking off and joining up these derivation fragments, using a pair of binary decisions about whether to use a word w to start a new derivation fragment (initially a complete category c):[2]

$$\frac{a/b \quad w}{a/b \quad c} \; b \xrightarrow{+} c \; \ldots \; ; \quad c \rightarrow w \tag{F=1}$$

$$\frac{a/b \quad w}{c} \; a = c; \; b \rightarrow w \tag{F=0}$$

and whether to use a grammatical inference rule to connect a complete category c to a previously disjoint derivation fragment a/b:

$$\frac{a/b \quad c}{a/b'} \; b \rightarrow c \; b' \tag{J=1}$$

$$\frac{a/b \quad c}{a/b \quad a'/b'} \; b \xrightarrow{+} a' \; \ldots \; ; \quad a' \rightarrow c \; b' \tag{J=0}$$

These two binary decisions have four possible outcomes in total: the parser can fork only (which increases the number of derivation fragments by one), join only (which decreases the number of derivation fragments by one), both fork and join (which keeps the number of derivation fragments the same), or neither fork nor join (which also preserves the number of derivation fragments).

An example derivation of the sentence '*We'll get you another one,*' in shown in Figure 1.

3.2 Probabilistic sequence model

A left-corner parser can be modeled as a probabilistic sequence model using hidden random variables at every time step for *Active* categories A, *Awaited* categories B, *Preterminal* or part-of-speech (POS) tags P, and an observed random variable W over *Words*. The model also makes use of two binary switching

[2]Here, $b \xrightarrow{+} c \; \ldots$ constrains c to be a leftmost descendant of b at some depth.

variables at each time step, F (for *Fork*) and J (for *Join*) that guide the transitions of the other states. These two binary switching variables yield four cases: 1/1, 1/0, 0/1 and 0/0 at each time step.

Let D be the depth of the memory store at position t in the sequence, and let the state $q_t^{1..D}$ be the stack of derivation fragments at t, consisting of one active category a_t^d and one awaited category b_t^d at each depth d. The joint probability of the hidden state $q_t^{1..D}$ and observed word w_t, given their previous context, are defined using Markov independence assumptions and the fork-join variable decomposition of van Schijndel et al. (2013), which preserves PCFG probabilities in incremental sentence processing:

$$\begin{aligned}
\mathsf{P}(q_t^{1..D}\ w_t \mid q_{1..t-1}^{1..D}\ w_{1..t-1}) &= \mathsf{P}(q_t^{1..D}\ w_t \mid q_{t-1}^{1..D}) && (1)\\
&\stackrel{\text{def}}{=} \mathsf{P}(p_t\ w_t\ f_t\ j_t\ a_t^{1..D}\ b_t^{1..D} \mid q_{t-1}^{1..D}) && (2)\\
&= \mathsf{P}_{\theta_P}(p_t \mid q_{t-1}^{1..D}) \cdot \\
&\quad \mathsf{P}_{\theta_W}(w_t \mid q_{t-1}^{1..D}\ p_t) \cdot \\
&\quad \mathsf{P}_{\theta_F}(f_t \mid q_{t-1}^{1..D}\ p_t\ w_t) \cdot \\
&\quad \mathsf{P}_{\theta_J}(j_t \mid q_{t-1}^{1..D}\ p_t\ w_t\ f_t) \cdot \\
&\quad \mathsf{P}_{\theta_A}(a_t^{1..D} \mid q_{t-1}^{1..D}\ p_t\ w_t\ f_t\ j_t) \cdot \\
&\quad \mathsf{P}_{\theta_B}(b_t^{1..D} \mid q_{t-1}^{1..D}\ p_t\ w_t\ f_t\ j_t\ a_t^{1..D}) && (3)
\end{aligned}$$

The part-of-speech p_t only depends on the lowest awaited (b_{t-1}^d) category at the previous time step, where d is the depth of the stack at the previous time step and $q_\perp$ is an empty derivation fragment:

$$\mathsf{P}_{\theta_P}(p_t \mid q_{t-1}^{1..D}) \stackrel{\text{def}}{=} \mathsf{P}_{\theta_P}(p_t \mid d\ b_{t-1}^d);\ \ d = \max_{d'}\{q_{t-1}^{d'} \neq q_\perp\} \tag{4}$$

The lexical item (w_t) only depends on the part of speech tag (p_t) at the same time step:

$$\mathsf{P}_{\theta_W}(w_t \mid q_{t-1}^{1..D}\ p_t) \stackrel{\text{def}}{=} \mathsf{P}_{\theta_W}(w_t \mid p_t) \tag{5}$$

The fork decision f_t is assumed to be independent of previous state $q_{t-1}^{1..D}$ variables except for the previous lowest awaited category b_{t-1}^d and part of speech tag p_t:

$$\mathsf{P}_{\theta_F}(f_t \mid q_{t-1}^{1..D}\ p_t\ w_t) \stackrel{\text{def}}{=} \mathsf{P}_{\theta_F}(f_t \mid d\ b_{t-1}^d\ p_t);\ \ d = \max_{d'}\{q_{t-1}^{d'} \neq q_\perp\} \tag{6}$$

The join decision j_t is decomposed into fork and no-fork cases depending on the outcomes of the fork decision:

$$\mathsf{P}_{\theta_J}(j_t \mid q_{t-1}^{1..D}\ f_t\ p_t\ w_t) \stackrel{\text{def}}{=} \begin{cases} \mathsf{P}_{\theta_J}(j_t \mid d\ a_{t-1}^d\ b_{t-1}^{d-1});\ \ d = \max_{d'}\{q_{t-1}^{d'} \neq q_\perp\} & \text{if } f_t = 0 \\ \mathsf{P}_{\theta_J}(j_t \mid d\ p_t\ b_{t-1}^d);\ \ d = \max_{d'}\{q_{t-1}^{d'} \neq q_\perp\} & \text{if } f_t = 1 \end{cases} \tag{7}$$

When f_t=1, that is, a fork has been created, the decision of j_t is whether to immediately integrate the newly forked derivation fragment and transition the awaited category above it (j_t=1) or keep the newly forked derivation fragment (j_t=0). When f_t=0, that is, no fork has been created, the decision of j_t is whether to reduce a stack level (j_t=1) or to transition both the active and awaited categories at the current level (j_t=0).

Decisions about the active categories $a_t^{1..D}$ are decomposed into fork- and join-specific cases depending on the previous state $q_{t-1}^{1..D}$ and the current preterminal p_t. Since the fork and join outcomes only allow a single derivation fragment to be initiated or integrated, each case of the active category model only nondeterministically modifies at most one a_t^d variable from the previous time step:[3]

$$\mathsf{P}_{\theta_A}(a_t^{1..D} \mid q_{t-1}^{1..D}\ f_t\ p_t\ w_t\ j_t) \stackrel{\text{def}}{=}$$

$$\begin{cases} [\![a_t^{1..d-2} = a_{t-1}^{1..d-2}]\!] \cdot [\![a_t^{d-1} = a_{t-1}^{d-1}]\!] \cdot [\![a_t^{d+0..D} = a_\perp]\!];\ \ d = \max_{d'}\{q_{t-1}^{d'} \neq q_\perp\} & \text{if } f_t = 0,\ j_t = 1 \\ [\![a_t^{1..d-1} = a_{t-1}^{1..d-1}]\!] \cdot \mathsf{P}_{\theta_A}(a_t^d \mid d\ b_{t-1}^{d-1}\ a_{t-1}^d) \cdot [\![a_t^{d+1..D} = a_\perp]\!];\ \ d = \max_{d'}\{q_{t-1}^{d'} \neq q_\perp\} & \text{if } f_t = 0,\ j_t = 0 \\ [\![a_t^{1..d-1} = a_{t-1}^{1..d-1}]\!] \cdot [\![a_t^{d} = a_{t-1}^{d}]\!] \cdot [\![a_t^{d+1..D} = a_\perp]\!];\ \ d = \max_{d'}\{q_{t-1}^{d'} \neq q_\perp\} & \text{if } f_t = 1,\ j_t = 1 \\ [\![a_t^{1..d-0} = a_{t-1}^{1..d-0}]\!] \cdot \mathsf{P}_{\theta_A}(a_t^{d+1} \mid d\ b_{t-1}^d\ p_t) \cdot [\![a_t^{d+2..D} = a_\perp]\!];\ \ d = \max_{d'}\{q_{t-1}^{d'} \neq q_\perp\} & \text{if } f_t = 1,\ j_t = 0 \end{cases} \tag{8}$$

[3]Here $[\![\phi]\!]$ is a (deterministic) indicator function, equal to one when ϕ is true and zero otherwise.

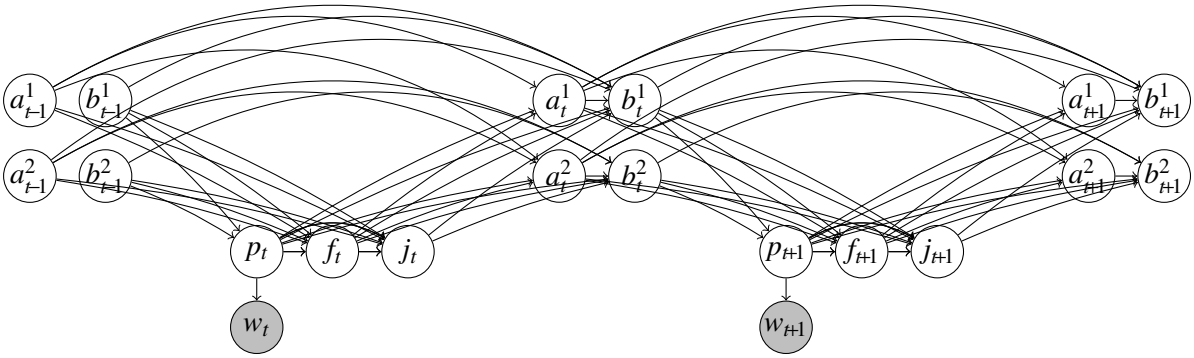

Figure 2: Graphical representation of probabilistic left-corner parsing model expressed in Equations 6–9 across two time steps, with $D = 2$.

Decisions about the awaited categories $b_t^{1..D}$ also depend on the outcome of the fork and join variables. Again, since the fork and join outcomes only allow a single derivation fragment to be initiated or integrated, each case of the awaited category model only nondeterministically modifies at most one b_t^d variable from the previous time step:

$$\mathsf{P}_{\theta_B}(b_t^{1..D} \mid q_{t-1}^{1..D}\ f_t\ p_t\ w_t\ j_t\ a_t^{1..D}) \stackrel{\text{def}}{=}$$

$$\begin{cases} [\![b_t^{1..d-2} = b_{t-1}^{1..d-2}]\!] \cdot \mathsf{P}_{\theta_B}(b_t^{d-1} \mid d\ b_{t-1}^{d-1}\ a_{t-1}^{d}) \cdot [\![b_t^{d+0..D} = b_\perp]\!]; \ d = \max_{d'}\{q_{t-1}^{d'} \neq q_\perp\} & \text{if } f_t = 0,\ j_t = 1 \\ [\![b_t^{1..d-1} = b_{t-1}^{1..d-1}]\!] \cdot \mathsf{P}_{\theta_B}(b_t^{d} \mid d\ a_t^{d}\ a_{t-1}^{d}) \cdot [\![b_t^{d+1..D} = b_\perp]\!]; \ d = \max_{d'}\{q_{t-1}^{d'} \neq q_\perp\} & \text{if } f_t = 0,\ j_t = 0 \\ [\![b_t^{1..d-1} = b_{t-1}^{1..d-1}]\!] \cdot \mathsf{P}_{\theta_B}(b_t^{d} \mid d\ b_{t-1}^{d}\ p_t) \cdot [\![b_t^{d+1..D} = b_\perp]\!]; \ d = \max_{d'}\{q_{t-1}^{d'} \neq q_\perp\} & \text{if } f_t = 1,\ j_t = 1 \\ [\![b_t^{1..d-0} = b_{t-1}^{1..d-0}]\!] \cdot \mathsf{P}_{\theta_B}(b_t^{d+1} \mid d\ a_t^{d+1}\ p_t) \cdot [\![b_t^{d+2..D} = b_\perp]\!]; \ d = \max_{d'}\{q_{t-1}^{d'} \neq q_\perp\} & \text{if } f_t = 1,\ j_t = 0 \end{cases} \tag{9}$$

Thus, the parser has a fixed number of probabilistic decisions to make as it encounters each word, regardless of the depth of the stack. A graphical representation of this model is shown in Figure 2.

3.3 Model priors

Induction in this model follows the approach of Van Gael et al. (2008) by applying nonparametric priors over the active, awaited, and part-of-speech variables. This approach allows the model to learn not only the parameters of the model—such as what parts of speech are likely to be created from what awaited categories—but also the cardinality of how many active, awaited, and part of speech categories are present, in a fully unsupervised fashion. No labels are needed for inference, which alternates between inferring these unseen categories and the associated model parameters.

The probabilistic sequence model defined above, augmented with priors, can be repeatedly sampled to obtain an estimate of the posterior distribution of its hidden variables given a set of observed word sequences. Priors over the syntactic models are based on the infinite hidden Markov model (iHMM) used for part-of-speech tagging (van Gael et al., 2009). In that model, a hierarchical Dirichlet process HMM (Teh et al., 2006) is used to allow the observed number of states—corresponding to parts of speech—in the HMM to grow as the data requires. The hierarchical structure of the iHMM ensures that transition distributions share the same set of states, which would not be possible if we used a flat infinite mixture model.

A fully infinite version of this model uses nonparametric priors on each of the active, awaited, and part-of-speech variables, allowing the cardinality of each of these variables to grow as the data requires. Each model draws a base distribution from a root Dirichlet process, which is then used as a parameter to an infinite set of Dirichlet processes, one each for each applicable combination of the conditioning

variables a_{t-1}, b_{t-1}, p_{t-1}, j_t, f_t, a_t, and b_t:

$$\beta_A \sim GEM(\gamma_A) \tag{10}$$

$$\mathsf{P}_{\theta_A}(a_t^d \mid d\ b_{t-1}^{d-1}\ a_{t-1}^d) \sim DP(\alpha_A, \beta_A) \tag{11}$$

$$\mathsf{P}_{\theta_A}(a_t^{d+1} \mid d\ b_{t-1}^d\ p_t) \sim DP(\alpha_A, \beta_A) \tag{12}$$

$$\beta_B \sim GEM(\gamma_B) \tag{13}$$

$$\mathsf{P}_{\theta_B}(b_t^{d-1} \mid d\ b_{t-1}^{d-1}\ a_{t-1}^{d-1}) \sim DP(\alpha_B, \beta_B) \tag{14}$$

$$\mathsf{P}_{\theta_B}(b_t^d \mid d\ a_t^d\ a_{t-1}^d) \sim DP(\alpha_B, \beta_B) \tag{15}$$

$$\mathsf{P}_{\theta_B}(b_t^d \mid d\ b_{t-1}^d\ p_t) \sim DP(\alpha_B, \beta_B) \tag{16}$$

$$\mathsf{P}_{\theta_B}(b_t^{d+1} \mid d\ a_t^{d+1}\ p_t) \sim DP(\alpha_B, \beta_B) \tag{17}$$

$$\beta_P \sim GEM(\gamma_P) \tag{18}$$

$$\mathsf{P}_{\theta_P}(p_t \mid d\ b_{t-1}^d) \sim DP(\alpha_P, \beta_P) \tag{19}$$

where DP is Dirichlet process and GEM is the stick-breaking construction for DPs (Sethuraman, 1994). Models at depth greater than one use the corresponding model at the previous depth as a prior.

3.4 Inference

Inference is based on the beam sampling approach employed in van Gael et al. (2009) for part-of-speech induction. This inference approach alternates between two phases in each iteration. First, given the distributions θ_F, θ_J, θ_A, θ_B, θ_P, and θ_W, the model resamples values for all the hidden states $\{q_t^d, p_t\}$. Next, given the state values $\{q_t^d, p_t\}$, it resamples each set of multinomial distributions θ_F, θ_J, θ_A, θ_B, θ_P, and θ_W. The sampler is initialized by conservatively setting the cardinalities of the number of active, awaited, and part-of-speech states we expect to see in the data set, randomly initializing the state space, and then sampling the parameters for each distribution θ_F, θ_J, θ_A, θ_B, θ_P, and θ_W given the randomly initialized states and fixed hyperparameters.

As noted by Van Gael et al. (2008), token-level Gibbs sampling in a sequence model can be slow to mix. Preliminary work found that mixing with token-level Gibbs sampling is even slower in this model due to the tight constraints imposed by the switching variables—it is technically ergodic but exploring the state space requires many low probability moves. Therefore, the experiments described in this paper use sentence-level sampling instead of token-level sampling, first computing forward probabilities for the sequence and then doing sampling in a backwards pass; resampling the parameters for the probability distributions only requires computing the counts from the sampled sequence and combining with the hyperparameters. To account for the infinite size of the state spaces, these experiments employ the beam sampler (Van Gael et al., 2008), with some modifications for computational speed.

The standard beam sampler introduces an auxiliary variable u at each time step, which acts as a threshold below which transition probabilities are ignored. This auxiliary variable u is drawn from $Uniform(0, p(q_t^{1..D}|q_{t-1}^{1..D}))$, so it will be between 0 and the probability of the previously sampled transition. The joint distribution over transitions, emissions, and auxiliary variables can be reduced so that the transition matrix is transformed into a boolean matrix with a 1 indicating an allowed transition. Depending on the cut-off value u, the size of the instantiated transition matrix will be different for every time-step.

Values of u can be sampled for active, awaited, and POS variables at every time step, rather than a single u for the transition matrix. It is possible to compile all the operations at each time step into a single large transition matrix, but computing this matrix is prohibitively slow for an operation that must be done at each time step in the data.

To address this issue, the learner may interleave several iterations holding the cardinality of the instantiated space fixed with full beam-sampling steps in which the cardinality of the state space can change.

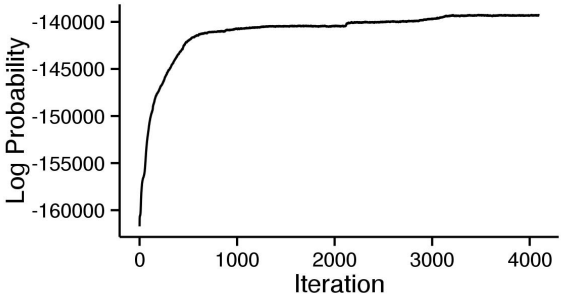

Figure 3: Log Probability (with punc)

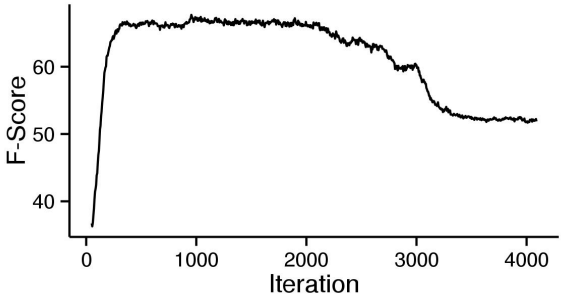

Figure 4: F-Score (with punc)

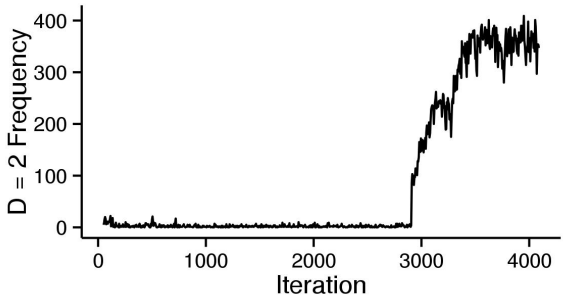

Figure 5: Depth=2 Frequency (with punc)

When the cardinality of the state space is fixed, the learner can multiply out the states into one large, structured transition matrix that is valid for all time steps. The forward pass is thus reduced to an HMM forward pass (albeit one over a much larger set of states), vastly improving the speed of inference. Alternating between sampling the parameters of this matrix and the state values themselves corresponds to updating a finite portion of the infinite possible state space; by interleaving these finite steps with occasional full beam-sampling iterations, the learner is still properly exploring the posterior over models.

3.5 Parsing

There are multiple ways to extract parses from an unsupervised grammar induction system such as this. The optimal Bayesian approach would involve averaging over the values sampled for each model across many iterations, and then use those models in a Viterbi decoding parser to find the best parse for each sentence. Alternatively, if the model parameters have ceased to change much between iterations, the learner can be assumed to have found a local optimum. It can then use a single sample from the end of the run as its model and the analyses of each sentence in that run as the parses to be evaluated. This latter method is used in the experiments described below.

4 Experimental Setup

We ran the UHHMM learner for 4,000 iterations on the approximately 14,500 child-directed utterances of the Eve section of the Brown corpus from the CHILDES database (MacWhinney, 2000).[4] To model the limited memory capacity of young language learners, we restricted the depth of the store of derivation fragments to two.[5] The input sentences were tokenized following the Penn Treebank convention and converted to lower case. Punctuation was initially left in the input as a proxy for intonational phrasal cues (Seginer, 2007; Ponvert et al., 2011), then removed in a follow-up experiment.

[4]We used 4 active states; 4 awaited states; 8 parts of speech; and parameter values 0.5 for α_a, α_b, and α_c, and 1.0 for α_f, α_j, and γ. The burnin period was 50 iterations.

[5]This limited stack depth permits discovery of interesting syntactic features – like subject-aux inversion – while modeling the severe memory limitations of infants (see §2.1). Greater depths are likely unnecessary to parse child-directed input (e.g., Newport et al., 1977).

	With punc			No punc		
	P	R	F1	P	R	F1
UPPARSE	60.50	51.96	55.90	38.17	48.38	42.67
CCL	64.70	53.47	58.55	56.87	47.69	51.88
BMMM+DMV (directed)	62.08	62.51	62.30	61.01	59.24	60.14
BMMM+DMV (undirected)	63.63	**64.02**	**63.82**	61.34	**59.33**	**60.32**
UHHMM-4000, binary	46.68	58.28	51.84	37.62	46.97	41.78
UHHMM-4000, flattened	**68.83**	57.18	62.47	**61.78**	45.52	52.42
Right-branching	68.73	**85.81**	**76.33**	**68.73**	**85.81**	**76.33**

Table 1: Parsing accuracy on Eve with and without punctuation (phrasal cues) in the input. The UHHMM systems were given 8 PoS categories while the BMMM+DMV systems were given 45. UPPARSE and CCL do not learn PoS tags. Only the UHHMM systems model limited working memory capacity or incremental left-corner parsing.

To generate accuracy benchmarks, we parsed the same data set using the three competing raw-text induction systems discussed in §2: CCL (Seginer, 2007), UPPARSE (Ponvert et al., 2011),[6] and both directed and undirected variants of BMMM+DMV (Christodoulopoulos et al., 2012).[7] The BMMM+DMV system generates dependency graphs which are not directly comparable to our phrase-structure output, so we used the algorithm of Collins et al. (1999) to convert the BMMM+DMV output to the flattest phrase structure trees permitted by the dependency graphs.

We evaluated accuracy against hand-corrected gold-standard Penn Treebank-style annotations for Eve (Pearl and Sprouse, 2013). All evaluations were of unlabeled bracketings with punctuation removed.[8] Accuracy results reported for our system are extracted from arbitrary samples taken after convergence had been reached: iteration 4000 for the with-punc model, and iteration 1500 for the no-punc model (see Figures 3 and 6, respectively).

5 Results

Figures 3, 4, and 5 show (respectively) log probability, f-score, and depth=2 frequency by iteration for the UHHMM trained on data containing punctuation. As the figures show, the model remains effectively depth 1 until around iteration 3000, at which point it discovers depth 2, rapidly overgeneralizes it, then scales back to around 350 uses over the entire corpus. Around this time, parsing accuracy drops considerably. This result is consistent with the 'less-is-more' hypothesis (Newport, 1990), since accuracy decreases near the point when the number of plausible hypotheses suddenly grows. In our system, we believe this is because the model reallocates probability mass to deeper parses. Nonetheless, as we show below, final results are state of the art.

We sampled parses from iteration 4000 of our learner for evaluation. As shown in Table 1, initial accuracy measures are worse than all four competitors. However, our system generates exclusively binary-branching output, while all competitors can produce the higher arity trees attested in the PTB-like evaluation standard (notice that our recall measure for the binary branching output beats both CCL and UPPARSE). To correct this disadvantage, we flattened the UHHMM output by first converting binary trees to dependencies using a heuristic that selects for each parent the most frequently co-occurring child category as the head, then converting these dependencies back into phrase structures using the Collins et al. (1999) algorithm. As shown in Table 1, recall remains approximately the same while precision predictably improves, resulting in higher overall F-measures that beat or closely match those of all competing systems.[9]

[6]Using the best cascaded parser settings from that work: probabilistic right-linear grammar with uniform initialization.

[7]We ran both variants of the BMMM+DMV system for 10 generations, with 500 iterations of BMMM and 20 EM iterations of DMV per generation, as was done by Christodoulopoulos et al. (2012).

[8]Note that while punctuation was removed for all evaluations, inclusion/removal of punctuation in the training data was an independent variable in our experiment.

[9]It happens to be the case that these child-directed sentences are heavily right-branching, likely due to the simplicity and

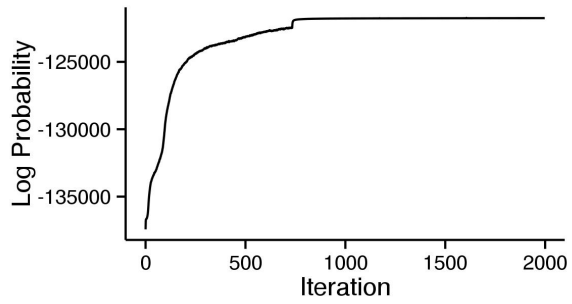

Figure 6: Log Probability (no punc)

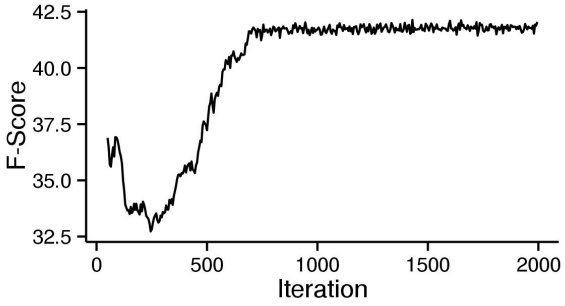

Figure 7: F-Score (no punc)

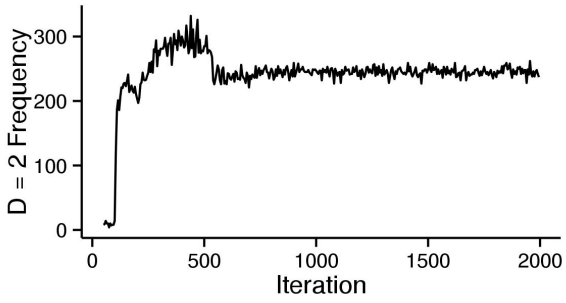

Figure 8: Depth=2 Frequency (no punc)

Figures 6, 7, and 8 show (respectively) log probability, f-score, and depth=2 frequency by iteration for the UHHMM trained on data containing no punctuation. Somewhat surprisingly, the model discovers depth 2 and converges much more quickly than it did for the with-punc corpus, requiring fewer than 1000 iterations to converge. This is possibly due to the slight reduction in corpus size. As in the case of the with-punc trained learner, once depth 2 is discovered, the system quickly overgeneralizes, then converges in a consistent range (in this case around 250 uses of depth 2).

To evaluate accuracy on the punctuation-free data, we sampled parses from iteration 1500 of our learner. Results are given in Table 1. Binary UHHMM results are on par with UPPARSE, worse than CCL, and considerably worse than BMMM+DMV, while flattened UHHMM results show higher overall F-measures than both CCL and UPPARSE. BMMM+DMV suffers less in the absence of punctuation than the other systems (and therefore generally provides the best induction results on no-punc). The large drop in UHHMM accuracy with the removal of punctuation provides weak evidence for the use of intonational phrasal cues in human syntax acquisition.

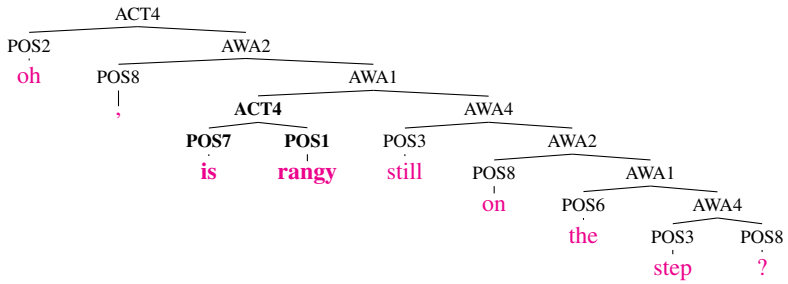
While the BMMM+DMV results are on par with ours, it is important to note that we used a severely restricted number of categories in order to improve computational efficiency. For example, our system was given 8 PoS tags to work with, while BMMM+DMV was given 45. Finer grained state spaces in a more efficient implementation of our learner will hopefully improve upon the results presented here.

Finally, it is interesting to observe that the uses of depth 2 shown in Figures 5 and 8 are in general linguistically well-motivated. They tend to occur in subject-auxiliary inversion, ditransitive, and contraction constructions, in which depth 2 is often necessary in order to bracket auxiliary+subject, verb+object, and verb+contraction together, as illustrated in Figure 9. Unfortunately, due to the flat representation of these constructions in the gold standard trees, this insight on the part of our learner is not reflected in the accuracy measures in Table 1.

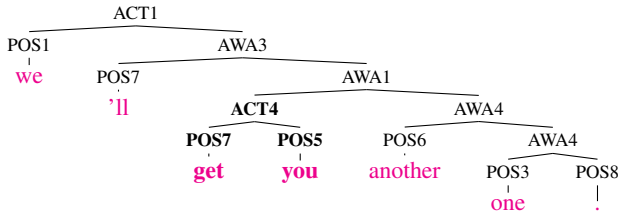
---

short length of child-directed utterances, and therefore the right-branching baseline (RB) outperforms all systems by a wide margin on this corpus. However, we argue that such utterances are a more realistic model of input to human language learners than newswire text, and therefore preferable for evaluation of systems that purport to model human language acquisition. Our system learns this directional bias from data, and does so at least as successfully as its competitors.

1. **Subject-auxiliary inversion:**



2. **Ditransitive:**



3. **Contraction:**

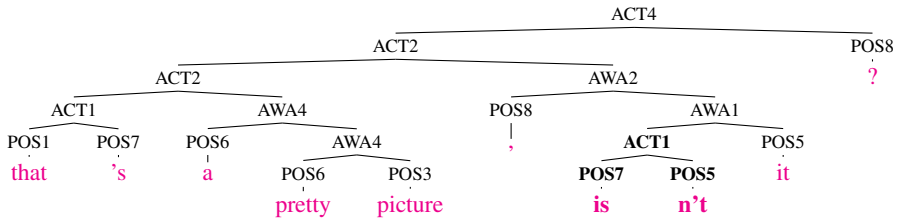


Figure 9: Actual parses from UHHMM-4000 (with punctuation), illustrating the use of depth 2 (bold) for subject-aux inversion, ditransitives, and contractions.

6 Conclusion

This paper presented a grammar induction sytem that models the working memory limitations of young language learners and employs a cognitively plausible left-corner incremental parsing strategy, in contrast to existing raw-text induction systems. The fact that our system can model these aspects of human language acquisition and sentence processing while achieving the competitive results shown here on a corpus of child-directed speech indicates that humans can in principle learn a good deal of natural language syntax from distributional statistics alone. It also shows that modeling cognition more closely can match or improve on existing approaches to the task of raw-text grammar induction.

In future research, we intend to make use of parallel processing techniques to increase the speed of inference and (1) allow the system to infer the optimal number of states in each component of the model, permitting additional granularity that might enable it to discover subtler patterns than is possible with our currently-restricted state inventories, and (2) allow the system to make use of depths 3 and 4, modeling working memory capacities of older learners.

Abstract

In this paper we discuss three key points related to error detection (ED) in learners’ English. We focus on content word ED as one of the most challenging tasks in this area, illustrating our claims on adjective–noun (AN) combinations. In particular, we (1) investigate the role of context in accurately capturing semantic anomalies and implement a system based on distributional topic coherence, which achieves state-of-the-art accuracy on a standard test set; (2) thoroughly investigate our system’s performance across individual adjective classes, concluding that a class-dependent approach is beneficial to the task; (3) discuss the data size bottleneck in this area, and highlight the challenges of automatic error generation for content words.

1 Introduction

Error detection (ED) in the prose of ‘English as a Second Language’ (ESL) learners has recently attracted much attention (Ng et al., 2014; Ng et al., 2013; Dale et al., 2012; Dale and Kilgarriff, 2011). Earlier work on ED in ESL writing mostly focused on grammatical errors and errors in function words (Felice and Pulman, 2008; Gamon et al., 2008; Tetreault et al., 2010; Gamon, 2010; Rozovskaya and Roth, 2010a; Dahlmeier and Ng, 2011b; Ng et al., 2013). Lately, the focus has shifted to other error types, with the recent shared tasks encompassing all errors (Ng et al., 2014; Daudaravicius et al., 2016). In Ng et al. (2014), errors in content words are reported to be the second most frequent error type among 28 categories, accounting for 11.8% of all errors in the training and for about 14% in the test data, yet most teams scored poorly in this category suggesting that this is a challenging and mostly unsolved problem.

Current ED approaches can be broadly described as either *modular*, addressing one error type in particular, or as *comprehensive*, spanning all error types, as in case of the SMT-based techniques (Felice et al., 2014; Junczys-Dowmunt and Grundkiewicz, 2014). The modular approaches rely on the systematic and recurrent nature of the error patterns, and on the availability of closed confusion sets which enable casting the task as a multi-class classification problem. Since content words do not assume a finite set of confusions, it has been shown that ED for these combinations cannot be performed in a similar way (Kochmar and Briscoe, 2014; Rozovskaya et al., 2014). State-of-the-art SMT-based approaches also struggle with content word errors. We argue that ED systems for words which carry lexical meaning should necessarily involve a semantic component, which is typically not needed for other error types.

From a pedagogical point of view, detecting content word errors is an important task. Since content words carry the semantics of a sentence as well as the communicative intent of the writer, incorrect uses may lead to misunderstandings and meaning distortions: for example, *classic* and *classical* are frequently confused by language learners, yet *classic dance* and *classical dance* clearly have different denotations. The importance of content word knowledge in language learning has been demonstrated in the previous ESL studies: James (1998) points out that language learning itself is sometimes equated with mastering vocabulary. Leacock et al. (2014) mention an experiment in which teachers of English were asked to rank errors according to their gravity, and word choice errors were ranked as one of the two most serious

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 976–986, Osaka, Japan, December 11-17 2016.

error categories. The study of Leacock and Chodorow (2003) also demonstrates that errors in content words have a direct impact on overall results in the *Test of English as a Foreign Language* (*TOEFL*).

In this paper, we focus on the underexplored task of content word error *detection*, independently of correction (see §2). We follow the semantically motivated approach outlined by Kochmar and Briscoe (2014) (henceforth K&B) for adjective–noun (AN) combinations,[1] building on their work by integrating context information in the classification. That is, we want to learn that although *classical dance* is more frequent than *classic dance*, the latter is correct in a context such as *They performed a classic Scottish dance*. In §3, we propose that features based on distributional topic coherence (Newman et al., 2010) can catch semantically anomalous ANs by modelling the effects of errors on the coherence of their context. A simple system based on this idea obtains state-of-the-art results. In §4, we show that the combination of the proposed in-context (*IC*) system with the out-of-context (*OOC*) ED system of K&B can further improve results, as long as the *OOC* system's error recall is sufficient. A thorough investigation of our system reveals that its performance is dependent on the adjective classes (see §5). This leads us to the conclusion that content word errors should be treated in a class-dependent way.

Finally, we show that availability of high-quality learner data for training the ED algorithms is of paramount importance. We note that certain error types, having recurrent error patterns, allow for straightforward artificial error data generation. However, we experimentally show that quality artificial data cannot be so easily generated for content words (see §6).

2 Related work

2.1 ED in content words

Previous approaches to error detection and correction of content words fall into two paradigms. One focuses on correction only, assuming that errors are detected by a separate ED algorithm (Liu et al., 2009; Dahlmeier and Ng, 2011a). The second performs error detection and correction through a single algorithm (Chang et al., 2008; Futagi et al., 2008; Park et al., 2008; Yi et al., 2008). The latter type relies on comparison of the learner's choice with possible alternatives: if any alternative scores higher than the original according to the chosen frequency-based metric, the original combination is flagged as an error and the alternative is suggested as a correction (Leacock et al., 2014). Approaches based on this idea have a number of weaknesses. In particular, they rely on the availability of a set of plausible alternatives and are unable to detect errors in the absence of such alternatives, even though a number of studies (Leacock et al., 2009; Chodorow et al., 2010; Andersen et al., 2013) have shown that ED alone (without correction) is useful for language learners. Crucially, K&B have also shown that some original word combinations can be felicitous even when some alternatives score higher, leading to over-corrections which can be hugely detrimental to ESL learners. Such considerations speak for considering ED as a separate task.

Prior proposals have rarely analysed content word errors from a semantic perspective. K&B have focused on ED for AN phrases and shown that approaches aimed at detecting semantic deviance can also identify errors in content words. These authors cast ED as a binary classification task and train a machine learning classifier using features derived from compositional distributional semantics. They obtain 81% accuracy, and show that their semantically motivated approach outperforms the state-of-the-art in ED so far. One drawback of their method is that they do not take context into account: features are based on the distributions of an AN's components and their composition, but not on the particular context where it is used. When evaluating their system in context by comparing the system's predictions with human, context-sensitive annotation, the authors note that accuracy drops to 65%. Our approach takes both semantic aspect *and* surrounding context into account.

2.2 Learner data

Since the standard approaches to ED rely on machine learning, availability of learner data is of paramount importance. Some error types allow for straightforward generalisation from seen examples (e.g., errors in function words or mechanical errors), but errors in content words appear to be less systematic. Therefore, it is crucial to have sufficient, thoroughly annotated learner data. To the best of our knowledge,

[1] We also believe that our approach can ultimately be applied to other types of content word combinations.

the AN dataset released by K&B[2] is the only publicly available dataset of learners' errors in content words that satisfies quality requirements. ANs are labelled with error type (semantically-related or form-related confusion, or no relation) and possible corrections are suggested. The data contains a two-level annotation, with the ANs being labelled as correct or incorrect out of their context (*OOC*), as well as in the original context of use (*IC*). For example, *classic dance* is annotated as correct *OOC*, but incorrect *IC* whenever it is used erroneously in place of *classical dance*. The dataset contains 798 ANs that are extracted from the *Cambridge Learner Corpus* (*CLC*)[3] and are unattested in the *British National Corpus* (*BNC*). This data is interesting for a linguistically-motivated investigation of learners' errors: K&B demonstrated that approaches that simply rely on frequency and collocational strength do not perform well on it.

The dataset contains 892 unique contexts, and in our experiments, we use a subset of 824 contexts (see §3). The lower bound for *IC*-annotated ANs is estimated as the majority class baseline and equals 0.55. The upper bound estimated as the average inter-annotator agreement is 0.74.

3 Topic coherence for error detection

3.1 Topic coherence

Topic coherence is a measure of the semantic relatedness of the items in a given set of words, which has mostly been studied from the perspective of 'topic modelling' techniques (Steyvers and Griffiths, 2007). Topic modelling is a text classification method which generates so-called topics from a corpus by analysing word co-occurrences, and subsequently models any new text in terms of those topics. A topic is expressed as a list of keywords supposed to be highly characteristic for a subject: for instance, {*film, actor, cinema, Hollywood*} might be the main keywords for a *film* topic. In order to obtain an intrinsic evaluation of such models, recent work has started investigating whether topics produced by standard techniques can be said to be 'coherent', i.e. whether topic keywords belong together, from a human point of view (Chang et al., 2009; AlSumait et al., 2009; Newman et al., 2010; Mimno et al., 2011).

Even though they stem from research on topic modelling, topic coherence measures can be applied to any set of words, and might for instance tell that the set {*chair, table, office, team*} is more coherent than {*chair, cold, elephant, crime*}. They are well suited to model semantic association and we hypothesise that they can tell us something about the semantic validity of a sentence.

3.2 Experimental setting

Following Newman et al. (2010), we define the coherence $\mathcal{COH}$ of a set of words $w_1...w_n$ as the mean of their pairwise similarities:

$$\mathcal{COH}(w_{1...n}) = mean\{Sim(w_i, w_j), ij \in 1...n, i < j\}$$

We estimate similarity as the cosine distance between two words in a distributional space (Turney and Pantel, 2010). In that setup, the meaning of a word is a vector that lives in a space where dimensions correspond to linguistic contexts. The vector's components reflect how characteristic a context is for the word under consideration.

Our hypothesis is that some lexical errors might result in a sharp variation of semantic coherence. Consider an example from learners' data:

(1) ... it was very difficult for my friends to call me with the *classical* *phone*...

The adjective *classical* is distributionally associated with the arts, collocating with nouns like *dance, music, style* or *literature*. Its similarity to *friend, call* or *phone* is much lower than the pairwise similarities of those words alone. We hypothesise that the inclusion of the unrelated *classical* in the sentence would thus have an adverse effect on its overall coherence.

Context size	1	2	3	4	5
SVM (low)	0.59 (± 0.02)	0.58 (± 0.02)	0.58 (± 0.01)	0.58 (± 0.02)	0.58 (± 0.02)
SVM (high)	0.59 (± 0.02)	0.59 (± 0.03)	0.58 (± 0.02)	0.59 (± 0.02)	0.59 (± 0.02)
+ adj. (low)	0.62 (± 0.04)	0.62 (± 0.04)	0.62 (± 0.03)	0.62 (± 0.02)	0.62 (± 0.04)
+ adj. (high)	0.64 (± 0.04)	**0.66** (± 0.06)	0.64 (± 0.04)	0.63 (± 0.02)	0.64 (± 0.02)

Table 1: SVM classification accuracy over different context sizes with three $\mathcal{COH}$ features, and with added *adjective* feature. The 'low/high' scores are the lowest/highest across all values of the C parameter.

Our learners' data consists of the AN dataset (see §2), spell-checked to correct orthographic errors. We build a distributional semantics space from the BNC,[4] using lemmatised word windows as context (size=10), the top 2000 most frequent content words as dimensions, and Positive Pointwise Mutual Information (PPMI) as weighting measure.[5] For each instance in the learners' data, we define a context window W as the AN under consideration and n words on each side of that AN. Allowable context words are nouns, verbs, adjectives and adverbs for which a BNC distribution is available. When the AN contains a word not found in the BNC, we discard the corresponding instances, ending up with 824 items out of the original 892 in the AN dataset. We are interested in three measures:

- the topic coherence $\mathcal{COH}$ of context W;
- the topic coherence $\mathcal{COH}_{\text{-}adj}$ of the context without the *adjective*;
- the topic coherence $\mathcal{COH}_{\text{-}noun}$ of the context without the *noun*.

Our starting hypothesis is that when the AN is erroneous, omitting either the adjective or the noun in the calculation results in a significant variation of the original coherence score.

3.3 Topic coherence results

We perform SVM classification with 5-fold cross-validation, using the coherence figures $\mathcal{COH}$, $\mathcal{COH}_{\text{-}adj}$ and $\mathcal{COH}_{\text{-}noun}$ as features. The order of the data is randomised before creating the folds, and the ratio of correct/incorrect instances kept equal between folds (55% correct to 45% incorrect). We use *SVM^{light}* (Joachims, 1999) with an RBF kernel to classify the data. We tune penalty parameter C, experimenting with the values of C in the range 10-200. Since the size of the AN dataset does not allow for the use of a development set, we report the lowest and highest system performance across all folds.

Table 1 shows that our simple 3-feature system reaches 59% accuracy. We attempt to improve on this by specifying which adjective occurs in the AN: we add 61 binary features to the SVM, corresponding to the 61 different adjectives in the data, and 'turn on' the feature matching the adjective under consideration for each data point. This step results in a further increase in accuracy, reaching 66%, which is on a par with the result reported by K&B when taking the *OOC* annotation to an in-context setting. This result is highly encouraging since our system is overall much simpler: given an available distributional semantic space, coherence values can be computed very straightforwardly and the SVM classifier relies on few features. We also note that the system is stable across various values of C: the differences between lowest and highest scores are not significant given the variability observed across all 5 folds. In the rest of this paper, we only report our highest scores under the understanding that varying C does not significantly affect results.

The best accuracy is obtained for a context size of 2, but the differences in performance between various context sizes are not statistically significant either. Most likely, the ideal context window for the task depends on the sentence. In some cases, larger context is actually harmful to ED, as in Ex. 2 below, where the context words are mostly about shopping/buying and do not have a straightforward association with either *cat* or *funny*. In contrast, Ex. 3 needs a larger window to catch that the sentence is not about different *bears* drinking but rather about a restaurant with *beers*.

[5] The space was built using the DISSECT toolkit (Dinu et al., 2013), available at http://clic.cimec.unitn.it/composes/toolkit/index.html.

	System description	Classifier	Accuracy
COH	§3.3	SVM	0.66
+ COMPDIST	feat. combination (§4.1)	SVM	0.68
+ COMPDIST	pipeline (§4.2)	SVM	0.67
+ *OOC* gold	§4.2	SVM	0.76
COMPDIST	K&B	DT	0.64
+ COH	feat. combination (§4.1)	DT	0.66

Table 2: Classifier combination accuracies

(2) I went shopping yesterday, and I've bought a new shirt. I had to buy it because it had a *funny cat* on it. It was quite cheap, it costs just £4.

(3) In the second one you can eat some easy food as salads, but you also can drink a great number of *different bears*.

An analysis of our results shows that the classifier is well-balanced, achieving 0.66 and 0.65 precision for correct and incorrect instances, as well as 0.65 and 0.66 recall. This is an improvement over the context-insensitive system from K&B, which scored much better recall on correct than incorrect instances (72% vs 58%).

4 Combining classifiers

K&B showed that it is possible to classify *OOC*-annotated content word errors with high accuracy: the authors reported an accuracy of 81% on this task. This means that regardless of context, we can learn that e.g. **big quantity* is incorrect. In the next set of experiments, we investigate the benefits of including context-insensitive classifier in our system: since the ANs that are annotated as errors *OOC* are also errors *IC*, we would expect the system to benefit overall from context-insensitive annotation.

We consider combinations of the following two systems and their respective semantic information:

- COMPDIST is the *context-insensitive* system of K&B, which we ran on our subset of 824 contexts. The AN vectors are built using the *multiplicative* model of semantic composition (Mitchell and Lapata, 2008). A set of measures that can distinguish between the representations of the correct and incorrect ANs is applied, including, for example, *vector length*, *cosine similarity* between the AN vector and the input noun, and so forth.[6] The values of these measures are then used by an ED algorithm running over a *Decision Tree* (DT) classifier.[7]

- COH is the *context-sensitive* system presented in this paper, with three coherence-based features and a feature representing the adjective in the AN (see §3.3).

We examine two architectures: in a first experiment, we simply concatenate the features from COMPDIST and COH and input the resulting vector into (a) an SVM classifier, as used in this paper; (b) a DT classifier, as used in K&B. In a second experiment, we design a pipeline system, where the classification of COMPDIST is fed into the topic coherence model. All results reported in this section are for a context size of 2. A summary can be found in Table 2.

4.1 Direct feature combination

We first run COMPDIST in isolation over the *IC* annotation, to get a baseline accuracy. This results in a performance of 64%, just below our COH system accuracy of 66% (see Table 2).

We then proceed with feature concatenation, starting with the full feature set and then applying ablation tests to identify the best-performing features. The features are fed into the DT classifier of K&B on one hand (line COMPDIST+COH in Table 2) and our SVM classifier on the other hand (line COH+COMPDIST).

[6] For the full feature set, please consult K&B.

[7] We use the *NLTK* implementation (Bird et al., 2009).

1 usual (4/4)	.83 strong (15/18)	.63 fast (7/11)	.41 historical (5/12)
1 rapid (1/1)	.83 clear (5/6)	.62 small (15/24)	.40 economic (2/5)
1 magic (1/1)	.80 actual (4/5)	.62 nice (39/62)	.33 deep (1/3)
1 incorrect (3/3)	.75 bad (24/32)	.62 important (18/29)	.30 whole (3/10)
1 elder (16/16)	.72 good (39/54)	.60 unique (6/10)	.25 heavy (2/8)
1 economical (33/33)	.71 hard (5/7)	.60 high (3/5)	.20 true (1/5)
1 classical (5/5)	.70 main (7/10)	.60 electric (3/5)	.18 certain (2/11)
1 classic (3/3)	.70 different (29/41)	.60 correct (3/5)	.14 precious (1/7)

.89 suitable (8/9)	.68 typical (11/16)	.53 wrong (7/13)	.14 ancient (1/7)
.89 soft (8/9)	.67 big (63/94)	.50 short (6/12)	0 far (0/2)
.89 full (8/9)	.66 various (6/9)	.50 present (2/4)	0 false (0/2)
.89 convenient (8/9)	.64 proper (9/14)	.47 common (8/17)	0 electrical (0/3)
.87 large (7/8)	.63 great (26/41)	.42 appropriate (3/7)	

Table 3: Per-adjective precision values for SVM classification, sorted from highest to lowest

Using the DT classifier, the best accuracy of the direct combination of features is 66% with the feature set including *cosine similarity* to the input noun, *ranked density*, *adjective* and a *coherence-based* feature based on $(\mathcal{COH} - \mathcal{COH}_{\text{-}adj})$. The improvement over baseline is however not statistically significant.

Adding the COMPDIST features to the SVM COH system results in a similar improvement, reaching 68% from a 66% baseline, using the *cosine similarity* to the noun, and semantic neighbourhood features.

4.2 Pipeline system

To test the actual effect of the topic coherence features at in-context classification stage, we first attempt to add the *OOC* gold annotation to our system, in the form of a new feature. The baseline created by the *OOC* gold annotation is very high: running the classifier over that one feature results in 73% accuracy. Nevertheless, performance increases when the gold annotation is combined with COH. The best result is 76% – a 3% improvement (statistically significant at $p = 0.03$). This is over the human upper bound of 74%, and it shows that the topic coherence features perform well in contextualising the *OOC* annotation.

However, since a 'real-world' pipeline system does not have access to the gold annotations, we replace the gold annotations with the output of COMPDIST. In this setting, the combination only produces minimal improvement, reaching 67% accuracy with the SVM and 66% with the DT classifier. The reason for this result is low error recall of the *OOC* system which is tuned towards high precision because of the strong negative impact on the learners when wrongly reporting an error. While this is sensible from an educational point of view, it means that we are only recalling 17% of erroneous ANs at the *OOC* stage. We conclude that improving *OOC* detection can hugely benefit the overall system.

5 Adjective-dependent classification analysis

5.1 COH analysis

Our experiments with the coherence-based system showed that it is particularly accurate in classifying form-related errors: the accuracy on *classic*, *classical*, *economical*, *elder*, *electric*, *electrical* and *historical* – which are responsible for 80% of the form-related errors in our data – is 77%. Otherwise, the accuracy of the system is generally dependent on the adjective being classified. Table 3 shows precision values for each adjective in our data.[8] While *economical* (33 instances) and *funny* (11 instances) achieve 100% and 90% precision respectively, *certain* (11 instances) and *ancient* (7 instances) only reach 18% and 14%. Roughly speaking, adjectives expressing a sentiment (*funny*, *suitable*, *convenient*, *bad*, *good*, *best*, *great*, *nice*) are to be found at the top of the table, while no such consistency is to be found for the quantity adjectives: *large*, *big*, *small*, *high*, *deep*, *short* and *heavy* span a whole range of precision values, from 87% down to 25%. We conclude that the adjectives in our dataset can behave very differently with respect to the types of errors they attract, and a single classifier may not be able to model all cases equally well. In the next set of experiments, we thoroughly investigate our system's performance

[8] Morphologically related forms, for example *big* and *biggest*, are collapsed together.

Adjective	Best training elements	Accuracy
appropriate	{nice, good, best, different, bad, short, fast}	71.43%
bad	{unique}	78.12%
best	{nice, good, different, fast, funny, unique}	71.70%
big	{proper}	68.09%
correct	{nice, good, best, different, bad, short, fast, unique}	80.00%
economic	{strong, typical, elder, certain}	80.00%
economical	{small, strong, typical, elder, proper, certain}	100.00%
elder	{economical, small, strong, typical, proper, certain}	100.00%
funny	{big}	90.91%
good	{nice, best, different, fast}	70.91%
great	{wrong, main}	69.05%
nice	{good, best, different, fast}	67.74%
precious	{funny}	71.43%
small	{big, proper, funny}	68.00%

Table 4: Best training elements for a subset of adjectives, together with accuracy

across individual adjective classes. Since we lack data for a separate development set, these experiments present the analysis of the data rather than actual classification results but we believe that these results can inform future studies.

5.2 Modelling the AN data

We hypothesise that some adjectives behave in a similar way with respect to their interaction with topic coherence, and may be classifiable under a joint category. Since there are no obvious confusion sets for content words to guide category formation (see §1), we attempt to model the AN set in a purely data-driven way. We first train a classifier over each adjective with frequency ≥ 10, thus obtaining 27 individual classifiers. We then apply each classifier to every single other adjective and record which one(s) perform(s) best for that item. For example, we verify how well *ancient* is classified by each of the 26 models and record the classifier trained on *unique* as the one performing best. We take this as evidence that *ancient* and *unique* share some properties with respect to the task.

Table 4 shows accuracy for some adjectives, with the best recorded training set(s). The overall accuracy, averaged over all adjectives, is 75%. This result is on a par with human performance estimated at 74% (see §2). Per-class precision is 80% on errors and 73% on correct instances, while recall is 59% for errors and 88% for correct ANs.

We note two trends: (a) adjectives of judgement (*appropriate*, *bad*, *correct*, *nice*, *precious*) tend to be best trained by other judgement adjectives (*best*, *good*, *nice*); (b) adjectives for which form-related errors are frequent (*classic*/*classical*, *economic*/*economical*, *elder*) tend to get their best accuracy when trained on the same set (*strong*, *typical*, *elder*, *certain*).

These results suggest that training adjective classes separately could have a very positive impact. For instance, let's consider the set {*nice*, *good*, *best*, *bad*, *convenient*, *suitable*, *appropriate*}. Training each adjective over the other members of the set results in an increase in performance for those adjectives: e.g., accuracy for *nice* increases by 5 points, for *appropriate* by 14 points. Similarly, training {*small*, *big*, *large*} as a set gives a 5-point improvement on our best results.

However, due to the relatively small size of the dataset, it is impossible to have a development phase to choose the best training sets, and a separate test phase to verify robustness: confirming that *bad* is indeed best trained on *unique* would overall require more data than the 32 and 10 instances currently available.

5.3 Adjective-specific system combination

We have shown that COH performs differently on adjective-specific subsets and we have assumed a complex interaction between topic coherence and error patterns specific for particular adjectives. Our tests using COMPDIST and COH with the DT classifier confirm that the performance of the two systems on the adjective-specific subsets in the data is also different: for example, COH performs well on the adjectives *large*, *bad* and *good* (see Table 3), while COMPDIST achieves better results on *short* and *heavy*. In the next experiment, we combine the two systems in an integrated adjective-specific ED algorithm.

We implement an oracle system via a voting step based on the COMPDIST and COH adjective-specific performance. That is, for each test item, we use the prediction of the system which has best accuracy for the particular adjective under consideration. This oracle system achieves an accuracy of 71% which compares favourably to the results of COMPDIST (64%), COH (66%) alone, as well as the direct combination of the features used by the two systems (68%). Although this result is an upper bound since we lack data to set up a separate development set, we can reliably make two observations. First, we confirm that using adjective-specific information in ED improves the algorithm performance. Second, we note that the voting system's upper bound is comparable to human performance, indicating that the combination of a strong *OOC* baseline and a relatively simple semantic model of context provides the necessary conditions for ideal results: the combined system covers all relevant information for the task, and training on an expanded dataset can be expected to drastically improve performance.

6 Generating errors

Earlier we noted that high-quality learner data is crucial for ED and that, due to the size of the K&B dataset, we could not verify the results of our experiments on a separate development set (§3 and §5). Since annotated content word error data is expensive and time-consuming to produce, in this final set of experiments we attempt to generate more data in an automated way. Artificial error generation has previously been demonstrated to be useful for function word ED (Foster and Andersen, 2009; Rozovskaya and Roth, 2010b; Felice and Yuan, 2014). Following this line of work, we attempt to produce data by random substitution of adjectives.

For each adjective, we extract new data from a section of *ukWaC* (Baroni et al., 2009) totalling 1M tokens, POS-tagged and parsed with the RASP parser (Briscoe et al., 2006). We collect word windows containing the adjective under consideration, using the pattern [word$_{-2}$] [word$_{-1}$] [ADJ] [noun] [word$_{+1}$] [word$_{+2}$], thus using a 2-word context around the AN. Next, we randomly shuffle the adjectives and their contexts so that for a particular context window W_k associated with an adjective a_k, we replace a_k with a_m – an adjective linked to another context window – assuming that in most cases, such substitutions will produce incorrect instances. Then, we collect all incorrect instances for a given adjective and concatenate them with an equal number of correct uses, giving us a balanced training set for that adjective. The size of each training set is dependent on the overall frequency of the adjective, ranging from 20 to 2600 instances. Around half of the adjectives have a training set with over 1000 instances, the vast majority (93%) have at least 100 training examples.

Training and testing on this data unfortunately does not produce the expected improvements, with the accuracy falling to 56%. We conclude that the nature of the training data is vital to the performance of the system: in complex tasks like content word ED, automatically generated examples are no substitute for real human errors, and the subtle semantic phenomena occurring in learners' writing cannot be easily reproduced. The absence of clear confusion sets for content word errors makes the task of error generation particularly arduous. The erroneous *calling on the classical phone* is a case in point, showing that a wrong use of *classical* does not necessarily derive from a confusion with *classic*: the speaker probably meant *landline*. Such cases show that the diversity of content words errors makes artificial error generation less viable than for function words, and illustrates the value of 'real', annotated learner data.

7 Conclusion

We have investigated the linguistic felicity of AN phrases through the lens of distributional topic coherence and conclude by showing how this work can inform future research on content word ED.

First, we showed that using topic coherence features to model context leads to accuracy figures that are competitive with previously reported results (K&B). Framing ED in terms of coherence is linguistically sensible and computationally efficient. There are benefits in using *OOC* and *IC* systems in a pipeline architecture, but this relies on the *OOC* system having good enough recall.

Second, we found that per-adjective classification could in principle approach human-like performance. However, proper training and evaluation requires a larger dataset than is currently available.

Thirdly, we investigated the automatic creation of training data. Our experiments demonstrated that real learners' data cannot be easily substituted: in contrast with function words, content words are not naturally associated with clear confusion sets which might guide data generation.

In further work, we would like to pursue our investigation of the linguistic factors that govern certain types of errors. One interesting avenue would be to research the influence of the learner's L1 language on the observed semantic mistakes: we could imagine, for instance, that some systematicity could be captured in the effects of polysemy across languages (e.g. *heavy* might be more—or at least differently—polysemous in English compared to the learner's L1).

We will also concentrate on the expansion of the available dataset in a controlled fashion, ensuring that enough data is supplied for individual adjective training and testing. Whilst our results on error generation indicate that automatic methods may not be suited to the task, more sophisticated procedures could be tried out. For instance, it is conceivable that a distributional analysis of a (non-annotated) learners' corpus would highlight certain systematic errors which would be replicable on a larger scale. With more training data available, another interesting avenue would be to further explore adjective-dependent classification approaches and adjective category formation.

Acknowledgments

We are grateful to the COLING reviewers for their helpful feedback, and for their interesting suggestions for further work. Abstract

This paper investigates the effectiveness of 65 cohesion-based variables that are commonly used in the literature as predictive features to assess text readability. We evaluate the efficiency of these variables across narrative and informative texts intended for an audience of L2 French learners. In our experiments, we use a French corpus that has been both manually and automatically annotated as regards to co-reference and anaphoric chains. The efficiency of the 65 variables for readability is analyzed through a correlational analysis and some modelling experiments.

1 Introduction

Since the 1920's, various readability formulae have been designed to match texts with the reading skills of specific readers. The most famous of these formulas, such as Flesch's (1948) or Dale and Chall's (1948) are typical of what are called "classic" formulas. They rely on a few lexico-syntactic characteristics (e.g., the average number of words per sentence or the average number of syllables per word) to estimate the reading difficulty of a text. This strategy worked to some extent, but, from the late 70's onward, classic formulae have been seriously criticised. Zakaluk and Samuels (1988, 124) thus said: "A basic limitation of readability formulas is that they ignore such critical text factors as cohesiveness and macrolevel organization".

Studies in readability from this period stressed the importance of higher textual dimensions, focusing on inference load (Kemper, 1983), conceptual density (Kintsch and Vipond, 1979), or organisational aspects (Meyer, 1982). As a result, the classic lexico-syntactic features were disregarded for years. However, Miller and Kintsch (1980) soon noticed that including lexico-syntactic features in their cognitive readability formulas improved performance. Chall and Dale (1995, 111) had a more mixed opinion, arguing that variables based on higher textual dimensions "discriminate better among materials requiring greater maturity in reading ability", while classic lexico-syntactic variables work better to discriminate at lower levels of difficulty.

Recently, taking advantage of the opportunities offered by Natural Language Processing (NLP) techniques, readability studies have tried to leverage the semantic and discursive properties of texts to better model text difficulty (Pitler and Nenkova, 2008; Feng et al., 2009). Among those high-level dimensions that have attracted substantial attention are the level of cohesion and coherence of texts. Although psycholinguistic experiments have shown that a higher level of cohesion and coherence between a pair of related sentences decreases their reading time (Kintsch et al., 1975; Mason and Just, 2004), the added value of these textual dimensions for readability models (compared to traditional features) remains unclear, as it will be covered in more details in Section 2.

This is why this paper aims at further investigating the importance of cohesion aspects for the assessment of text readability, as the cohesive dimension is the one that have been investigated the most (see Section 2.2). Based on a corpus of texts for learners of French as a foreign language (L2), which has

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 987–997, Osaka, Japan, December 11-17 2016.

been manually annotated for co-reference chains, the three following research questions will be investigated: (1) are cohesive features relevant for text readability assessment? (2) what is the impact of NLP routines, which are error-prone, on the efficiency of cohesiveness features? and (3) does the genre of the texts (here narrative and informative) influence the discriminating power of cohesiveness features? The methodology applied to investigate these three questions is described in Section 3, while the results are presented in Section 4. The paper concludes with a discussion and some perspectives in Section 5.

2 Cohesion Features to Assess Text Readability

2.1 Coherence and Cohesion

Coherence is defined as a "semantic property of discourse, based on the interpretation of each individual sentence relative to the interpretation of other sentences" (Van Dijk, 1977, 93). The order of the ideas, a logical structuring of the text and coherent relations (consequence, cause-effect) between sentences facilitate the reader's understanding of a specific topic. In addition, readers might use external knowledge as regards the specific situation described in the text.

Cohesion is a property of text represented by explicit formal grammatical ties (discourse connectives) and lexical ties that signal how utterances or larger text parts are related to each other. Halliday and Hasan (1976) identify specific cohesive devices aiming to reinforce lexical ties, such as anaphoric chains or co-reference chains (Schnedecker, 1997), as well as lexical chains (sets of expressions related by hypernymy or hyponymy relations or expressions from the same domain, e.g. *patient–disease-treatment*).

Anaphoric chains are composed of two expressions, one antecedent and one anaphora. In Figure 1, the interpretation of the definite noun phrase *the ship* (the anaphora) is dependent on its antecedent (*the RMS Titanic*). Co-reference chains are composed of at least three referring expressions corresponding to the same discourse entity (Schnedecker, 1997). In Figure 1, the expressions *Edward Smith, an English naval reserve officer, He, He* refer to the same entity, the Titanic's commander. Lexical chains are composed of associated words or expressions related by ontological relations (synonymy, hypernymy, hyponymy) or relative to the same domain (Hirst and St-Onge, 1998), such as *naval reserve officer, vessels, ship sank, voyage* (Figure 1).

Edward John Smith was *an English naval reserve officer*. *He* served as commanding officer of numerous White Star Line vessels. *He* is best known as *the captain of* ***the RMS Titanic***, perishing when **the ship** sank on the 15th April 1912. (Wikipedia)

Figure 1: Example of anaphoric and of co-reference chain.

These three devices strengthen the links between several utterances and contribute to the overall understanding of the text (Charolles, 1995). Lexical chains are effective mechanisms to find the main domain or theme of the document. Cohesive devices such as anaphora or co-reference chains correspond to one entity expressed by various linguistic expressions (so called mentions). These expressions are related by complex morpho-syntactic, syntactic or semantic constraints (Grosz et al., 1995). Mentioning the same entity several times reinforces text cohesion (Poesio et al., 2004), (Hobbs, 1979). Cohesive devices reinforce local coherence relations in some specific genres (persuasive genres) (Berzlnovich and Redeker, 2012).

An interesting characteristic of cohesive devices is that their use is dependent on the type or genre of texts (Carter-Thomas, 1994). For instance, informative texts use specific referential expressions such as definite or demonstrative noun phrases as mentions, while narrative texts contain more chains composed of proper nouns or personal pronouns (Schnedecker, 2005). The composition, the length or the choice of the first mention of the co-reference chain is also dependent on the genre. For instance, in newspapers portraits (Schnedecker, 2005), co-reference chains start with a proper noun and contain mainly definite noun phrases and personal pronouns. For example, in law and administrative texts, reference chains start with indefinite noun phrases and the mentions are mainly definite or demonstrative noun phrases (Longo and Todirascu, 2014).

In this article, we consider explicit lexical ties such as anaphoric, co-reference and lexical chains as cohesive features. We study the correlation between these cohesive features and text complexity.

2.2 Coherence and Cohesion in Readability

As both coherence and cohesion are important text properties that are known to influence the readability of texts, readability studies have attempted to exploited both dimensions. However, most studies focused on phenomena that falls inside the category of cohesion as defined in Section 2.1 which is why we decided to focus on cohesive features in this paper.

The first to investigate the issue of text cohesion in readability analysis is probably Bormuth (1969). He considered that the correct identification of anaphoric relations was a prerequisite to the correct understanding of a text and thus computed 12 variables based on various characteristics of anaphora, showing that the density of anaphora to be the best predictor with a $r = 0.532$.

More recently, text cohesion were investigated in readability with another approach that relies on latent semantic analysis (LSA) (Landauer et al., 1998). This technique projects sentences in a semantic space in which each dimension roughly corresponds to a semantic field. This makes it possible to better measure the semantic similarity between sentences, since it can capture lexical chains through lexical repetitions, even through synonyms or hyponyms. However, this method cannot detect cohesive clues such as ellipsis, pronominal anaphora, substitution, causal conjunction, etc. Folz et al. (1998) were the first to apply this technique to readability, by computing the average similarity between each pair of sentences in a text. This variable was also included in Coh-Metrix (Graesser et al., 2004), along with similar measures such as word overlap, noun overlap, stem overlap, and argument overlap. However, the efficiency of this variable for readability was not assessed before Pitler and Nenkova (2008), who measured its association with text difficult and obtained a non significant correlation ($r = -0.1$). Later, McNamara et al. (2010) reached a similar conclusion, showing that an LSA-based variable has not much of a predictive power. On the opposite, François and Fairon (2012; 2013) obtained a higher correlation ($r = 0.63$) for an L2 corpus, while Dascalu et al. (2013) got good discriminating features using both LSA and LDA (Latent Dirichlet Allocation), when classifying TASA (Touchstone Applied Science Associates) texts.

An alternative approach to LSA, Lexical Tightness (LT), was suggested by Flor et al. (2013). They define the LT of a text as the mean value of the Positive Normalized Pointwise Mutual Information for all pairs of content-word tokens in a text. It represents "the degree to which a text tends to use words that are highly inter-associated in the language". They obtained a good correlation between this new cohesive metric and the grade levels on two corpora (respectively $r = -546$ and $r = -0,441$). Interestingly, they also show that LT works better to discriminate between literary texts than informative ones.

Another approach is to detect co-reference chains and compute some of their characteristics. Barzilay and Lapata (2008) considered a text as a matrix of discourse entities present in each sentence. The cohesive level of a text is then computed based on the transitions between those entities. Pitler and Nenkova (2008) implemented this model through 17 readability variables, but none was significantly correlated with difficulty. Feng et al. (2009) also replicated this technique, without getting more efficient features. Dascalu et al. (2013) computed other characteristics of lexical chains and co-reference pairs (such as the number of chains, the distance between entities, the average word length of entities, etc.). However, with these features, they only reached a precision of respectively 0.367 and 0.384 for a six-class classification problem.

Todirascu et al. (2013) argued that these mixed results might be due to approximations of the NLP systems, since automatically annotating co-reference chains remains a challenge. They manually annotated co-reference chains in 20 texts and correlated various characteristics of lexical chains with the difficulty of these texts. They showed that considering the type of entities, and not only their syntactic transitions, could be valuable. However, only four features appeared to be significantly correlated with difficulty, possibly due to the limited size of their corpus.

3 Methodology

Faced with this mixed findings in the literature regarding the efficiency of cohesive features for the assessment of text readability, our goal is to further investigate this issue. In particular, we present experiments focusing on cohesive features : anaphora chains, reference chains and lexical chains (evaluating sentence similarity).

For this purpose, we followed three steps: (1) we manually annotated a corpus of 83 French texts with co-reference chains and anaphoric chains; (2) we applied RefGen (Longo and Todirascu, 2010; Longo, 2013), a tool that automatically identifies co-reference and anaphoric chains in French, on the same corpus ; and (3) we evaluated the discriminating power of 65 coherence and cohesion-based features to assess text readability, comparing the results obtained on the manual and automatic annotation.

3.1 Corpus Description and Annotation

The corpus used in this study is a subset of the corpus of FFL (French as a Foreign Language) texts gathered by François (2009), which includes 2,160 texts extracted from 28 FFL textbooks. All the textbooks comply with the Common European Framework of Reference for Languages (CEFR), a standard scale for foreign language education in Europe that uses 6 levels (A1 to C2). Therefore, each text was assigned the level of the textbook it came from. In this study, we use a stratified sampling to select informative texts and narrative texts from the levels A2 to C1 (about 11 texts for each combination of level and genre).

In a second step, the corpus was annotated for co-reference chains (containing at least three mentions) and anaphoric chains (two mentions) by six human annotators, following an annotation guide. The annotation process was as follows: first, all mentions were detected, then we assigned an identification number to the chain containing the mention, finally the syntactic role as well as the type of the mention were annotated (see Figure 2 for an example of the annotation format). We used 16 different mention categories (e.g. proper names, indefinite NP, definite NP, personal pronouns, etc.) and 6 syntactic functions: S-subject, OD - direct object, OI - indirect object, CN - genitive, Mod - modifier, and X - other functions. Additionally, we annotated adverbs (*ici, là-bas*), resumptive anaphora or groups (the pronoun *ils* in Fig. 2 refers to the group composed of Antoine and Catherine).

Based on these guidelines, a common batch, composed of 10 randomly selected files, was annotated by all the annotators. It was used to identify annotation divergences between annotators[1] and to correct the annotation guide. We computed the overall inter-annotator agreement on this common batch using the mean Krippendorff's alpha on each text and we obtained 0.47, which corresponds to a *moderate* agreement between annotators. Such value is however not unusual in co-reference annotation (Muzerelle et al., 2014). Then, following the annotation guide, each expert annotated a batch of 12 texts from the corpus. At the end of the process, the principal annotator checked all batches against the guidelines, thus creating the reference for our experimentation.

[Antoine]_1/S/NPr/partie(3) fait la connaissance de [Catherine]_2/CN/NPr/partie(3). [Antoine]_1/S/NPr est [un beau parleur]_1/X/GNI et [la jeune fille]_2/S/GND [s']_2/X/Pronref intéresse à [lui]_1/OI/Pron. [Ils]_3/S/Pron vont au cinéma ensemble.

Figure 2: Example of annotated data : the number of the entity, the syntactic function and the category, eventually the relation with other referents : []_nb/syn/category/relation.

3.2 Automatic Annotation

For the automatic annotation of co-reference chains, we used a rule-based tool which identifies co-reference chains for French written texts, RefGen (Longo and Todirascu, 2010), (Longo, 2013). RefGen is one of the few systems available for French[2]. This tool integrates a POS-tagger adapted for French,

[1]Common problems that arose are: incorrect delimitation of mentions, wrong labelling of mention type or of the syntactic functions, wrong chain delimitation and relation categories (anaphoric vs co-reference).

[2]Other systems for French were proposed by Lassalle and Denis (2011) - but it detects only bridging anaphora - and by Desoyer et al. (2014), whose system detects coreference in oral data.

TTL[3](Ion, 2007), which provides the lexical category, the lemmas and simple chunk annotations (noun phrases, verb phrases). RefGen applies a set of preprocessing tools to identify complex noun phrases, named entities and impersonal pronouns.

Using information from the preprocessing step, RefGen identifies candidates for low accessibility mentions (proper nouns or named entities, definite noun phrases, indefinite noun phrases) (Ariel, 2001). These candidates open new co-reference chains. Anaphoric candidates with a high accessibility (personal pronouns, reflexive pronouns, demonstrative determiners or possessive determiners, demonstrative pronouns) are compared with possible antecedents. If the pair of candidates satisfies a complex set of syntactic, morpho-syntactic and semantic constraints, then the pair is included in a co-reference chain.

RefGen identifies almost all of the manually annotated categories, with the exception of resumptive anaphora. Concerning demonstrative NPs, the tool identifies only simple cases of antecedence (those with the same lexical head *le chien - ce chien*). Another significant drawback of this tool is that it is not able to handle complex referents such as groups or collections of objects. Adverbs are not considered as potential mentions by the tool.

3.3 Features

We replicated most features introduced in the literature described in section 2 and added new variables: the proportion of deictic pronouns, of resomptive anaphora and of adverbs, as well as the probability that a specific type of mention might open a co-reference chain in a given text. We ended up with 67 variables, divided in six classes :

1. **POS tag-based variables**: Pronouns and articles are crucial elements of cohesion. We computed 10 variables based on these parts-of-speech, namely the ratio of pronouns and nouns (1); the average proportion of pronouns per sentence (2) and per word (3); the average proportion of personal pronouns per sentence (4) and per word (5); the average proportion of possessive pronouns per sentence (6) and per word (7); the average proportion of definite articles per sentence (8), per word (9), and the ratio of definite articles with respect to the total number of articles (10). We also computed the ratio of proper names per word (11).

2. **Lexical cohesion measures**: We replicated several methods aimed at measuring lexical cohesion in a text as the average cosine similarity between adjacent sentences. These sentences were projected either in a word space, transformed with tf-idf (term frequency-inverse document frequency) only, or in a concept space, which was obtained with LSA. We defined 6 features, taking into account various linguistic entities: the inflected forms in the texts (word overlap) (12); the lemmas (13); only the nouns, proper names, and pronouns, either through their lemmas (14), or their inflected forms (15); a token-based LSA (16) and a lemma-based LSA (17).

3. **Entity cohesion**: Mentions of co-reference chains are often found in adjacent sentences and they often have the same syntactic function as the antecedent found in the previous sentence. For example, a proper noun is the subject of sentence *n* and the anaphoric pronoun referring to it is often the subject of sentence *n+1* (" Subject to Subject" transition). However, the syntactic functions of mentions might change across sentences : the object of the sentence *n* becomes the subject of the next sentence. Drawing from Pitler and Nenkova (2008)'s work, we replicated several variables evaluating the relative frequency of the possible transitions between the four syntactic functions played by the entity in sentences *n* and *n+1* : subject (S), object (O), other complements (X), and (N) when the entity is absent in the next sentence (variables 18 to 29), but also the number of transitions (30).

4. **Entity density**: We computed the average proportion of referring entities included in co-reference chains (simple and complex noun phrases, pronouns, etc.) per document normalized by the number of words (31), the proportion of the number of entities per document normalized by the number of words (32), the proportion of unique entities per document normalized by the number of words (33), and the average number of words per entity normalized by the number of words (34).

[3]Tokenizing, Tagging and Lemmatizing free running texts

5. **Co-reference chain properties**. We included several properties of co-reference chains: the proportion of various types of mentions (variables 35–46): indefinite NP, definite NP, proper names, personal pronouns, possessive determiners, demonstrative determiners, reflexive pronouns, relative pronouns, NPs without a determiner, indefinite pronouns, demonstrative pronouns, the average length of reference chains. The proportion of the opening mentions of the co-reference chains are also computed (variables 47–57): indefinite NPs, definite NPs, proper names, NPs without a determiner, demonstrative NPs but also pronouns (personal, demonstrative, indefinite, relative), possessives. As we mentioned in section 2.2., the composition and the structure of the co-reference chains are influenced by the genres or the type of the texts. These variables are used to evaluate the correlation between text types and the various types of mentions. Additionally, for the manually annotated corpus, we count additional features such as the proportion of specific deictic pronouns (such as *en,y*) (58), the proportion of adverbs as mentions (59), the resumptive pronouns (60), complex mentions (including groups or collections) (61). We compute also the proportion of these categories being used to open a new chain (variables 62–65).

6. **Classic features** : Finally, we replicated two efficient features from the readability literature as a baseline: the mean number of word per sentence or NMP (66), which provides an indication of the syntactic complexity, and a unigram model (67), estimating the vocabulary difficulty.

4 Results

We assessed the efficiency of our cohesive features through three devices. First, we computed their Spearman correlation with the CEFR levels of the texts in our corpus (see Table 1) in order to evaluate their informativeness when considered in isolation. Second, we computed a semi-partial correlation ($sr_{k(66,67)}$) (Kerlinger and Pedhazur, 1973, 92) between the target variable and the text CEFR levels, while controlling for the two classic variables (NMP and unigram). The reason for this analysis had been put forward by Boyer (1992) who said "it is conceivable that there are relations between the surface features of the text measured by [classic] readability formula and text characteristics of higher level". Therefore, semi-partial correlation will help determine whether our variables contribute to text readability prediction with additional information besides sentence length and word frequency. Third, all significant variables as regards the semi-partial correlation have been combined within a readability model and compared with a classic readability formula. In this section, we will first discuss the efficiency of the variables on the manually annotated corpus, then on the one automatically annotated with RefGen, then modelling experiments are discussed.

4.1 Results on the Manually-annotated Corpus

First, simple variables measuring the use of pronouns and articles based on POS-tagged information are correlated with text readability (e.g. nb. of pronouns per sentence: $\rho = 0.24$; nb. of definite articles per sentence: $\rho = 0.22$). This effect was also found by Todirascu et al. (2013), but it is likely to be due to sentence length because the semi-partial correlations – when controlling for sentence length – are not significant neither for the number of pronouns per sentence ($sr = 0.14$) nor for the number of definite articles per sentence ($sr = -0.11$). Besides, the correlations for the number of pronouns ($\rho = 0.04$) and of definite articles ($\rho = 0.01$) are nonsignificant when normalized at the word level. The situation is the same on narrative and informative texts.

Interestingly, semi-partial correlation are significant for the number of pronouns per word ($sr = 0.25$) and for the number of personal pronouns ($sr = 0.23$), on all texts. The more difficult a text is, the more pronouns are used. Pronoun resolution requires background knowledge and high reading proficiency, which explains their higher frequency in difficult texts, even when text length is controlled. For comparison, Pitler and Nenkova (2008) found no effect for both variables.

There is a very interesting pattern of results for lexical coherence measures. As regards the correlation, there is a clear distinction between the four features based on word overlap (and their variation) – none of which are significant –, and the two LSA-based features, which are significant. The LSA-based feature using lemma is the second best feature after NMP on the whole corpus, while the token variant is the

very best feature for the informative texts. Such efficiency is in line with previous results (François and Fairon, 2012; Dascalu et al., 2013), but the semi-partial correlation offers a more nuanced figure, since the features based on LSA are not efficient when word frequency and sentence length are controlled. On the other hand, a more naive approach such as word overlap appears to provide more specific information as shown by the semi-partial correlations computed on informative texts ($sr = -0.41$ for lemma overlap and $sr = -0.4$ for NP word overlap).

Another interesting feature is the number of chains, which is negatively correlated with text complexity for all texts ($\rho = -0.22$) and narrative texts ($\rho = -0.35$): the lower the number of chains is (which means less referents but longer chains), the more difficult a text is. Besides, the ratio of unique entities is a valuable feature for all texts ($\rho = -0.26$) as well as for narrative texts ($\rho = -0.38$). More difficult narrative texts have a lower number of unique entities, probably because they include longer descriptions of the same elements, psychological introspection, or repetitions of the same mention. However, semi-partial correlations show that these variables are redundant with sentence length and word frequency, whereas the average word length of entity then becomes significant ($sr = -0.28$).

On the contrary, the proportion of the various syntactic transition types in a text hardly conveys information about text difficulty. Out of the 12 types of transitions, only "Object to None" is significant for all texts ($\rho = 0.24$) and for informative texts ($\rho = 0.42$). This feature means that the distance between two consecutive mentions of the same chain is larger than one sentence, a phenomenon that often occurs in informative texts where the same referent may be repeated across the text, even after several sentences. It should also be mentioned that the "Object to Object" transition was found significant ($\rho = 0.41$ and $sr = 0.40$) exclusively in narrative texts. On the whole, we are much in line with the negative results of Pitler and Nenkova (2008) as regards this category of variables.

Finally, Todirascu et al. (2013) suggested to consider the proportion of the different types of the entities and found both the proportion of pronouns and indefinite NP to be useful features. Globally, variables in this category show a poor correlation in our experiment. The type of entities that emerged as noticeable is the proportion of demonstrative NP ($\rho = 0.22$) in all texts, which nevertheless loses significance on the two sub-genre corpora as well as when sentence length and word frequency are controlled ($sr = -0.06$). It is also interesting to note that the proportion of the first mention of a chain being specific deictic pronouns is significant for all texts ($\rho = 0.22$), and even stronger when the two classic variables are controlled ($sr = 0.24$). A summary of the correlations for the most interesting features is available in Table 1.

4.2 Results on the Automatically-annotated Corpus

When comparing the manual and the automatic annotations, when relevant,[4] we find some features in which the two approaches converge such as the number of transitions, the proportion of mentions being a pronoun or a proper noun, etc. These are cases corresponding to easier phenomena to detect automatically. Conversely, some variables demonstrate large discrepancies in effectiveness between their manual and automatic versions, such as the average word length of entities, the proportion of "Object to Object" transitions, the proportion of definite mention, or the proportion of the first mention being a definite or a proper noun.

In such cases, especially in narrative texts, the automatic version appears to be more efficient, even when the semi-partial correlation is concerned. This is probably a side effect of annotation errors by RefGen, but as a result, more variables appear significant with the automatic annotation. Text complexity in narrative texts is thus correlated with the proportion of definite articles ($\rho = 0.37$) and proper nouns ($\rho = -0.39$), the proportion of chains starting with definite articles ($\rho = 0.52$) or proper noun ($\rho = -0.38$), the average word length of entities ($\rho = -0.48$) as well as with the proportion of syntactic transition "O to O" ($\rho = 0.41$). For informative texts, text difficulty is positively correlated with the proportion of transitions "O to N" ($\rho = 0.32$) and the proportion of first mention being a proper noun ($sr = 0.32$), but negatively correlated with average word length of entities ($\rho = -0.31$).

[4]Several features – those from the first, second, and sixth class in Section 3.3–, were only computed automatically. As a consequence, Table 1 provides only one value per subcorpus.

Variables	corpus (all)		corpus (narr.)		corpus (inf.)

4.3 Cohesion and Coherence Variables in Readability Models

In this section, the efficiency of our cohesive and coherence features for readability is tested in the context of actual readability models. On the corpus of 83 texts, we defined 4 sets of features to be used either for a classification task (with SVM classifier) or a regression task (with ϵ-SVR). The first set, that serves as a baseline, includes only sentence length (NMP) and a unigram model (ML1)[5] model have been trained. The second set includes NMP, ML1, and all variables that have been detected as significant by the correlation on the manual corpus (parsimonious_manu) and was trained on the manually annotated version of the data. The third set includes NMP, ML1 and all variables that have been detected significant by the correlation on the automatic corpus (parsimonious_auto) and was trained on the automatically annotated version of the data. The last set includes all variables (full model) and was trained on the manually annotated data, as we are interested to get the best performance possible. The optimal kernel and associated meta-parameters for all models (see Table 2) were selected via a grid-search conducted using a 10-fold cross-validation process. Once the best parameters were known, the performance of each model were then measured with two metrics – accuracy and mean average error (MAE).

Feature set	nb. variables	Model	kernel	C	Others param.	accuracy	MAE
baseline	2	SVM	RBF	5	$\gamma = 0.5$	43.6	0.89
baseline	2	SVR	polynomial	5	deg = 2; $\epsilon = 0.5$	/	1.03
parsimonious_manu	10	SVM	linear	0.1	/	43.4	0.81
parsimonious_manu	10	SVR	RBF	100	$\epsilon = 0.1$; $\gamma = 0.0001$		0.91
parsimonious_auto	8	SVM	RBF	500	$\gamma = 0.1$	41.5	0.85
parsimonious_auto	8	SVR	RBF	100	$\epsilon = 0.5$; $\gamma = 0.0001$	/	0.94
full model	67	SVM	polynomial	5	deg. = 2	40.6	0.89
full model	67	SVR	RBF	5	$\epsilon = 1$; $\gamma = 0.01$	/	0.93

Table 2: Accuracy and values of meta-parameters for the 4 models.

First, all classification models perform better than their regression counterparts. However, even for the former, no model using coherence or cohesive features is able to overcome a simple model based

[5] As those variables have been automatically computed, the results are the same for both versions of the corpus (manually and automatically annotated).

on sentence length and word frequency. The one that performs better is the SVM parsimonious model based on the manual annotation (MAE = 0.81), but compared to the SVM baseline (MAE = 0.89), the difference is not significant using a paired T-test ($t = -1.43; p = 0.19$). It is also interesting to note that using automatically detected features seems to slightly degrade performance compared to the manual annotation, although such difference is clearly not significant with a paired T-test ($t = -0.78; p = 0.45$). This is the case even though automatically-computed variables were characterized by slightly better correlations as found in Section 4.2.

5 Discussion and Conclusion

To conclude, we have performed a detailed analysis of 65 cohesive features commonly used in the readability literature. The parameterization of these variables requires heavy NLP processing and is prone to errors. We showed that nevertheless they do not seem to contribute much to the prediction of text readability when compared with simple predictors such as word frequency and sentence length. On the one hand, 6 features only were found to be significant by semi-partial correlation (when sentence length and word frequency were controlled for). On the other hand, integrating the best cohesive features in a readability model did not bring significant improvement over a simple baseline on our French data. The first lesson learned is that such kind of features, although quite popular in the literature, have an efficiency that is subject to caution, at least in the context of readability prediction, as it was already reported by some of the previous studies.

Another interesting insight of our analysis is the use of semi-partial correlation to analyze the efficiency of variables for readability. Previously, some authors (Pitler and Nenkova, 2008; François and Fairon, 2012; Todirascu et al., 2013) only used Pearson or Spearman correlations to identify and quantify the effect of a text characteristic on readability and we showed that, as was suggested by Boyer (1992), higher textual dimensions can be much correlated with lexical or syntactic features. A good example in this regard was the impact of LSA-based features. Similar to previous studies (François and Fairon, 2012; Dascalu et al., 2013), we found a large effect for this predictor, which completely vanished once word frequency and sentence length were controlled for. This allowed us to reconcile to some extent contradictory findings in this regard.

Our experiments also showed large differences between the manual and automatic annotation of lexical chain properties, which seems to lead to a loss of performance when such predictors are included into a full readability model. This should however be replicated using different co-reference extraction tools, as some of the errors are typical of the RefGen tool that we used.

Finally, the third question that we planned to investigate was whether the behavior of lexical and co-reference chains differs in narrative and informative texts, in relation to text difficulty. We noticed that the variables significantly correlated with difficulty vary depending on the genre of texts. On narrative texts, the number of chains, the number of unique entities or the ratio of first mention being a specific deictic pronoun were relevant, whereas the average word length of entities, the LSA-based features and the word overlap features were relevant for informative texts.

However, there are some limitations to our study and further investigation would be necessary before discarding co-reference chain-based features for readability. First, we have experimented on an L2 corpus, while the cohesive aspects might be more relevant for L1 texts. Moreover, the study was performed on French and the results might vary from one language to another (although our findings are mostly in line with results on English). Finally, it is not excluded that some properties of the lexical and co-reference chains that we did not consider (e.g. mean distance in words between the various entities of a chain) could demonstrate a stronger discriminative power.

Abstract

This paper describes our construction of named-entity recognition (NER) systems in two Western Iranian languages, Sorani Kurdish and Tajik, as a part of a pilot study of *Linguistic Rapid Response* to potential emergency humanitarian relief situations. In the absence of large annotated corpora, parallel corpora, treebanks, bilingual lexica, etc., we found the following to be effective: exploiting distributional regularities in monolingual data, projecting information across closely related languages, and utilizing human linguist judgments. We show promising results on both a four-month exercise in Sorani and a two-day exercise in Tajik, achieved with minimal annotation costs.

1 Introduction

This paper describes our rapid construction of NER systems, as a part of a pilot study of *Linguistic Rapid Response* to potential emergency humanitarian relief situations. When a disaster strikes a community that speaks a low-resource language without an existing NLP infrastructure, how long would it take to put such an infrastructure, however imperfect, in place? What kinds of systems can be in place within 24 or 48 hours, and what levels of performance can we expect? What resources – besides existing gazetteers, parallel corpora, etc. – can be assembled in this timeframe and brought to bear on NER?

Contemporary techniques for creating natural language processing (NLP) tools are dominated by supervised learning approaches, in which large quantities of high quality data are annotated in a task-specific fashion and utilized along with manually-built collaborate resources like WordNet, Ontonotes, etc. These techniques have provided very good performance, but with 7,000 languages in the world these resources cannot feasibly be compiled in advance, and could not be assembled within an emergency timeframe.

Following many examples of "surprise language exercises" (Oard, 2003), the work described in this paper tackles the problem of rapid development of important NLP tools and resources, with a focus on NER, for low resource languages. We assume that for a "low resource" language, there is some monolingual corpus data and little to no annotated data for supervised training. A major theme underlying this work is a focus on building "omnivorous" models and pipelines that, instead of relying on elaborate and robust linguistic resources compiled ahead of time, try to opportunistically incorporate linguistic theory, informal and non-expert intuitions about the language and task at hand, and resources adapted from closely related languages, all while avoiding extensive manual annotation.

An important feature of our work is the use of human linguists who do not speak the language but are familiar with the structure of human languages in general, have some knowledge about the language family in question, and can absorb facts about the language quickly by reading reference grammars and looking at data. Specifically, in this project, linguists worked interactively with unsupervised morphology induction, annotated named entities, and identified thresholds for automatic tagging of multi-word named entities.

We illustrate this approach for two low resource languages, Sorani Kurdish and Tajik, provided during two surprise language evaluations. Software development and Sorani NER processing took place over

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 998–1006, Osaka, Japan, December 11-17 2016.

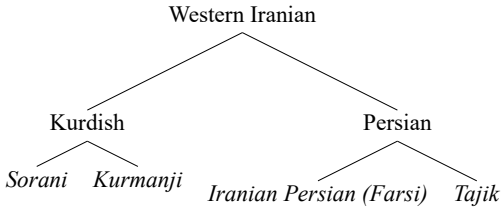

Figure 1: Sorani, Tajik, and selected relatives

a four-month period, while the Tajik surprise-language event took place in only 36 hours. Hence, all techniques described in this paper, whether performed by machines or humans or both, have runtimes in minutes or hours rather than days.

2 Data sources

2.1 Sorani Kurdish

Sorani (or "Central") Kurdish is a Western Iranian language in the Kurdish family, spoken by about 6.7 million people in Iraqi Kurdistan and the Kurdistan Province of Iran. Unlike other Kurdish languages, but like the more distantly related Persian (or "Farsi"), it is written in a Perso-Arabic script, albeit with modifications (like additional vowel glyphs) that make it more suitable for writing Sorani. We obtained Sorani monolingual data from the LCTL language pack (Simpson et al., 2008).

2.2 Kurmanji Kurdish

Some of the challenge of Sorani NER is orthographic in nature, since its Perso-Arabic script, while closer to the phonemic form of words than most other Perso-Arabic scripts, still has some significant ambiguities in vowel representation, and lacks an uppercase-lowercase distinction, which is an important feature for NER. In order to partially mitigate these ambiguities, we also made use of Kurmanji (or "Northern") Kurdish data from the Pewan news corpus (Esmaili et al., 2013). Kurmanji is spoken primarily in eastern Turkey by about 20 million speakers, and unlike Sorani is written in a Roman script. Sorani and Kurmanji are sometimes described as dialects of the same languages, but sometimes described as different languages due to their significant morphological differences.

2.3 Tajik Persian

Tajik is a variety of Persian spoken primarily in Tajikistan by about 8 million speakers, and is written primarily in Cyrillic script. We obtained Tajik monolingual data from the Leipzig corpus of news crawls (Biemann et al., 2007).

2.4 IPA representations

So that resources in different languages and scripts could be more directly compared, and so that judgments about the data could be made rapidly by linguists without native proficiency in the Perso-Arabic and Cyrillic writing systems, we produced representations of the Sorani, Kurmanji, and Tajik data in the International Phonetic Alphabet (IPA). To disambiguate ambiguous Sorani forms, we used a conditional random field (CRF) (Lafferty et al., 2001) that utilized a combination of human judgments, universal phonetic features, and language models of related languages; we describe this "IPAization" process in more detail in Mortensen et al. (2016) and Littell et al. (2016).

3 Named Entity Recognition

For the NER task, we focused on identifying mentions of persons (PER), locations (LOC), and organizations (ORG) in the textual data. Our core system is a CRF based system with L1-regularization, where x is the input sequence and output y is the appropriate tag sequence, and no features look beyond a history of length 1.

$$f(\mathbf{y} \mid \mathbf{x}) = \sum_{i=1}^{|\mathbf{x}|} f(\mathbf{x}, \mathbf{y}_i, \mathbf{y}_{i-1}). \quad (1)$$

Based on previous work in the area (Tjong Kim Sang and De Meulder, 2003; McCallum and Li, 2003; Sha and Pereira, 2003), we begin with a standard set of features commonly used for training NER systems:

- Current token and Current tag
- Previous token and Current tag
- Next token and Current tag
- Current+previous token and current tag
- Current+next token and current tag
- First five features but with previous tag
- First five features conjoined with both current and previous tags
- Contains foreign script characters
- Indicator features for tokens containing digits
- Features about capitalization information
- Prefix features

However, given the paucity of training data, these features are numerous and sparse, we do not expect the CRF model to perform well with standard features alone, even with L1 regularization.

Hence, keeping up with the general theme of this work, we aim to induce features in an unsupervised manner by exploiting the distributional regularities in the monolingual data, guiding the unsupervised sub-components to encode our intuitions and knowledge about the task and the target language, and utilize features from closely-related languages.

3.1 Gazetteers

For Sorani, the absence of a capitalization feature in its Perso-Arabic script posed a difficulty, as capitalization serves as a valuable feature for NER. However, as noted in §2, the closely related Kurmanji Kurdish is written in a Roman script that does distinguish capitalization.

Using the IPA representations of the Sorani and Kurmanji texts and a frequency-weighted edit distance algorithm, we inferred for each Sorani token a corresponding Kurmanji token (e.g., ⟨ɛvɣanistan,ɛfganistan⟩), and assigned to each Sorani token the capitalization frequency of the Kurmanji word (in this case, *Efganistan*, which had a capitalization frequency of 1.0). These features were used a "probabilistic gazetteer" in lieu of a real Sorani gazetteer, where the capitalization frequency is treated as if it represented the probability that a word occurred in a gazetteer. We describe this gazetteer inference strategy in greater detail in Littell et al. (2016).

For Tajik, we constructed a more traditional gazetteer using Tajik's relatively extensive Wikipedia. Since Wikipedia titles are linked between Wikipedias in different languages, we had parallel English and Tajik titles; we filtered the English titles by heuristics including capitalization, and used the corresponding Tajik titles as the gazetteer entries.

3.2 Unsupervised morphology induction

The Western Iranian languages are morphologically rich, with Sorani in particular having a high degree of morphological complexity (Walther, 2011; Esmaili and Salavati, 2013). In such languages, the presence of certain morphemes is strongly correlated with certain grammatical functions being present, which could be informative for the problem of identifying and discriminating named entities.[1]

While unsupervised induction of morphological grammars is a long-standing problem, the inferred morphological analyses typically diverge from conventional linguistic analyses rather substantially. We addressed this shortcoming by using feedback from human linguists using a modification of the interactive learning paradigm proposed by Hu et al. (2011). While superficially related to active learning (Settles,

[1] While Western Iranian languages also utilize prefixes and root modification, we concentrated here on suffixes alone; this simplifies the model and concentrates on those morphological alternations we believe more likely to be relevant to NER.

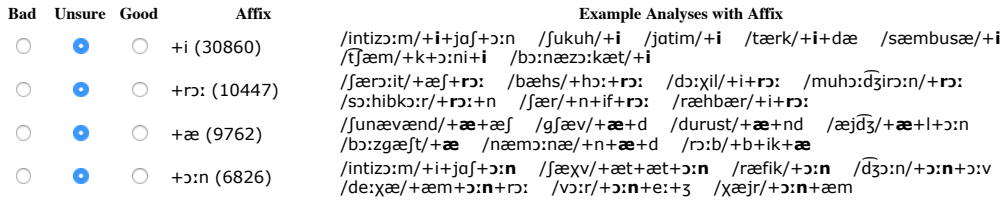

Figure 2: Screenshot of the feedback interface containing analyses for Tajik.

2012), the interactive paradigm charges the annotator with the task of identifying subjective systematic errors, instead of picking new instances to be annotated. In case of morphology learning, we let linguists give their judgment on the quality of affixes, which is used to constrain the hypothesis space and tune the parameters of the unsupervised learner. The feedback interface is shown in Fig. 2.

We used a hierarchical Bayesian model of morphological segmentation. Our prior expectations are (1) that stems should be more diverse than suffixes, but both should be reused when possible, (2) that individual suffixes are likely to be very short, and (3) that suffixes are likely to proceed in a characteristic order (e.g., *-ion* and *-al* are both English suffixes, but *-ion-al* is valid and occurs in many words, for example in *inspirational*, while *-al-ion* is not valid).

To encode the first two assumptions, we assumed that the distributions over stems and suffixes are governed by a Dirichlet processes with parameters set to encourage lower entropy samples for suffixes and higher entropy samples for stems. The base distribution $\mathsf{Word}(\lambda)$ is a process that generates a word by sampling a length from a Poisson distribution with mean λ and then choosing characters randomly for each position. To capture the fact that affixes proceed in a characteristic order, we in turn assumed these were generated by a bigram Markov process governed by a hierarchical Dirichlet process (Teh et al., 2006). The generative process is stated in Algorithm 1.

Algorithm 1 Morphological induction

$\boldsymbol{\theta} \sim \mathsf{DP}(\alpha_1, \mathsf{Word}(\lambda = 6))$
$\boldsymbol{\varphi} \sim \mathsf{DP}(\alpha_2, \mathsf{Word}(\lambda = 1))$
$\boldsymbol{\varphi}_{\cdot|x} \sim \mathsf{DP}(\alpha_3, \boldsymbol{\varphi})\ \forall x \in \Sigma^*$
for `each word` w `in surface vocabulary` V **do**
  `Draw # of suffixes` $\ell \sim \mathsf{Geom}(\rho = 0.9)$
  `Draw stem` $b \sim \mathsf{Cat}(\boldsymbol{\theta})$
  $s_{-1} = \langle \mathsf{b} \rangle$
  for `each suffix index` i `from 1 to` ℓ **do**
    `Draw affix` $s_i \sim \mathsf{Cat}(\boldsymbol{\varphi}_{\cdot|s_{-1}})$
    $w = w + s_i$
    $s_{-1} = s_i$
  end for
end for

Since our model does not depend on anything but word types, the observed data is just the vocabulary (in IPA form) of the target language, and the goal of inference is to find the distribution over segmentations given our model and the vocabulary. To do so, we use block Gibbs sampling (marginalizing the draws from the Dirichlet processes). Since we are considering all analyses of a word at once, constraints against certain morphemes are trivial to incorporate. For the experiments reported below, we ran 1000 iterations of Gibbs sampling, then obtained feedback followed by a further 1000 iterations twice.

3.3 Unsupervised class induction: Hard clustering

One way of reducing sparseness due to the lexicalization of the features is to map the types or tokens of the monolingual corpus to a smaller number of classes. We try to obtain mappings such that the tokens/types sharing similar characteristics are mapped to one class. For example, if "Lord" and "Lady" are mapped to the same class, then two different sequences "Lord Palmerston" and "Lady Grey" will share the class information and will, if "Palmerston" is annotated as a name in the training data, be more likely to predict "Grey" as a name as well. We focus on context-aware class induction, particularly modeling the classes

with a first-order Markovian assumption.

Brown et al. (1992) introduced a bottom-up agglomerative word clustering algorithm which generates a hard clustering (i.e., a word belongs to only one cluster). With this hard clustering assumption, we aim to achieve a clustering C that maximizes the log-likelihood of the data, $\log P(w_1, ...w_n, \mathbf{C}(w_1), ..\mathbf{C}(w_n))$, i.e.

$$\arg\max_{\mathbf{C}} \log \prod_{i=1}^{n} p(\mathbf{C}(w_i) \mid \mathbf{C}(w_{i-1})) \times p(w_i \mid \mathbf{C}(w_i))$$

We experimented with 500 and 1000 clusters. Manual qualitative analysis of these clusters revealed that they created several meaningful groups: foreign words, numbers, names, etc.

3.4 Unsupervised class induction: Soft clustering with the influence of collocations

In addition to the traditional "hard" Brown clusterings, we also experimented with soft clusterings where the parameters can be influenced by external knowledge, using Expectation Maximization (Dempster et al., 1977). We focused on influencing our NER system using information about collocations – bigrams that co-occur with frequency greater than chance – in the monolingual text. The intuition behind collocations is that many names of people ("barak obama"), places ("arabistani saudi"), and organizations ("bomdodi telefonhoi") are expected to be identified as collocations.

We warm-started with the distributions obtained by the Brown cluster algorithms, smoothed via additive (dirichlet) smoothing. Our pilot experiments showed that this resulted in better performance when compared to the performance with random initializations. The runtime (O($token * iterations * C^2$)) is higher than that of Brown algorithm (O($types * C^2 + tokens$)) because we estimate all the distributions of the probabilistic HMM using dynamic programming (Rabiner and Juang, 1986). Hence, subsequent models used interpolated stochastic batch updates (Liang and Klein, 2009) instead of batch updates so that the convergence is faster.

We used a likelihood ratio test (Dunning, 1993), which is a form of hypothesis testing that decides whether the second word in the bigram is unusually associated with the first word of the bigram or not, to determine an initial list of possible NE collocations. For both Sorani and Tajik, this measure results in desirable LR score graphs for bigrams with a distinct "elbow" for both the languages. However, determining the threshold, below which a collocation should not be considered genuine for the purposes of further steps, was done manually by a human linguist looking at IPA representations of the collocations. This is a judgment that need not be made by a native speaker, or even an expert in the language in question, but just someone with some familiarity with the language or language group, the ability to read IPA, and enough real-world knowledge to recognize when a list of two-word phrases in IPA switches from mostly referring to names and places, to referring to names and places only occasionally.

We use these collocations, as generated by the likelihood ratio test and thresholded by human judgment, to bias unsupervised class induction over words in the target language, so that collocations are encouraged to fall into the same clusters. To our knowledge, this work is the first to bias unsupervised class induction using collocation knowledge.[2]

EM based optimization allows us to bias the parameters of the HMM, to encourage collocations to fall into same clusters. Hence, whenever we observe collocations in the monolingual data during the E step, we use an Identity matrix as the transition matrix, i.e. $P(C(w_i) \mid C(w_{i-1})) = 1$. The M step is performed as usual, resulting in learning of parameters affected by the biased expectation counts.

As discussed above, constraining the collocation members to belong to the same clusters is attractive, but the collocations that we estimated automatically are certainly not pure. Hence, we introduce posterior regularization (PR) (Ganchev et al., 2010) into our HMM inference algorithm. We want the posterior of the HMM distribution to reflect the fact that adjacent tokens in identified collocations in the monolingual data tended to belong to same clusters.

[2]It should be noted that this is different from work in Liang (2005), which used the mutual information between adjacent types directly as features in the learning model. We avoid this method to keep our feature space small, in light of the paucity of training data.

For this technique, if we denote the original HMM distribution by $p(\mathbf{C} \mid \mathbf{W})$ with parameters θ, and a variational approximation $q(\mathbf{C})$ to the original distribution which respects our collocation based constraints i.e. $E_q(\phi(\mathbf{W}, \mathbf{C})) = -1$ where, $\phi(w_i, C(w_i), C(w_{i-1})) = -1$ if $C(w_i) = C(w_{i-1})$ and 0 otherwise, for $w_i s$ that are members of collocations; then the objective that we optimize becomes:

$$\arg\min_{\theta} \text{KL}(q \mid\mid p) \text{subject to } E_q(\phi(\mathbf{W}, \mathbf{C})) = -1 + \epsilon$$

When this objective is solved using its dual, the variational approximation q (after optimization for the dual variable λ) looks like:

$$q^*(\mathbf{C}) = \frac{p_\theta(\mathbf{C}|\mathbf{W}) exp(-\lambda^*.\phi(\mathbf{W}, \mathbf{C}))}{Z(\lambda^*)}$$

Since the constraints ϕ are local at the level of transition probabilities, the PR solution can be easily incorporated into the dynamic program of HMM.

3.5 Experiments

We present our results on the task of named entity recognition for Sorani and Tajik. For Sorani, the training (2175 instances) and test (212 instances) data was obtained from the annotated NER data in the LCTL language pack. For Tajik, we had access to a native speaker who, in about four hours, annotated 600 examples, which we split into 250 training instances, 250 test instances, and 100 development instances.

Table 2: Results on Tajik NER

In Tables 1 and 2, 'Std' refers to the standard features used in supervised NER systems (§3), 'Br' to the class features obtained from the Brown algorithm (§3.3), 'PR' to the class features from the EM and posterior regularization algorithm (§3.4), 'Gaz' to Gazetteer based features (§3.1), and 'Mph' to features from morphology induction (§3.2).

As we can observe, systems based only on standard features (§3) perform comparatively poorly, while adding Brown clusters lead to a large gain in recall especially in the Tajik condition. In both languages, the Brown and PR conditions perform similarly on F1, with the Brown condition having higher precision and the PR condition having higher recall. The reduction of precision in the PR condition is most likely a result of expanding the feature space with both Brown clusters and EM-based clusters.

The "gazetteer" for Sorani, which attempts to fabricate capitalization values for Sorani by comparison with Kurmanji words (§3.1), led to improvements in both recall and precision, while the Tajik gazetteer, collected from Tajik Wikipedia titles, did not lead to significant gains. Manual inspection of the resulting

Table 4: Results on Tajik NER, using 1350 linguist annotations in lieu of native-speaker annotations

gazetteer revealed it to be fairly noisy with respect to the forms of the names; while the entries appeared to be, for the most part, genuinely named entities, many of them appear to have been converted directly from the Persian Wikipedia. Since Persian script does not completely represent vowels, the Tajik authors in many cases were likely guessing at the vowels when they were unfamiliar with the named entity.

Morphological features (§3.2) provided small improvements for both languages. Interestingly, the morphological features affected both the languages differently; while the Sorani system relied more on the induced stems, the Tajik system relied more on the suffixes. This may reflect the complexity of Sorani morphology (Walther, 2011; Esmaili and Salavati, 2013), in which many apparent affixes are actually enclitic, and therefore might not provide category information about their hosts as reliably as true suffixes do.

In Table 3, we observe that our NER systems are best at identifying LOC and are slightly worse at identifying PER. However, they perform substantially worse on identifying ORG because their proper noun parts can be confused with both locations and persons, and they often involve common words (e.g. "association", "for", etc.) that in other contexts are not part of NEs. Note that unlike in English, capitalization is not as helpful in distinguishing multiword NEs in Sorani and Tajik. Sorani "capitalization" here is only a feature inferred on a word-by-word basis from Kurmanji text, as detailed in §3.1, and Tajik generally uses Russian-style capitalization conventions in which only the first word in a multiword NE needs to be capitalized, making ORG identification much more difficult than in languages that capitalize all or most words in an ORG.

For the Tajik condition, we also had linguists – without prior experience in Tajik but generally familiar with Western Iranian languages – annotate another 1350 instances in sixteen person-hours. This was made possible by the IPA conversion step mentioned in §2.4, since the linguists did not have native proficiency in reading Cyrillic text.

Using this larger set instead of the smaller native-speaker-annotated set, we achieved similar results, with lower recall but higher precision (Table 4). This is a promising result, as it suggests that a team of linguists, even those without prior familiarity with the language, can create useful training data in a short time even when native informants are unavailable.

4 Conclusion

Our work demonstrates that, by using tools, data resources, and human resources (like linguists and language consultants) in innovative ways, it is possible to overcome some of the obstacles to developing standard NLP tools like NER systems for low-resource languages.

We built Named Entity Recognizers for Sorani Kurdish and Tajik in a manner which, while requiring minimal human annotator effort, managed to successfully incorporate informal intuitions and linguistic knowledge about the task and the languages into the system and seeks to identify and exploit latent patterns in the monolingual data.

To this end, we developed unsupervised class induction systems that were influenced by noisy collocation lists, and morphology induction systems that could be biased by subjective human feedback.

Moreover, we also showed that mapping the orthographic representation of a language to a general phonological representation not only enables efficient human analysis and annotation, but also opens avenues for transferring linguistic information from related languages.

Abstract

In this paper, we investigate the annotation projection of semantic units in a practical setting. Previous approaches have focused on using parallel corpora for semantic transfer. We evaluate an alternative approach using loosely parallel corpora that does not require the corpora to be exact translations of each other. We developed a method that transfers semantic annotations from one language to another using sentences aligned by entities, and we extended it to include alignments by entity-like linguistic units. We conducted our experiments on a large scale using the English, Swedish, and French language editions of Wikipedia. Our results show that the annotation projection using entities in combination with loosely parallel corpora provides a viable approach to extending previous attempts. In addition, it allows the generation of proposition banks upon which semantic parsers can be trained.

1 Introduction

Data-driven approaches using natural language processing tackle increasingly complex tasks with ever growing scales and in more varied domains. Semantic role labeling is a type of shallow semantic parsing that is becoming an increasingly important component in information extraction (Christensen et al., 2010), question answering (Shen and Lapata, 2007), and text summarization (Khan et al., 2015).

The development of semantic resources such as FrameNet (Baker et al., 1998) and PropBank (Palmer et al., 2005) made the training of models for semantic role labelers using supervised techniques possible. However, as a consequence of the considerable manual efforts needed to build proposition banks, they exist only for a few languages. An alternative approach to using supervision is to transfer knowledge between resources, a form of distant or related supervision. Methods for directly projecting semantic labels from a resource-rich language to a resource-scarce one were introduced in Padó (2007).

In this paper, we describe a method for aligning and projecting semantic annotation in loosely parallel corpora by using entities and entity-like linguistic units. Our goal is to generate multilingual PropBanks for resource-scarce languages. We used multiple language editions of Wikipedia: An English edition annotated up to a semantic level using the PropBank semantic roles, and syntactically annotated editions of Swedish and French Wikipedias. By aligning Wikipedias by entities, we constructed loosely parallel corpora and we used them to generate PropBanks in Swedish and French. We provide an evaluation of the quality of the generated PropBanks, together with an evaluation on two external FrameNets.

2 Previous Work

As an alternative to using supervised efforts for relation extraction, distant supervision can be employed to transfer relational knowledge representations from one resource to another. Distant supervision for relation extraction was introduced by Craven and Kumlien (1999) in the context of biomedical information extraction. Mintz et al. (2009) describe a method of using an external knowledge base as an indirect way of annotating text. Hoffmann et al. (2010) introduced the usage of Wikipedia infoboxes in distantly supervised relation extraction.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1007–1017, Osaka, Japan, December 11-17 2016.

The concept of transferring linguistic annotation, in the context of part-of-speech tags, across parallel corpora was introduced in Yarowsky et al. (2001). Cross-lingual annotation projection of FrameNet semantics has been described by Padó and Lapata (2009) and Basili et al. (2009). In Van der Plas et al. (2011), the authors describe an automatic method of direct transfer of PropBank semantics requiring no manual effort. Akbik et al. (2015) describe an approach to generate multilingual PropBanks using filtered annotation projection and bootstrap learning in order to handle errors stemming from translation shifts in corpora.

Most previous approaches have used professionally translated parallel corpora, mainly EuroParl (Koehn, 2005) and United Nations Corpora (Rafalovitch and Dale, 2009), to transfer semantic annotation. However, creating these resources requires manual efforts; they are thus limited in size and in the number of languages they cover. In contrast to parallel corpora, loosely parallel corpora describe similar concepts and events, but are not necessarily the result of a focused effort to translate a large corpus.

In Exner et al. (2015), we introduced the concept of using entities as a method for aligning sentences and transferring semantic content in loosely parallel corpora. However, the presented approach has the following limitations: (1) it was evaluated on one language only and (2) the evaluation was performed on the generated PropBank itself.

The contributions of this paper are the following: (1) We extend Exner et al. (2015) by including pronouns and other linguistic units that in a local context exhibit the characteristics of entities. (2) We present and evaluate two methods for aligning sentences by using entities. (3) We demonstrate the effectiveness and generalizability of our approach by projecting semantic annotations to two languages, Swedish and French, and we evaluate it using two external proposition databases, the Swedish SweFN++ (Borin et al., 2010) and French ASFALDA (Candito et al., 2014; Djemaa et al., 2016) that are both semantically-annotated corpora using adaptations of FrameNet frames. (4) We release the source code used in the annotation projection and we provide the generated PropBanks in Swedish and French[1].

3 Method

The aim of the method is to generate PropBank-like resources by fully annotating sentences in target languages using semantic content, in whole or partially, from a source language. We start with loosely parallel corpora in two languages: a **source language** (SL) expressing the semantic content that we want to transfer to a **target language** (TL). We then disambiguate and uniquely identify the entities in all the sentences. By using the unique identifier of each entity, we gain the ability to align sentences from two different languages forming sentence pairs (s_{SL}, s_{TL}). We annotate the (s_{SL}, s_{TL}) pairs, s_{SL} to semantic and syntactic levels and s_{TL} to a syntactic level. From each (s_{SL}, s_{TL}) pair, we learn the alignments between predicates (p_{SL}) in s_{SL} and verbs (v_{TL}) in s_{TL}. Finally, using the aligned entities and the predicate-verb alignments in each (s_{SL}, s_{TL}) pair, we transfer the semantic annotation in the form of predicate-argument structures. Figure 1 shows an overview of this approach.

3.1 Using Loosely Parallel Corpora

A prerequisite to projecting semantic annotation between two sentences is that they share the same semantic structure. To this end, we assumed that entities have a constraining property on the sets of predicate-argument structures they can instantiate. By aligning loosely parallel corpora through entities, pairs of sentences in two different languages that we will extract, although they are not translations of each other, should overall express the same semantic content. Furthermore, we believe that by applying our method on a large scale, the most frequent alignments of entities will elicit valid alignments.

In this context, even partial semantic content from a source sentence, s_{SL}, may be useful for annotating a target sentence, s_{TL}. As an example, consider the following sentence pair:

s_{SL} It$_{\text{A0}}$ features$_{01}$ Kelsey Grammer$_{\text{A1}}$ in his ninth ...
and is the first time$_{\text{AM-TMP}}$ the Simpsons$_{\text{A0}}$ visit$_{01}$ Italy$_{\text{A1}}$
s_{TL} I avsnittet besöker familjen Simpsons Italien
In the episode visit the family Simpsons Italy

[1] http://semantica.cs.lth.se

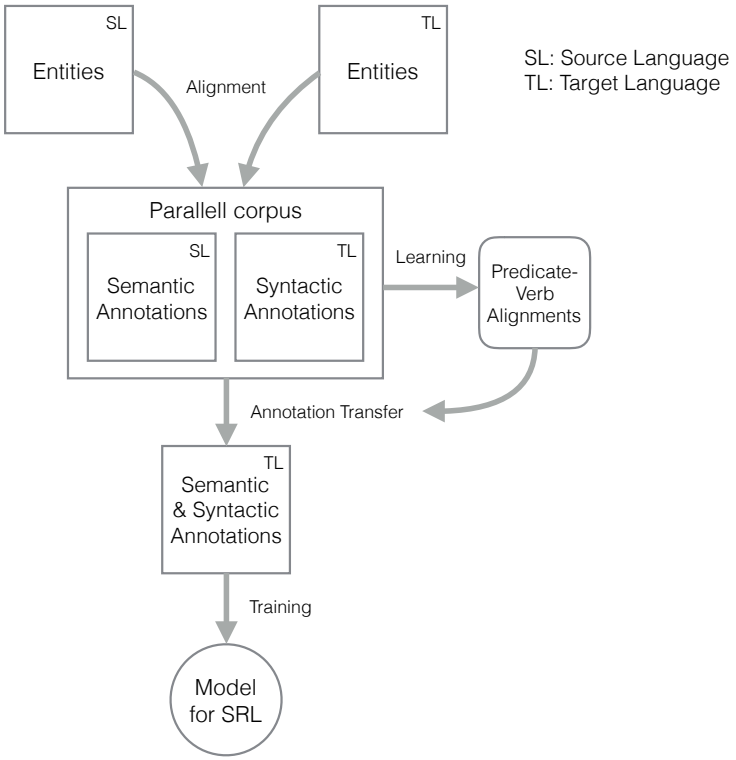

Figure 1: An overview of the approach for transferring semantic annotation from a **source language** (SL) to a **target language** (TL)

in which s_{SL} has been aligned with s_{TL} through the entities $(the\ Simpsons,\ Italy)$. s_{SL} expresses the two predicates $feature.01(it_{A0},\ Kelsey\ Grammer_{A1})$ and $visit.01(the\ first\ time_{AM-TMP},\ the\ Simpsons_{A0},\ Italy_{A1})$. Although s_{TL} is not an exact translation of s_{SL}, as it lacks the predicate $features.01$ and the temporal argument ($AM\text{-}TMP$) of $visit.01$, the partial transfer of the semantic content enables us to annotate s_{TL} with the predicate $besöka.01(familjen\ Simpsons_{A0},\ Italien_{A1})$.

3.2 Entity Disambiguation

Entity linking is the process of finding mentions, e.g. persons, cities, organizations, events, concepts, in text, and if available, assign them with a unique identifier provided by a knowledge base. We used Wikidata Q-numbers as identifiers as they provide globally unique identifiers between the different language editions of Wikipedia. As an example, consider the following entities:

Beijing, *Pékin*, and *Pequim*

as expressed in English, French, and Portuguese respectively. Although they have differing surface forms, they are all linked to the Q956 Wikidata number, as well as in 190 other languages. In total, Wikidata covers a set of more than 13 million items that defines the entity search space.

To carry out entity linking, we reimplemented a variant of TagME (Ferragina and Scaiella, 2010). The motivating factors behind our reimplementation were:

1. It enabled us to resolve mentions to identifiers in Wikidata, providing us with multilingual and coherent entity identifiers.

2. By using the same entity linker for multiple languages, we obtained a more consistent mention resolution across all the languages.

3. It eased the adaptation to new execution environments, in our case a cluster of computing nodes.

Our implementation of TagME requires minimal grammatical information as it only needs mention statistics derived from anchors and a dictionary of mention-entity pairs and of incoming links.

The entity linking algorithm consists of four steps: detection, candidate voting, selection, and resolution of overlapping mentions.

1. We find all the possible mentions consisting of tokens in sequences up to a maximum length of 6. The mentions found at this stage might be overlapping. We treat overlapped mentions independently and they contribute votes to all the other mentions. As an example, consider the following sentence:

   Prime Minister of Japan

   containing the two mentions: *Japan* and *Prime Minister of Japan*. In this case, the overlapped mention *Japan* will contribute a vote to the overlapping mention *Prime Minister of Japan*.

2. We compute the votes for each candidate belonging to a mention. To bound the computation time, we use voting groups consisting of a collection of mentions using a sliding window approach. The vote weight per candidate is the sum of all the inlink relatedness between all the candidates (Ferragina and Scaiella, 2010). In our case, we use all the candidates in a voting group.

3. We rank all the candidates per mention using the computed votes. We then prune the mention list using a coherence criterion and a threshold that we set empirically.

4. In the final step, we resolve the mention overlap using a greedy algorithm. The algorithm selects the overlapping mention, where the entity candidate has the largest global vote, removing all the locally overlapping mentions, until there is no overlap globally.

3.3 Syntactic and Semantic Annotation

In our experimental setup, we used the English edition of Wikipedia as our SL, and we annotated it with syntactic and semantic dependencies. For the syntactic-semantic parsing, we used an open-source semantic role labeler (Choi, 2012) trained on OntoNotes 5.0 (Weischedel et al., 2013).

We transferred the semantic annotation to two TLs, the Swedish and French editions of Wikipedia, both annotated with syntactic dependencies. For French syntactic parsing, we applied a transition-based dependency parser (Bohnet and Nivre, 2012; Bohnet and Kuhn, 2012) trained on a French Treebank described in Candito et al. (2010). Correspondingly, to preprocess the Swedish edition of Wikipedia, we applied a pipeline consisting of a POS tagger (Östling, 2013) and a syntactic dependency parser (Nivre et al., 2006).

3.4 Extension to Entity-like Tokens

Entities have the property of being uniquely identifiable across languages on a global scope. However, an obvious drawback to using entities as a means of aligning sentences and transferring roles, is that roles are not always instantiated by entities. To reclaim these instances, we extended the entity alignment to include entity-like **linguistic units** (LU). We focused on units that have the property of being uniquely identifiable and limited to the scope of a sentence pair. Units correspond to sequences of tokens the entity disambiguator has either failed to classify as an entity or otherwise lack the ability to be uniquely identified in a global context.

Our algorithm detects entity-like LUs as spans of tokens sharing the same surface form in both s_{SL} and s_{TL}. In addition, we set the constraint that they occur at most once in each sentence. As a consequence, this removes any misalignment issue since a LU in s_{SL} can be matched to only one LU in s_{TL}. This method enables us to include amounts, dates, and noun phrases that the entity disambiguator fails to detect.

Using similar constraints, we also include pronouns in the detection of entity-like LUs. However, rather than using the surface form of pronouns, which would unlikely match across languages, we instead categorize them by case, gender, and number. For English, Swedish, and French, third person singular pronouns have different surface forms based on gender. Therefore, in order to increase precision, we

limit the detection to only include third person pronouns. Although this constraint certainly limits the recall, this should not significantly impact the training procedure as the pronouns in the first and second persons are in very limited numbers in Wikipedia.

3.5 Aligning Sentences

The first challenge in transferring semantic annotation between loosely parallel corpora is to align sentences expressing the same semantic content. Our baseline method for aligning sentences extracts all the entities from a sentence and forms entity-sentence pairs, $(e_1...e_n, s)$. By aligning entities in different entity-sentence pairs, we form new triples containing a source sentence, a target sentence, and the subset of entities by which they are aligned $(s_{SL}, s_{TL}, e_1...e_s)$, where $k_{min} \leq s \leq k_{max}$ and k_{min}, k_{max} are prior parameters of our choice.

The baseline method is, in its simplicity, independent of any syntactic or lexical markup. It only requires the annotations from an entity disambiguator. However, one drawback lies in the inclusion of entities ungoverned by any predicate. As a consequence, the alignment of partial semantic content, as described in Sect. 3.1, becomes problematic. We therefore extended this baseline algorithm by using sets of entities projected by either arguments in s_{SL} or a verb in s_{TL}. Using this projection method, we then form entity-sentence pairs:

> $(e_1...e_p, s)$, where each entity in $(e_1...e_p)$ is governed by an argument belonging to a predicate in s_{SL}

and

> $(e_1...e_v, s)$, where each entity in $(e_1...e_v)$ is governed by a verb in s_{TL}.

The method for aligning entities in different entity-sentence pairs remains the same as for the baseline method. In Sect. 4.1, we investigate the effectiveness of the two methods under different settings.

3.6 Forming Predicate-Verb Alignments

Although we use entities as a mechanism to align sentences and transfer predicate-argument roles, predicates in s_{SL} and verbs in s_{TL} cannot be aligned by entities alone. In addition, some sentence pairs contain more than one predicate or verb, sharing the same subset of entities. This creates a combinatorial problem, where one predicate in s_{SL} could possibly be aligned to two or more verbs in s_{TL}, or vice versa. Furthermore, the application of a semantic parser to each s_{SL} annotates each predicate with a sense. This requires a method to induce new predicates and senses for the verbs in s_{TL}.

Most previous work relies on word alignments or uses bilingual dictionaries to transfer the predicate annotation between languages. However, when applied to new languages and domains, these approaches face a scaling problem requiring either training on parallel corpora or otherwise dictionaries which may not be available for every language.

Our approach builds on Exner et al. (2015) and automatically infers new predicate labels while scaling with the size of corpora and domains. A formal description of our alignment is:

1. We determine all the combinations of predicate-verb pairs, (p_i, v_k), extracted from all (s_{SL}, s_{TL}) pairs, where $p_i \in s_{SL}$ and $v_k \in s_{TL}$.

2. We assign $count(p_i, v_k)$ as the number of (p_i, v_k) in all (s_{SL}, s_{TL}), where $s_{SL} \in SL$ and $s_{TL} \in TL$.

3. For each $p_i \in SL$, we form alignments as $(p_i \rightarrow v_k) = max(count(p_i, v_1), ..., count(p_i, v_n))$.

4. For each $v_k \in (p_i \rightarrow v_k)$, we form a new TL predicate by using the lemma of v_k and an incremental counter based on the number of times v_k has appeared in an alignment.

We select the verb candidates for the alignment using lexical and syntactical rules to filter auxiliary verbs and other non-predicates.

3.7 Transferring Propositions

Given a pair of aligned sentences, (s_{SL}, s_{TL}), we transfer the semantic annotation from a predicate, $p_{SL} \in s_{SL}$, to a verb, $v_{TL} \in s_{TL}$, if $(p_{SL} \rightarrow v_{TL}) = max(count(p_i \rightarrow v_{TL})), \quad (p_i \rightarrow v_{TL}) \in (s_{SL}, s_{TL}), \quad \forall p_i \in s_{SL}$. If a s_{TL} is supervised by more than one s_{SL}, we select the s_{SL} having the larger subset of aligned entities with s_{TL}. We restrict the semantic transfer to predicate-argument structures containing at least one numbered argument and a temporal or location modifying argument, or at least two numbered arguments.

We transfer the argument roles by using the aligned entities between s_{SL} and s_{TL}. We assign the argument role to the governing token in the token span covered by each entity. However, if the argument token in s_{SL} is dominated by a preposition, we search for a preposition in s_{TL} governing the entity and assign it the argument role. We obtain the complete argument spans by taking the yield from the argument token.

4 Evaluation

In this section, we evaluate the approach described in Sect. 3 and we apply it to three language editions of Wikipedia in order to generate PropBanks for two languages: Swedish and French. The evaluation tries to answer the following questions:

1. How do different parameters and methods affect our approach?

2. What is the quality of the generated PropBanks and what level of performance can we expect in a practical setting?

3. Are there any differences between the languages, and if so what causes them?

4.1 Experimental Setup

For our experimentations, we chose the English, Swedish, and French editions of Wikipedia. These three Wikipedias are all among the top 6 in terms of article counts. As SL, we selected the English edition, and as TLs we select Swedish and French editions. We preprocessed all the articles to filter infoboxes, lists, diagrams, and to keep only text without any markup. Table 1 summarizes the statistics of the linguistic units in our chosen Wikipedias.

LANGUAGE	TOKENS	SENTENCES	ENTITIES	PREDICATES	ARGUMENTS
English	3825M	279M	439M	186M	450M
Swedish	481M	71M	58M	-	-
French	1269M	74M	181M	-	-

Table 1: Characteristics of Wikipedias used in the experimental setup

4.2 Predicate-Verb Alignment

We first evaluated how the predicate→verb alignment method described in Sect. 3.6 performs under different conditions and we examined how the number of entities, the method used, and the frequency affect the quality of the alignments. We grouped the English→Swedish alignments by their frequency into three bands: High, medium, and low. We then randomly sampled alignments from each band, in total 100 alignments and we used them to evaluate their precision. We defined precision as the number of English→Swedish alignments that we evaluate as correct divided by the total number of alignments in a sample. Figure 2 shows the precision and number of alignments using different number of entities and methods.

We observe that the precision increases with the number of entities used in the alignments. However, this increase is followed by a decrease in the number of alignments created. We also note that in all the

alignments, our projection method outperforms our baseline method for aligning sentences in terms of precision. Using three projected entities, we reach a precision of roughly 80% and 1,000 alignments.

We also investigated if the higher frequency of an alignment improved precision. Figure 3 shows the breakdown of precision curves into three frequency bands, formed using projected alignments. We observe that using three projected entities, alignments with high-medium frequencies show little to no error. This provides empirical evidence to our hypothesis in Sect. 3.1, that the most frequent alignments of entities will elicit valid alignments and that precision will scale with the amount of data used by the method.

The combination of aligning sentences with three projected entities gave us the optimal trade off between precision and number of alignments created. Therefore, in the rest of the evaluation, we use these settings.

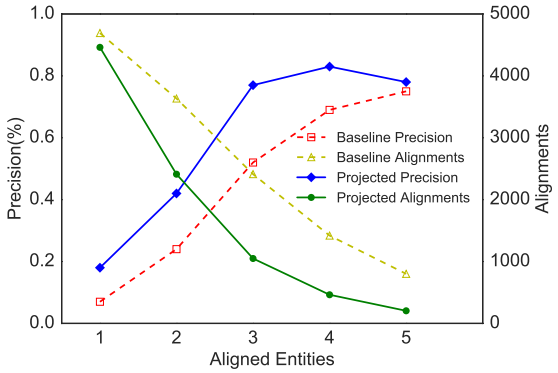

Figure 2: Graph of predicate→verb alignment precision and count under different parameter settings.

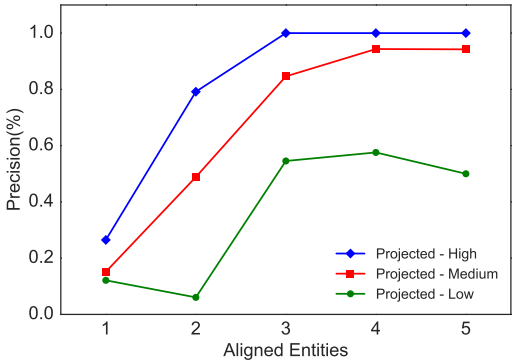

Figure 3: Graph of projected predicate→verb alignment precision, broken down by frequency band: high, medium, and low

4.3 Generated PropBanks

Using the annotation projection methods described in Sect. 3, we generated PropBanks in Swedish and French. We limited the PropBanks to only include fully annotated sentences and we removed the sentences exhibiting parsing errors, such as sentences having more than one syntactic root. We used these generated corpora to perform the error analysis in Sect. 4.5.

To evaluate our approach in a practical and automatic setting, we used samples of two linguistic resources: the Swedish FrameNet project (Borin et al., 2010) and the French FrameNet (Candito et al., 2014; Djemaa et al., 2016). We evaluated the generated Swedish and French corpora on a random sample of 100 sentences, from the Swedish FrameNet and the French FrameNet respectively. As PropBank and FrameNet have different annotation styles, we converted the sampled sentences from frame semantics to the semantics used in PropBank.

Table 2 shows the characteristics of the generated PropBanks and the FrameNets used in the evaluations.

DATASET	TOKENS	SENTENCES	PREDICATES	ARGUMENTS
Generated-Swedish	198,008	13,767	14,552	32,659
Generated-French	968,417	47,795	50,091	121,641
SweFN++ (TEST)	1,258	101	101	265
French FrameNet (TEST)	3,606	100	107	227

Table 2: Characteristics of the generated PropBanks used for training the SRL models and the FrameNets used for evaluating the trained models

4.4 Experimental Results

We evaluated the quality of the generated PropBanks in a practical setting as well as the effectiveness of using entity-like LUs in addition to entities. To assess the usefulness of the generated corpora, we first trained a semantic role labeler (Björkelund et al., 2010) on them. We split the generated corpora into 60:20:20 training, development, and testing sets, and we ran a selection process using a greedy forward selection and greedy backward elimination procedure to find the optimal set of features (Johansson and Nugues, 2008; Björkelund et al., 2009). We then used the trained models to automatically parse the test sets described in Sect. 4.3. Table 3 shows the evaluation of the semantic role labeler trained on the generated corpora.

The performance of the semantic role labeler, trained on the generated PropBanks, compares favorably with the automatic evaluations on parallel corpora described in Padó and Lapata (2009). For Swedish, using entity-like LUs, we observe an improvement of the labeled F1-measure by 10%. For French, we do not see the same dramatic increase, which we believe is caused by the large differences in pronoun classification and surface forms between English and French. We believe this discrepancy in improvement stems from projecting entity-like LUs across language groups: while English and Swedish belong to the Germanic branch, French belongs to the Romance group. Although more investigation is needed, these early results suggest that the annotation projection using entity-like LUs is most efficient when applied within a language group.

		LABELED			UNLABELED		
LANGUAGE	LINGUISTIC UNITS	P	R	F1	P	R	F1
Swedish	Entities (Baseline)	79.88	36.89	50.47	93.49	43.17	59.07
	Entities + Unique Tokens	84.82	44.26	58.17	92.67	48.36	63.55
	Entities + Unique Tokens + Pronouns	72.18	52.46	**60.76**	81.58	59.29	**68.67**
French	Entities (Baseline)	68.64	45.21	54.51	75.45	49.70	59.93

4.5 Error Analysis

To understand the quality of the generated PropBanks, we conducted an analysis of the predicate and argument errors. We randomly sampled 200 errors, of which 100 errors stemmed from the incorrect projection of argument labels and 100 were incorrect projections of predicates. Tables 4 and 5 show the type of errors for predicates and arguments respectively.

Using loosely parallel corpora, it is no surprise that the largest group of errors in predicate projection stems from sentences expressing differing semantic content. This error comes from sentence pairs, that although they contain the same subset of entities, express differing semantic content. However, as shown in Sect. 4.2, the precision of alignments increases with the number of alignments, leading us to believe that this category of error can be corrected using more data. The second largest error group is formed by different types of parsing errors occurring during the preprocessing stage. Encouragingly, only 6% of predicate projection errors stem from translation shifts, which is a further indication that entities exhibit a constraining property on the types of predicates that can instantiate them, even across languages.

Looking at argument projection errors, we again notice a group of errors stemming from misaligned sentences in loosely parallel corpora, *Differing Semantic Content* and *No Source Equivalent*. Looking beyond, alignment errors due to argument labels being assigned to the wrong token is the single most frequent error. The second largest category of errors is composed of expressions that can not be considered as entities, e.g. *In other words* and *During this time*. Finally, we observed a class of error stemming from entities undergoing a shift in specificity across sentences in two languages. These translation shifts included entities being referred to by their name in one language and by their entity type in the other

language, e.g. *London→the city*.

ERROR CLASS	NUMBER

5 Conclusion

In this paper, we have described the construction of multilingual PropBanks by aligning loosely parallel corpora using entities. We have trained a semantic role labeler on the generated PropBanks and that we evaluated in a practical setting on frame-annotated corpora. Our results compares favorably to annotation transfer using parallel corpora. In addition, we have extended the entity alignment to include alignment by entity-like linguistic units such as pronouns and dates.

We believe the growing source of loosely parallel corpora and their alignment using entities offers an alternative way to creating multilingual hand-annotated corpora. By performing a semantic projection on loosely parallel corpora, in our case multiple language editions of Wikipedia, we have presented an alternative approach to using parallel corpora. We believe our approach can be extended beyond encyclopedias to similar resources, such as news articles in multiple languages describing the same events.

One future improvement could be to leverage ontologies that categorize entities into types. We believe that such ontologies would prove useful in adjusting the specificity of entities in order to handle some translation shifts across languages. In addition, our current method of forming predicate→verb alignments could be extended by including information about the entity type.

While projecting pronouns from English to Swedish showed an improvement, we did not observe the same improvement when projecting from English to French. Therefore, an additional avenue of investigation could compare the performance of annotation projection within versus across language groups. In addition, a coreference solver could provide an alternative means of resolving pronominal mentions to entities.

Siamese Convolutional Networks for Cognate Identification

Taraka Rama
Department of Linguistics
University of Tübingen, Germany
taraka-rama.kasicheyanula@uni-tuebingen.de

Abstract

In this paper, we present phoneme level Siamese convolutional networks for the task of pair-wise cognate identification. We represent a word as a two-dimensional matrix and employ a siamese convolutional network for learning deep representations. We present siamese architectures that jointly learn phoneme level feature representations and language relatedness from raw words for cognate identification. Compared to previous works, we train and test on larger and realistic datasets; and, show that siamese architectures consistently perform better than traditional linear classifier approach.

1 Introduction

Cognates are words that are known to have descended from a common ancestral language. In historical linguistics, identification of cognates is an important step for positing relationships between languages. An example of cognates are German *Fuß* and English *foot* whereas, Hindi *chakra* and English *wheel* are cognates that can be traced back to the Proto-Indo-European $*k^wek^wlo-$ and do not exhibit similarity on surface.

In NLP, automatic identification of cognates is associated with the task of determining if two words are descended from a common ancestor or not. In NLP, word similarity measures based on number of shared bi-grams, minimum-edit-distance, and length of longest common subsequence are supplied as features for a linear classifier or a sequence labeler on a set of labeled positive and negative examples; and then employ the trained classifier to classify new word pairs. The features for a classifier consist of string similarity scores (Hauer and Kondrak, 2011; Inkpen et al., 2005).

It has to be noted that the Indo-European dating studies (Bouckaert et al., 2012; Chang et al., 2015; Rama, 2016) employ human expert cognacy judgments for inferring phylogeny and internal dates of a well-studied language family. Therefore, there is a need for developing automated cognate identification methods that can be applied to those families of the world that are not as well-studied as Indo-European language family.

The supervised approaches (Kondrak, 2009; Bergsma and Kondrak, 2007) employ orthographic similarities and character alignments as features for training classifiers. In this work, we show how convolutional networks can be employed to extract phonetic features for the purpose of cognate identification. We also include a neural network approach to integrate language features for jointly training the neural networks. To the best of our knowledge, this work is the first to apply convolutional networks (CNN) for the purpose of cognate identification.

The work is organized as follows. In section 2, we define the task of cognate identification. In section 3, we motivate and describe convolutional network architectures for cognate identification. In section 4, we describe the related work for cognate identification. We present the experimental setup in section 5 and results in section 6. Finally, we present our conclusions in section 7.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1018–1027, Osaka, Japan, December 11-17 2016.

2 Cognate detection

In this paper, we work with Swadesh lists (Swadesh, 1952) that are composed of meanings which are supposed to be resistant to lexical replacement and borrowing.

Meaning	Swedish	English	German
foot	fut (B)	fut (B)	fus (B)
belly	mag3 (N)	bEli (B)	baux (B)
to sew	si (F)	s3u (F)	nE3n (B)

Table 1: A excerpt of Swadesh list from Indo-European Lexical database for Swedish, German, and English for three meanings "foot", "bell", and "to sew". The lexical items are transcribed in ASJP alphabet which is given in table 2. The cognate class labels, indicated in parentheses, do not carry additional information across meanings.

Table 1 shows the cognate class of each lexical item. Within a meaning, if two lexical items belong to a same cognate class, then they are cognates otherwise, they are treated as non-cognates. For example, all word pairs in meaning "foot" belong to the same cognate class "B" and are cognates whereas, the word pairs for English and German are cognate in meaning class "belly" and are not cognate in the meaning class "to sew". The task at hand is to correctly identify if two words from different languages belonging to a meaning class is cognate or not.

3 Convolutional Networks

In this section, we briefly describe some past work that uses CNNs for NLP tasks such as text classification and part-of-speech tagging. Then, we motivate the use of CNNs for cognate identification task.

The supervised approaches to cognate identification supply string similarity or phonetic similarity scores as features which might not capture all the information in two words. Character alignments extracted from minimum-edit-distance are used to train a linear classifier; and, the alignment features are further augmented by the context to capture processes of sound correspondences between two words (Bergsma and Kondrak, 2007; Ciobanu and Dinu, 2014). In a recent paper, Ciobanu and Dinu (2014) use character alignments from word pairs (extracted from a etymological dictionary) as features to train and test SVM classifiers. This method seems to require thousands of word pairs; and, might not be practically feasible in a low-data scenario. The approach of Bergsma and Kondrak (2007) which learns the alignment weights of characters requires monolingual corpora for source and target languages which is not available for many of the world's languages.

In this context, CNNs can be an alternative way to avoid explicit feature engineering through similarity computation and can extract relevant features from a raw word pair. Also, CNNs do not require explicit character alignment since the weights for non-monotonic shared features between two words can be learned through back-propagation.

3.1 CNNs in NLP

Collobert et al. (2011) proposed ConvNets for NLP tasks in 2011 and have been applied for sentence classification (Kim, 2014; Johnson and Zhang, 2015; Kalchbrenner et al., 2014; Zhang et al., 2015), part-of-speech tagging (dos Santos and Gatti, 2014), and information retrieval (Shen et al., 2014).

Santos and Zadrozny (2014) use character embeddings in conjunction with word embeddings to train a convolutional architecture for the classification of short texts. The authors find that their architecture performs better than the systems reported in Socher et al. (2013). In a recent work, Zhang et al. (2015) treat documents as a sequence of characters and transform each document into a sequence of one-hot character vectors. The authors designed and trained two nine layer convolutional networks for the purpose of text classification. The authors report competitive or state-of-the art performance on a wide range of text classification datasets.

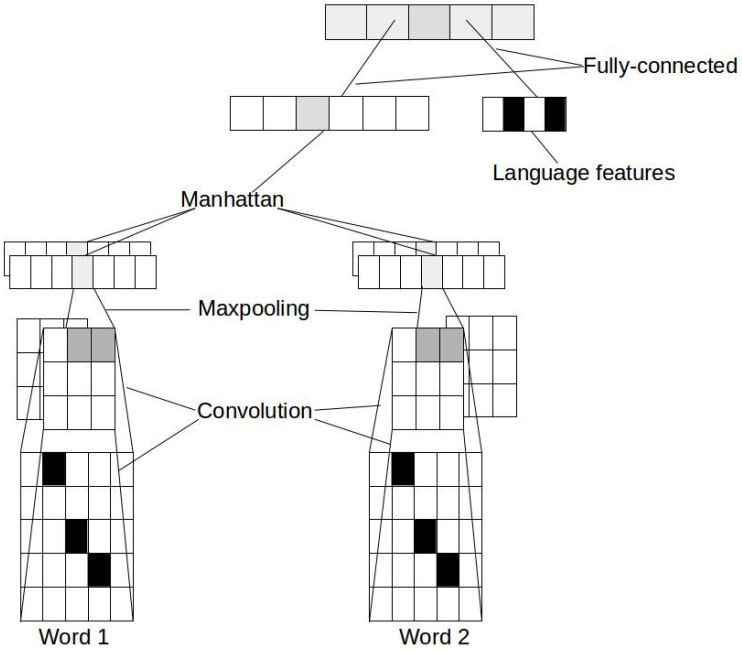

Figure 1: Illustration of Manhattan Siamese Convolutional network. We show the language features as a separate vector. Hot cells are shown in black whereas, real-valued cells are shown in grayscale.

3.2 Siamese Manhattan CNNs

Formally, we define the supervised problem setting where each training example x_i consists of two words x_{ia}, x_{ib} and a label $y_i \in \{0, 1\}$. Each phoneme $x_{iap} \in \mathbb{R}^k$ is a k-dimensional vector. A word is zero-padded or clipped at a pre-determined length n when necessary. A word x_{ia} of length n is represented as:

$$x_{ia} = x_{ia1} \oplus x_{ia2} \oplus \ldots \oplus x_{ian} \tag{1}$$

where, $\oplus$ is a concatenation operator. A convolution operation has a filter $W \in \mathbb{R}^{hm}$ where $h \leq k$ and $m < n$. The window size m defines the size of the filter. The feature map $C \in \mathbb{R}^{pq}$ where, $p = k - h + 1, q = n - m + 1$ is formed by convoluting the filter W with word x_{ia}. A max-pooling operation takes as input $C \in \mathbb{R}^{pq}$ feature map and applies the $max(C_{s \times t})$ to generate a feature $\hat{C} \in \mathbb{R}^{\lfloor p/s \rfloor \lfloor q/t \rfloor}$. The features generated by multiple filters are passed to a sigmoid function $\frac{1}{(1+exp(-x))}$ that computes the probabilities for y_i.

In the original siamese architecture proposed by Chopra et al. (2005), the weights are tied for each input x_{ia}, x_{ib}. The ℓ_2-norm (D) between the representations R_{ia}, R_{ib} computed using the shared convolutional networks of x_{ia}, x_{ib} and the label y_i is used to train a contrastive loss function $y_i \cdot D + (1 - y_i) \cdot max\{0, m - D\}$ where, m is a constant that can be tuned during training.

In this paper, we extend the siamese architecture to include an element-wise absolute difference layer which can then be stacked with multiple fully-connected layers. The final layer would be a sigmoid layer for binary classes. The idea behind this step is to push the CNNs to learn the phonological differences during training. The absolute difference ($-$) operation resembles ℓ_1 norm and is defined as

$$M_{iab} = |R_{ia} - R_{ib}| \tag{2}$$

where, $M_{iab} \in \mathbb{R}^r$ and r is the length of the representation vector at the end of convolutional layer. Hence, we call this architecture as Manhattan CNN. Parts of this architecture is shown in figure 1.

3.3 Phoneme encodings

Santos and Zadrozny (2014) train character embeddings for boosting their short text classification system based on CNNs. However, the cognate identification task typically deals with short word lists ($\sim$ 200) and short words ($\sim$ 5). However, many of the languages such as those studied in this paper do not have enough corpora to train character embeddings. Due to these reasons, we use 1-hot and hand-crafted phoneme encodings to train our convolutional networks.

1-hot phoneme CNN In this representation, each phoneme p is represented as 1-hot vector $\in \mathbb{R}^{|P|}$ where, P is the set of phonemes in a language family. Each word is either zero-padded to attain a length of n or clipped if the length exceeds a fixed length. We use the phonetic alphabet developed by Brown et al. (2008)[1] – for computerized historical linguistics – in our experiments. The ASJP alphabet and its phonetic properties are given in table 2. Word delimiters are represented by $\mathbf{0}$ vectors. We refer this architecture as CharCNN.

Phonetic features CNN In this representation, we encode each phoneme p as a $1/0$ vector of phonetic features. The description of phonetic properties of each phoneme is given in table 2. The features are ordered as they appear in the description of the alphabet in Brown et al. (2008). The first motivation behind this approach is to test if we can use the phonetic information (that is available with the word lists) for cognate identification. The second motivation is to test if CNNs can directly learn the patterns of sound change from underlying phonetic representations for the purpose of cognate identification. We refer this architecture as PhoneticCNN.

Table 2: The ASJP alphabet is given in columns $2-35$ and the phonetic value of each symbol in the ASJP alphabet. Each phoneme is a multi-hot vector of fixed dimension 16.

3.4 Language features

One major limitation of previous work in cognate identification is that the weight training of word similarity features is not performed jointly with language relatedness information. We present an architecture to learn the phonological similarity jointly with weighted language relatedness. We extend the Manhattan architecture to include language relatedness information during training.

Some languages share more cognate pairs than other language pairs due to genetic relatedness. We can train the model to learn language relatedness jointly with phonological relatedness by representing the languages as 2-hot vector. Formally, two words x_{ia}, x_{ib} belong to different languages $l_a, l_b \in$ language set L is represented as 2-hot vector $\in \mathbb{R}^{|L|}$ which is concatenated with the learned representation M_{iab}. The concatenated vector is then passed to a fully-connected layer whose output is then passed to a sigmoid layer. All our models are trained with binary cross-entropy loss function defined as $-(y_i \cdot log(s_i) + (1-y_i) \cdot log(s_i))$ where s_i is the score for an instance i at the final sigmoid layer. The architecture with language features and the fully connected layer is shown in figure 1.

[1]Known as Automated Similarity Judgment Program; `asjp.clld.org`. The website provides 40 length word lists for more than 4000 of the world's languages and lists of length 100 for some languages. Very few word lists have cognate judgments such as Mayan language family which we include in this work.

We observe that including language relatedness (phylogeny) information seems to be quite challenging. For instance, the work of Bouchard-Côté et al. (2013) uses the inferred phylogeny of Austronesian languages (Greenhill and Gray, 2009) and do not infer the phylogeny themselves. In the case of Indo-European, Bouckaert et al. (2012) infer a Indo-European phylogeny from the cognacy information encoded for 200-word Swadesh lists and do not infer the cognacy judgments jointly with phylogeny.[2]

Using the Indo-European phylogeny information given in Glottolog (Nordhoff and Hammarström, 2011) can be circular since the cognacy judgments used by Bouckaert et al. (2012) are also used by human experts to derive the phylogeny information given in Glottolog. Therefore, we include the language information that is available with the word lists and hypothesize that a fully connected neural network layer can learn the weights of the language features jointly with the phonological representations generated by siamese CNNs through back-propagation.

4 Related work

The past work on cognate identification is mostly based on supervised approaches such as (Hauer and Kondrak, 2011; Bergsma and Kondrak, 2007; Inkpen et al., 2005) and graphical model approaches (Bouchard-Côté et al., 2013). In a different line of work, Kondrak (2000) and List (2012) employ linguistically motivated phoneme correspondence weights for computing the similarity between word pairs.

Inkpen et al. (2005) test the efficacy of different machine learning algorithms to determine if a pair of words are cognates or not. They use various orthographic similarity measures as features for the machine learning algorithms. They train and test their models on word pairs extracted from parallel texts and English-French cognate list; and find that there is no single machine learning algorithm that is good at both the datasets.

Hauer and Kondrak (2011) motivate a SVM classifier for the purpose of clustering word pairs within a meaning. They supply string similarity measures as features for their SVM classifier and then use the trained model to score the extracted word pairs from the testing part of their data. In this paper, we compare our neural network models against their classifier.

Ciobanu and Dinu (2014) test if character alignments extracted from Longest Common Subsequence alignments can be employed for the purpose of pair-wise cognate detection. They train a binary SVM classifier using the multi-gram character alignments as features for four pairs of Romance languages: Romanian-French, Romanian-Italian, Romanian-Spanish, and Romanian-Portuguese. They find that the SVM classifier trained on character alignments performs better than the orthographic similarity measures such as Edit distance, Longest Common Subsequence Ratio, and number of common bigrams.

Bouchard-Côté et al. (2013) employ a graphical model to reconstruct the word forms in Proto-Austronesian using Swadesh lists. They find that the inferred proto-forms largely agree with the reconstructed proto-forms. However, their method requires cognate information and the phylogeny of the language family to be known beforehand. In this article, we also experiment with a subset of Austronesian language family.

5 Experiments

5.1 Hyperparameters and training

The number of feature maps in a convolutional layer is fixed at 10. The architecture features a max-pooling layer that halves the output of the previous convolutional layer. We used the dropout technique with 0.5 probability (Srivastava et al., 2014) to prevent a fully-connected layer from over-fitting. A fully connected layer is trained with ReLU non-linearity ($max(0, x)$). The filter width m is fixed at 2 for 1-hot phoneme CNNs and 3 for phonetic feature CNNs. The filter length h is fixed as the size of $|P|$ for 1-hot phoneme CNNs and 2 for phonetic feature CNNs. The word length parameter n is fixed at 10. We used adadelta optimizer (Zeiler, 2012) with learning rate of 1.0, $\rho = 0.95$, and $\epsilon = 10^{-6}$. We fixed the mini-batch size to 128 in all our experiments. Both our architectures are relatively shallow – only

[2]The Indo-European work also includes higher level subgrouping information as priors to infer the divergence ages along the root and internal nodes of the phylogeny.

three layers – as compared to the text classification architecture of Zhang et al. (2015). We trained all our networks using Keras (Chollet, 2015) and Tensorflow (Abadi et al., 2016).

5.2 Datasets

We evaluate the performance of phoneme CNNs on three different language families: Austronesian, Indo-European, and Mayan.

Austronesian The Austronesian Basic Vocabulary Database[3] has word lists for 210 concepts in 378 languages. The database also has a cognacy judgment for each word. However, the database is not in an uniform transcription. Hence, we semi-automatically processed the words and converted a subset of 100 languages into uniform ASJP alphabet. We extracted a total of $525,941$ word pairs from the processed data of which $167,676$ are cognates.

Indo-European The second dataset comes from the Indo-European Lexical database which was originally created by Dyen et al. (1992) and curated by Michael Dunn.[4] The database is transcribed in a mix of International Phonetic Alphabet (IPA) and Romanized IPA. The database has word lists for 207 concepts in 139 languages. We extracted word lists for only those languages which are in phonemic transcription in more than 80% of the concepts. This filtering step leaves us with a total of $326,758$ word pairs for 52 languages of which $83,403$ are cognates.

Mayan The third dataset comes from the Mayan language family (Wichmann and Holman, 2013) that is spoken in Meso-America. This dataset has word lists in ASJP format for 100 concepts in 30 languages. We extracted $63,028$ word pairs from the dataset out of which $22,756$ are cognates.

Family	Training		Testing		$\|P\|$	$\|L\|$	Avg. # Cognate Classes
	Non-Cognates	Cognates	Non-Cognates	Cognates			
Austronesian	$244,978$	$125,018$	$113,287$	$42,658$	35	100	22.095
Indo-European	$162,818$	$62,120$	$80,537$	$21,283$	38	52	12.21
Mayan	$17,740$	$10,482$	$8,047$	$4,297$	33	30	8.58

Table 3: The number of positive and negative examples in training and testing datasets is given for each family. The size of the alphabet ($|P|$), number of languages ($|L|$) and, the average number of cognate classes per concept for each family.

5.3 Evaluation metrics

The performance of the baseline and the different CNN models is evaluated using Accuracy (ACC) and F-score. Given W word pairs, Accuracy is defined as the number of word pairs that have been assigned the correct labels (both cognate and non-cognate) divided by W. The F-score is defined as the harmonic mean of the Precision (P) and Recall (R) ($\frac{2PR}{P+R}$).

5.4 Baseline

We compare the performance of CNNs against the SVM classifier system trained on the following features from Hauer and Kondrak (2011). We used a linear kernel and optimized the SVM hyperparameter (C) through ten-fold cross-validation and grid search on the training data.

- Edit distance.
- Common number of bigrams.
- Length of longest common prefix.
- Lengths of both the words.
- Absolute difference between lengths of words.

[3] `http://language.psy.auckland.ac.nz/austronesian/` (Greenhill et al., 2008). We accessed the database on 09-12-2015.

[4] `http://ielex.mpi.nl/`

6 Results

For each family, we train our models on word pairs extracted from $\sim 70\%$ of the meanings and test on the remaining meanings. The details of the training and testing datasets are given in table 3. The results of our experiments are given in table 4.

Systems	Indo-European		Austronesian		Mayan	
	F-score	Accuracy	F-score	Accuracy	F-score	Accuracy
Baseline	80.1	78.92	77.1	76.54	81.3	80.96
PhoneticCNN	85.8	**86.6**	77.6	79.24	85.4	85.56
PhoneticCNN + Langs.	**86.1**	86.42	78.3	79.8	86.2	86.23
CharCNN	84.6	85.05	79.1	80.11	86.3	86.4
CharCNN + Langs.	85.7	86.03	**80.3**	**80.94**	**87.5**	**87.5**

Table 4: Accuracies and F-scores of different CNN models against the system of Hauer and Kondrak (2011). CNNs with language features are denoted with a suffix "+ Langs.".

All the CNN models perform better than the baseline across all the language families. The PhoneticCNNs perform better than the CharCNN only on the Indo-European language family. In the case of Austronesian language family, joint training of language features improve the performance over baseline. This is reasonable since the Austronesian language family is spread over a wide range of geographical area spreading from Madagascar to Hawaii. The joint training of language features also improves the accuracy and F-score for Mayan language family.

CharCNN performs the best on the Mayan language family. One reason for this could be that the Mayan language family is a geographically proximal family and does not exhibit great amount of phonological divergence. Moreover, the Mayan language family shows less number of average cognate classes per concept as compared to Austronesian or Indo-European (cf. table 3) which can interpreted as a measure of genetic closeness within a family. In the case of Indo-European, the phonetic CNNs trained jointly with language information perform the best.

6.1 Do CNNs work with small training sets?

Zhang et al. (2015) note that CNNs require large amount of data for training. We test this hypothesis by training our CNNs on a smaller subset of 20 concepts. The results of our experiments are given in table 5.

Systems	Indo-European		Austronesian		Mayan	
	F-score	Accuracy	F-score	Accuracy	F-score	Accuracy
Baseline	81.8	81.05	**77.9**	**77.7**	80.5	80.02
PhoneticCNN	83	**84**	73.6	75.86	84.6	84.64
PhoneticCNN + Langs.	**83**	83.78	73.1	75.82	84.1	84.25
CharCNN	79.6	81.62	74.3	76.69	**85.6**	**85.55**
CharCNN + Langs.	80.9	82.61	76.0	77.84	81.2	81.36

Table 5: Accuracies and F-scores of different CNN models trained on 20 meanings in the training data.

In the case of Indo-European and Mayan, the CNNs perform better than the baseline whereas for Austronesian the CNNs do not outperform the baseline system. The results for Indo-European and Mayan (cf. table 5) are similar to that of the results reported in table 4. That is, the CharCNN system performs the best for Mayan language family, while the PhoneticCNN system performs the best for the Indo-European language family. Surprisingly, for the Austronesian family, the baseline system performs better at F-score than the top-performing system for this language family in table 4, namely the CharCNN (with language features); the Accuracy measure of the Baseline system is also higher, but the difference is not statistically significant. The reason for this could be that there is not enough information in the 20 meanings to learn phonological similarity for 100 languages.

The results for Mayan family suggests that the CharCNN can be used with small datasets for a closely related language family. We believe that this is an important result due to the abundance of small number of language families in the world.

To support our claim, we cite family size numbers from Glottolog[5] which show that there are about 50 language families of size between 10 and 100. Due to this reason, we claim that a cognate identification system that can perform well on geographically proximal, closely related languages is useful for identifying cognates, which, in turn, can be used for inferring phylogenies of under-studied language families.

7 Conclusion

In this article, we proposed siamese CNNs for cognate identification and compared it against a SVM classifier trained on orthographic similarities. Our results suggest that CharCNNs and PhoneticCNNs can be used for the purpose of cognate identification. Our results on Mayan language families suggest that CNNs can be applied for NLP tasks in closely related languages or varieties. The language features improve the performance of CNNs across all the language families.

The performance of CharCNNs suggest that deep learning can be applied for small datasets (language families). Many deep learning systems reported in the NLP literature require huge amount of training data. Here, we show that handcrafted embedding and 1-hot encodings can learn useful representations from raw words for capturing phonological similarities between a word pair.

In the future, we hope to apply CNNs for more language families of the world for the purpose of cognate identification and phylogenetic inference.

Acknowledgements

I thank the reviewers for the useful comments which helped improve the paper. This work has been supported by the ERC Advanded Grant 324246 EVOLAEMP, which is gratefully acknowledged. I thank Simon Greenhill for the permission to use the Austronesian data in the experiments. The data for the experiments was processed by Johann-Mattis List and Pavel Sofroniev. I thank Çağrı Çöltekin for the comments on the initial draft that helped improved the paper.

Abstract

This paper investigates differential topic models (*dTM*) for summarizing the differences among document groups. Starting from a simple probabilistic generative model, we propose *dTM-SAGE* that explicitly models the deviations on group-specific word distributions to indicate how words are used differentially across different document groups from a background word distribution. It is more effective to capture unique characteristics for comparing document groups. To generate *dTM*-based comparative summaries, we propose two sentence scoring methods for measuring the sentence discriminative capacity. Experimental results on scientific papers dataset show that our *dTM*-based comparative summarization methods significantly outperform the generic baselines and the state-of-the-art comparative summarization methods under ROUGE metrics.

1 Introduction

Today, the interconnected nature of real-world applications brings more cross-field research problems leading to a much closer relationship between research areas. Real-world challenges require researchers to quickly get acquainted with knowledge in other areas. For example, imagine a researcher who is familiar with topic models wants to extend her research to opinion summarization. She would be more interested in finding out the current development of sentiment analysis and how topic models can be used in sentiment analysis, rather than the common background knowledge such as topic models and basic NLP technologies. Such a real-world demand encourages the study of multi-document comparative summarization for scientific papers in multiple subject areas. This paper presents the initial study on this problem.

Comparative summarization aims at summarizing the differences among document groups (Wang et al., 2012). The core is to compare different topics and find unique characteristics for each document group. The main motivation of this paper is to apply *dTM* to comparative summarization and to model the group-specific topics to capture the unique word usage for characterising documents in the same group. To our best knowledge, there is no previous study providing in-depth model analysis and detailed experimental results on *dTM* applied for comparative summarization.

We first propose a probabilistic generative model *dTM-Dirichlet* to model the group-specific word distributions to capture the unique word usage for each document group. However, *dTM-Dirichlet* is not a truly differential topic model and it suffers from the problems of high inference cost, over-parameterization and lack of sparsity. Evolving from the idea of *SAGE* (Eisenstein et al., 2011), we develop *dTM-SAGE* to make the word probability distributions for each document group to share a common background word distribution and explicitly models how words are used differently in each group from the background word distribution.

Our main contributions include the following two points: (1) we propose *dTM* to capture unique characteristics of each document group in the application background of comparative summarization for cross-area scientific papers; and (2) we propose two sentence scoring methods to measure the sen-

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1028–1038, Osaka, Japan, December 11-17 2016.

tence discriminative capacity and a greedy sentence selection method to automatically generate summary for *dTM*-based comparative summarization.

2 Related Work

Multi-document Summarization. Existing multi-document summarization can be either extractive or abstractive (Sekine and Nobata, 2003). Our work focuses on the extractive techniques which involve in assigning saliency scores to sentences and extracting high-scored sentences in a greedy manner to construct a summary (Wan et al., 2007; Cai et al., 2010; Gupta and Lehal, 2010; Celikyilmaz and Hakkani-Tur, 2011). Graph-based ranking techniques such as TextRank (Mihalcea and Tarau, 2004) and LexPageRank (ErKan and Radev, 2004) have been widely used in extractive summarization. A bigram based supervised method was proposed for extractive summarization in ILP framework (Li et al., 2013; Li, 2015). Jha et al. (2015) proposed an extractive algorithm that combines a content model with a discourse model to generate coherent summaries for scientific articles. A multi-dimensional summarization methodology was proposed to transform the paradigm of traditional summarization research through multi-disciplinary fundamental exploration on semantics, dimension, knowledge, computing and cyber-physical society (Zhuge, 2016).

Comparative Summarization. Unlike the generic summarization that summarizes the common information in document collection, the comparative summarization aims to summarize the differences among document groups. Wang et al. (2012) proposed a discriminative sentence selection method to generate summary by selecting sentences in a greedy manner to minimize the generalized variance of a covariance matrix using a multivariate normal model. Shen and Li (2010) proposed a method by building the sentence graph for each document group and extracting a complementary minimum dominating set on each graph to form a discriminative summary.

Update Summarization. The most similar task to comparative summarization is update summarization, which aims to detect and summarize novel information in a document set B under the assumption that users have already learnt the documents in set A, where documents in A chronologically precede the documents in B. The update summarization has been well studied. Most existing methods solve it as a redundancy removal problem by adding functionality to remove redundant sentences using filtering rules (Fisher and Roark, 2008), Maximal Marginal Relevance (Boudin et al., 2008), or graph-based algorithms (Shen and Li, 2010; Li et al., 2008).

More related to this paper is the work of a topic-model based update summarization approach *DualSum* (Delort and Alfonseca, 2012), which learns a general background distribution across the corpus and a document-specific distribution for each document, but also learns two collection-specific distributions for each pair of update collection and base collection: the joint topic distribution and the update topic distribution. This paper revises *DualSum* as a baseline for evaluation in Section 5.2.

Topic Models for Documents Comparison. The other type of related work is the comparison of documents. Most existing studies for this goal focus on topic models to discover common and specific themes among document collections, referred to as cross-collection topic models (Paul, 2009). This idea was first explored with an initial topic model *PLSI* (Zhai et al., 2004), and later improved with *LDA* topic model (Blei, 2012; Pual, 2009) which inspires our *dTM-Dirichlet*. There are a number of real-world applications extending cross-collection topic models in different scenarios (Ahmed and Xing, 2010; Li et al., 2011). For example, Paul and Girju (2009) employed cross-collection *LDA* (*cc-LDA*) for cross-cultural analysis of blogs and forums and later they proposed a two-dimensional topic-aspect model (*TAM*) to jointly discover topics and aspects in scientific literature (Paul and Girju, 2010). The common idea behind these cross-collection topic models is that using latent topics capture the common and unique word usage among document collections. Cross-collection topic models neglect the correlations between each collection-specific topic and the common background topic, thus make it insufficient to capture differential word usage. More importantly, the correlations are the essence of the differential topic models.

3 Differential Topic Models

In this section, the differential topic models are explored for comparative summarization. We first develop a simple probabilistic generative model, *dTM-Dirichlet*. Evolved from *dTM-Dirichlet*, *dTM-SAGE* is developed by modelling the correlations as additive relation between the group-specific devi-

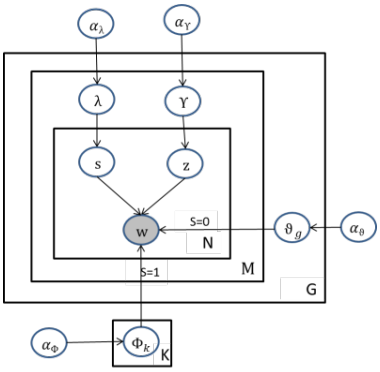

Fig.1 dTM-Dirichlet Model Graph Representation.

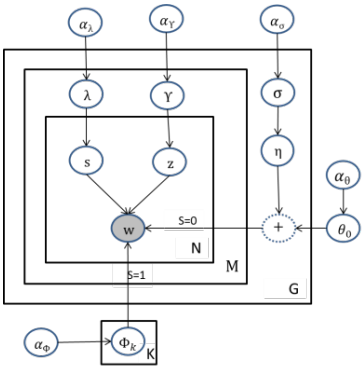

Fig.2 dTM-SAGE Model Graph Representation.

ations and a background word distribution, which enables to capture more salient group-specific words and bypass the problems of high inference cost, over-parameterization and lack of sparsity.

To illustrate *dTM*, we first define some notations to express a document corpus *C*. Let *G* be the number of groups in the corpus, M_g be the number of papers in group g and $N_{g,m}$ be the number of words in paper *m*. A word $w_{g,m,n}$ representing the n^{th} word in paper *m* of group g is a discrete observed variable, defined to be an item in the vocabulary list of the whole corpus.

3.1 *dTM-Dirichlet* Model

dTM-Dirichlet model is a simplified version of cross-collection LDA (*ccLDA*) (Paul and Girju, 2009) for comparing multiple text collections. *dTM-Dirichlet* builds two types of word model. One is for each document group g, in which there is a group-specific content word model ϑ_g that emits discriminative words for the group. The other type is a superset of group-independent word models φ_k that generates either background words shared by all document groups or salient words occurring in several documents of different groups. Reconsidering the example in section 1, the group-independent word model represents two classes of words, i.e. the background words like topic model that are shared by almost all papers; and the salient words like NP chunk and dependency parsing that only occur in several papers of different groups.

We focus on the group-specific word model for comparative summarization. Since background words and salient words provide no group-specific knowledge, they are not distinguished in *dTM-Dirichlet*. Following probabilistic topic models, we assume that word models φ_k and ϑ_g are multinomial distributions over words, drawn from uniform *Dirichlet* distribution (*Dir*) with priors α_φ and α_ϑ.

As shown in Fig. 1, dTM-Dirichlet associates each document a topic distribution $\gamma \sim Dir\ (\alpha_\gamma)$, and the topic assignment variable *z* for each word in the document thus can be multinomially sampled from γ. Besides a topic variable *z*, each word is also assigned with a binary variable *s* that indicates whether the word is a group-independent topic word (*s*=1) or a group-specific content word (*s*=0). Each document has a group-specific word controller $\lambda \sim Beta(\alpha_\lambda)$, which reflects the proportion of group-specific content in a document. s is sampled from a Bernoulli test with the probability of λ.

Formally, the generative process of dTM-Dirichlet model for a corpus *C* divided into *G* document groups is shown in Table 1. When $s_{g,m,n} = 1$, the sample of the group-independent topic word is identical to *LDA*. When $s_{g,m,n} = 0$, the sample of the word $w_{g,m,n}$ is independent from the document's topic distribution $\gamma_{g,m}$ and directly drawn from the group-specific content word distribution θ_g.

dTM-Dirichlet models group-specific word distributions to capture the differential lexicon usage of document groups. However, *dTM-Dirichlet* is not a truly differential topic model, which requires the development of *dTM-SAGE* for comparative summarization.

3.2 *dTM-SAGE* Model

When generating topics for multiple document collections, *LDA*-style generative models associate a multinomial distribution with each document group, which is the same as how we model the group-specific content words in *dTM-Dirichlet* model.

In contrast, *SAGE* (Sparse Additive Generative model) (Eisenstein et al., 2011) provides an alternative way to *LDA* by endowing each document group with a model of the deviation in log-frequency

Table 1: The generation process of *dTM-Dirichlet* and *dTM-SAGE*.

from a constant background distribution, which brings three advantages: First, a sparsity-inducing prior can be applied to limit the number of terms whose probability diverges from the background term frequencies. Second, multi-facets latent variables can be easily combined by adding each facet component together to reduce the inference cost. Third, it is redundant to learn unique probabilities for high-frequency background words of each group. Modelling the deviation of each group-specific word distribution cancels the relearn process for the background words.

We propose *dTM-SAGE* which explicitly models the deviation in log-frequency of each group-specific word distribution from a background lexical distribution. *dTM-SAGE* also builds word models for group-independent topic words and group-specific content words. The group-independent topic words consist of background topic words and salient topic words.

dTM-SAGE models two types of group-independent words separately: as shown in Fig. 2, the salient topic words captured by φ_k and the background topic words captured by ϑ_0. The word models φ_k and ϑ_0 are multinomial distributions drawn from uniform Dirichlet prior with parameter α_φ and α_ϑ. To enable ϑ_0 to capture real background topic words shared by all document groups, we replace the constant background distribution in *SAGE* with a latent distribution learnt by MAP estimation using a Newton optimization.

The major difference between *dTM-SAGE* and *dTM-Dirichlet* is how the group-specific topics are generated. In Fig.2, each document group g has a group component vector η_g representing the deviations in log-frequencies from the background distribution ϑ_0. The group-specific topic is represented by log frequency deviations rather than word probabilities. Given the background distribution ϑ_0 and the group component vector η_g, the group-specific topic distribution ϑ_g for each word in a document in the group g, denoted by $\boldsymbol{\vartheta_g} \propto exp(\boldsymbol{\vartheta_0} + \boldsymbol{\eta_g})$, is computed by Equation (1):

$$p(w \mid \theta_0, \eta_g) \;/\; \sum_v \exp(\theta_{0,v}, \eta_{g,v}) \tag{1}$$

In Equation (1), g indexes the group component vector and v indexes the term in the corpus vocabulary. Following *SAGE*, we ignore covariance between terms. For each term v, $\eta_{g,v}$ is drawn from a zero-mean Gaussian distribution $N(0, \sigma_{g,v})$, where the variance $\sigma_{g,v}$ is drawn from the Exponential distribution parameterized by α_σ. The compound model $\int N(\eta; 0, \sigma) Exponential(\sigma; \alpha_\sigma) d\sigma$ is equivalent to a zero-mean Laplace prior on η inducing sparsity and meanwhile permitting large degrees of deviations. In *dTM-SAGE*, we treat the variance σ as a latent variable and develop variational inference on it, which is the same as *SAGE*. The remaining part of *dTM-SAGE* is the same as *dTM-Dirichlet* model. Formally, the generative process of *dTM-SAGE* is shown in Table 1. See Appendix A for inference details of $\boldsymbol{\vartheta_0}$ and $\boldsymbol{\eta_g}$.

4 Comparative Summary Generation

To summarize differences among document groups, we rely on group-specific topics ϑ_g to select most discriminative sentences for summary generation. This section introduces the sentence scoring and the sentence selection techniques developed for *dTM*-based comparative summarization.

4.1 Sentence Scoring

Both *dTM-Dirichlet* and *dTM-SAGE* model the group-specific word distributions ϑ_g to capture the unique content in each document group. For *dTM-SAGE*, we can also get a corpus background topic distribution ϑ_0 that reflects the common themes shared by all groups. To measure the sentence discriminative capacity, we develop two sentence scoring methods: one is based on the word discriminative scores and the other is measured by the difference of the probabilities that a sentence is generated from a group-specific topic distribution and the background topic distribution.

First, given a set of group-specific word distributions ϑ_g ($1 \le g \le$ G), we define the *w*ord *d*iscriminative score $DSW(v, g)$ of a term v to a group g as $DSW(v,g) = \sum_{g' \neq g}(\vartheta_{g,v} - \vartheta_{g',v}) / \sqrt{\sum_g \vartheta_{g,v}^2 + \epsilon}$, where ϵ is a small number (set to 0.05) to avoid the error of division by zero. Larger value of the word discriminative score indicates more discriminative ability the word has. The intuition is that a word more likely to occur in a particular group and less likely to occur in other groups tends to be more discriminative. The *d*iscriminative *c*apacity of a sentence s to a group g $DCS\_dsw(s, g)$ is the average over the word discriminative scores:

$$DCS\_dsw(s, g) = \sum_{w \in s} DSW(w, g) \,/\, len(s) \tag{2}$$

The other method to measure the discriminative capacity of a sentence relies on the likelihood that the sentence is generated from a group-specific distribution and the background topic distribution. Its design is motivated by the idea that a word is more discriminative if it occurs more often in a group-specific topic and occurs rarely in the shared background topic. Given a topic-word distribution ϑ, the probability of a sentence *s* generated from ϑ:

$$\log P(s \mid \theta) = \sum_{w \in s} \log \theta_w \tag{3}$$

Given a set of group-specific word distributions ϑ_g ($1 \le g \le$ G) and the background topic distribution ϑ_0, the *d*iscriminative *c*apacity of a sentence s to a group g is defined as the *d*ifference of sentence *g*enerative *p*robabilities $DCS\_dgp(s, g)$:

$$DCS\_dgp(s, g) = u \log P(s \mid \theta_g) - (1 - u) \log P(s \mid \theta_0) \tag{4}$$

where u is a balance factor trading off between group-specific words and background words.

4.2 Sentence Selection

To select discriminative sentences to form group summary, we use different sentence selection methods according to sentence scoring techniques.

For the sentence scoring based on the word discriminative scores, we first rank the sentences according to the sentence discriminative capacity score DCS_dsw. Then we select a sentence with the highest score if it satisfies the redundancy constraint that indicated by a cosine similarity threshold (empirically set to 0.8).

For the scoring based on difference sentences generative probabilities, suppose we have a set of candidate sentences S to form a summary for group g and we want to select k sentences denoted as S_k. A greedy sentence selection schema is proposed to build S_k by iteratively choosing a j$^{\text{th}}$ sentence that currently has the maximum sentence discriminative capacity score DCS_dgp:

$$s_j^* = \arg\max_{s_j \in S \setminus S_{j-1}} DCS\_dgp(s, g) \tag{5}$$

In order to discourage redundancy, after select one sentence, we update the group-specific topic distribution ϑ_g by setting $\vartheta_{g,w} \propto \vartheta_{g,w}^2$ for each word w in the selected sentence s_j^*. Sentences are selected in this manner until reaching the summary limit.

5 Experiments and Results

5.1 Data Collection and Annotation

Comparative summarization is not a new task. However, to our best knowledge there is no public benchmark data set available. For collecting experiment data, we choose three tasks in NLP: summarization (*SUMMA*), sentiment analysis (*SA*) and geographical NLP tasks (*GEO*) to form three document groups. To make different groups share more salient themes, we focus on papers using probabilistic

Group	Keywords		|D|	|S|

Table 3: Comparisons of Perplexity and Topic Coherences for Different Topic Models.

topic models. We collect 129 papers in total for the three groups from ACL Anthology Searchbench providing full-text search for 28,000 papers in the ACL Anthology. For each group, we search with two types of keyword filters: plain text filter and title filter. Table 2 shows the general information of each document group, including the keywords, the number of documents |D| and the number of sentences |S|. To pre-process the dataset, we exclude all tables, figures and formulas, remove stop words, perform stemming with Porter Stemmer, and prune words less than 5 times across the corpus. There are 3720 tokens after pre-processing.

We hire three PhD students in Aston University to annotate the dataset. After reading papers in each group, each annotator is asked to first pick out all discriminative sentences in each paper and then write reference summaries delivering the major differences for each group. Additional instructions are given to annotators: Each reference summary should be no more than 300 words; and the discriminative sentences should enable the judgment of which group the paper belongs to. Equipped with the annotated dataset, two parts of evaluations are performed: evaluation of differential topic models and evaluation of the summarization methods.

5.2 Evaluations on *dTM*

In this section, we compare *dTM-Dirichlet* and *dTM-SAGE* with other three topic models in terms of model perplexity and topic coherences: (1) the standard *LDA* topic model, which we run across the corpus and perform Newton optimization to update hyper-parameters; (2) *SAGE*, which a sparse additive generative model proposed in (Eisenstein et al., 2011), and the non-parametric Jeffrey's prior make it parameter-free; (3) the variant of *DualSum*, which is proposed for update summarization (Delort and Alfonseca, 2012) and revised to perform comparative summarization by replacing pairs of collection-specific distributions with group-specific distributions. We implement the variant of *DualSum*, *dTM-Dirichlet* and *dTM-SAGE* models. Experimental settings are detailed below.

Settings for the variant of *DualSum*. The dirichlet priors for word distributions are empirically set to 0.1 and $\alpha_\lambda = (2.0,2.0,1.0)$ to encourage more words generated from the group-specific distributions and document-specific distributions.

Settings for *dTM-Dirichlet*. The dirichlet priors for word distributions α_Φ and α_θ are set to 0.1. For other papramenters, we set the number of group-independent topics $K = 20$, the prior for the topic distribution $\alpha_\gamma = 50/K$, and the prior for the group-specific word controller $\alpha_\lambda = 2.0$. *Beta*(2.0, 2.0) yields equal probabilities that words sampling from the group-specific distribution and the group-independent distributions.

Settings for *dTM-SAGE*. Parameters are set the same as those in dTM-Dirichlet: $\alpha_\Phi = \alpha_\theta = 0.1$, $K = 20$, $\alpha_\gamma = 50/K$ and $\alpha_\lambda = 2.0$. The variational distribution of the variance $\boldsymbol{\sigma}$ is $Gamma(\tilde{\alpha}, \tilde{b})$ which is initialized as $\tilde{\alpha} = 10.0$ and $\tilde{b} = 5.0$. The initialization for $\boldsymbol{\vartheta_0}$ and $\boldsymbol{\eta}$ are from the Uniform distribution $U(0,1)$ and the Normal distribution $N(0,0.5)$ respectively.

First, we investigate the model perplexity. Perplexity is a general measure for evaluating the generative ability of a probabilistic topic model. We compute the perplexity on a held-out test set, 20% of the original dataset. Note that we calculate the perplexity for all models except the variant of *DualSum*, since it models the document-specific distribution for each document and thus there is no natural way to assign probability to new document. For the variant of *DualSum*, we train the model on the whole dataset and report the results on the test set, though it by no means can reflect the generalization capacity of the model.

Perplexity results are shown in the first row in Table 3, from which we can see that the perplexity scores decrease by 7% and 13% respectively between *dTM-Dirichlet* and standard *LDA* and between *dTM-SAGE* and standard *SAGE*. The better results of differential topic models over the standard ones are due to the discrimination between group-specific topics and group-independent topics. Both *SAGE* methods outperform their counterparts of the Dirichlet-multinomial, because the sparsity-inducing prior enables *SAGE* to control sparsity adaptively without over-fitting (Eisenstein et al., 2011).

Table 5: Comparison of Rouge Scores (F-score) and Precision.

Summary by dTM-Dirichlet.

①Most of the existing multi-document summarization methods decompose the documents into sentences and work directly in the sentence space using a term-sentence matrix.

②Bayesian sentences-based topic model, every sentences in a document is assumed to be associated to a unique latent topic.

③While previous MDS systems have focused primarily on salience and coverage but not coherence, G-Flow generates an ordered summary by jointly optimizing coherence and salience.

④Markov Random Walk Model (MRW) Graphs methods have been successfully applied to weighting sentences for generic and query-focused summarization.

⑤The topic distributions are used to get the sentence scores and rank sentences.

Summary by dTM-SAGE.

①In recent years, three major techniques have emerged to perform multi-document summarization: graph-based methds such as LexRank, Biased-LexRank for query-focused summarization, language models such as KLSum and variants based on topic models, such as BayeSum and TopicSum.

② Bayesian Query-Focused Summarization, we present BayeSum (Bayesian summarization), a model for sentence extraction in query-focused summarization.

③Sentence Selection Strategy, The task of timeline summarization aims to produce a summary for each time and the generated summary should meet criteria such as relevance, coverage and coherence.

④Models that use more structure in the representation of documents have also been proposed for generating more coherent and less redundant summaries, such as HierSUM and TTM.

⑤In generating a summary, we use MMR (Maximal Marginal Relevance for multi-document) to avoid redundancy in a summary.

Table 6: Comparison of 5-Sentence Summary Generated by *dTM-Dirichlet* and *dTM-SAGE*.

To check the quality of the generated group-specific topics, we investigate various topic coherence measures. The intuition behind the topic coherence measures is that words clustering into a single topic tend to co-occur in the same document. It has been previously verified that topic coherence score is highly correlated with human-judged topic coherence in many works. We rely on Palmetto library (Röder et al., 2015), an online open source implementation, which offers a framework to calculate many coherence measures within a reference corpus of the English Wikipedia.

In our experiment, we compare three widely-used coherence scores over the five topic models: (1) *C_A*, which is the pairwise comparison of the top words based on a context window of size 5, and proposed in (Aletras and Stevenson, 2013); (2) *C_V*, which is a one-set segmentation of the top words based on a sliding window of size 110, and proposed in (Röder et al., 2015); (3) *C_UCI*, which is the pointwise mutual information (PMI) of all word pairs of the top words based on a sliding window of size 10, and proposed in (Newman et al., 2010).

We focus on the group-specific topics. For each group-specific topic-word distribution we get a word list containing the top-20 words and calculate the coherence scores for each word list. The topic coherence results shown in Table 3 are the average coherence scores of the three group word lists. The coherence scores are calculated within two reference corpus: the English Wikipedia (*Wiki*) and the original dataset (*Intra*). Table 4 shows the top 10 words selected by *SAGE*, *dTM-SAGE* and *dTM-Dirichlet* for the group *SUMMA*. Main observations found in Table 3 include:

(1) The three differential topic models generally perform much better than the standard *LDA* and *SAGE* models on all coherence measures, which shows the superiority of our *dTM* models by distinguishing group-specific words and group-independent words;

(2) *dTM-SAGE* consistently performs the best among all the five models in terms of *C_A* and *C_UCI* with the significant increase at least by 6.5% over *dTM-Dirichlet* and 8.2% over the variant of *DualSum*, which shows the advantage of *dTM-SAGE* in accurately ranking the group-specific words due to the essence of the differential word model;

(3) *dTM-Dirichlet* outperforms the variant of *DualSum* with *C_A* and *C_V*, however, it performs nearly the same or even worse when measured with *C_UCI*.

As shown in Table 4, words selected by *dTM-SAGE* (like rouge, lexrank, redundant) are more informative and discriminative than words selected by *SAGE* and *dTM-Dirichlet*.

5.3 Evaluations on Summarization

To evaluate the quality of the generated summaries, we compare our *dTM*-based comparative summarization methods with five other typical methods under ROUGE metrics (Lin and Hovy, 2003). Further, to check the discriminative ability of the comparative summaries, following the evaluation method of (Wang et al., 2012), we investigate the precision of the discriminative sentence selection.

In our experiment, we implement three types of summarization methods: (1) Generic baseline methods, including the centroid-based method (Radev et al. 2004), the graph-based method LexPag-

eRank (Radev et al., 2004) and the MMR-based method (Carbonell and Goldstein, 1998); (2) State-of-the-art comparative summarization methods, including the discriminative sentence selection (*DSS*) method (Wang et al., 2012) and the complementary dominating set (*CDS*) method (Shen and Li, 2010); (3) TM-based comparative summarization methods, which combine four different TMs with two sentence scoring strategies DCS_dsw and DCS_dgp defined in section 4.1, including the basic $LDA\ (dsw)$, the variant of $DualSum\ (dsw)$, *dTM-Dirichlet* (dsw), *dTM-SAGE* (dsw) and *dTM-SAGE* (dgp). For each group, we select 20 sentences to form the final summary.

First, we examine the precision of the discriminative sentence selection. For each group we have 20 sentences in a summary and count how many sentences belong to the annotated discriminative sentence set. Comparisons of the precision results of discriminative sentence selection by different methods are shown at the last column in Table 5. From the precision results, we find that (1) our *dTM*-based comparative summarization methods can select over 70% discriminative sentences, which significantly outperform the state-of-the-art methods with a nearly 20% increase on the precision score; (2) All generic summarization methods perform rather worse due to different concerns on summarization resulting in the lack of discriminative ability of summaries.

We use ROUGE-1.5.5 toolkit to evaluate the quality of generated summaries by comparing them with human-written reference summaries. In our experiment, we limit the length of all summaries to 250 words and report the average ROUGE scores (F-Scores) on various summarization methods in Table 5. According to the results, we observe that: (1) our *dTM*-based comparative summarization methods perform much better (paired t-test with $p<0.05$) than all the baselines, which demonstrates that targeting at a different goal for summarizing the general information among document groups, generic summarization methods are less applicable for comparative summarization, though by removing redundancy, MMR performs better than the other two baselines but still lags behind other summarization methods specifically proposed for comparative summarization; (2) our *dTM*-based comparative summarization methods significantly outperform (paired t-test with $p<0.05$) the other two state-of-the-art comparative summarization methods, which shows that summarizing differences by extracting group-specific topics is more effective than directly summarizing at the sentence level; (3) Both *dTM-SAGE* methods achieve better ROUGE scores than *dTM-Dirichlet*, which is ascribe to the advantage of a differential word model contributing to more informative and discriminative group-specific topics (discussed in section 5.2); and, (4) For *dTM-SAGE*, the greedy sentence selection schema based on DCS_dgp is more effective than simply ranking sentence with DCS_dsw.

5.4 Summary Example

We show an example of the summary generated for the group *SUMMA* by our *dTM-SAGE* and *dTM-Dirichlet* in Table 6. Looking into the summaries, we find that all sentences in both summaries are related to summarization but different in the degree of their discriminative ability. Apparently, the summary generated by *dTM-SAGE* is more specific and unique to summarization, while the summary generated by *dTM-Dirichlet* still contains some general information about topic models in sentence ② and ⑤. Another observation is that the summary of *dTM-SAGE* tends to contain more salient group-specific terms that may not occur in most of group documents but still possess high discrimination, like '*query-focused*', '*MMR*' and '*HierSUM*'. In contrast, the summary by *dTM-Dirichlet* covers more background group-specific words, like '*summarization*' and '*MDS*'. Although these background group-specific terms are discriminative for the group, they are relatively less informative than the salient terms for the purpose of summarization.

6 Conclusions

This paper studies the differential topic models for comparative summarization on cross-area scientific papers. A differential topic model *dTM-SAGE* is proposed to capture the unique characteristics of each document group and generate coherent group-specific topics. A greedy sentence selection method with two sentence discriminative capacity scoring schemas is designed to automatically generate summary for *dTM*-based comparative summarization methods, which achieve significant improvements with various ROUGE metrics. The analysis on experiment results shows that the summaries generated by our *dTM-SAGE* method can cover major differences for each group.

Appendix A. Variational Inference of ϑ_0 and η_g

Generally, we take MAP (maximum a posterior) estimation for the background word distribution ϑ_0 and the group component vectors η and develop variational inference techniques for all other variables.

In dTM-SAGE, the lower bound L with regarding to ϑ_0, η and σ is:

$$L = \log P(\theta_0 \mid \alpha_\theta) + \sum_g \sum_m \sum_n E_Q[\log P(w_{g,m,n} \mid s_{g,m,n} = 0, \theta_0, \boldsymbol{\eta_g})]$$

$$+\sum_g E_Q[\log P(\boldsymbol{\eta_g} \mid 0, \boldsymbol{\sigma_g})] + \sum_g E_Q[\log P(\boldsymbol{\sigma_g} \mid \alpha_\sigma)] - \sum_g E_Q[\log Q(\boldsymbol{\sigma_g})]$$

Maximize L with respect to $\boldsymbol{\vartheta_0}$:

$$L(\theta_0) = \sum_v (\alpha_g^v - 1) * \log \vartheta_0^v + \sum_g \sum_m \sum_n \tilde{\lambda}_{gmn}^0 * \{\vartheta_0^{w_{g,m,n}} - \log(\sum_{v'} \exp(\eta_g^{v'} + \theta_0^{v'}))\}$$

By Assuming $T(v) = \frac{\exp(\eta_g^v + \theta_0^v)}{\sum_j^V \exp(\eta_g^j + \theta_0^j)}$, taking derivatives with respect to ϑ_0^v:

$$\frac{\partial L}{\partial \vartheta_0^v} = \frac{\alpha_g^v - 1}{\vartheta_0^v} + \sum_g \sum_m \sum_n \tilde{\lambda}_{gmn}^0 * \{I(w_{g,m,n} = v) * (1 - T(v)) + I(w_{g,m,n} \neq v) * (-T(v))\}$$

We use Newton-Raphson method to optimize $\boldsymbol{\vartheta_0}$. First, we derive the Hessian matrix by setting:

$$H_{vv}(\theta_0) = \frac{\partial^2 L}{\partial \vartheta_0^{v2}} = -\frac{\alpha_g^v - 1}{(\vartheta_0^v)^2} + \sum_g \sum_m \sum_n \tilde{\lambda}_{gmn}^0 * (T(v)^2 - T(v))$$

$$H_{vv'}(\theta_0) = \frac{\partial^2 L}{\partial \vartheta_0^v \partial \vartheta_0^{v'}} = \sum_g \sum_m \sum_n \tilde{\lambda}_{gmn}^0 * T(v)T(v')$$

After getting Hessian matrix, we invert it with Sherman-Morrison formula and compute the Newton step: $\Delta\boldsymbol{\vartheta_0} = H^{-1}(\boldsymbol{\vartheta_0})\nabla_{\boldsymbol{\vartheta_0}} L(\boldsymbol{\vartheta_0})$. Same procedure on η:

$$\frac{\partial L}{\partial \eta_g^v} = -\eta_g^v * [(\tilde{a}_g^v - 1)\tilde{b}_g^v]^{-1} + \sum_m \sum_n \tilde{\lambda}_{gmn}^0 * \{I(w_{g,m,n} = v) * (1 - T(v)) + I(w_{g,m,n} \neq v) * (-T(v))\}$$

$$H_{vv}(\boldsymbol{\eta}_g) = \frac{\partial^2 L}{\partial \eta_g^{v2}} = -[(\tilde{a}_g^v - 1)\tilde{b}_g^v]^{-1} + \sum_g \sum_m \sum_n \tilde{\lambda}_{gmn}^0 * (T(v)^2 - T(v))$$

$$H_{vv'}(\boldsymbol{\eta}_g) = \frac{\partial^2 L}{\partial \eta_g^v \partial \eta_g^{v'}} = \sum_g \sum_m \sum_n \tilde{\lambda}_{gmn}^0 * T(v)T(v')$$

Bridging the gap between extractive and abstractive summaries: Creation and evaluation of coherent extracts from heterogeneous sources

Abstract

Coherent extracts are a novel type of summary combining the advantages of manually created abstractive summaries, which are fluent but difficult to evaluate, and low-quality automatically created extractive summaries, which lack coherence and structure. We use a corpus of heterogeneous documents to address the issue that information seekers usually face – a variety of different types of information sources. We directly extract information from these, but minimally redact and meaningfully order it to form a coherent text. Our qualitative and quantitative evaluations show that quantitative results are not sufficient to judge the quality of a summary and that other quality criteria, such as coherence, should also be taken into account. We find that our manually created corpus is of high quality and that it has the potential to bridge the gap between reference corpora of abstracts and automatic methods producing extracts. Our corpus is available to the research community for further development.

1 Introduction

The sheer amount of information available via news agencies, social media, scientific publications, etc. overwhelm information seekers. Not only the information overload itself, but also the heterogeneity of the data poses an obstacle to the aggregation and assessment of information, as text structures, styles, and forms of information presentation vary across different genres and domains of text. Therefore, automatic summarization of multiple heterogeneous sources is a key research demand.

Previous efforts such as DUC[1], TAC[2], and MultiLing[3] have mostly focused on homogeneous data. Heterogeneous data poses many new challenges to Multi-Document Summarization (MDS) that have not been extensively covered so far, such as abstracting from deviating text structures, maintaining topic diversity, resolving potentially opposing opinions, and adapting a text for different target audiences. In our work, we aim at creating a novel MDS corpus of heterogeneous sources.

Besides the lack of heterogeneous MDS corpora, we consider the type of summaries available in MDS corpora in general as an even more severe problem: Existing corpora contain primarily *abstractive summaries*, whereas automatic systems typically utilize extractive methods yielding *extractive summaries* (i.e., bags of sentences taken from the source documents). Producing a coherent, human-understandable text, however, requires steps beyond mere extraction. These steps include, among others, compression, co-reference resolution, paraphrasing, and content structuring. Though there are multiple works striving for abstractive summaries, it is very hard to evaluate them, since current MDS corpora do not explicitly address these tasks.

Although ROUGE is the primary evaluation metric used so far, it only compares n-gram overlap between at least one model summary and a reference summary and thus gives a mere *quantitative* impression of the lexical coverage, leaving the coherence of a summary largely unconsidered.

Table 1: Comparison of manual multi-document corpora († = no predefined summary size)

In contrast, there are corpora containing only extracts, which are suitable for evaluating extractive MDS systems. However, this yields an overly artificial evaluation, since neither their creation guidelines nor the evaluation metrics employed take coherence, fluency, and organization of the summary into account. We argue that such bag-of-sentences-based extracts are of limited use for real users, who prefer a coherent, meaningful text over an unordered collection of sentences.

In order to bridge the gap between the system results (primarily extractive) and the reference data (primarily abstractive), we need high-quality corpora that allow for training and evaluation of automatic systems and their intermediate steps, such as the identification of important nuggets or the removal of redundancy. To this end, we introduce and analyze a novel type of reference summary: *coherent extracts*. Coherent extracts are based on information explicitly taken from the source documents allowing to create a straight-forward evaluation setup based on the selection of important content. At the same time, coherent extracts have a meaningful order and are redacted to ensure a coherent text, which is substantially more helpful for humans than purely extractive summaries. Our vision is to use the data collected during structuring and redaction in order to research improved extractive MDS systems.

In this paper, we introduce our idea of coherent extracts and we create and evaluate a novel MDS corpus of coherent extracts from heterogeneous source documents. In Section 2 we discuss previous work in manual summarization and corpus construction. We describe coherent extracts and our summarization workflow in Section 3 and we evaluate our work in Section 4. Finally, we conclude the paper in Section 5.

2 Related work

Our work is inspired by two main aspects of multi-document summarization: the manual creation of MDS corpora and the evaluation of the resulting summaries. There are two main approaches to summarization: abstractive and extractive. Humans typically produce abstractive summaries by paraphrasing and condensing information from the sources. Automatic systems primarily generate extractive summaries by copying information from the sources without modifying and ordering them. For evaluating an automatic system, however, we require gold standard summaries that fit well to the system output, cf. (Endres-Niggemeyer, 2012). This major discrepancy between the human-generated abstractive gold standard and the system-generated extractive summaries has largely been neglected in previous work.

2.1 Existing multi-document summarization corpora

Endres-Niggemeyer (2012) states that the process of summarization includes three subtasks: *analysis of the input information*, *performance of the core summarization task (condensation, abstraction)* and *representation of the results in an appropriate form*. Schlesinger et al. (2003, p. 46) observe that MDS "lacks complementary documentation of procedures and methodologies for human performance".

Table 1 gives an overview over various MDS corpora in comparison to our work. Most of them are based on homogeneous data such as news (DUC, TAC, MultiLing, Goldstein et al. (2000a), Hirao et al. (2004)), e-mails (Ulrich et al., 2008), and transcribed speech (Zechner, 2002). Lloret et al. (2013) take the top ten results from a regular web search engine as the source documents for their summaries, but do not specify the types of documents used. Therefore, it is unclear whether their data is heterogeneous or not. To the best of our knowledge, only Nakano et al. (2010) specifically use a collection of heteregeneous documents and discuss the corresponding challenges, such as subjectivity and contradictions.

Although the majority of the works presented in Table 1 mention guidelines for producing the summaries, most of them neither describe these guidelines in detail, nor divide the summarization process into clear-cut subtasks. Zechner (2002) gives descriptions for individual annotation tasks, but they are not necessarily subsequently applied. Additionally, their process is targeted towards the summarization of transcribed speech, which requires additional tasks, such as the annotation of topic boundaries, which are not necessary in thematically clustered document collections.

Lloret et al. (2013) use crowdsourcing and therefore the instructions are very limited. Their results show that summaries created via crowdsourcing are unsuitable for reference or gold standard summaries. Although the crowd authors are able to create summaries very quickly, if high-quality results are a priority, it is still advisable to employ trained annotators, despite the slower progress. Hirao et al. (2004) and Nakano et al. (2010) put an extraction task before the actual summarization, but there was no further division of the summarization process. They allow the editing of the text extracts without limitation, thus their summaries cannot be regarded as purely extractive. However, as they do neither provide any instructions on the summary creation process nor evaluate the coherence of the results, it is unknown whether their results are coherent summaries. Hirao et al. (2004) realize a three-step annotation process for producing summaries: (1) extracting important sentences, (2) minimizing redundant sentences, and (3) rewriting the result of the previous step in order to match the size constraint. Their goal is a summary that consists of a collection of informative sentences from the source text.

Another issue in the creation of summaries is coherence and cohesion. None of the methods mentioned above specifically addresses this. Although Zechner (2002, p. 456) states that the "overall goal [...] was to create a concise and readable summary", they do not specify how they reach the goal of coherent summaries. Neither Hirao et al. (2004) nor Zechner (2002) explicitly perform co-reference resolution, although the latter states that it would "certainly be desirable, for the sake of increased coherence and readability, to employ a well-working anaphora resolution component" (ibid., p. 451). Lloret et al. (2013, p. 346) observed that summaries based on crowdsourcing have a poor quality, as they "frequently present lost anaphoric and pronominal references". To our knowledge, none of the mentioned works address this issue in their evaluation.

2.2 Previous summary evaluation

Summaries are primarily evaluated intrinsically, either based on *qualitative* or *quantitative* measures. Early DUC evaluations (Over, 2001; Over and Liggett, 2002; Over and Yen, 2003) used Likert scales, which are psychometric response scales that are often used in questionnaires, for summary evaluation. This evaluation focuses on *qualitative* aspects of a summary. To perform a *quantitative* evaluation of the summaries, model units (Over and Liggett, 2002; Over and Yen, 2003) were used. These are manually annotated semantic units in human summaries, which are compared to automatic summaries according to the frequency of occurrence. Lloret et al. (2013) uses the overall quality for evaluation, based on a five-point Likert-type scale. Later on, Nenkova et al. (2007) introduced the Pyramid method. So-called *Summary Content Units (SCUs)*, which are semantically motivated, subsentential units, serve as the basis for the evaluation. They are variable in length, but not bigger than a sentential clause (Nenkova et al., 2007), and are closely related to model units. In both cases, system summaries are evaluated based on the content overlap rankings. A widely used *quantitative*, automatic evaluation metric is ROUGE (Lin, 2004), which has also been used to evaluate manual summaries, for instance, by Nakano et al. (2010), Lloret et al. (2013), and in DUC evaluations (up to 2007).

In our work, we focus on manual qualitative evaluation using various aspects of text quality, similar to

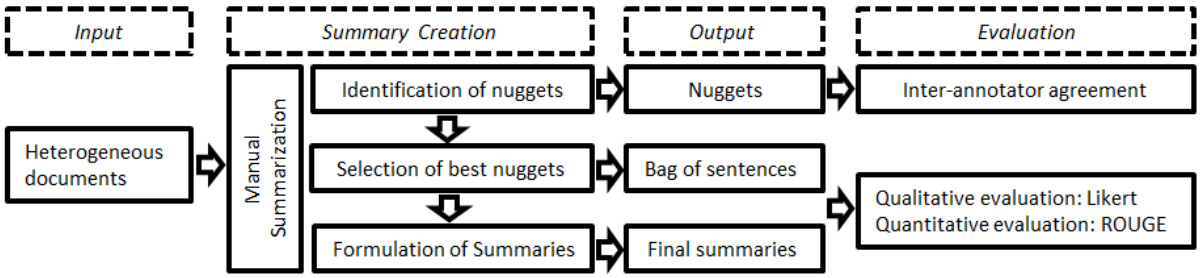

Figure 1: Process of creation and evaluation of coherent extracts and the intermediate processing steps.

the evaluation approach taken in the early DUC evaluations (Over, 2001; Over and Liggett, 2002; Over and Yen, 2003). More specifically, we focus on coherence in summary evaluation and statistically prove that this feature, which is very important for human understanding of text, has not only been neglected in the creation, but also in the evaluation process. In particular, we focus on coherence in our evaluation, which has previously been neglected in the creation process. Our results indicate that this feature is very important for human understanding and should therefore gain more importance.

3 Coherent Extracts

We propose *coherent extracts* as a new type of reference summary, bridging the gap between human-optimized abstracts and (automatic) extracts lacking coherence and fluency. Coherent extracts consist of important nuggets extracted from (multiple) source documents, which are meaningfully ordered and minimally redacted to ensure a coherent text that is close to a completely manually written text.

To substantiate this idea, we create a novel MDS corpus of coherent extracts, which we make freely available.[4] Figure 1 shows an overview of our corpus creation and evaluation procedure discussed in the remaining paper. First, we introduce the *Input* in form of the source document collection and topic selection procedure (Section 3.1). Our MDS process consists of three steps: In the first step the most important units are selected (so-called *Identification of Nuggets*). Next, the selected nuggets are clustered into groups with similar content and for each cluster the best nugget is selected (*Selection of best nuggets*). Finally, during the *Formulation of Summaries*, the best nuggets are co-reference resolved, grammaticalized and sorted coherently. Details for each step are given in Section 3.2 and in Meyer et al. (2016). In Section 4, we describe the *Evaluation* of our work using inter-annotator agreement measures, automatic summarization scoring with ROUGE, and human judgments based on Likert scales.

3.1 Heterogeneous Document Collection

Deutscher Bildungsserver[5] (DBS) is a large web portal that collects links to educational resources in German. As a publicly funded project, it fulfills an important information need of different stakeholders, including teachers, students, parents, politicians, and educational researchers. DBS contains links to highly heterogeneous text types, such as interviews, book reviews, teaching material, NGO profiles, newspaper and scientific articles. Although all topics focus on the educational domain, they vary enormously in terms of audience and specialized subject area (e.g., educational reforms, social impact, educational research, political decisions). Domain experts organize the links according to different topics, different audiences (teachers, students, parents, etc.) and strive for introducing each topic with a brief overview text. However, writing a manual overview for each topic is hardly feasible, as there are hundreds of topics, which are continuously updated by the editors. As we consider the processing of heterogeneous documents as a particularly important research challenge, the DBS makes an excellent basis and use case for research in automatic MDS of heterogeneous sources.

For our corpus, we select 10 topics from DBS and crawl their linked pages yielding between 4 and 14 documents per topic. Table 2 shows the properties of each topic and its documents. Our choice

Table 2: Overview of the topics, documents, genres, and summaries in our MDS corpus

of topic and document sizes is guided by the parameters of similar corpora (e.g., the DUC corpora) and by practical constraints of the DBS portal. The genre columns highlight the heterogeneity of the individual topics and the corpus overall. Although there is at least one news-like article in each topic, the source documents are highly heterogeneous, covering brief introductory texts, syllabi, term definitions, presentations of interest groups, and many other text genres.

Once we identify the source documents, we shorten those with more than 40 pages and topics with more than 30,000 tokens in order to reduce the annotation effort. We do not remove documents in order to conserve the full diversity of subtopics and genres. Conversely, we define a minimum of 3 documents and 1,500 tokens to ensure that there is enough information to summarize. We use the boilerplate removal tool by Habernal et al. (2016) to remove HTML markup and non-content (e.g., advertisement, navigation menu).

3.2 Creating Coherent Extracts

We divide the task of creating coherent extracts into three subsequent steps, which in turn consist of further substeps which we explain in an extensive, publicly available annotation guidebook. These detailed instructions ensure a reliable, reproducible annotation workflow and allow us to produce informative, non-redundant, grammatically correct coherent extracts.

Step 1: Identification of nuggets We first instruct the annotators to read each text *before* annotating, to ensure that they understand the full context of the topic. Afterwards, they identify important *nuggets* in the source documents. Our notion of nuggets includes a grammatical and a semantic constraint. The grammatical constraint is that a nugget has to contain at least one verb and one corresponding noun and can maximally span over one sentence. The minimum restriction is based on the assumption that this would facilitate the reformulation of nuggets to grammatically correct sentences as part of the third annotation step (see below). Our semantic constraint of nuggets is similar to previous work on *model units* (Over and Liggett, 2002), *factoids* (Halteren and Teufel, 2003), and *SCUs* (Nenkova et al., 2007) in that they should be important in the context of the given topic.

Step 2: Selection of best nuggets *Redundancy* is a more severe issue in MDS (Goldstein et al., 2000b; Goldstein et al., 2000a) compared to single-document summarization, as recurring facts are more likely to occur in multiple different documents about the same topic than within a single one. Thus, we ask the annotators to group the selected nuggets from step 1 if they "convey the same meaning using different wording" (Bhagat and Hovy, 2013, p. 463). For selecting the *best nugget* of a group, the annotators are required to prefer declarative, objective, and co-reference-free nuggets wherever possible.

Step 3: Formulation of summaries We divide the formulation of the coherent extract into several substeps: First, we ask the annotators to resolve co-references in the best nuggets in order to prevent references to context which are not part of any nugget. This is an important requirement for producing

coherent extracts, although it has been largely ignored in previous works.

Subsequently, the annotators reformulate the nuggets into full, grammatically correct sentences, which form the basis for our coherent extract. The annotators perform as few changes as necessary to prevent them from adding additional semantic content. Typical transformations are the introduction of function words or clarifying indirect speech (e.g., explicitly adding phrases, such as *"according to John Doe"*).

Once the best nuggets are transformed into grammatically correct sentences, the annotators order them in a meaningful way to structure the extract. Depending on the topic, annotators may choose a topic-based or argumentation-based information flow. Based on this structure, the annotators formulate the final extracts. They may add discourse connectives and conjunctions, such as *after*, *however*, or *as well as*. They may re-introduce co-references, if the referring object, person or event is available in the context, to create a fluent and readable text that closely resembles manually written texts. We do not restrict the length of the resulting summaries.

Annotation It is important to note that each annotation step builds upon the results of the previous steps (e.g., the structuring of the sentences builds upon the set of reformulated best nuggets). To implement this annotation setup, we use the MDS*Writer* tool recently introduced by Meyer et al. (2016).

Our annotation team consists of four German native speakers, who are graduate students in linguistics or computational linguistics. We trained the annotators using two smaller topics with 2 and 5 documents. For the actual corpus creation, we assign at least two annotators to each topic and we instruct them to finish all annotation steps of a specific topic before moving to the next one.

Final Corpus Our final corpus consists of 92 input documents with over 61,000 tokens and 33 multi-document summaries with over 18,000 tokens (566 per summary on average). As we did not restrict the length of the summaries, their texts range from 6 to 127 sentences and from 173 to 2,494 tokens. The average token compression rate is 12.2 %. During the summarization process, the annotators identify between 15 and 228 nuggets per topic (48 on average, 1,596 in total), which they process in the later steps in order to remove redundancy and co-references, formulate complete sentences and ultimately the coherent extracts. Our corpus is freely available from our GitHub project page (`https://github.com/AIPHES/DBS`).

4 Evaluation

We evaluate our corpus creation procedure in three experiments: In Section 4.1, we measure the inter-annotator agreement to assess the quality of the identification of nuggets. In Section 4.2, we conduct a quantitative evaluation of our coherent extracts in comparison to bag-of-sentence-based and automatically created summaries using ROUGE. In Section 4.3, we present results on a qualitative evaluation of the three summary types using a range of quality criteria judged on a five-point Likert scale. Finally, Section 4.4 compares the results of the qualitative analysis with the results from the quantitative analysis.

4.1 Inter-Annotator Agreement of the Nugget Identification Step

To ensure the reproducibility of our corpus creation procedure, we first assess how well the annotators agree on the results of the nugget identification step. The agreement scores reveal to what extent the annotation experiment can be repeated with different annotators or data. Furthermore, they yield insight into the degree of subjectivity of the task. Besides the average proportion of observed agreement (A_{O}) of nuggets jointly identified by two annotators, we use the standard metrics from content analysis, namely Fleiss' κ and Krippendorff's α, as defined by Artstein and Poesio (2008).

We first model the nugget identification step as a coding task (i.e., assigning categories to predefined units) by aggregating each annotator's nuggets to the levels of sentences and paragraphs. That is, a sentence or paragraph is considered important, if it contains at least one nugget. This setup allows us to compute the usual A_{O}, κ and α agreement scores. Although κ has been used in some previous works, it is not well-suited for this setup, as it has no explicit notion of missing values. Rather, it assumes that all annotators processed the entire corpus, which is neither true for our work nor for many other previous

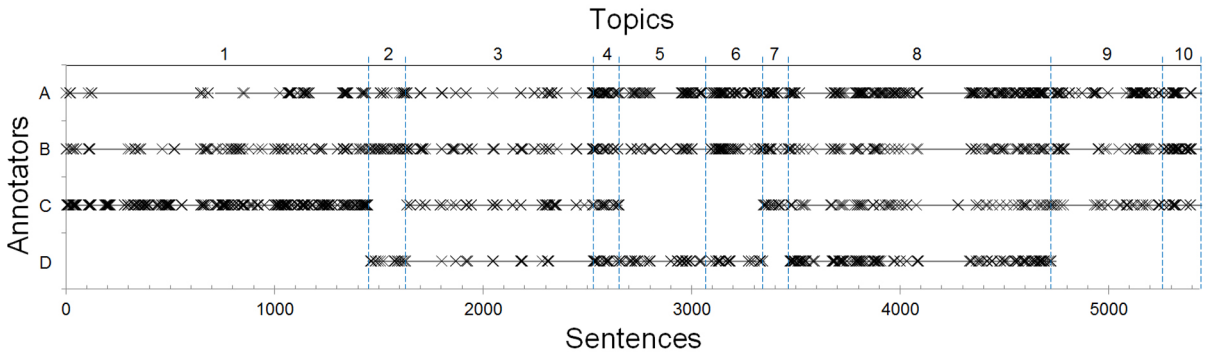

Figure 2: Plot marking all sentences, in which an annotator identified at least one nugget

works, such as Zechner (2002). We therefore recommend to always report Krippendorff's α as well, which uses a similar scale, but explicitly deals with missing annotations.

Since our nugget identification procedure is not limited to selecting entire sentences but to mark spans of varying lengths starting at arbitrary positions, we also model the nugget identification step as a unitizing task (i.e., finding the margins of the unit to be annotated) in order to take the inter-annotator agreement on the nugget boundaries into consideration. Krippendorff's α_{U} is a suitable metric for such setups (Krippendorff, 1995), as it uses the same scale as the regular α and therefore allows for comparison. All measures were calculated using DKPro Statistics (Meyer et al., 2014).[6]

Figure 2 illustrates the resulting annotation. Every $\times$ marks a sentence (bottom x-axis; pooled over all topics indicated by the top x-axis) containing at least one nugget as annotated by one of the four annotators (y-axis). The gray line indicates sentences, which do not contain any nugget, although they have been assigned to a particular annotator. Empty space thus counts towards the missing values mentioned above – i.e., sentences that have not been assigned to the corresponding annotator. The plot shows that the annotators largely vary in the number of nuggets they consider important: Annotator C identified more nuggets in the sentences with low index, while annotator A more extensively marked nuggets in sentences with higher index (Note that the annotators did not perform the task strictly in order of this sentence index). When zooming in, we can observe a fair overlap of sentences considered important or unimportant by a majority of annotators, despite the fact that annotators rarely fully agree on what is important. There are, however, sentences that are very consistently considered unimportant for writing a summary, for example, in topic 8 around sentence index 4200, which is a scientific article about reading with overly detailed information and a list of references.

Table 3 shows the inter-annotator agreement scores in the coding and unitizing setups. Our annotators agree that 85 % of the sentences either contain an important nugget or are not important at all. This is substantially higher than the 56–62 % reported by Goldstein et al. (2000a) and in line with what could be observed in Figure 2. Although agreement scores for nugget identification are rarely reported, we find that our κ score of 0.23 exceeds the $\kappa = 0.13$ reported by Zechner (2002). It is not surprising to find rather low overall κ and α scores, since judging importance is known to be a subjective task. Additionally, we face a highly skewed class distribution between important and unimportant sentences. Disagreement on the smaller class has a high impact on the final κ and α scores. For the unitizing setup, the discrepancy between observed agreement and statistically corrected agreement becomes extreme: Given the large parts of the documents for which no annotator identified a nugget, the observed unitizing disagreement is only 1 %, whereas α_{U} is only 0.19. Comparing α and α_{U} is highly interesting, because the small difference indicates that the annotators mostly agree on a nugget's boundaries. The main decision is therefore *what* to judge as important, not the specific nugget boundaries.

Table 3 also shows the inter-annotator agreement scores individually for each topic. We find a higher agreement for topics with less sentences and tokens (e.g., topic 4), where the annotators mostly agree on the important nuggets. Instead, we observe much lower agreement scores for large topics, in which

B	0.29	—	0.15	0.22
C	0.18	0.15	—	0.05
D	0.24	0.22	0.05	—

Table 4: Pairwise inter-annotator agreement using sentence-based α (left) and nugget-based α_U (right)

the annotators put different foci or in which they identified an overly high or low number of nuggets. Especially for topic 1, the α_U drops extremely, because of the different number of identified nuggets: 49 by annotator A, 76 by B, and 228 by C. Moreover, we find that the specificity of the topic has a large impact on the inter-annotator agreement. Broad topics such as *Reading* (topic 8) tend to have lower agreement than specific topics (e.g., topic 5, *Reform of the dual education system*) with a very clear focus.

In Table 4, we additionally assessed the agreement for each pair of annotators individually. We find the sentence-based α to range from 0.14 to 0.28 and the nugget-based α_U to range from 0.05 to 0.29 across the annotator pairs. Annotator C achieved consistently lower agreement with the others. When looking into the data, we note that this annotator persistently chose more nuggets per topic (58 on average) than the other annotators (45 on average). The qualitative evaluation of the annotator's coherent extracts revealed high quality. Given that our agreement figures are clearly higher than reported for previous corpora, we consider our identified nuggets reliable and our procedure reproducible. However, we also note that the identification of important nuggets is a fairly subjective task. Thus, producing *at least* 3 reference summaries is essential to cover the different notions of what is important.

4.2 Quantitative Evaluation

Quantitative evaluations based on ROUGE have been used both for the evaluation of automatic systems (e.g., in the context of DUC) and for manual summaries, for instance by Nakano et al. (2010) and Lloret et al. (2013). In our evaluation, we compare results on three different summary types: First, we create automatic summaries using various standard summarization methods, including TextRank (Mihalcea and Tarau, 2004), LexRank (Erkan and Radev, 2004), and LSA (Steinberger and Ježek, 2004) as implemented in the SUMY[7] tool.[8] Second, we use *bag of sentences (BoS)*, which are an intermediate result of our manual summarization process, namely the reformulated best nuggets (see Section 3.2). These BoS essentially correspond to purely extractive MDS summaries, as they contain full sentences, which then serve as the basis for coherent extracts. They are already ordered in a meaningful way and annotators are required to not add content, but to only add (for example) connectives in order to create a coherent text (see Section 3.2 for details).[9] Third, we use the coherent extracts, which are the final results of our summarization process. In order to evaluate automatic summaries and BoS we use the manual summaries as references. For the manual summaries, we take individual manual summaries and use the remaining

[7] `https://github.com/miso-belica/sumy`

[8] We used standard settings, except for the length, which we wanted to keep comparable across all summary types.

[9] Examples for the various summary types (automatic, BoS and manual) are available for download.

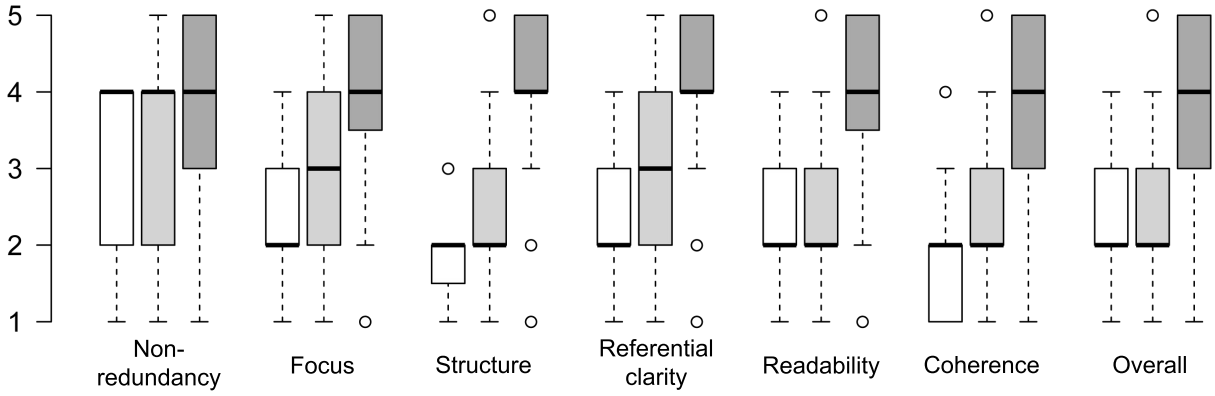

Figure 3: Boxplot of our qualitative judgments of automatic summarization systems (white), bags of sentences (light gray), and coherent extracts (dark gray)

manual summaries as references. The motivation for the latter step is to gain an intuition about the upper bound for the ROUGE scores, but also about the deviation based on individual differences.

We compute the ROUGE-1 recall metric (R-1) for each summary of the three types, in which we use the coherent extracts as peers. For BoS and coherent extracts, we remove the summary of the same author from the set of peers. Our coherent extracts achieve R-1 = 0.42, which is very similar to the R-1 = 0.43 reported by Nakano et al. (2010), but considerably higher than the R-1 = 0.35 discussed by Lloret et al. (2013) for their crowdsourcing setup. BoS achieve the best results with R-1 = 0.49, followed by the coherent extracts (R-1 = 0.42) and then the automatic summaries ($0.32 \leq$ R-1 ≤ 0.35). The scores of automatic methods are comparable to Lloret et al. (2013), but significantly lower than the BoS of coherent extracts. BoS, which are the basis for the coherent extracts, achieve the best results, as they vary less. For the coherent extracts, we asked our annotators to minimally revise the text for readability, fluency, and coherence, which causes a slightly lower n-gram overlap and thus lower R-1 score.

4.3 Qualitative Evaluation

We complement our ROUGE-based evaluation by manually rating the three different summary types on a five-point Likert scale. Our quality criteria are based on early DUC evaluations, but slightly extended for our purposes: We judge *non-redundancy*, *focus*, *structure*, *referential clarity*, *readability*, *coherence*, *length*, *grammaticality*, *spelling*, *layout*, and *overall quality* for 25 automatically produced summaries (as introduced in the previous section) and 16 BoS and coherent extracts from our corpus. We asked six human raters, of mixed gender and age, with different academic degrees in linguistics or computational linguistics, to participate in the evaluation. To prevent a bias, we randomly shuffled the summaries, such that the participants did not know how a summary was created.

Figure 3 shows a boxplot of the average scores for each summary type according to the seven most relevant quality criteria. *Non-redundancy* achieves good results across all summary types. This means that the automatic approaches as well as the two manual approaches (BoS and coherent extracts) manage to compile a mostly redundancy-free summary. However, both automatic approaches and the BoS-based approach fail to achieve high ratings for the other six quality criteria. The criteria *structure* and *readability* vary the most with coherent extracts achieving significantly higher scores than automatic summaries and BoS. *Referential clarity* is – at least for the manual summaries – the most consistently marked evaluation criterion. Additionally, we see that both BoS and automatic methods achieve considerably lower results than the coherent extracts. Especially for the automatic methods, the distribution of values is broadest, whereas for the BoS the distribution is more even. For *focus*, *structure*, and *referential clarity*, we observe a clear pattern with the lowest scores for automatic summaries, slightly better results for BoS, and the best scores for our coherent extracts. In terms of *readability* and *coherence*, both BoS and automatic summaries have similarly low scores, whereas the coherent extracts clearly achieve adequate results. The *overall* score reflects the results on individual quality criteria, in that automatic methods achieve the lowest scores, BoS are slightly better and coherent extracts are by far the best.

4.4 Discussion

Comparing the qualitative and the quantitative evaluation results, we find substantial differences between the automatic summaries, BoS, and coherent extracts. According to ROUGE, the BoS are better than coherent extracts, whereas the manual judgments suggest the opposite. This indicates that even high-quality, redundancy-free BoS with reasonable ROUGE scores are still not good enough to provide reasonable summaries for humans, as they lack in coherence, structure, and focus. We compute the correlation between ROUGE and all criteria judged by human raters, but no rater showed significant results, except for one. This annotator achieved very high scores on the qualitative evaluation, which also shows a significant correlation with ROUGE. It has been shown in the past by Liu and Liu (2010) that ROUGE does not reflect human judgements. Our results support this. But in addition, we show that: (a) BoS as mostly produced by automatic systems are not considered high-quality by humans, (b) although they do achieve very good ROUGE scores and (c) that quality criteria such as *coherence* and *structure*, which are important factors in human judgements, are not covered by a state-of-the-art ROUGE-based evaluation.

The coherent extracts we propose, take these quality criteria into account, as they achieve overall high scores in the manual evaluation. At the same time, they are not restricted to a ROUGE-based evaluation as is the case for abstractive summaries. Rather they allow for evaluating the identification of nuggets (i.e., content selection), redundancy removal, and the formulation of a coherent and fluent summary separately using the intermediate results collected during our corpus creation process. We render this highly important for taking extractive summarization methods to the next level.

5 Conclusion and Further Work

We introduced coherent extracts as a novel type of summary and presented a corresponding MDS corpus based on heterogeneous sources from the educational domain. To compile this corpus, we defined a workflow addressing the identification of important nuggets, the removal of redundancy, and the formulation of a coherent text in separate steps. For each step, we collect the individual results, which allows us to evaluate the corpus creation steps individually as well as their overall quality. We used inter-annotator agreement measures and ROUGE to quantitatively analyze the corpus and we relied on the human judgments for 11 quality criteria on a five-point Likert scale to assess the quality of our corpus and the value of coherent extracts. Our results show that ROUGE overestimates the quality of purely extractive summaries, which especially lack coherence, readability, and structure.

At the same time, our corpus provides data for evaluating automatic MDS systems beyond the typical ROUGE-based setup, because we have an explicit notion of important elements in the input documents and we can trace which sentence of the summary belongs to which source document. Though the latter is also possible with purely extractive summaries, they are not well-suited for human use and thus yield a rather artificial evaluation setup. At the same time, our detailed workflow allows researchers working on MDS systems to reconstruct how humans go beyond mere BoS-type summaries and incorporate this into automatic systems and evaluate the resulting quality. To this end, coherent extracts bridge an important gap between fluent, but difficult-to-evaluate abstracts and low-quality extracts lacking coherence and structure.

In future work, we plan to increase the size of the corpus, such that we can investigate the effects of certain summarizers, topics, genres, or even multiple languages. To complement our human judgments, we also consider to use the Pyramid method (Nenkova et al., 2007) in order to understand different means of summary evaluation for MDS of heterogeneous document collections. Furthermore, we plan to enrich our corpus with abstractive multi-document summaries written by experts. On the one hand this would give us the possibility to compute a qualitative comparison with the new kind of summary described in this paper, on the other hand it would provide data for more accurate evaluation and training.

Acknowledgments

This work has been supported by the DFG-funded research training group "Adaptive Preparation of Information from Heterogeneous Sources" (AIPHES, GRK 1994/1). We would like to thank our annotators for their valuable contribution.

Abstract

Chinese poetry generation is a very challenging task in natural language processing. In this paper, we propose a novel two-stage poetry generating method which first plans the sub-topics of the poem according to the user's writing intent, and then generates each line of the poem sequentially, using a modified recurrent neural network encoder-decoder framework. The proposed planning-based method can ensure that the generated poem is coherent and semantically consistent with the user's intent. A comprehensive evaluation with human judgments demonstrates that our proposed approach outperforms the state-of-the-art poetry generating methods and the poem quality is somehow comparable to human poets.

1 Introduction

The classical Chinese poetry is a great and important heritage of Chinese culture. During the history of more than two thousand years, millions of beautiful poems are written to praise heroic characters, beautiful scenery, love, friendship, etc. There are different kinds of Chinese classical poetry, such as Tang poetry and Song iambics. Each type of poetry has to follow some specific structural, rhythmical and tonal patterns. Table 1 shows an example of quatrain which was one of the most popular genres of poetry in China. The principles of a quatrain include: The poem consists of four lines and each line has five or seven characters; every character has a particular tone, Ping (the level tone) or Ze (the downward tone); the last character of the second and last line in a quatrain must belong to the same rhyme category (Wang, 2002). With such strict restrictions, the well-written quatrain is full of rhythmic beauty.

In recent years, the research of automatic poetry generation has received great attention. Most approaches employ rules or templates (Tosa et al., 2008; Wu et al., 2009; Netzer et al., 2009; Oliveira, 2009; Oliveira, 2012), genetic algorithms (Manurung, 2004; Zhou et al., 2010; Manurung et al., 2012), summarization methods (Yan et al., 2013) and statistical machine translation methods (Jiang and Zhou, 2008; He et al., 2012) to generate poems. More recently, deep learning methods have emerged as a promising discipline, which considers the poetry generation as a sequence-to-sequence generation problem (Zhang and Lapata, 2014; Wang et al., 2016; Yi et al., 2016). These methods usually generate the first line by selecting one line from the dataset of poems according to the user's writing intents (usually a set of keywords), and the other three lines are generated based on the first line and the previous lines. The user's writing intent can only affect the first line, and the rest three lines may have no association with the main topic of the poem, which may lead to semantic inconsistency when generating poems. In addition, topics of poems are usually represented by the words from the collected poems in the training corpus. But as we know, the words used in poems, especially poems written in ancient time, are different from modern languages. As a consequence, the existing methods may fail to generate meaningful poems if a user wants to write a poem for a modern term (e.g., Barack Obama).

In this paper, we propose a novel poetry generating method which generates poems in a two-stage procedure: the contents of poems ("what to say") are first explicitly planned, and then surface realization ("how to say") is conducted. Given a user's writing intent which can be a set of keywords, a sentence or

even a document described by natural language, the first step is to determine a sequence of sub-topics for the poem using a poem planning model, with each line represented by a sub-topic. The poem planning model decomposes the user's writing intent into a series of sub-topics, and each sub-topic is related to the main topic and represents an aspect of the writing intent. Then the poem is generated line by line, and each line is generated according to the corresponding sub-topic and the preceding generated lines, using a recurrent neural network based encoder-decoder model (RNN enc-dec). We modify the RNN enc-dec framework to support encoding of both sub-topics and the preceding lines. The planning based mechanism has two advantages compared to the previous methods. First, every line of the generated poem has a closer connection to user's writing intent. Second, the poem planning model can learn from extra knowledge source besides the poem data, such as large-scale web data or knowledge extracted from encyclopedias. As a consequence, it can bridge the modern concepts and the set of words covered by ancient poems. Take the term "Barack Obama" as the example: using the knowledge from encyclopedias, the poem planning model can extend the user's query, Barack Obama, to a series of sub-topics such as outstanding, power, etc., therefore ensuring semantic consistency in the generated poems.

The contribution of this paper is two-fold. First, we propose a planning-based poetry generating framework, which explicitly plans the sub-topic of each line. Second, we use a modified RNN encoder-decoder framework, which supports encoding of both sub-topics and the preceding lines, to generate the poem line by line.

The rest of this paper is organized as follows. Section 2 describes some previous work on poetry generation and compares our work with previous methods. Section 3 describes our planning based poetry generation framework. We introduce the datasets and experimental results in Section 4. Section 5 concludes the paper.

2 Related Work

Poetry generation is a challenging task in NLP. Oliveira (2009; 2012) proposed a Spanish poem generation method based on semantic and grammar templates. Netzer et al. (2009) employed a method based on word association measures. Tosa et al. (2008) and Wu et al. (2009) used a phrase search approach for Japanese poem generation. Greene et al. (2010) applied statistical methods to analyze, generate and translate rhythmic poetry. Colton et al. (2012) described a corpus-based poetry generation system that uses templates to construct poems according to the given constrains. Yan et al. (2013) considered the poetry generation as an optimization problem based on a summarization framework with several constraints. Manurung (2004; 2012) and Zhou et al. (2010) used genetic algorithms for generating poems. An important approach to poem generation is based on statistical machine translation (SMT). Jiang and Zhou (2008) used an SMT-based model in generating Chinese couplets which can be regarded as simplified regulated verses with only two lines. The first line is regarded as the source language and translated into the second line. He et al. (2012) extended this method to generate quatrains by translating the previous line to the next line sequentially.

Recently, deep learning methods achieve great success in poem generation. Zhang and Lapata (2014) proposed a quatrain generation model based on recurrent neural network (RNN). The approach generates the first line from the given keywords with a recurrent neural network language model (RNNLM) (Mikolov et al., 2010) and then the subsequent lines are generated sequentially by accumulating the status of the lines that have been generated so far. Wang et al. (2016) generated the Chinese Song iambics using an end-to-end neural machine translation model. The iambic is generated by translating the pre-

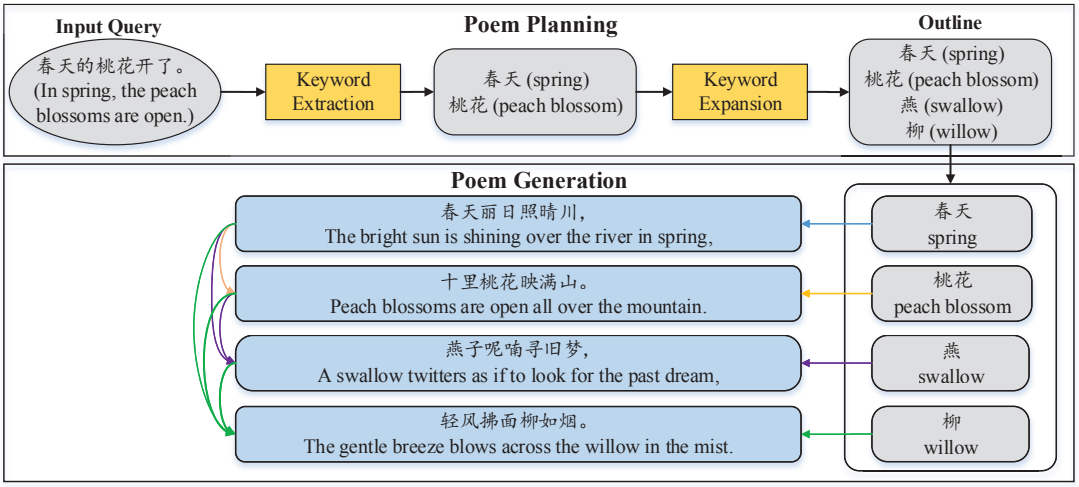

Figure 1: Illustration of the planning based poetry generation framework.

vious line into the next line sequentially. This procedure is similar to SMT, but the semantic relevance between sentences is better. Wang et al. (2016) did not consider the generation of the first line. Therefore, the first line is provided by users and must be a well-written sentence of the poem. Yi et al. (2016) extended this approach to generate Chinese quatrains. The problem of generating the first line is resolved by a separate neural machine translation (NMT) model which takes one keyword as input and translates it into the first line. Marjan Ghazvininejad and Knight (2016) proposed a poetry generation algorithm that first generates the rhyme words related to the given keyword and then generated the whole poem according to the rhyme words with an encoder-decoder model (Sutskever et al., 2014).

Our work differs from the previous methods as follows. First, we don't constrain the user's input. It can be some keywords, phrases, sentences or even documents. The previous methods can only support some keywords or must provide the first line. Second, we use planning-based method to determine the topic of the poem according to the user's input, with each line having one specific sub-topic, which guarantees that the generated poem is coherent and well organized, therefore avoiding the problem of the previous method that only the first line is guaranteed to be related to the user's intent while the next lines may be irrelevant with the intention due to the coherent decay problem (He et al., 2012; Zhang and Lapata, 2014; Wang et al., 2016; Yi et al., 2016). Third, the rhythm or tone in (Zhou et al., 2010; Yan et al., 2013; Zhang and Lapata, 2014; Yi et al., 2016; Marjan Ghazvininejad and Knight, 2016) is controlled by rules or extra structures, while our model can automatically learn constrains from the training corpus. Finally, our poem generation model has a simpler structure compared with those in (Zhang and Lapata, 2014; Yi et al., 2016).

3 Approaches

3.1 Overview

Inspired by the observation that a human poet shall make an outline first before writing a poem, we propose a planning-based poetry generation approach (PPG) that first generates an outline according to the user's writing intent and then generates the poem. Our PPG system takes user's writing intent as input which can be a word, a sentence or a document, and then generates a poem in two stages: Poem Planning and Poem Generation. The two-stage procedure of PPG is illustrated in Figure 1.

Suppose we are writing a poem that consists of N lines with l_i representing the i-th line of the poem. In the Poem Planning stage, the input query is transformed into N keywords $(k_1, k_2, ..., k_N)$, where k_i is the i-th keyword that represents the sub-topic for the i-th line. In the Poem Generation stage, l_i is generated by taking k_i and $l_{1:i-1}$ as input, where $l_{1:i-1}$ is a sequence concatenated by all the lines generated previously, from l_1 to l_{i-1}. Then the poem can be generated sequentially, and each line is

generated according to one sub-topic and all the preceding lines.

3.2 Poem Planning

3.2.1 Keyword Extraction

The user's input writing intent can be represented as a sequence of words. There is an assumption in the Poem Planning stage that the number of keywords extracted from the input query Q must be equal to the number of lines N in the poem, which can ensure each line takes just one keyword as the sub-topic. If the user's input query Q is too long, we need to extract the most important N words and keep the original order as the keywords sequence to satisfy the requirement.

We use TextRank algorithm (Mihalcea and Tarau, 2004) to evaluate the importance of words. It is a graph-based ranking algorithm based on PageRank (Brin and Page, 1998). Each candidate word is represented by a vertex in the graph and edges are added between two words according to their co-occurrence; the edge weight is set according to the total count of co-occurrence strength of the two words. The TextRank score $S(V_i)$ is initialized to a default value (e.g. 1.0) and computed iteratively until convergence according to the following equation:

$$S(V_i) = (1-d) + d \sum_{V_j \in E(V_i)} \frac{w_{ji}}{\sum_{V_k \in E(V_j)} w_{jk}} S(V_j), \tag{1}$$

where w_{ij} is the weight of the edge between node V_j and V_i, $E(V_i)$ is the set of vertices connected with V_i, and d is a damping factor that usually set to 0.85 (Brin and Page, 1998), and the initial score of $S(V_i)$ is set to 1.0.

3.2.2 Keyword Expansion

If the user's input query Q is too short to extract enough keywords, we need to expand some new keywords until the requirement of keywords number is satisfied. We use two different methods for keywords expansion.

RNNLM-based method. We use a Recurrent Neural Network Language Model (RNNLM) (Mikolov et al., 2010) to predict the subsequent keywords according to the preceding sequence of keywords: $k_i = \arg\max_k P(k|k_{1:i-1})$, where k_i is the i-th keyword and $k_{1:i-1}$ is the preceding keywords sequence.

The training of RNNLM needs a training set consisting of keyword sequences extracted from poems, with one keyword representing the sub-topic of one line. We automatically generate the training corpus from the collected poems. Specifically, given a poem consisting of N lines, we first rank the words in each line according to the TextRank scores computed on the poem corpus. Then the word with the highest TextRank score is selected as the keyword for the line. In this way, we can extract a keyword sequence for every poem, and generate a training corpus for the RNNLM based keywords predicting model.

Knowledge-based method. The above RNNLM-based method is only suitable for generating sub-topics for those covering by the collected poems. This method does not work when the user's query contains out-of-domain keywords, for example, a named entity not covered by the training corpus.

To solve this problem, we propose a knowledge-based method that employs extra sources of knowledge to generate sub-topics. The extra knowledge sources can be used include encyclopedias, suggestions of search engines, lexical databases (e.g. WordNet), etc. Given a keyword k_i, the key idea of the method is to find some words that can best describe or interpret k_i. In this paper, we use the encyclopedia entries as the source of knowledge to expand new keywords from k_i. We retrieve those satisfying all the following conditions as candidate keywords: (1) the word is in the window of $[-5, 5]$ around k_i; (2) the part-of-speech of the word is adjective or noun; (3) the word is covered by the vocabulary of the poem corpus. Then the candidate words with the highest TextRank score are selected as the keywords.

3.3 Poem Generation

In the Poem Generation stage, the poem is generated line by line. Each line is generated by taking the keyword specified by the Poem Planning model and all the preceding text as input. This procedure can be

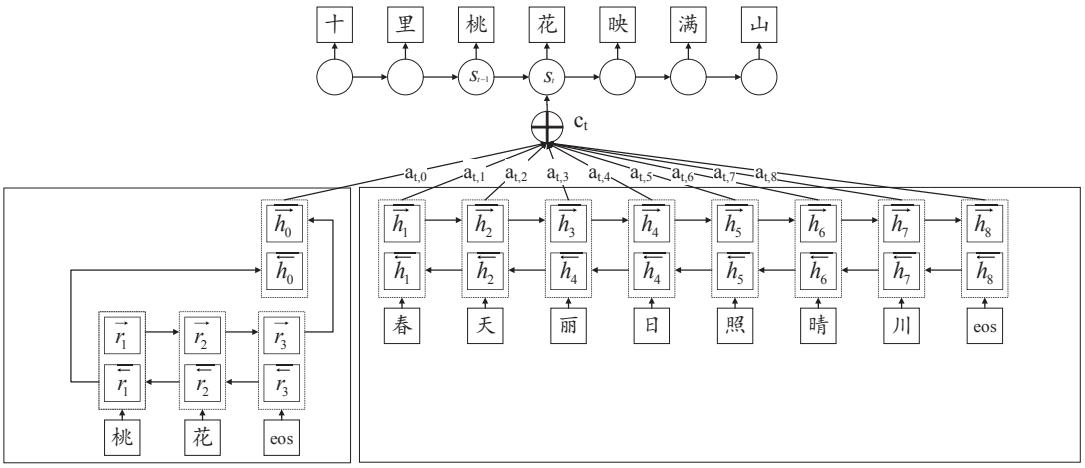

Figure 2: An illustration of poem generation model.

considered as a sequence-to-sequence mapping problem with a slight difference that the input consists of two different kinds of sequences: the keyword specified by the Poem Planning model and the previously generated text of the poem. We modify the framework of an attention based RNN encoder-decoder (RNN enc-dec) (Bahdanau et al., 2014) to support multiple sequences as input.

Given a keyword $\mathbf{k}$ which has T_k characters, i.e. $\mathbf{k} = \{a_1, a_2, ..., a_{T_k}\}$, and the preceding text $\mathbf{x}$ which has T_x characters, i.e. $\mathbf{x} = \{x_1, x_2, ..., x_{T_x}\}$, we first encode $\mathbf{k}$ into a sequence of hidden states $[r_1 : r_{T_k}]$, and $\mathbf{x}$ into $[h_1 : h_{T_x}]$, with bi-directional Gated Recurrent Unit (GRU) (Cho et al., 2014) models. Then we integrate $[r_1 : r_{T_k}]$ into a vector r_c by concatenating the last forward state and the first backward state of $[r_1 : r_{T_k}]$, where

$$r_c = \begin{bmatrix} \overrightarrow{r_{T_k}} \\ \overleftarrow{r_1} \end{bmatrix}. \tag{2}$$

We set $h_0 = r_c$, then the sequence of vectors $\mathbf{h} = [h_0 : h_{T_x}]$ represents the semantics of both $\mathbf{k}$ and $\mathbf{x}$, as illustrated in Figure 2. Notice that when we are generating the first line, the length of the preceding text is zero, i.e. $T_x = 0$, then the vector sequence $\mathbf{h}$ only contains one vector, i.e. $\mathbf{h} = [h_0]$, therefore, the first line is actually generated from the first keyword.

For the decoder, we use another GRU which maintains an internal status vector s_t, and for each generation step t, the most probable output y_t is generated based on s_t, context vector c_t and previous generated output y_{t-1}. This can be formulated as follows:

$$y_t = \arg\max_y P(y|s_t, c_t, y_{t-1}). \tag{3}$$

After each prediction, s_t is updated by

$$s_t = f(s_{t-1}, c_{t-1}, y_{t-1}). \tag{4}$$

$f(\cdot)$ is an activation function of GRU and c_t is recomputed at each step by the alignment model:

$$c_t = \sum_{j=1}^{T_h} a_{tj} h_j. \tag{5}$$

h_j is the j-th hidden state in the encoder's output. The weight a_{tj} is computed by

$$a_{tj} = \frac{\exp(e_{tj})}{\sum_{k=1}^{T_h} \exp(e_{tk})}, \tag{6}$$

where

$$e_{tj} = v_a^T \tanh(W_a s_{t-1} + U_a h_j). \tag{7}$$

e_{tj} is the attention score on h_j at time step t. The probability of the next word y_t can be defined as:

$$P(y_t|y_1, ..., y_{t-1}, \mathbf{x}, \mathbf{k}) = g(s_t, y_{t-1}, c_t), \tag{8}$$

where $g(\cdot)$ is a nonlinear function that outputs the probability of y_t.

The parameters of the poem generation model are trained to maximize the log-likelihood of the training corpus:

$$\arg\max \sum_{n=1}^{N} logP(\mathbf{y_n}|\mathbf{x_n}, \mathbf{k_n}). \tag{9}$$

4 Experiments

4.1 Dataset

In this paper, we focus on the generation of Chinese quatrain which has 4 lines and each line has the same length of 5 or 7 characters. We collected 76,859 quatrains from the Internet and randomly chose 2,000 poems for validation, 2,000 poems for testing, and the rest for training.

All the poems in the training set are first segmented into words using a CRF based word segmentation system. Then we calculate the TextRank score for every word. The word with the highest TextRank score is selected as the keyword for the line. In this way, we can extract a sequence of 4 keywords for every quatrain. From the training corpus of poems, we extracted 72,859 keyword sequences, which is used to train the RNN language model for keyword expansion (see section 3.2.2). For knowledge-based expansion, we use Baidu Baike[1] and Wikipedia as the extra sources of knowledge.

After extracting four keywords from the lines of a quatrain, we generate four triples composed of (the keyword, the preceding text, the current line), for every poem. Take the poem in Table 1 as example, the generated triples are shown in Table 2. All the triples are used for training the RNN enc-dec model proposed in section 3.3.

Keyword	The Preceding Text	Current Line
床	–	床前明月光
霜	床前明月光	疑是地上霜
明月	床前明月光; 疑是地上霜	举头望明月
故乡	床前明月光; 疑是地上霜; 举头望明月	低头思故乡

Table 2: Training triples extracted from the quatrain in Table 1.

4.2 Training

For the proposed attention based RNN enc-dec model, we chose the 6,000 most frequently used characters as the vocabulary for both source and target sides. The word embedding dimensionality is 512 and initialized by word2vec (Mikolov et al., 2013). The recurrent hidden layers of the decoder and two encoders contained 512 hidden units. Parameters of our model were randomly initialized over a uniform distribution with support [-0.08,0.08]. The model was trained with the AdaDelta algorithm (Zeiler, 2012), where the minibatch was set to be 128. The final model is selected according to the perplexity on the validation set.

4.3 Evaluation

4.3.1 Evaluation Metrics

It is well known that accurate evaluation of text generation system is difficult, such as the poetry generation and dialog response generation (Zhang and Lapata, 2014; Schatzmann et al., 2005; Mou et al., 2016). There are thousands of ways to generate an appropriate and relative poem or dialog response given a specific topic, the limited references are impossible to cover all the correct results. Liu et al. (2016) has recently shown that the overlap-based automatic evaluation metrics adapted for dialog responses, such

[1] A collaborative online encyclopedia provided by Chinese search engine Baidu: `http://baike.baidu.com`.

Poeticness	Does the poem follow the rhyme and tone requirements ?
Fluency	Does the poem read smoothly and fluently?
Coherence	Is the poem coherent across lines?
Meaning	Does the poem have a certain meaning and artistic conception?

Table 3: Evaluation standards in human judgement.

Models	**Poeticness**		**Fluency**		**Coherence**		**Meaning**		**Average**	
	5-char	**7-char**	**5-char**	**7-char**	**5-char**	**7-char**	**5-char**	**7-char**	**5-char**	**7-char**
SMT	3.25	3.22	2.81	2.48	3.01	3.16	2.78	2.45	2.96	2.83
RNNLM	2.67	2.55	3.13	3.42	3.21	3.44	2.90	3.08	2.98	3.12
RNNPG	3.85	3.52	3.61	3.02	3.43	3.25	3.22	2.68	3.53	3.12
ANMT	**4.34**	4.04	**4.61**	4.45	4.05	4.01	4.09	4.04	4.27	4.14
PPG	4.11	**4.15**	4.58	**4.56***	**4.29***	**4.49****	**4.46****	**4.51****	**4.36****	**4.43****

Table 4: Human evaluation results of all the systems. Diacritics ** ($p < 0.01$) and * ($p < 0.05$) indicate that our model (PPG) is significantly better than all other systems.

as BLEU and METEOR, have little correlation with human evaluation. Therefore, we carry out a human study to evaluate the poem generation models. Following (He et al., 2012; Yan et al., 2013; Zhang and Lapata, 2014), we use four evaluation standards for human evaluators to judge the poems: "Poeticness", "Fluency", "Coherence", "Meaning". The detailed illustration can be seen in Table 3. The score of each aspect ranges from 1 to 5 with the higher score the better. Each system generates twenty 5-character quatrains and twenty 7-character quatrains. All the generated poems are evaluated by 5 experts and the rating scores are averaged as the final score.

4.3.2 Baselines

We implemented several poetry generation methods as baselines and employed the same pre-processing method for all the methods.

SMT. A Chinese poetry generation method based on Statistical Machine Translation (He et al., 2012). A poem is generated iteratively by "translating" the previous line into the next line.

RNNLM. A method for generating textual sequences (Graves, 2013), which is proposed by Mikolov et al. (2010). The lines of a poem are concatenated together as a character sequence which is used to train the RNNLM.

RNNPG. In the approach of RNN-based Poem Generator (Zhang and Lapata, 2014), the first line is generated by a standard RNNLM and then all the other lines are generated iteratively based on a context vector encoded from the previous lines.

ANMT. The Attention based Neural Machine Translation method. It considers the problem as a machine translation task, which is similar to the traditional SMT approach. The main difference is that in ANMT, the machine translation system is a standard attention based RNN enc-dec framework (Bahdanau et al., 2014).

4.3.3 Results

The results of the human evaluation are shown in Table 4. We can see that our proposed method, Planning based Poetry Generation (PPG), outperforms all baseline models in average scores. The results are consistent with both settings of 5-character and 7-character poem generations.

The poems generated by SMT are better in Poeticness than RNNLM, which demonstrates that the translation based method can better capture the mapping relation between two adjacent lines. ANMT is a strong baseline which performs better than SMT, RNNLM and RNNPG, but lower than our approach. Both ANMT and PPG use the attention based enc-dec framework. The main difference is that our method defines the sub-topics for each line before generating the poem. The ANMT method just translates the preceding text into the next line. Without the guide of sub-topics, the system tends to generate more general but less meaningful results. In contrast, our approach explicitly considers the keywords, which

	Wrongly Identified MP as HP	Cannot Distinguish	Successfully Identified HP as HP
Normal Group	38.6%	11.3%	50.1%
Expert Group	6.3%	10.0%	83.7%

Table 5: Blind test to distinguish Human-written Poems (HP) from Machine-generated Poems (MP).

秋夕湖上 By a Lake at Autumn Sunset 一夜秋凉雨湿衣， A cold autumn rain wetted my clothes last night, 西窗独坐对夕晖。 And I sit alone by the window and enjoy the sunset. 湖波荡漾千山色， With mountain scenery mirrored on the rippling lake, 山鸟徘徊万籁微。 A silence prevails over all except the hovering birds.	秋夕湖上 By a Lake at Autumn Sunset 荻花风里桂花浮， The wind blows reeds with osmanthus flying, 恨竹生云翠欲流。 And the bamboos under clouds are so green as if to flow down. 谁拂半湖新镜面， The misty rain ripples the smooth surface of lake, 飞来烟雨暮天愁。 And I feel blue at sunset .

Table 6: A pair of poems selected from the blind test. The left one is a machine-generated poem, and the right one is written by Shaoti Ge, a poet lived in the Song Dynasty.

has better controls of the sub-topic for every line. From the results of the human evaluation, it can be seen that the proposed method obtained very close performances in Poeticness and Fluency compared with ANMT but much higher Coherence and Meaning scores, which verified the effectiveness of the sub-topic prediction model.

4.4 Automatic Generation vs. Human Poet

We conducted an interesting evaluation that directly compares our automatic poem generation system with human poets, which is similar to the Turing Test (Turing, 1950). We randomly selected twenty poems from the test set, which are written by ancient Chinese poets. We used the titles of these poems as the input and generated 20 poems by our automatic generation system. Therefore, the machine-generated poems were under the same subject with human-written poems. Then we asked some human evaluators to distinguish the human-written poems from machine-generated ones. We had 40 evaluators in total. All of them were well-educated and had Bachelor or higher degree. Four of them were professional in Chinese literature and were assigned to the Expert Group. The other thirty-six evaluators were assigned to the Normal Group. In the blind test, we showed a pair of poems and their title to the evaluator at each time, and the evaluator was asked to choose from three options: (1) poem A is written by the human; (2) poem B is written by the human; (3) cannot distinguish which one is written by the human.

The evaluation results are shown in Table 5. We can see that 49.9% of the machine-generated poems are wrongly identified as the human-written poems or cannot be distinguished by the normal evaluators. But for expert evaluators, this number drops to 16.3%. We can draw two conclusions from the result: (1) under the standard of normal users, the quality of our machine-generated poems is very close to human poets; (2) but from the view of professional experts, the machine-generated poems still have some obvious shortages comparing to human-written poems. Table 6 gives an example for a pair of poems selected from our blind test.

4.5 Generation Examples

Besides the ancient poems in Table 6, our method can generate poems based any modern terms. Table 7 shows some examples. The title of the left poem in Table 7 is 啤酒 *(beer)*, the keywords given by our poem planning model are 啤酒 *(beer)*, 香醇 *(aroma)*, 清爽 *(cool)* and 醉 *(drunk)*. The title of the right one is a named entity 冰心 *(Xin Bing)*, who was a famous writer. The poem planning system generates three keywords besides 冰心 *(Xin Bing)*: 春水 *(spring river)*, 繁星 *(stars)* and 往事 *(the past)*, which are all related to the writer's works.

啤酒	冰心
Beer	Xin Bing
今宵啤酒两三缸， I drink glasses of beer tonight, 杯底香醇琥珀光。 With the bottom of the glass full of aroma and amber light. 清爽金风凉透骨， Feeling cold as the autumn wind blows, 醉看明月挂西窗。 I get drunk and enjoy the moon in sight by the west window.	一片冰心向月明， I open up my pure heart to the moon, 千山春水共潮生。 With the spring river flowing past mountains. 繁星闪烁天涯路， Although my future is illuminated by stars, 往事萦怀梦里行。 The past still lingers in my dream.

Table 7: Examples of poems generated from titles of modern concepts.

5 Conclusion and Future Work

In this paper, we proposed a novel two-stage poetry generation method which first explicitly decomposes the user's writing intent into a series of sub-topics, and then generates a poem iteratively using a modified attention based RNN encoder-decoder framework. The modified RNN enc-dec model has two encoders that can encode both the sub-topic and the preceding text. The evaluation by human experts shows that our approach outperforms all the baseline models and the poem quality is somehow comparable to human poets. We have also demonstrated that using encyclopedias as an extra source of knowledge, our approach can expand users' input into appropriate sub-topics for poem generation. In the future, we will investigate more methods for topic planning, such as PLSA, LDA or word2vec. We will also apply our approach to other forms of literary genres e.g. Song iambics, Yuan Qu etc., or poems in other languages.

Predicting sentential semantic compatibility for aggregation in text-to-text generation

Abstract

We examine the task of aggregation in the context of text-to-text generation. We introduce a new aggregation task which frames the process as grouping input sentence fragments into clusters that are to be expressed as a single output sentence. We extract datasets for this task from a corpus using an automatic extraction process. Based on the results of a user study, we develop two gold-standard clusterings and corresponding evaluation methods for each dataset. We present a hierarchical clustering framework for predicting aggregation decisions on this task, which outperforms several baselines and can serve as a reference in future work.

1 Introduction

In text-to-text generation, existing sentence compression and sentence fusion systems assume that the input takes the form of one or more sentences, and the output is one suitably modified sentence (Barzilay et al., 1999; Knight and Marcu, 2000; Marsi and Krahmer, 2005; Filippova, 2010; Thadani and McKeown, 2013, for example). This line of work has led to new, knowledge-lean methods for sentence generation for applications such as text simplification and automatic summarization.

The next step in expanding the scope of text-to-text generation is to relax assumptions about the forms of the input and output, with the eventual goal of generating entire passages or documents in an abstractive manner. We focus in this paper on aggregation, the task of determining what input units belong in the same output sentence. Aggregation is an important step in micro-planning in the traditional data-to-text NLG pipeline (Reiter et al., 2000). However, it has been little examined within the context of text-to-text generation outside of restricted syntactic contexts, such as entity-driven noun phrase rewriting (Nenkova, 2008).

In this paper, we propose a new aggregation task suited for text-to-text generation. The goal of the task is to aggregate content into sentence-sized units by taking sentence fragments (i.e., meaningful bits of text) as input, and outputting clusters of these fragments. Figure 1 shows an example of such a clustering. It can be viewed as a preceding step for sentence fusion or other text-to-text generation methods.

Inspired by surface realization tasks (Belz et al., 2011), we use pre-existing sentences as a source of data in order to cheaply and automatically generate datasets with different granularities. We conduct a user study to confirm the validity of these datasets and design two gold-standard clusterings. We use these gold standards to define two methods of evaluation, and introduce two baselines for the task.

Then, we propose a simple clustering model for this task based on logistic regression and hierarchical clustering. All variants of the model are shown to outperform both baselines on our datasets, but an analysis of the results identifies shortcomings in the clustering that could be overcome in future models.

2 Related work

Microplanning, or sentence planning, encompasses the tasks of natural language generation (NLG) that occur after the general organization of arguments and before the syntactic realization of phrases (Hovy

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1061–1070, Osaka, Japan, December 11-17 2016.

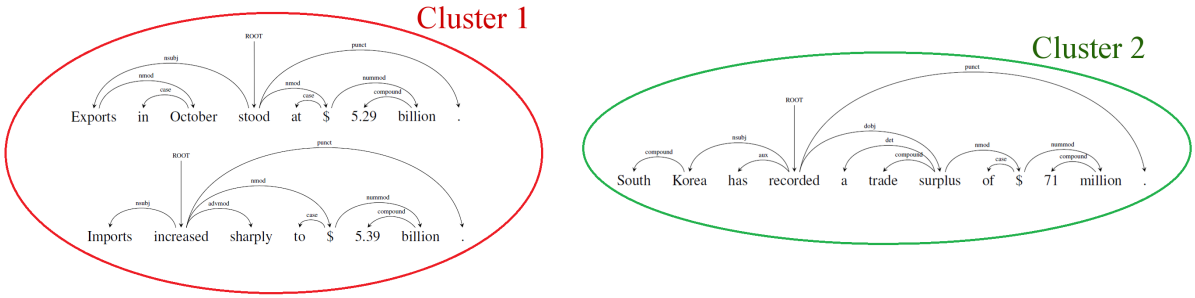

Figure 1: An example of clustering 3 sentence fragments into 2 clusters

and Wanner, 1996). Traditionally, a microplanner uses abstract domain-specific representations to produce linguistic representations. These representations are often used in domain-specific or user-specific generation systems (Mellish et al., 1998; Langkilde, 2000; Walker et al., 2002; Stent et al., 2002) and need to be adapted when changing domains (Stent et al., 2004; Walker et al., 2007). Previous work considered sentence planning to be a rigid succession of three distinct tasks: lexical choice, aggregation and referring expression generation (Reiter et al., 2000). However, more recent approaches have integrated them into a joint system (Angeli et al., 2010; Konstas and Lapata, 2013; Kondadadi et al., 2013).

Microplanning has not been considered relevant as an independent step in most recent work on text-to-text generation, because many microplanning decisions can be directly derived from the input text. For example, sentence fusion and sentence compression systems rely directly on surface text and make assumptions about the similarity of input sentences with limited rewording. Sentence compression, which consists of taking one sentence and removing redundant parts has been heavily studied (Knight and Marcu, 2000; McDonald, 2006; Galley and McKeown, 2007; Cohn and Lapata, 2008; Clarke and Lapata, 2008). Similarly, a large body of work exists in sentence fusion (Barzilay et al., 1999; Barzilay and McKeown, 2005; Marsi and Krahmer, 2005; Filippova, 2010; Thadani and McKeown, 2013).

However, relying so heavily on the input text has limited the scope of text-to-text systems. In terms of aggregation, most current systems in sentence fusion focus on fusing very similar input sentences, as determined by lexical overlap, though several recent approaches expand fusion to more disparate ones (Elsner and Santhanam, 2011; Cheung and Penn, 2014). Our work in this paper can be seen as a systematic investigation to determine what content is semantically compatible at a sentence-level, in order to generate inputs to such systems.

We focus on predicting in this paper on *what* content should be expressed in the same sentence. Other work has examined the issue of *how* the content should be expressed syntactically, such as by applying hand-crafted rules (Pan and Shaw, 2004). White and Howcroft (2015), for example, show that rules for aggregation for clause combination can automatically be learned.

3 Clustering task

3.1 Task definition

The task consists of clustering sentence fragments (see next subsection) into clusters of fragments that can be merged into a single sentence. Figure 1 shows an example of clustering. In this instance, cluster 1 fragments can be combined into the sentence "*Exports in October stood at $5.29 billion while imports increased sharply to $5.39 billion.*". This particular resulting sentence is an example and others can be generated from the same cluster.

The structure of our task can be defined as follows. Given a set of N sentence fragments $\mathbf{x} = \{x_1, x_2, ..., x_N\}$, we compute $\mathbf{y} = \{y_1, y_2, ..., y_k\}$ with $y_i \subseteq \mathbf{x}$, a partitioning of $\mathbf{x}$ into k clusters. The performance of the clustering $\mathbf{y}$ can then be measured by comparing it to a partitioning $\mathbf{c} = \{c_1, c_2, ..., c_m\}$ of $\mathbf{x}$ into m gold-standard clusters (see Section 5.2).

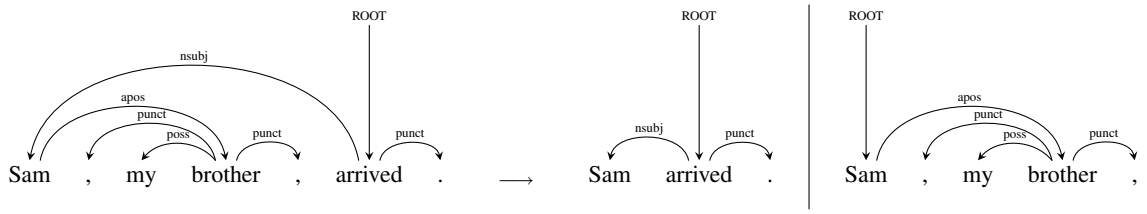

Figure 2: Example of two fragments (right) being extracted from one sentence (left)

3.2 Sentence fragment definition

Sentence fragments are defined as parts of sentences that are semantically consistent and that could be considered as grammatical sentences on their own provided small adjustments such as modifying determiners or punctuation. Sentence fragments are therefore very close to clauses, and a sentence in a text can contain one or multiple fragments. For example, the sentence *"Barack Obama, president of the United States, was born in Hawaii"* contains two fragments: *"Barack Obama (is) president of the United States"* and *"Barack Obama was born in Hawaii"*.

Fragments, as opposed to clauses, can have different levels of granularity while retaining their defining properties. For instance, the sentence *"Bell, based in Los Angeles, makes and distributes electronic, computer and building products"* can be split into two fragments: *"Bell (is) based in Los Angeles"* and *Bell makes and distributes electronic, computer and building products*. The latter fragment could then be further divided into *"Bell makes electronic, computer and building products"* and *"Bell distributes electronic, computer and building products"*. Similarly, these two fragments could then be divided into three subfragments each by removing the conjunction *"and"*.

4 Dataset generation

4.1 Splitting sentences

Sentence fragments are extracted by splitting corpus sentences on specific dependencies. The subtree resulting from such a dependency is extracted and the head word (or compound words) are copied to the new fragment. Figure 2 shows an example of extraction[1].

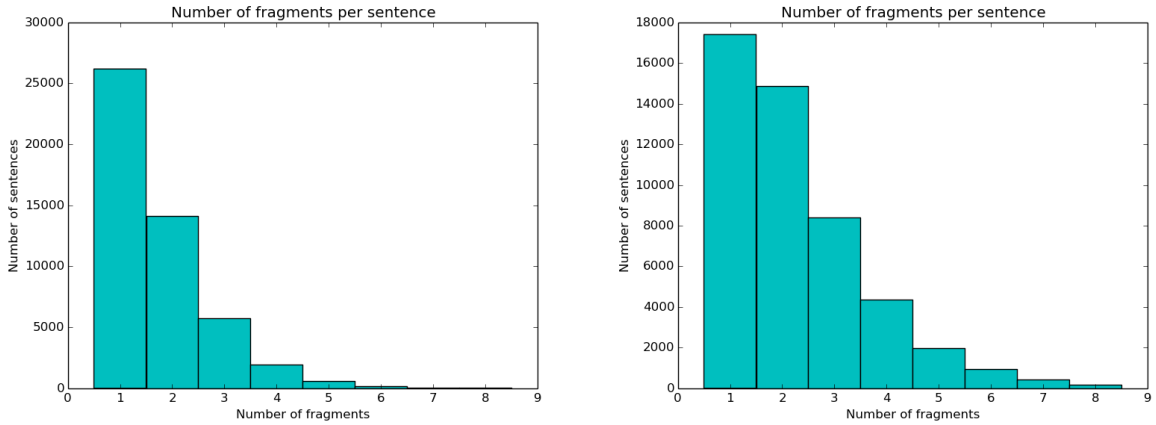
Several types of dependencies can be used to extract such fragments: appositional modifiers (e.g. *"Sam, my brother, arrived"*), adjectival and verbal modifiers (e.g. *"Pierre Vinken, 61 years old,..."*) and relative clauses (e.g. *"South Korea's economic boom, which began in 1986,..."*). To ensure that adjectival and verbal modifiers could be considered as a sentence on their own once extracted, only the subtrees with size at least four are extracted. These rules were designed to make fragments similar to propositions and ensure that they can be interpreted as sentences.

Previous examples show that conjunctions can also be used to extract fragments (see Section3.2). However, extracting conjunctions involves a different splitting mechanism: a fragment is not removed from the original sentence but the sentence is rather copied in two separate instances corresponding to each element from the conjunction (e.g. *"they either ski or snowboard"* is split into *they ski* and *they snowboard*). This different mechanism and the imperfections in the dependency trees make splitting on conjunctions a complex task and can lead to fragments that are not consistent. As a result, we generate two datasets of different granularities from the original corpus: the first one does not involve any action on conjunctions while the second one contains fragments extracted from conjunctions. These datasets will be referred to as *KeepConj* and *SplitConj*, respectively.

4.2 Creation of the datasets

We used the Penn Treebank Wall Street Journal corpus (Marcus et al., 1993). Manually-annotated constituent trees were converted into dependency trees using the the Stanford CoreNLP framework (Manning

[1]Technically, in this example, the first extracted fragment should be post-processed from "*Sam, my brother,*" to "*Sam is my brother*" (and the corresponding dependency tree) to represent a new individual sentence. However, all features used in our models (see Section 6.1) are indifferent to these modifications so the extracted fragments are not modified.



(a) KeepConj

(b) SplitConj

Figure 3: Distribution of the number of fragments per sentence

et al., 2014). Two datasets were created by extracting fragments from all sentences in all documents following the process described in the previous subsection. Each dataset was divided into a training set containing 2000 documents, a development set containing 254 documents and a test set containing 200 documents.

From the 48810 original sentences in the corpus, 84051 fragments were extracted into the *KeepConj* dataset and 111593 fragments were extracted into the *SplitConj* dataset.

Figure 3 shows that the generated datasets contain a lot of singletons, i.e. sentences from which one fragment has been extracted. The less fine-grained the dataset is, the more pronounced the imbalance. In our later experiments, we will define a singleton-only baseline which will form a non-trivial baseline to beat due to this distribution (see Section 7.1).

5 Establishing the Gold Standard

5.1 Validation by user study

In order to validate our automatic dataset extraction process (i.e. ensuring that fragments extracted from a given sentence could be combined back) and establish a gold-standard clustering to compare the results of the task with, we conducted a user study. Participants, all native English speakers, were presented with pairs of sentence fragments and were asked to decide whether the fragments were mergeable (positive pair) or not (negative pair). Mergeable fragments are defined as fragments that can be combined into a single consistent and grammatical sentence without having a significant impact on their structure. Participants were shown detailed instructions describing the task, the allowed mechanisms for merging fragments as well as examples of positive and negative cases. Each participant was presented with 60 pairs of fragments: 10 pairs originated from the same original sentence, 10 pairs originated from different documents, 20 pairs originated from different sentences within a same paragraph and 20 pairs originated from different paragraphs within a same document. Three separate annotations were recorded for each form of 60 pairs of fragments. A total of 18 participants annotated 360 pairs, 180 pairs per dataset.

The results of the study are shown in Figure 4. The study confirms the validity of the automatic dataset generation process: fragments coming from the same original sentence are mostly considered mergeable by human annotators. A qualitative analysis of the cases when such pairs were labelled as negative show that they either come from an error in the fragment extraction process (that can come from the conversion from constituent trees to dependency trees) or a situation when three or more fragments were extracted from a sentence.

Inter-agreement between participants was measured using Fleiss' kappa (Fleiss, 1971). Agreement is high when fragments come from the same sentence or when they come from different documents. These categories correspond to "easy" cases, respectively positive and negative most of the time. On the other

(b) SplitConj

Figure 4: Results of the user study. Pairs are divided into four categories by source: (1) fragments that come from different documents; (2) fragments that come from different sentences within a same document and that do not contain coreferent entity mentions; (3) fragments that come from different sentences within a same document and that contain coreferent entity mentions; (4) fragments that come from the same sentence.

Pairs considered	Fleiss' κ
All pairs	0.401
(1) Different documents	0.641
(2) Fragments w/o coref	0.261
(3) Fragments w/ coref	0.252
(4) Same sentence	0.731

(a) KeepConj

Pairs considered	Fleiss' κ
All pairs	0.461
(1) Different documents	0.636
(2) Fragments w/o coref	0.358
(3) Fragments w/ coref	0.317
(4) Same sentence	0.727

(b) SplitConj

Table 1: Inter-agreement among human annotators. Pairs are divided into four categories by source, as seen in Figure 4.

hand, agreement in other instances is lower, suggesting that deciding if two fragments are mergeable is a difficult task. However, results show that fragments that contain coreferent entity mentions are more likely to be mergeable (see Figure 4). This result is consistent across datasets.

The study shows that although fragments extracted from the same sentence are indeed mergeable, a significant number of positive cases exist where fragments originate from different sentences within a given document. Most of these cases correspond to fragments that contain coreferent entity mentions, yet not all of these fragments are mergeable. A chi-squared test showed that for both datasets, the proportion of positive pairs among fragments containing coreferent entity mentions (see category (3) in Figure 4) is significantly greater ($p < 0.05$) than the proportion of positive pairs among fragments that originated from the same document but do not contain such mentions (see category (2) in Figure 4). Based on these observations, we will define two different gold-standard clusterings: one optimistic clustering and one pessimistic clustering.

5.2 Evaluation measures

Based on the results from the user study, we define two gold-standards that act as lower and upper bounds on the clustering performance. The first one consists of using the original sentences from the corpus as gold-standard. This means that fragments should be clustered together if and only if they were extracted

from the same sentence. The second gold-standard consists of using fragments that contain coreferent entity mentions in addition to the original sentences. This means that fragments should be clustered together if and only if they were extracted from the same sentence or if they that contain coreferent entity mentions. The first gold-standard evaluation acts as a lower bound on the performance: it restricts the gold-standard to one specific clustering corresponding to the original corpus. On the other hand, the second gold-standard evaluation acts as an upper-bound on the performance: clustering of fragments that contain coreferent entity mentions is always considered to be positive while the user study showed that this is an oversimplification.

To evaluate the performance of a system clustering against one of the gold-standards, the measures of purity and collocation are used. Consider items $x_1, ..., x_N$ to be clustered, $y_1, ..., y_k$ the k system clusters outputted by the algorithm and $c_1, ..., c_m$ the m gold-standard clusters. Purity measures the proportion of items that belong to the same gold-standard cluster in a system cluster, while collocation measures the proportion of items that belong to the same system cluster in a gold-standard cluster:

$$\textit{Purity} = \frac{1}{N}\sum_{j=1}^{k}\max_{i\in[\![1,m]\!]}|y_j \cap c_i| \qquad \textit{Collocation} = \frac{1}{N}\sum_{j=1}^{m}\max_{i\in[\![1,k]\!]}|c_j \cap y_i|$$

When all items x_i are clustered by the system as singletons we have $\textit{Purity} = 1$, while we have $\textit{Collocation} = 1$ when all items x_i are clustered by the system as one cluster. To evaluate the trade-off between purity (that favours a large number of clusters) and collocation (that favours a small number of clusters), we use the $F1$ measure: $\textit{F1} = \frac{2\cdot\textit{Purity}\cdot\textit{Collocation}}{\textit{Purity}+\textit{Collocation}}$.

The mergeability relation in the second gold-standard is not considered to be transitive (i.e. if fragments A and B contain coreferent entity mentions and fragment C originates from the same sentence as fragment B, then fragments A and C should not be clustered together without fragment B); therefore, the second gold-standard only has an impact on purity, and not collocation. Specifically, when computing purity, a gold-standard cluster is the union of the fragments originating from a corpus sentence and all fragments that contain coreferent entity mentions with said sentence. However, when computing collocation, a gold-standard cluster is only the union of the fragments originating from a corpus sentence. This ensures that clustering the fragments back into the original corpus has a collocation score of 1.

We will refer to the metrics associated with the first gold-standard as "$\textit{Metric}^{\textit{LOW}}$" (e.g. $\textit{Purity}^{\textit{LOW}}$) and the metrics associated with the second gold-standard as "$\textit{Metric}^{\textit{UP}}$" (e.g. $\textit{Purity}^{\textit{UP}}$).

6 Hierarchical clustering model

We design a model that uses a logistic regression classifier to learn a similarity measure between two fragments. Based on this similarity function, we perform different methods of hierarchical clustering.

6.1 Learning of the similarity measure

Given a pair of fragments, we train a logistic regression classifier that returns the probability that the pair is positive, which we interpret as the similarity ϕ between the two fragments.

Given two items, x_i and x_j, we compute their joint feature representation $\Psi(x_i, x_j)$. We used a total of 27 pairwise features, detailed in Table 2.

For each document in the training set, each possible positive pair of fragments, i.e. its joint feature representation, is fed to the classifier with a positive label and a number of negative pairs less or equal than the number of positive pairs is fed to the classifier with a negative label. The number of negative cases considered per document is limited to account for the high number of singletons in the corpus and reduce training time.

After training, the similarity function ϕ is defined as $\phi(x_i, x_j) = \sigma_w(\Psi(x_i, x_j))$ where σ_w is the logit function learned by the classifier.

6.2 Variants of the model

Given a set of items $x_1, ..., x_N$ to be clustered, we compute the $N \times N$ similarity matrix K such that $K_{ij} = \phi(x_i, x_j)$. Each line (or column) of K corresponds to a cluster. We then perform bottom-up

Category	Example of feature	Value in example (see Figure 2)
Words in common	number of words in common	1 ("*Sam*")
	weight (*tf-idf*) of words in common	0
	weight (*tf-idf*) of nouns in common	0
	share of common words in longer fragment	0.33
Verb presence	share of fragments containing a verb other than "be"	0.5
Length	difference in length between fragments	1
Semantic roots	share of roots that are a verb other than "be"	0.5
	same root	0

Table 2: Examples of pairwise features used to learn the similarity function ϕ between the fragments "Sam arrived" and "Sam, my brother"

hierarchical clustering on K: we start with each item as a singleton cluster and successively merge clusters that have the highest similarity (clusters corresponding to the line and column of the highest value in K). We stop when a threshold similarity value has been reached. Values in K are updated after each step using one of these methods:

- **Single** linkage: the similarity between two clusters is the maximum similarity between two elements of these clusters
- **Complete** linkage: the similarity between two clusters is the minimum similarity between two elements of these clusters
- **Average** linkage: the similarity between two clusters is the average similarity between two elements of these clusters

In addition to these static methods, we also implement a dynamic **iterative** clustering method: after each step, we recompute new similarity scores by concatenating the fragments in each cluster.

7 Experiments and analysis

7.1 Baselines

We implement two baselines to compare the results of our model with. These baselines rely on specific aspects of the corpus and the fragment extraction process.
SINGLETON: Due to the large number of sentences containing only one fragment in the original corpus, the first implemented baseline consists of clustering each fragment into a separate cluster. This singleton baseline performs particularly well on coarse-grained dataset *KeepConj*.
SAMEROOT: We implemented a second baseline which consists of clustering together fragments that have the same semantic root (node(s) in the dependency tree that have no governor). This "same root" baseline performs well on both datasets.

7.2 Results

Table 3 shows the comparisons between the performances of the baselines and four variants of the hierarchical clustering model. The stopping threshold for each model has been tuned on the development set.

Results show that all variants significantly[2] outperform the baselines on both datasets ($p < 0.01$). The hierarchical clustering method has an inconsistent impact across datasets. The dynamic iterative aggregation performs best on dataset *KeepConj* ($p < 0.05$) while the average-link and complete-link aggregations perform better than other methods on dataset *SplitConj* ($p < 0.05$).

[2]All significance tests were performed using a two-tailed paired sample t-test on F1-scores at the document level.

Model	$Purity^{LOW}$	$Collocation^{LOW}$	$F1^{LOW}$	$Purity^{UP}$	$Collocation^{UP}$	$F1^{UP}$
Singleton baseline	**1.00**	0.588	0.741	**1.00**	0.588	0.741
"Same root" baseline	0.829	0.651	0.729	0.876	0.651	0.747

Average-link	0.909	0.733	**0.811**	0.966	0.733	**0.833**
Iterative	0.894	0.731	0.804	0.961	0.731	0.830

(b) SplitConj

Table 3: Evaluation results of the baselines and variants of the model against both gold-standard clusterings

7.3 Analysis

Results show that our model consistently favours purity over collocation, generating a higher number of clusters compared to the gold-standards. Examples in this section were generated by the *iterative* hierarchical clustering model on dataset *KeepConj* but are representative of the behaviour of all variants of the model.

This higher number is mainly due to the fact that our model fails to cluster together some long fragments that share a small number of common words. For example, the sentence "*Influential members of the House Ways and Means Committee introduced legislation that would restrict how the new savings-and-loan bailout agency can raise capital, creating another potential obstacle to the government's sale of sick thrifts.*" is divided during extraction into the fragments "*Influential members of the House Ways and Means Committee introduced legislation*" and "*legislation would restrict how the new savings-and-loan bailout agency can raise capital, creating another potential obstacle to the government's sale of sick thrifts*". These fragments are then rendered as singletons by the model.

On the other hand, shorter fragments are more easily clustered. For instance, fragments "*Another $20 billion would be raised through Treasury bonds*" and "*Treasury bonds pay lower interest rates*" are clustered back into the sentence "*Another $20 billion would be raised through Treasury bonds, which pay lower interest rates.*".

Our model clusters also show instances of coreferent fragments clustering, as evidenced by the significant increase in purity when the second gold-standard is used ($Purity^{UP}$). Fragments "*thrifts are sold, until the assets can be sold separately*" and "*the assets the RTC holds*" are clustered together. While they originate from different sentences, the fragments contain coreferent entity mentions ("*the assets*") and can be merged into the sentence "*Thrifts are sold, until the assets the RTC holds can be sold separately.*".

8 Conclusion

This paper introduced an aggregation task suited for text-to-text generation based on clustering sentence fragments. We presented evaluation metrics that were designed using human-annotated results. These results show that most mergeable pairs of fragments either originate from the same original sentence or contain coreferent entity mentions. We designed a hierarchical clustering model that uses a logistic regression classifier to learn a similarity measure between fragments. Its results were shown to outper-

form simple baselines and can be used as a reference for the task. Given that the task relies on shallow semantic analysis and the evaluation metrics only require coreference resolution, it is highly adaptable. Generating datasets from multi-document corpora can be the object of future work. Other clustering models, using neural networks to learn a similarity measure for instance, can also be considered. Integration of other aspects that were considered outside of the scope of our task, for example discourse relations analysis or information aggregation is another possible future avenue.

Abstract

Unexpected events such as accidents, natural disasters and terrorist attacks represent an information situation where it is crucial to give users access to important and non-redundant information as early as possible. Previous work uses either a fast but inaccurate pipeline approach or a precise but slow clustering approach. Instead, we propose to use sequential clustering for grouping information so that we are able to publish sentences at each time step. By doing so, we combine the best of both clustering and pipeline approaches and create a fast and precise real-time system. Experiments on the TREC Temporal Summarization 2015 shared task dataset show that our system achieves better results compared to the state-of-the-art.

1 Introduction

Events such as accidents, natural disasters and terrorist attacks provide an important and challenging information problem. Shortly after such an event has occurred, the information situation is usually unclear. Initially, only vague information about the event may become available, for example that an earthquake has occurred, but details such as magnitude, epicenter, and whether a tsunami has to be expected are not known at this early point in time. Such information becomes only available as the event develops over time. In such situations, it is crucial for responders, crisis management organizations, and victims to get information as soon as possible. However, it is impossible for humans to monitor *vast amount of textual information* contained in sources such as news articles, tweets, social media posts, forum discussions, and live blogs. In incremental update summarization (IUS) (McCreadie et al., 2014b) the *detection of important information in a timely manner* is a major challenge. Since the information sources are also *highly redundant*, detecting and filtering redundancy is a second important challenge in IUS.

In the past, two types of systems were used for IUC: pipeline systems (McCreadie et al., 2014a; McCreadie et al., 2015) and ordinary clustering systems (Kedzie et al., 2014; Zhao et al., 2014; Yingzhe Yao and Fan, 2015; McCreadie et al., 2015). Pipeline systems process document or sentence and decide about importance of information and novelty immediately and achieve therefore a good timeliness. However, they publish a large amount of unimportant information (low precision) or miss important information (low recall) since they do not make use of the redundancy of information as signal for importance, which is a usually a very good feature in newswire documents (Nenkova et al., 2006). Traditional clustering systems on the other hand are able to exploit redundancy and therefore produce better summaries according to precision and recall. Since they collect documents (for example all documents within one hour) before they decide whether or not to publish information, timeliness is a major issue of these approaches.

Instead of choosing between one of these architectures, we propose to use sequential clustering (Section 3.1) for incremental update summarization. With a sequential clustering, we are able to combine best of both worlds: clustering for redundancy avoidance to achieve high precision and recall and the ability to publish information at every time step to achieve a good timeliness. Hence, sequential clustering seems to be a natural fit for the task of IUS. In the sequential clustering, we jointly identify importance

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1071–1082, Osaka, Japan, December 11-17 2016.

and redundancy by using contextual importance measures (Section 3.2). They are used to assign utility scores to clusters, sentences, and tokens depending on already selected information. An additional redundancy avoidance methodology, as used by the other systems, becomes therefore obsolete.

We show in an experimental evaluation by using data of the TREC 2015 shared task on temporal summarization (Aslam et al., 2015) that our system `SeqCluSum` is able to outperform state-of-the-art. A substantial improvement is achieved even though the computed scores can only be considered a lower bound on the performance since the original competition used a manual and individual evaluation which cannot be reconstructed without loss of precision.

2 Related Work

Traditional extractive multi-document summarization approaches (Nenkova and McKeown, 2011) extract unmodified sentences from source documents to produce a summary. Graph-based approaches (Erkan and Radev, 2004; Mihalcea and Tarau, 2004; Parveen and Strube, 2015) represent source documents as graph and use algorithms such as HITS (Kleinberg, 1999) and PageRank (Brin and Page, 2012) to find important information. Centroid-based summarization (Carbonell and Goldstein, 1998; Radev et al., 2000) systems estimate sentences importance by computing their centrality in the source documents. Similarly to these systems, our approach extracts unmodified sentences and uses centrality as a signal for importance. The systems above perform a retrospective summarization, meaning that the systems analyze all source documents at once independently from their publication date. In IUS however, this is not possible, since important information has to be published as soon as possible. Furthermore, the mentioned systems create summaries of fixed lengths. In IUS we observe a situation where it is not clear in advance how long a summary has to be for a proper summarization of an event. Standard extractive summarization systems are therefore not suited for IUS.

In update summarization (Dang and Owczarzak, 2008), a summary is presented to the systems in addition to source documents which contain new information. The task is to summarize the source documents without repeating information which is already contained in the summary. Since this task is very similar to extractive summarization, methods, which are successfully applied to extractive, were also applied to update summarization.

Research in incremental update summarization (McCreadie et al., 2014b) is strongly influenced by the TREC Temporal Summarization (TREC-TS) shared task (Guo et al., 2013). The TREC-TS 2014 shared task (Aslam et al., 2014) provided a high-volume, pre-filtered version of the TREC KBA 2014 dataset.[1] The best performing run (Kedzie et al., 2014) in the challenge according to the official target metric uses affinity propagation clustering. Zhao et al. (2014), best performing system according to expected latency gain, applies a query expansion and information retrieval step in addition to a k-means clustering and sentence selection step. McCreadie et al. (2014a) proposes a real-time summarization system which achieved best comprehensiveness scores. They use a processing pipeline to filter out irrelevant documents, to classify sentences according to their relevance, and to filter out redundant sentences.

In the TREC-TS 2015 shared task (Aslam et al., 2015) systems competing in the "summarization only" subtask 3 were provided with a low-volume stream of documents.[2] The best system according to the official evaluation score in 2015 was proposed by Raza et al. (2015). The authors use BM25 for sentence scoring and redundancy avoidance based on cosine similarity values. McCreadie et al. (2015) focuses on entity importance and entity-entity interaction to identify important entities in an event. Kedzie et al. (2015) processes documents in hourly batches and combine salience prediction for sentences with affinity propagation clustering.

Our approach aims to combine the timeliness of a pipeline approach such as McCreadie et al. (2014a) with the importance detection strategy of a clustering approach such as Zhao et al. (2014).

3 Approach

In this section, we propose sequential clustering in combination with contextual importance measures for incremental update summarization. The algorithm, `SeqCluSum`, consists of two subsystems, which are alternatingly applied to the documents in the stream. In the first subsystem, a sequential clustering algorithm clusters all sentences in a document according to similarity measures (Section 3.1). The second subsystem, a contextual importance measure, estimates scores for clusters (Section 3.2). Both subsystems work hand in hand in order to satisfy the three objectives to publish (i) *important information* while (ii) *avoiding redundancy* in a (iii) *timely manner*.

To detect important information, we make use of the property that important information occurs frequently in newswire data (Nenkova et al., 2006). We define the utility of a cluster as the sum of the utilities of the contained sentences the size of a cluster is an important factor for the cluster importance. By this definition, larger clusters tend to obtain higher utility scores than smaller clusters. Furthermore, we use normalized temporal TF-IDF scores in the contextual importance measure to estimate the utility of a sentence (cf. Section 3.2). Frequent terms in the input documents tend to obtain higher scores than infrequent terms. A cluster containing sentences with frequent terms will therefore obtain higher scores than a cluster with infrequent terms. We prevent publishing redundant information by allowing at most one update per cluster. This is reasonable since one cluster is assumed to represent one particular information which is not represented by another cluster. If a cluster is selected to publish a sentence, this cluster will be marked as *published* and will not be considered for publishing a sentence again. Since the system processes each document sequentially, it is able to publish sentences after each processing step which enables it to satisfy the third objective of timeliness. The pseudo-code of the complete system is shown in Algorithm 1. Line references are given in parenthesis with respect to this pseudo-code.

Algorithm 1 Sequential Clustering and Contextual Importance Measuring

```
   documents = ordered list of documents, clusters ← ∅, updates ← ∅
 1: for each document ∈ documents do
 2:     document ← preprocess (document)                ▷ remove boilerplate content and stem words
 3:     for each sentence ∈ document do                  ▷ add each new sentences to a clusters
 4:         nearestCluster = arg max_{c∈clusters} similarity(sentence, c)
 5:         if clusters = ∅ or (similarity(sentence, nearestCluster) > Θ) then
 6:             clusters ← clusters ∪ {{sentence}};      ▷ create a new cluster
 7:         else
 8:             nearestCluster ← nearestCluster ∪ sentence   ▷ add to nearest cluster
 9:         end if
10:     end for
11:     for each cluster ∈ clusters do                   ▷ evaluate clusters and generate updates
12:         if cluster is not published and w(cluster) > μ then
13:             bestSentence = arg max_{s∈cluster} v(s)  ▷ find best sentence in cluster
14:             updates ← updates ∪ (document.timestamp, bestSentence)
15:             set cluster to published
16:         end if
17:     end for
18: end for
19: return updates
```

Before we apply our system for incremental update summarization to the document stream, we apply three preprocessing steps. We remove duplicate occurrences of web pages, utilize a boilerplate removal, and stem all words in the source documents with the well-known Porter-stemming algorithm (Porter, 1980).

3.1 Sequential Clustering

For the first part of our proposed incremental update summarizer, we adapt the sequential clustering algorithm (Theodoridis and Koutroumbas, 2009) to IUS. The algorithm iterates over all sentences in the currently processed document (line 3) and searches for the nearest existing cluster for each sentence using a similarity measure (line 5), which is described below. If the similarity to all existing clusters is lower than a fixed threshold Θ or no cluster has been created yet, a new cluster is created and the

sentence is added to the new cluster (line 6). Otherwise, the sentence is added to the nearest existing cluster (line 8).

The similarity measure reduces the similarity between a sentence s and a cluster c to the similarity between the sentence s and the first sentence of the cluster c. This has several advantages in comparison to considering all sentences in the cluster. First, the center of the cluster is fixed when we compare only with the first sentence of the cluster. This prevents the cluster from a topic drift. Adding more and more sentences and also using the newly added sentences in the similarity calculations could instead change the initial notion of the cluster significantly since the center of the cluster could move. We observed that this can be a serious issue which leads to a poor clustering. Second, the approach is computationally efficient in comparison to an approach where we would compute the similarity by considering all sentences in a particular cluster. The number of maximal comparisons is reduced from the number of all sentences in a topic to the number of clusters created for a topic. Third, it emphasizes the notion of a cluster as a set of sentences, each of which contains the same information. The system chose the first sentences of each cluster to be its representative since each first sentence has a special role. This special role derives from the fact that the first sentence of each cluster was the reason why the cluster was created. The sentences did not fit to another cluster and were the reason for creating its own, new cluster.

The actual similarity measure (line 4+5) is based on Cosine similarity based on TF-IDF vectors (Salton and McGill, 1986). To calculate the TF-IDF vectors, we use a background corpus B created from 100,000 randomly sampled English Wikipedia articles in addition to all Wikipedia articles which are longer than 10,000 characters (5,794 documents). We use DKPro Similarity (Bär et al., 2013) to calculate the Cosine similarity. A detailed analysis of similarity measures is given in Section 5.2.

3.2 Measuring Importance

After the sentences in a document are clustered, the system evaluates the current cluster landscape to detect important information. We introduce the utility functions u, v, and w to measure the utility of tokens, sentences, and clusters, respectively. The score of a cluster c is measured with a cluster utility function w and equals to the sum of the scores of all sentences s_i in the cluster. We define $w(c) = \sum_{s_i \in c} v(s_i)$, where v is a utility function for sentences. Summing the scores of all sentences in a cluster addresses the property of the corpus that more important information is repeated more frequently in the source documents since larger clusters obtain higher utility scores (c.f. Section 1). The score of a sentence s is defined as the sum of the weights of the tokens t_i contained in sentence s. Thus, we define $v(s) = \sum_{t_i \in s} u(t_i)$, where u is a utility function for a token. In the following, we define a contextual importance measure to estimate the utility of a single token. Since we summarize an ongoing event and do not know which documents will appear later in the stream, we cannot compute TF-IDF scores over all documents. Nevertheless, we want to estimate how salient a token is relatively to the already observed documents D_τ at time τ. This will provide us with a signal about the relative relevance of the tokens very similarly to the well-known TF-IDF. To measure the importance of a token, we first define a context-free utility function u_{cf} in Equation 1. This gives us an impression on how salient a token is in a document collection D_τ. Since the document collection D_τ changes after each time step τ, the utility scores are constantly updated when new documents are processed. We define

$$u_{cf}(t, D_\tau) = \sum_{D \in D_\tau} \frac{n_D(t)}{|D|} \cdot log\left(\frac{|B|}{n_B(t)}\right) \quad (1)$$

where $n_B(t)$ denotes the number of occurrences of the token t in the background corpus B and $|B|$ refers to the total number of tokens in B. Unknown tokens, which do not appear in the background corpus (i.e. $n_B(t) = 0$), are ignored in the calculation of sentences importance. The contextual similarity measures defined in Equation 2 takes already published tokens into account when estimating the utility of a token. It captures therefore the importance of a token with respect to already published tokens. Hence, it avoids publishing sentences which are similar to already published sentences by discounting the scores for already published tokens and therefore provides redundancy avoidance implicitly. We discount the context-free values by dividing the context-free score $u_{cf}(t, D_\tau)$ by the number of occurrences of token

t in the already published updates. We define $u_c(t, D_\tau)$ in Equation 2, where $n_U(t)$ denotes the number of occurrences of token t in the current list of updates U.

$$u_c\left(t, D_\tau\right) = \frac{v_{cf}\left(t, D_\tau\right)}{1 + n_U(t)} \tag{2}$$

3.3 Publishing an Information Update

A cluster is considered as sufficiently important if a fixed threshold μ is exceeded (line 12). As a consequence, one sentence from the cluster is published (line 14). The threshold can easily be adapted on demand to produce more or less verbose summaries. If a cluster exceeds the threshold, the best sentence according to the sentence utility score v is published. The cluster is marked as *published* in this case (line 15), which means that the cluster will not be selected in the future.

4 Evaluation

In this section, we describe the evaluation of our approach. First, we provide detailed information about the used evaluation data in Section 4.1. The evaluation methodology is described in Section 4.2. We use a trace-driven simulation which simulates the course of events to evaluate our system. Results are presented in Section 6 after a detailed analysis of our system in Section 5.

4.1 Data

As evaluation dataset, we use the TREC-TS-2015RelOnly[3] dataset, which was created by the organizers of the 2015 Temporal Summarization shared task (Aslam et al., 2015). The corpus is a filtered version of the KBA Stream Corpus 2014[4], contains documents from various text genres like mainstream news articles, blogs/microblogs, and forum posts, and is divided into 21 clusters of documents. Each cluster represents one topic and has additional meta-data about the start and the end of the event as well as a query term indicating the topic of the event. Each document has sentence segmentation annotations and is guaranteed to contain at least one relevant sentence for the topic. All documents in the corpus have an associated timestamp which equals the crawling time of the document.

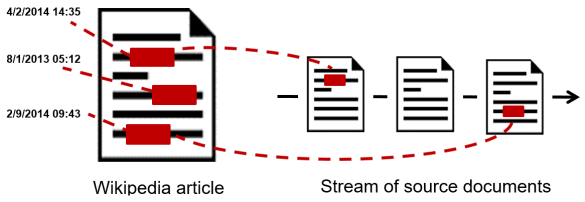

Figure 1: Illustration of the TREC-TS dataset. Information nuggets were retrieved from Wikipedia articles and annotated with timestamps at which this information became publicly available. Sentences in the source documents are matched against the extracted information nuggets.

For the evaluation in the shared task, the organizers extracted time-stamped information nuggets based on the Wikipedia article revision histories of the corresponding events. In a first step, information nuggets were extracted from the revision histories by the track organizers. The nuggets were classified with an importance score of 1, 2, or 3, and tagged with a timestamp, which represents the time when this information became publicly available. In a second step, sentences were pooled from each submission in the TREC-TS 2015 shared task. For each submission, at most 60 sentences were pooled per topic and were manually matched with the extracted information nuggets. A sentence can match multiple nuggets as well as no nugget. Figure 1 illustrates the annotation. Due to the huge annotation effort, only a small set of sentences in the corpus is labeled. This is problematic, since one cannot train, validate, or evaluate a system accurately without additional annotation effort.

[4] http://trec-kba.org/kba-stream-corpus-2014.shtml

4.2 Methodology

In the task of IUS, the documents have to be processed in temporal order. The result of a system is a list of updates. When a system decides that a sentence from the stream should be published, this particular sentence is marked with the timestamp of the currently processed document according to Algorithm 2.

Algorithm 2 Incremental Update Summarization (IUS)

S = summarizing system; $documents$ = time-ordered list of documents; $updates = \emptyset$
for each $document \in documents$ **do**
  $t \leftarrow document.time$
  $S.process(document)$
  $updates_t \leftarrow S.getUpdates()$
  for each $u \in updates_t$ **do** $updates \leftarrow updates \cup \{(t, u)\}$ **end for**
end for
return $updates$

The systems are not allowed to use information from the future to make this decision. Incorporating information that only became available after the current timestamp is not allowed. One example for such an improper use of information would be the computation of TF-IDF values over the whole corpus since this would provide information about which words will become important in the future.

In our evaluation, we use the same metrics as in the TREC-TS 2015 shared task. The first metric is *normalized expected gain* $n\mathbf{EG}(\mathcal{S})$. This metric is comparable to precision since it measures whether a system publishes updates which are on-topic and novel. It will give a low score to systems which publish irrelevant or redundant information. The second metric $\mathbf{C}(\mathcal{S})$ measures the *comprehensiveness* of a summary. It is similar to recall since it measures how many of the information nuggets that could have been retrieved are covered by the summary. Systems which miss a large amount of important information will obtain a low score according to $\mathrm{C}(\mathcal{S})$. A third metric, the *expected latency* metric E[Latency], measures to which degree the information in the summary is outdated.[5] This metric reflects the requirement that systems are supposed to publish sentences as early as possible to produce the maximal benefit for the users. The later a system identifies important information, the lower its expected latency score. The final measure $\mathcal{H}$ combines the three individually measured properties precision, recall, and timeliness and served as official target measure for the task and is also our main metric to evaluate the systems. It computes the harmonic mean of a latency discounted version of $n\mathbf{EG}(\mathcal{S})$ and a latency discounted version of $\mathbf{C}(\mathcal{S})$. We refer to Aslam et al. (2015) for more detailed information about the metrics.

5 Analysis

In the following, we provide a detailed analysis of our system. We investigate the impact of three parts of our system: the boilerplate removal (Section 5.1), the used similarity measure (Section 5.2), and the clustering (Section 5.3).

5.1 Boilerplate Removal

In this section, we evaluate the boilerplate removal preprocessing step in terms of precision and recall. Although preprocessing is not part of the contribution of this paper, it has an impact on the system performance and is therefore discussed briefly. False positive errors made by the preprocessing cannot be corrected by the subsequent clustering and therefore limits the performance of the overall system irrevocably. It gives also an impression about the dataset itself which is otherwise hard to grasp. For the analysis, we use only non-duplicate documents (i.e. only the first version of each document). Since we do not have gold standard boilerplate removal data for the dataset, we use the nugget annotations instead. Table 1 provides the results of this analysis. Since both boilerplate systems work on the document level, we had to map the result of the boilerplate removal to single sentences. To do this, we used the Jaccard

[5]The name for the metric is a little counter-intuitive, since it used as a discount factor for nugget importance. A value of 1 means that the update is in-line with the Wikipedia article and results in no discount. Values smaller than 1 mean that an update was only published after it was included in the reference. Values bigger than 1 mean that a system published a nugget before it occurred in the Wikipedia article the first time.

Boilerplate system	Similarity	Thr	Max length	tp	tn	fp (critical)	fn
-	-	-	5	294,993	8,472	180	474,017
-	-	-	6	341,444	8,396	256	427,566

Kohlschütter et al. (2010)	Jaccard	0.6	5	684,059	4,266	4,386	84,951
Kohlschütter et al. (2010)	Jaccard	0.8	5	714,653	3,194	5,458	54,357
Kohlschütter et al. (2010)	Cosine	0.6	5	639,374	5,706	2,946	129,636
Kohlschütter et al. (2010)	Cosine	0.8	5	695,350	3,859	4,793	73,660
Habernal et al. (2016)	Jaccard	0.4	5	682,985	4,392	4,260	86,025
Habernal et al. (2016)	Jaccard	0.6	5	721,033	3,187	5,465	47,977
Habernal et al. (2016)	Cosine	0.6	5	686,671	4,340	4,312	82,339
Habernal et al. (2016)	Cosine	0.8	5	729,665	2,820	5,832	39,345

Table 1: We report the performance according to true positives (tp), true negatives (tn), false positives (fp), and false negatives (fn) of the length cutoff baseline and two boilerplate removal system. False positives (falsely pruned valuable sentences) are critical, since the pruned sentences are not processed by the following sequential clustering.

and the Cosine similarity. We tagged the sentence as boilerplate if it was less similar to the most similar sentence in the text retrieved by the boilerplate system according to a threshold and had a maximum length of 5. We observe that we can discard a lot of sentences with only a lengths criterion without too many false positives. Both boilerplate removal systems, Boilerpipe (Kohlschütter et al., 2010) and the tool used in Habernal et al. (2016), do not perform very well in combination with the two similarity measures since both generate a large number of false positives.

5.2 Similarity Measures

One key component of summarization systems are similarity measures which estimate the semantic similarity of two texts or sentences. We therefore performed experiments with different measures in the TREC-TS dataset. We evaluate the similarity measure by comparing the score of similar sentences, which contain exactly the same nuggets and for dissimilar sentences which do not share any nuggets. We define sets of sentence $ss_1, \dots ss_L$ according to the information nuggets contained in the sentences. Since each sentence can contain multiple nuggets, we first define nugget sets $ns_1, \dots, ns_M$ which represent all sets of nuggets similarly to label powersets in multi-label classification. Sentences in a particular sentence set ss_i contain exactly the same information nuggets, i.e. each sentence is contained in exactly one sentence set. For sets $ss_1, \dots ss_L$, and sentences $S = \{s_1, \dots, s_K\}$ we define the sim score of a similarity measure σ as the average similarity of all similar sentences

$$\mathrm{sim}(\sigma) = \sum_{l=1}^{L} \frac{1}{|ss_l|} \sum_{l_1,l_2=1,l_1<l_2}^{|ss_l|} \sigma(s_{l_1}, s_{l_2}) \tag{3}$$

and the dissim score of a similarity measure σ as the average similarity of all dissimilar sentence

$$\mathrm{dissim}(\sigma) = \sum_{l_1,l_2=1,l_1<l_2}^{L} \frac{1}{|ss_{l_1}| \cdot |ss_{l_2}|} \sum_{\substack{s_1 \in ss_{l_1} \\ s_2 \in ss_{l_2}}} \sigma(s_1, s_2). \tag{4}$$

An appropriate similarity measure can perform both, assigning high scores to similar sentences and low scores to dissimilar sentences. Therefore, we measure both by computing $\mathrm{diff}(\sigma) = \mathrm{sim}(\sigma) - \mathrm{dissim}(\sigma)$. We report the scores of various similarity measures in Table 2.

We observe that the TF-IDF-based Cosine similarity with $\log +1$ IDF weighting and L2 normalization performs best.[6] For details regarding the similarity measures, we refer to Bär et al. (2013). Cosine similarity based on the sum of GloVe (Pennington et al., 2014) word embeddings to represent a sentences

[6]The results provided in the table were computed for the complete dataset. Results on the splitted datasets, which were used for the evaluation of the system, confirmed the results.

		TF-IDF-based Cosine			Jaccard-n		Word embedding-based Cosine	
	random	log+1 L1	log+1 L2	binar L2	$n=1$	$n=2$	unweighted	weighted
$\mathrm{sim}(\sigma)$	0.50	0.16	0.41	0.40	0.29	0.19	0.79	0.69
$\mathrm{dissim}(\sigma)$	0.50	0.01	0.15	0.20	0.10	0.01	0.70	0.52
$\mathrm{diff}(\sigma)$	0.00	0.15	**0.26**	0.20	0.19	0.18	0.09	0.17

Table 2: Results of $\mathrm{sim}(\sigma)$ and $\mathrm{dissim}(\sigma)$ for different similarity measures.

yields the lowest results.[7] A weighted version, where we multiply the word vectors with the corresponding IDF score achieves better results than the unweighted Cosine based on the word embeddings.

5.3 Clustering

In this section, we evaluate the cluster landscape by computing cluster purity (Manning et al., 2008) and nugget concentration. Cluster purity measures how many different nugget sets ($ns_1, \ldots, ns_M$) are contained in the clusters. According to the underling idea that one cluster represents one nugget set, one cluster should only contain sentences that belong to the same information nuggets. With the definition of a cluster as a set of sentences (i.e. $c \subset S$), the cluster purity of the clusters $C = \{c_1, \ldots c_I\}$, sentence sets $ss_1, \ldots ss_L$, and K sentences (Manning et al., 2008) is defined as

$$\mathrm{purity}(C) = \frac{1}{K} \sum_{i=1}^{I} \max_l |c_i \cap ss_l| \tag{5}$$

Similarity to purity, we also define a purity purity^+ where we do not consider the sentence set which contains all sentences without any nuggets as majority class in $\max_l |c_i \cap ss_l|$. This provides a better insight into the mixture of non-empty nugget sets. In a perfect clustering, we get a score of 1, i.e. that all clusters contain only sentence which belong to a particular nugget set. Since a purity of 1 is easy to achieve with K clusters, we introduce the term nugget concentration (nc), which is defined as

$$\mathrm{nc} = \frac{1}{L} \sum_{l=1}^{L} \frac{\max_i |c_i \cap ss_l|}{|ss_l|} \tag{6}$$

Boilerplate system	Θ	# cluster	purity	purity^+	nc	nc (after bpr)
max length 8	1.0	1	0.4874	0.1779	0.5134	1.0000

Habernal et al. (2016) + Cosine < 0.8	0.6	323	0.7826	0.7900	0.3558	0.9219

Table 3: Results of the cluster evaluation for difference boilerplate versions and difference values of Θ.

We use for the analysis the TF-IDF-based Cosine similarity with $log + 1$ IDF weighting and L2 normalization (according to Section 5.2). Since the boilerplate removal can have a significant impact, we report the results based on different boilerplate removal versions. In Table 3 we see that more clusters (due to a lower Θ) lead to a higher purity as expected. Nugget concentration decreases, because it becomes more likely that one nugget set is distributed across multiple clusters. If we only consider

[7] We used pre-calculated word embeddings from `http://nlp.stanford.edu/projects/glove`

sentences which passed the boilerplate removal step (column nc (after bpr)) we see that the system performs best with the stricter boilerplate removal. This can be explained due to the fact that the nugget sets are smaller and a distribution across multiple clusters is less likely. If we consider all sentences in the data, the system based on the first boilerplate removal performs best (column nc). A strict boilerplate removal with many false positives harms the overall performance of the systems. However, processing fewer sentences in the rather computational expensive clustering (compared to the boilerplate removal) leads to better computational performance. A better boilerplate removal would therefore be desirable to improve the performance in IUS.

6 Results
