COLING 2016

The 26th International Conference on Computational Linguistics

Proceedings of COLING 2016: Technical Papers

December 11-16, 2016
Osaka, Japan

ISBN978-4-87974-702-0

Preface: General Chair

Welcome to COLING 2016 – the 26th International Conference on Computational Linguistics — held in Osaka, Japan! It is the third COLING in Japan after Tokyo (1980) and Kyoto (1994). It is a special pleasure for me to be General Chair (10 years after chairing the joint COLING-ACL 2006 in Sydney) of a COLING held in Japan, a country I love.

COLING is organised under the auspices of the International Committee on Computational Linguistics (ICCL, http://nlp.shef.ac.uk/iccl/index.html). ICCL is a very special committee, with no fixed rules and no funding, whose only function is to make sure that a COLING appears every two years and that it is a good and friendly conference.

I have participated to many COLINGs, since the one in Pisa in 1973. It was a COLING without email! I still remember when Antonio Zampolli (Local chair) received by Hans Karlgren (Program chair) a sketch of the program written by hand, almost unreadable, and asked me (very young at the time) to interpret it. I have seen COLINGs where submissions arrived on paper and many packages were sent around the world to area chairs, to be sent to reviewers, and all the results back again by normal mail. It seems impossible now.

COLING has changed over the years, together with the changes in our field. But it has always been important for ICCL to maintain the COLING "spirit": we always wanted COLING to be an inclusive and broad conference. We also want to underline that in our field "language" is important and we therefore pay special attention to having papers and workshops focusing on understanding language properties and complexities. Moreover, for us the social part of the conference is as important as the scientific one.

An outstanding competent and dedicated team has worked for the organisation of COLING 2016. I wish to warmly thank, also on behalf of ICCL, all the various Chairs, too many to mention them all here, for the wonderful work they have done. It has been a pleasure and a privilege for me to work together with all of them: they made my work as General chair very easy. But I owe a special thanks to Yuji Matsumoto and Rashmi Prasad, Program chairs, for their hard work in managing so smoothly an impressive number of submissions, many more than we expected. And I wish to express my deepest gratitude to the Local chairs – Eiichiro Sumita, Takenobu Tokunaga and Sadao Kurohashi – who have done a fantastic work with great dedication in all the various phases of the conference organisation, always keeping everything under control. Not an easy task, as I know too well!

I also want to thank the generosity of all the sponsors for their great support to COLING.

Last but not least, I thank the colleagues (so many) who submitted their work to COLING, the organisers of Workshops and Tutorials, the participants (more than 900 at the time of writing) and the many students among them. It is important that many young researchers can attend COLINGs. They show the great interest of our community in COLING.

I hope that you benefit not only from the scientific programme but also from the social parts of COLING. I hope you get from this COLING both new exciting ideas and also new friends.

Enjoy COLING 2016 in Japan!

Nicoletta Calzolari (ICCL, ILC-CNR and ELRA)

Preface: Program Chairs

It is with great pleasure that we welcome you to the 26th International Conference on Computational Linguistics (COLING 2016) in Osaka, Japan! COLING covers a broad spectrum of technical areas related to natural language and computation. This year, we received 1,039 valid submissions (from a total of 1127 submissions), of which we accepted 337 papers (32.4% acceptance rate). 134 papers were selected for oral presentation and 203 papers for poster presentation. No distinction is made in these proceedings between papers presented orally or as a poster, as they were not distinguished qualitatively but rather by judging the best mode for delivering the paper content.

To effectively cover the broad spectrum of topics included in the conference, we have 18 thematic areas, each chaired by two or more area chairs. We are extremely grateful to the area chairs, who led and monitored the reviewing and reviewer discussions, and sent us detailed recommendation reports resulting from the reviewing process, including best paper recommendations. We cannot thank enough the over 800 reviewers who have put in the requisite time and effort to carefully assess the very large number of submissions we received this year. Their dedication and commitment, and willingness to work with us even when there were tight time constraints, made the entire task proceed much more smoothly than we had hoped! Almost all papers were reviewed by at least three reviewers and we are very happy with the highly strong set of papers accepted for presentation. We thank all authors for their submissions describing their very commendable research, and hope that authors of papers we could not accept have nevertheless benefited from the feedback they received from reviewers.

We have structured the accepted submissions into ten sessions, with multiple thematic areas included in parallel, either for oral presentation or poster presentation. Only one session – the first session – does not have a parallel poster session. We are delighted to have four invited speakers to the conference: Joakim Nivre from Uppsala University: "Universal Dependencies – Dubious Linguistics and Crappy Parsing?"; Reiko Mazuka from RIKEN Brain Science Institute & Duke University: "Getting the Input Right: Refining our Understanding of What Children Hear"; Dina Demner-Fushman from the U.S. National Library of Medicine: "NLP to support clinical tasks and decisions", and Simone Teufel from University of Cambridge: "A Look at Computational Argumentation and Summarisation from a Text-Understanding Perspective".

We are extremely grateful to the members of the best paper committee, Tim Baldwin, Vincent Ng, and Hinrich Schütze, who agreed to put in extra time to select the two best papers at the conference. Best paper nominations were collected in a bottom-up fashion, with reviewers first providing their recommendation for each paper, and area chairs then collecting the positive recommendations, and upon their own assessment of the corresponding reviews and papers, selecting some or all to be forwarded to the PC chairs. PC chairs then invited the three experts to form a committee (chaired by the PC chairs) to select the two best papers from this set of nominated papers.

We would like to thank the many members of the organizing committee who have helped us in crucial ways at various stages of organizing the technical program – the General Chair, Nicoletta Calzolari; the Local Chairs, Eiichiro Sumita, Takenobu Tokunaga and Sadao Kurohashi; the Publication Chairs, Hitoshi Isahara and Masao Utiyama; the Publicity Chairs, Srinivas Bangalore, Dekai Wu and Antonio Branco; and the Web Master Akifumi Yoshimoto. Our special thanks go to Swapna Somasundaran for her voluntary help to recruit additional reviewers to handle the much larger than expected submissions to the conference. Last but not the least, we are grateful to the softconf manager, Rich Gerber, for his continuous help with our various questions and needs.

We hope that you enjoy the conference!

Yuji Matsumoto, Nara Institute of Science and Technology, Japan
Rashmi Prasad, University of Wisconsin-Milwaukee, U.S.A.

Preface: Local Chairs

Welcome to the COLING 2016!

It is a pleasure to welcome you to COLING 2016 organized by the Japanese Association of Natural Language Processing (ANLP) in Osaka. It has been 22 years since Japan last held the conference. While we are meeting here to discuss NLP, there is no substitute for personal contact. Therefore, we have arranged breaks, a reception, an excursion and a delightful banquet to facilitate discussion, collaboration and making connections. We hope and the modern conference venue together with the ambience of western Japan including Osaka, Nara and Kyoto (famous for their nature, culture, history, and food), help to make this an enjoyable experience for all. We hope the conference will result in accelerated growth of NLP.

Organizing a conference always takes a lot of work, and fortunately, we have experienced people from all around the world in attendance at the COLING 2016 site. It is both an honor and a great pleasure to work with them, and we thank them gratefully.

Since the proposal to host COLING was accepted by ICCL in 2014, our world has experienced some drastic changes. Under unfavorable economic conditions in Japan and considering the distance from Europe and America, we had to make a very conservative financial plan for the conference. The sponsorship chairs worked very hard and collected 33 sponsors, which is considerably more than in previous COLINGs.

This year's conference has attracted a huge number of submissions and has a high level of participation, reflecting the ongoing dynamism in artificial intelligence around the globe. We were both overwhelmed by the numbers of visa applications we had to handle, and at the same time delighted and excited by the tremendous response.

We'd like to end by reporting two special features of COLING 2016: (1) COLING will assist student participants with registration subsidies. Successful applicants for the Student Support Program will receive all-inclusive free registration; (2) the collocation of the first international symposium for young researchers working on Natural Language Processing (YRSNLP) as an official satellite event at COLING 2016.

Welcome, and enjoy the conference!

Eiichiro SUMITA, Takenobu TOKUNAGA, and Sadao KUROHASHI

COLING 2016 Local Chairs

Organisers

Invited talk 1

Universal Dependencies – Dubious Linguistics and Crappy Parsing?

Joakim Nivre (Uppsala University)

Universal Dependencies is a framework for cross-linguistically consistent treebank annotation that has so far been applied to over 50 languages. It was developed primarily to support multilingual parsing research, but the resources have proven useful for a wide range of studies that were not foreseen originally, including research on language typology. A basic design principle in Universal Dependencies is to give priority to grammatical relations between content words, which are more likely to be parallel across languages, and to treat function words essentially as features of content words. This principle has been criticized both for being incompatible with theoretical linguistics, which tend to treat function words as syntactic heads, and for being suboptimal as a representation for dependency parsing, where higher accuracy is often observed with function words as heads. I will argue that both of these criticisms rest on a misinterpretation of the syntactic representations, and I will show that an alternative interpretation is compatible with both sound linguistics and improved parsing technology.

Invited talk 2

Getting the Input Right: Refining our Understanding of What Children Hear

Reiko Mazuka (RIKEN Brain Science Institute & Duke University)

As models for language learning become increasingly sophisticated, it is essential to pay close attention to the purported input received by learners. This talk presents two examples of phonological input for which a failure to account for relevant factors has led to misleading conclusions. A fully annotated dataset of infant-directed speech is now allowing a more refined analysis of what children actually hear. The first example concerns vowel-duration contrasts (long vs. short) in Japanese. One previous study, working under the assumption that long and short vowels occurred with equal frequency, concluded that the distinction could be learned by a simple distributional model. Our dataset, however, reveals that (a) in reality over 90% of vowels in Japanese are short, and (b) the distribution of long vowel duration is entirely encompassed within that of short vowels. The second example concerns the widely accepted claim that when adults speak to infants (infant-directed speech, IDS), they speak with a slower speech rate than when speaking to adults (adult-directed speech, ADS). Studies supporting this conclusion, however, have consistently failed to account for the fact that IDS utterances are shorter than those of ADS. Our dataset differentiates between utterance-internal speech rate and utterance-final lengthening, and finds taken separately, these values almost identical between IDS and ADS. As it turns out, IDS appeared to have a slower overall rate only because of the greater frequency of utterance-final segments.

Invited talk 3

NLP to support clinical tasks and decisions

Dina Demner-Fushman (U.S. National Library of Medicine)

Clinical decision support (CDS) provides clinicians and patients with information needed to enhance health and health care. Clinical NLP – natural language processing methods to support healthcare by operationalizing clinical information contained in clinical narrative – is an integral part of CDS. Clinical NLP has started in the early 1960s, with several successful applications now integrated in daily care. I will first discuss the successful applications that are already positively impacting clinical practice, as well as publicly available resources, including those developed by our group. Consumer language understanding is an equally important and rapidly evolving part of CDS. In the second part of the talk, I will present our work in understanding consumer health questions. I will conclude with the challenges and opportunities to contribute to these fascinating research areas that have practical implications for our health.

Invited talk 4

A Look at Computational Argumentation and Summarisation from a Text-Understanding Perspective

Simone Teufel (University of Cambridge)

In the past five years, computational argumentation has emerged as a new, active research field. This field studies all aspects of analysing and generating human argumentation, including argument mining, supportive debating technologies, logical representation of arguments, models of reasoning, and the connection of discourse processing and argumentation. As somebody who is mainly interested in the text-understanding challenges of computational argumentation, I think this new field has the potential to advance (and provide means of evaluating) the text-understanding capabilities of today's NLP systems.

When humans construct an argument in order to convince others, how do they order and structure the information they want to convey? I will argue that whatever principles are at work, they are almost identical to those needed when summarising a text. Amongst the relations of particular interest are entailment, causal and rhetorical relationships. I will give an overview of currently available (text understanding-based) analysis methods that can inform our understanding of these principles, and I will also say a few words about a proposition-based approach to summarisation we have developed at Cambridge University that has the potential to contribute insights to computational argumentation.

Table of Contents

Conference Program

Tuesday, December 13, 2016

09:00–09:30 Opening:

09:30–10:30 Invited talk 1: Joakim Nivre (Uppsala University)

11:00–12:30 Session 1-A: Syntactic and Semantic Parsing, Grammar Induction I

Boosting for Efficient Model Selection for Syntactic Parsing
Rachel Bawden and Benoît Crabbé

A Universal Framework for Inductive Transfer Parsing across Multi-typed Treebanks
Jiang Guo, Wanxiang Che, Haifeng Wang and Ting Liu

Grammar induction from (lots of) words alone
John K Pate and Mark Johnson

11:00–12:30 Session 1-B: Natural Language Generation, Summarization I

A Redundancy-Aware Sentence Regression Framework for Extractive Summarization
Pengjie Ren, Furu Wei, Zhumin CHEN, Jun MA and Ming Zhou

Generating Video Description using Sequence-to-sequence Model with Temporal Attention
Natsuda Laokulrat, Sang Phan, Noriki Nishida, Raphael Shu, Yo Ehara, Naoaki Okazaki, Yusuke Miyao and Hideki Nakayama

An Improved Phrase-based Approach to Annotating and Summarizing Student Course Responses
Wencan Luo, Fei Liu and Diane Litman

Tuesday, December 13, 2016 (continued)

11:00–12:30 Session 1-C: Applications I

CATENA: CAusal and TEmporal relation extraction from NAtural language texts
Paramita Mirza and Sara Tonelli

Forecasting Word Model: Twitter-based Influenza Surveillance and Prediction
Hayate ISO, Shoko WAKAMIYA and Eiji ARAMAKI

Task-Oriented Intrinsic Evaluation of Semantic Textual Similarity
Nils Reimers, Philip Beyer and Iryna Gurevych

11:00–12:30 Session 1-D: Resources, Software, Tools and Under-resourced languages I

Expanding wordnets to new languages with multilingual sense disambiguation
Mihael Arcan, John Philip McCrae and Paul Buitelaar

A Correlational Encoder Decoder Architecture for Pivot Based Sequence Generation
Amrita Saha, Mitesh M. Khapra, Sarath Chandar, Janarthanan Rajendran and Kyunghyun Cho

Zero-resource Dependency Parsing: Boosting Delexicalized Cross-lingual Transfer with Linguistic Knowledge
Lauriane Aufrant, Guillaume Wisniewski and François Yvon

12:30–14:00 ***Lunch break***

Tuesday, December 13, 2016 (continued)

14:00–16:00 Session 2-A: Machine Learning for NLP I

Improving historical spelling normalization with bi-directional LSTMs and multi-task learning
Marcel Bollmann and Anders Søgaard

Deceptive Opinion Spam Detection Using Neural Network
Yafeng Ren and Yue Zhang

Integrating Topic Modeling with Word Embeddings by Mixtures of vMFs
Ximing Li, Jinjin Chi, Changchun Li, Jihong Ouyang and Bo Fu

Bayesian Language Model based on Mixture of Segmental Contexts for Spontaneous Utterances with Unexpected Words
Ryu Takeda and Kazunori Komatani

14:00–16:00 Session 2-B: Morphology, Segmentation Tagging, Chunking I

Label Embedding for Zero-shot Fine-grained Named Entity Typing
Yukun Ma, Erik Cambria and SA GAO

The Role of Context in Neural Morphological Disambiguation
Qinlan Shen, Daniel Clothiaux, Emily Tagtow, Patrick Littell and Chris Dyer

Asynchronous Parallel Learning for Neural Networks and Structured Models with Dense Features
Xu Sun

An Empirical Exploration of Skip Connections for Sequential Tagging
Huijia Wu, Jiajun Zhang and Chengqing Zong

14:00–16:00 Session 2-C: Natural Language Generation, Summarization II

Exploring Text Links for Coherent Multi-Document Summarization
Xun Wang, Masaaki Nishino, Tsutomu Hirao, Katsuhito Sudoh and Masaaki Nagata

Syntactic realization with data-driven neural tree grammars
Brian McMahan and Matthew Stone

Abstractive News Summarization based on Event Semantic Link Network
Wei Li, Lei He and Hai Zhuge

A General Optimization Framework for Multi-Document Summarization Using Genetic Algorithms and Swarm Intelligence
Maxime Peyrard and Judith Eckle-Kohler

14:00–15:30 Session 2-D: Speech Recognition, Text-To-Speech, Spoken Language Understanding

Exploiting Sentence and Context Representations in Deep Neural Models for Spoken Language Understanding
Lina M. Rojas Barahona, Milica Gasic, Nikola Mrkšić, Pei-Hao Su, Stefan Ultes, Tsung-Hsien Wen and Steve Young

Predictive Incremental Parsing Helps Language Modeling
Arne Köhn and Timo Baumann

A Neural Attention Model for Disfluency Detection
Shaolei Wang, Wanxiang Che and Ting Liu

Tuesday, December 13, 2016 (continued)

14:00–16:00 Session 2-P: Poster Session 1

Morphology, Segmentation, Tagging, Chunking

Detecting Sentence Boundaries in Sanskrit Texts
Oliver Hellwig

Consistent Word Segmentation, Part-of-Speech Tagging and Dependency Labelling Annotation for Chinese Language
Mo Shen, Wingmui Li, HyunJeong Choe, Chenhui Chu, Daisuke Kawahara and Sadao Kurohashi

Attending to Characters in Neural Sequence Labeling Models
Marek Rei, Gamal Crichton and Sampo Pyysalo

A Word Labeling Approach to Thai Sentence Boundary Detection and POS Tagging
Nina Zhou, AiTi Aw, Nattadaporn Lertcheva and Xuancong Wang

Assigning Fine-grained PoS Tags based on High-precision Coarse-grained Tagging
Tobias Horsmann and Torsten Zesch

Data-Driven Morphological Analysis and Disambiguation for Morphologically Rich Languages and Universal Dependencies
Amir More and Reut Tsarfaty

Automatic Syllabification for Manipuri language
Loitongbam Gyanendro Singh, Lenin Laitonjam and Sanasam Ranbir Singh

Speech Recognition, Text-To-Speech, Spoken Language Understanding

Learning to Distill: The Essence Vector Modeling Framework
Kuan-Yu Chen, Shih-Hung Liu, Berlin Chen and Hsin-Min Wang

Continuous Expressive Speaking Styles Synthesis based on CVSM and MR-HMM
Jaime Lorenzo-Trueba, Roberto Barra-Chicote, Ascension Gallardo-Antolin, Junichi Yamagishi and Juan M Montero

An Automatic Prosody Tagger for Spontaneous Speech
Monica Dominguez, Mireia Farrús and Leo Wanner

Frustratingly Easy Neural Domain Adaptation
Young-Bum Kim, Karl Stratos and Ruhi Sarikaya

Syntactic and Semantic Parsing, Grammar Induction

A House United: Bridging the Script and Lexical Barrier between Hindi and Urdu
Riyaz A. Bhat, Irshad A. Bhat, Naman Jain and Dipti Misra Sharma

Deeper syntax for better semantic parsing
Olivier Michalon, Corentin Ribeyre, Marie Candito and Alexis Nasr

Language Independent Dependency to Constituent Tree Conversion
Young-Suk Lee and Zhiguo Wang

Promoting multiword expressions in A TAG parsing*
Jakub Waszczuk, Agata Savary and Yannick Parmentier

Under-resourced Languages

Incrementally Learning a Dependency Parser to Support Language Documentation in Field Linguistics
Morgan Ulinski, Julia Hirschberg and Owen Rambow

Inducing Multilingual Text Analysis Tools Using Bidirectional Recurrent Neural Networks
Othman ZENNAKI, Nasredine Semmar and Laurent Besacier

Bitext Name Tagging for Cross-lingual Entity Annotation Projection
Dongxu Zhang, Boliang Zhang, Xiaoman Pan, Xiaocheng Feng, Heng Ji and Weiran XU

Determining the Multiword Expression Inventory of a Surprise Language
Bahar Salehi, Paul Cook and Timothy Baldwin

A Hybrid Deep Learning Architecture for Sentiment Analysis
Md Shad Akhtar, Ayush Kumar, Asif Ekbal and Pushpak Bhattacharyya

Word Segmentation in Sanskrit Using Path Constrained Random Walks
Amrith Krishna, Bishal Santra, Pavankumar Satuluri, Sasi Prasanth Bandaru, Bhumi Faldu, Yajuvendra Singh and Pawan Goyal

Mongolian Named Entity Recognition System with Rich Features
Weihua Wang, Feilong Bao and Guanglai Gao

Applications

Appraising UMLS Coverage for Summarizing Medical Evidence
Elaheh ShafieiBavani, Mohammad Ebrahimi, Raymond Wong and Fang Chen

Large-scale Multi-class and Hierarchical Product Categorization for an E-commerce Giant
Ali Cevahir and Koji Murakami

Product Classification in E-Commerce using Distributional Semantics
Vivek Gupta, Harish Karnick, Ashendra Bansal and Pradhuman Jhala

16:00–16:30 ***coffee break***

Tuesday, December 13, 2016 (continued)

16:30–18:00 Session 3-A: Natural Language Generation, Summarization III

AttSum: Joint Learning of Focusing and Summarization with Neural Attention
Ziqiang Cao, Wenjie Li, Sujian Li, Furu Wei and Yanran Li

Using Relevant Public Posts to Enhance News Article Summarization
Chen Li, Zhongyu Wei, Yang Liu, Yang Jin and Fei Huang

A Proposition-Based Abstractive Summariser
Yimai Fang, Haoyue Zhu, Ewa Muszyńska, Alexander Kuhnle and Simone Teufel

16:30–18:00 Session 3-B: Syntactic and Semantic Parsing, Grammar Induction II

Cross-lingual Learning of an Open-domain Semantic Parser
Kilian Evang and Johan Bos

A subtree-based factorization of dependency parsing
Qiuye Zhao and Qun Liu

K-SRL: Instance-based Learning for Semantic Role Labeling
Alan Akbik and Yunyao Li

16:30–18:00 Session 3-C: Morphology, Segmentation Tagging, Chunking II

Keystroke dynamics as signal for shallow syntactic parsing
Barbara Plank

A Bayesian model for joint word alignment and part-of-speech transfer
Robert Östling

Splitting compounds with ngrams
Naomi Tachikawa Shapiro

16:30–18:00 Session 3-D: Applications II

GAKE: Graph Aware Knowledge Embedding
Jun Feng, Minlie Huang, Yang Yang and xiaoyan zhu

Ranking Responses Oriented to Conversational Relevance in Chat-bots
Bowen Wu, Baoxun Wang and Hui Xue

Probabilistic Prototype Model for Serendipitous Property Mining
Taesung Lee, Seung-won Hwang and Zhongyuan Wang

16:30–18:00 Session 3-P: Poster Session 2

Computational Psycholinguistics

Identifying Cross-Cultural Differences in Word Usage
Aparna Garimella, Rada Mihalcea and James Pennebaker

Reading-Time Annotations for "Balanced Corpus of Contemporary Written Japanese"
Masayuki Asahara, Hajime Ono and Edson T. Miyamoto

"How Bullying is this Message?": A Psychometric Thermometer for Bullying
Parma Nand, Rivindu Perera and Abhijeet Kasture

Learning grammatical categories using paradigmatic representations: Substitute words for language acquisition
Mehmet Ali Yatbaz, Volkan Cirik, Aylin Küntay and Deniz Yuret

Understanding the Lexical Simplification Needs of Non-Native Speakers of English
Gustavo Paetzold and Lucia Specia

How Interlocutors Coordinate with each other within Emotional Segments?
Firoj Alam, Shammur Absar Chowdhury, Morena Danieli and Giuseppe Riccardi

Linguistic Issues in NLP

Advancing Linguistic Features and Insights by Label-informed Feature Grouping: An Exploration in the Context of Native Language Identification
Serhiy Bykh and Detmar Meurers

Modeling Diachronic Change in Scientific Writing with Information Density
Raphael Rubino, Stefania Degaetano-Ortlieb, Elke Teich and Josef van Genabith

Different Contexts Lead to Different Word Embeddings
Wenpeng Hu, Jiajun Zhang and Nan Zheng

Machine Learning for Metrical Analysis of English Poetry
Manex Agirrezabal, Iñaki Alegria and Mans Hulden

Automated speech-unit delimitation in spoken learner English
Russell Moore, Andrew Caines, Calbert Graham and Paula Buttery

Learning to Identify Sentence Parallelism in Student Essays
Wei Song, Tong Liu, Ruiji Fu, Lizhen Liu, Hanshi Wang and Ting Liu

Evaluating anaphora and coreference resolution to improve automatic keyphrase extraction
Marco Basaldella, Giorgia Chiaradia and Carlo Tasso

Retrieving Occurrences of Grammatical Constructions
Anna Ehrlemark, Richard Johansson and Benjamin Lyngfelt

Automatic Extraction of Learner Errors in ESL Sentences Using Linguistically Enhanced Alignments
Mariano Felice, Christopher Bryant and Ted Briscoe

Contrasting Vertical and Horizontal Transmission of Typological Features
Kenji Yamauchi and Yugo Murawaki

How Regular is Japanese Loanword Adaptation? A Computational Study
Lingshuang Mao and Mans Hulden

Using Linguistic Data for English and Spanish Verb-Noun Combination Identification
Uxoa Iñurrieta, Arantza Diaz de Ilarraza, Gorka Labaka, Kepa Sarasola, Itziar Aduriz and John Carroll

Tuesday, December 13, 2016 (continued)

Applications

Analyzing Gender Bias in Student Evaluations
Andamlak Terkik, Emily Prud'hommeaux, Cecilia Ovesdotter Alm, Christopher Homan and Scott Franklin

Adverse Drug Reaction Classification With Deep Neural Networks
Trung Huynh, Yulan He, Alistair Willis and Stefan Rueger

Chinese Preposition Selection for Grammatical Error Diagnosis
Hen-Hsen Huang, Yen-Chi Shao and Hsin-Hsi Chen

Wednesday, December 14, 2016

09:00–10:00 **Invited talk 2: Reiko Mazuka (RIKEN Brain Science Institute & Duke University)**

10:00–10:30 ***coffee break***

10:30–12:00 **Session 4-A: Morphology, Segmentation, Tagging, Chunking III**

Extending the Use of Adaptor Grammars for Unsupervised Morphological Segmentation of Unseen Languages
Ramy Eskander, Owen Rambow and Tianchun Yang

CharNER: Character-Level Named Entity Recognition
Onur Kuru, Ozan Arkan Can and Deniz Yuret

A Neural Model for Part-of-Speech Tagging in Historical Texts
Christian Hardmeier

10:30–12:00 Session 4-B: Applications III

Extracting Discriminative Keyphrases with Learned Semantic Hierarchies
Yunli Wang, Yong Jin, Xiaodan Zhu and Cyril Goutte

Hashtag Recommendation Using End-To-End Memory Networks with Hierarchical Attention
Haoran Huang, Qi Zhang, Yeyun Gong and Xuanjing Huang

Automatic Labelling of Topics with Neural Embeddings
Shraey Bhatia, Jey Han Lau and Timothy Baldwin

10:30–12:00 Session 4-C: Computational Psycholinguistics and Linguistic Issues in NLP I

Memory-Bounded Left-Corner Unsupervised Grammar Induction on Child-Directed Input
Cory Shain, William Bryce, Lifeng Jin, Victoria Krakovna, Finale Doshi-Velez, Timothy Miller, William Schuler and Lane Schwartz

'Calling on the classical phone': a distributional model of adjective-noun errors in learners' English
Aurélie Herbelot and Ekaterina Kochmar

Are Cohesive Features Relevant for Text Readability Evaluation?
Amalia Todirascu, Thomas Francois, Delphine Bernhard, Nuria Gala and Anne-Laure Ligozat

10:30–12:00 Session 4-D: Resources, Software, Tools and Under-resourced languages II

Named Entity Recognition for Linguistic Rapid Response in Low-Resource Languages: Sorani Kurdish and Tajik
Patrick Littell, Kartik Goyal, David R. Mortensen, Alexa Little, Chris Dyer and Lori Levin

Multilingual Supervision of Semantic Annotation
Peter Exner, Marcus Klang and Pierre Nugues

Siamese Convolutional Networks for Cognate Identification
Taraka Rama

10:30–12:00 Session 4-P: Poster Session 3

Natural Language Generation, Summarization

Exploring Differential Topic Models for Comparative Summarization of Scientific Papers
Lei He, Wei Li and Hai Zhuge

Bridging the gap between extractive and abstractive summaries: Creation and evaluation of coherent extracts from heterogeneous sources
Darina Benikova, Margot Mieskes, Christian M. Meyer and Iryna Gurevych

Chinese Poetry Generation with Planning based Neural Network
Zhe Wang, Wei He, Hua Wu, Haiyang Wu, Wei Li, Haifeng Wang and Enhong Chen

Predicting sentential semantic compatibility for aggregation in text-to-text generation
Victor Chenal and Jackie Chi Kit Cheung

Sequential Clustering and Contextual Importance Measures for Incremental Update Summarization
Markus Zopf, Eneldo Loza Mencía and Johannes Fürnkranz

Natural Language Generation through Character-based RNNs with Finite-state Prior Knowledge
Raghav Goyal, Marc Dymetman and Eric Gaussier

A Hybrid Approach to Generation of Missing Abstracts in Biomedical Literature
Suchet Chachra, Asma Ben Abacha, Sonya Shooshan, Laritza Rodriguez and Dina Demner-Fushman

Imitation learning for language generation from unaligned data
Gerasimos Lampouras and Andreas Vlachos

Product Review Summarization by Exploiting Phrase Properties
Naitong Yu, Minlie Huang, Yuanyuan Shi and xiaoyan zhu

Generating Questions and Multiple-Choice Answers using Semantic Analysis of Texts
Jun Araki, Dheeraj Rajagopal, Sreecharan Sankaranarayanan, Susan Holm, Yukari Yamakawa and Teruko Mitamura

Resources, Software and Tools

Evaluation Strategies for Computational Construction Grammars
Tania Marques and Katrien Beuls

Building a Monolingual Parallel Corpus for Text Simplification Using Sentence Similarity Based on Alignment between Word Embeddings
Tomoyuki Kajiwara and Mamoru Komachi

Word2Vec vs DBnary: Augmenting METEOR using Vector Representations or Lexical Resources?
Christophe Servan, Alexandre Berard, zied elloumi, Hervé Blanchon and Laurent Besacier

Broad Twitter Corpus: A Diverse Named Entity Recognition Resource
Leon Derczynski, Kalina Bontcheva and Ian Roberts

Semantic overfitting: what 'world' do we consider when evaluating disambiguation of text?
Filip Ilievski, Marten Postma and Piek Vossen

Information Retrieval, Information Extraction, Question Answering

Extraction of Keywords of Novelties From Patent Claims
Shoko Suzuki and Hiromichi Takatsuka

Leveraging Multilingual Training for Limited Resource Event Extraction
Andrew Hsi, Yiming Yang, Jaime Carbonell and Ruochen Xu

LILI: A Simple Language Independent Approach for Language Identification
Mohamed Al-Badrashiny and Mona Diab

High Accuracy Rule-based Question Classification using Question Syntax and Semantics
Harish Tayyar Madabushi and Mark Lee

Incorporating Label Dependency for Answer Quality Tagging in Community Question Answering via CNN-LSTM-CRF
Yang Xiang, Xiaoqiang Zhou, Qingcai Chen, Zhihui Zheng, Buzhou Tang, Xiaolong Wang and Yang Qin

Semantically Motivated Hebrew Verb-Noun Multi-Word Expressions Identification
Chaya Liebeskind and Yaakov HaCohen-Kerner

Thursday, December 15, 2016

09:00–10:00 **Invited talk 3: Dina Demner-Fushman (U.S. National Library of Medicine)**

10:00–10:30 ***coffee break***

10:30–12:30 **Session 5-A: Semantic Processing, Distributional Semantics, Compositionality I**

Semantic Relation Classification via Hierarchical Recurrent Neural Network with Attention
Minguang Xiao and Cong Liu

A Unified Architecture for Semantic Role Labeling and Relation Classification
Jiang Guo, Wanxiang Che, Haifeng Wang, Ting Liu and Jun Xu

Facing the most difficult case of Semantic Role Labeling: A collaboration of word embeddings and co-training
Quynh Ngoc Thi Do, Steven Bethard and Marie-Francine Moens

Predictability of Distributional Semantics in Derivational Word Formation
Sebastian Padó, Aurélie Herbelot, Max Kisselew and Jan Šnajder

10:30–12:30 **Session 5-B: Computational Psycholinguistics and Linguistic Issues in NLP II**

Survey on the Use of Typological Information in Natural Language Processing
Helen O'Horan, Yevgeni Berzak, Ivan Vulic, Roi Reichart and Anna Korhonen

From phonemes to images: levels of representation in a recurrent neural model of visually-grounded language learning
Lieke Gelderloos and Grzegorz Chrupała

Linguistic features for Hindi light verb construction identification
Ashwini Vaidya, Sumeet Agarwal and Martha Palmer

Cross-lingual Transfer of Correlations between Parts of Speech and Gaze Features
Maria Barrett, Frank Keller and Anders Søgaard

10:30–12:30 Session 5-C: Lexical Semantics, Ontologies & Paraphrasing, Textual Entailment I

Sentence Similarity Learning by Lexical Decomposition and Composition
Zhiguo Wang, Haitao Mi and Abraham Ittycheriah

Chinese Hypernym-Hyponym Extraction from User Generated Categories
Chengyu Wang and Xiaofeng He

Dynamic Generative model for Diachronic Sense Emergence Detection
Martin Emms and Arun kumar Jayapal

Semi-supervised Word Sense Disambiguation with Neural Models
Dayu Yuan, Julian Richardson, Ryan Doherty, Colin Evans and Eric Altendorf

10:30–12:30 Session 5-D: Machine Translation I

Fast Gated Neural Domain Adaptation: Language Model as a Case Study
Jian Zhang, Xiaofeng Wu, Andy Way and Qun Liu

Machine Translation Evaluation for Arabic using Morphologically-enriched Embeddings
Francisco Guzmán, Houda Bouamor, Ramy Baly and Nizar Habash

Ensemble Learning for Multi-Source Neural Machine Translation
Ekaterina Garmash and Christof Monz

Phrase-based Machine Translation using Multiple Preordering Candidates
Yusuke Oda, Taku Kudo, Tetsuji Nakagawa and Taro Watanabe

10:30–12:30 Session 5-P: Poster Session 4

Information Retrieval, Information Extraction, Question Answering

Hand in Glove: Deep Feature Fusion Network Architectures for Answer Quality Prediction in Community Question Answering
Sai Praneeth Suggu, Kushwanth Naga Goutham, Manoj K. Chinnakotla and Manish Shrivastava

Learning Event Expressions via Bilingual Structure Projection
Fangyuan Li, Ruihong Huang, Deyi Xiong and Min Zhang

Global Inference to Chinese Temporal Relation Extraction
Peifeng Li, Qiaoming Zhu, Guodong Zhou and Hongling Wang

Improved relation classification by deep recurrent neural networks with data augmentation
Yan Xu, Ran Jia, Lili Mou, Ge Li, Yunchuan Chen, Yangyang Lu and Zhi Jin

Relation Extraction with Multi-instance Multi-label Convolutional Neural Networks
Xiaotian Jiang, Quan Wang, Peng Li and Bin Wang

Named Entity Disambiguation for little known referents: a topic-based approach
Andrea Glaser and Jonas Kuhn

Natural Language Generation, Summarization

Building RDF Content for Data-to-Text Generation
Laura Perez-Beltrachini, Rania SAYED and Claire Gardent

Parallel Sentence Compression
Julia Ive and François Yvon

An Unsupervised Multi-Document Summarization Framework Based on Neural Document Model
Shulei Ma, Zhi-Hong Deng and Yunlun Yang

From OpenCCG to AI Planning: Detecting Infeasible Edges in Sentence Generation
Maximilian Schwenger, Alvaro Torralba, Joerg Hoffmann, David M. Howcroft and Vera Demberg

The Next Step for Multi-Document Summarization: A Heterogeneous Multi-Genre Corpus Built with a Novel Construction Approach
Markus Zopf, Maxime Peyrard and Judith Eckle-Kohler

Sentiment Analysis and Computational Argumentation

SentiHood: Targeted Aspect Based Sentiment Analysis Dataset for Urban Neighbourhoods
Marzieh Saeidi, Guillaume Bouchard, Maria Liakata and Sebastian Riedel

On the Impact of Seed Words on Sentiment Polarity Lexicon Induction
Dame Jovanoski, Veno Pachovski and Preslav Nakov

Evaluating Argumentative and Narrative Essays using Graphs
Swapna Somasundaran, Brian Riordan, Binod Gyawali and Su-Youn Yoon

Selective Co-occurrences for Word-Emotion Association
Ameeta Agrawal and Aijun An

Weighted Neural Bag-of-n-grams Model: New Baselines for Text Classification
Bofang Li, Zhe Zhao, Tao Liu, Puwei Wang and Xiaoyong Du

A Deeper Look into Sarcastic Tweets Using Deep Convolutional Neural Networks
Soujanya Poria, Erik Cambria, Devamanyu Hazarika and Prateek Vij

Exploring Distributional Representations and Machine Translation for Aspect-based Cross-lingual Sentiment Classification.
Jeremy Barnes, Patrik Lambert and Toni Badia

A Bilingual Attention Network for Code-switched Emotion Prediction
Zhongqing Wang, Yue Zhang, Sophia Lee, Shoushan Li and Guodong Zhou

UTCNN: a Deep Learning Model of Stance Classification on Social Media Text
Wei-Fan Chen and Lun-Wei Ku

Computational Psycholinguistics

The Role of Intrinsic Motivation in Artificial Language Emergence: a Case Study on Colour
Miquel Cornudella, Thierry Poibeau and Remi van Trijp

Predicting the Evocation Relation between Lexicalized Concepts
Yoshihiko Hayashi

Collecting and Exploring Everyday Language for Predicting Psycholinguistic Properties of Words
Gustavo Paetzold and Lucia Specia

Applications

Using Argument Mining to Assess the Argumentation Quality of Essays
Henning Wachsmuth, Khalid Al Khatib and Benno Stein

Grammatical Templates: Improving Text Difficulty Evaluation for Language Learners
Shuhan Wang and Erik Andersen

Still not there? Comparing Traditional Sequence-to-Sequence Models to Encoder-Decoder Neural Networks on Monotone String Translation Tasks
Carsten Schnober, Steffen Eger, Erik-Lân Do Dinh and Iryna Gurevych

12:30–14:00 ***Lunch break***

14:00–16:00 Session 6-A: Information Retrieval, Information Extraction, Question Answering I

Towards Time-Aware Knowledge Graph Completion
Tingsong Jiang, Tianyu Liu, Tao Ge, Lei Sha, Baobao Chang, Sujian Li and Zhifang Sui

Learning to Weight Translations using Ordinal Linear Regression and Query-generated Training Data for Ad-hoc Retrieval with Long Queries
Javid Dadashkarimi, Masoud Jalili Sabet and Azadeh Shakery

Neural Attention for Learning to Rank Questions in Community Question Answering
Salvatore Romeo, Giovanni Da San Martino, Alberto Barrón-Cedeño, Alessandro Moschitti, Yonatan Belinkov, Wei-Ning Hsu, Yu Zhang, Mitra Mohtarami and James Glass

Simple Question Answering by Attentive Convolutional Neural Network
Wenpeng Yin, Mo Yu, Bing Xiang, Bowen Zhou and Hinrich Schütze

14:00–16:00 Session 6-B: Machine Learning for NLP II

Recurrent Dropout without Memory Loss
Stanislau Semeniuta, Aliaksei Severyn and Erhardt Barth

Modeling topic dependencies in semantically coherent text spans with copulas
Georgios Balikas, Hesam Amoualian, Marianne Clausel, Eric Gaussier and Massih R Amini

Consensus Attention-based Neural Networks for Chinese Reading Comprehension
Yiming Cui, Ting Liu, Zhipeng Chen, Shijin Wang and Guoping Hu

Semantic Annotation Aggregation with Conditional Crowdsourcing Models and Word Embeddings
Paul Felt, Eric Ringger and Kevin Seppi

14:00–16:00 Session 6-C: Machine Translation II

Interactive-Predictive Machine Translation based on Syntactic Constraints of Prefix
Na Ye, Guiping Zhang and Dongfeng Cai

Topic-Informed Neural Machine Translation
Jian Zhang, Liangyou Li, Andy Way and Qun Liu

A Distribution-based Model to Learn Bilingual Word Embeddings
Hailong Cao, Tiejun Zhao, Shu ZHANG and Yao Meng

Pre-Translation for Neural Machine Translation
Jan Niehues, Eunah Cho, Thanh-Le Ha and Alex Waibel

14:00–16:00 Session 6-D: Semantic Processing, Distributional Semantics, Compositionality II

Direct vs. indirect evaluation of distributional thesauri
Vincent Claveau and Ewa Kijak

D-GloVe: A Feasible Least Squares Model for Estimating Word Embedding Densities
Shoaib Jameel and Steven Schockaert

Predicting human similarity judgments with distributional models: The value of word associations.
Simon De Deyne, Amy Perfors and Daniel J Navarro

Distributional Hypernym Generation by Jointly Learning Clusters and Projections
Josuke Yamane, Tomoya Takatani, Hitoshi Yamada, Makoto Miwa and Yutaka Sasaki

14:00–16:00 Session 6-P: Poster Session 5

Discourse Relations, Coreference, Pragmatics

Incremental Fine-grained Information Status Classification Using Attention-based LSTMs
Yufang Hou

Detection, Disambiguation and Argument Identification of Discourse Connectives in Chinese Discourse Parsing
Yong-Siang Shih and Hsin-Hsi Chen

Multi-view and multi-task training of RST discourse parsers
Chloé Braud, Barbara Plank and Anders Søgaard

Implicit Discourse Relation Recognition with Context-aware Character-enhanced Embeddings
Lianhui Qin, Zhisong Zhang and Hai Zhao

Measuring Non-cooperation in Dialogue
Brian Plüss and Paul Piwek

Representation and Learning of Temporal Relations
Leon Derczynski

Revisiting the Evaluation for Cross Document Event Coreference
Shyam Upadhyay, Nitish Gupta, Christos Christodoulopoulos and Dan Roth

Modeling Discourse Segments in Lyrics Using Repeated Patterns
Kento Watanabe, Yuichiroh Matsubayashi, Naho Orita, Naoaki Okazaki, Kentaro Inui, Satoru Fukayama, Tomoyasu Nakano, Jordan Smith and Masataka Goto

Dialog Processing and Dialog Systems, Multimodal Interfaces

Multi-level Gated Recurrent Neural Network for dialog act classification
Wei Li and Yunfang Wu

Multimodal Mood Classification - A Case Study of Differences in Hindi and Western Songs
Braja Gopal Patra, Dipankar Das and Sivaji Bandyopadhyay

Detecting Context Dependent Messages in a Conversational Environment
Chaozhuo Li, Yu Wu, Wei Wu, Chen Xing, Zhoujun Li and Ming Zhou

Joint Inference for Mode Identification in Tutorial Dialogues
Deepak Venugopal and Vasile Rus

Dialogue Act Classification in Domain-Independent Conversations Using a Deep Recurrent Neural Network
Hamed Khanpour, Nishitha Guntakandla and Rodney Nielsen

Non-sentential Question Resolution using Sequence to Sequence Learning
Vineet Kumar and Sachindra Joshi

Context-aware Natural Language Generation for Spoken Dialogue Systems
Hao Zhou, Minlie Huang and xiaoyan zhu

Speech Recognition, Text-To-Speech, Spoken Language Understanding

Weakly-supervised text-to-speech alignment confidence measure
Guillaume Serrière, Christophe Cerisara, Dominique Fohr and Odile Mella

Domainless Adaptation by Constrained Decoding on a Schema Lattice
Young-Bum Kim, Karl Stratos and Ruhi Sarikaya

Sub-Word Similarity based Search for Embeddings: Inducing Rare-Word Embeddings for Word Similarity Tasks and Language Modelling
Mittul Singh, Clayton Greenberg, Youssef Oualil and Dietrich Klakow

Applications

Semi-automatic Detection of Cross-lingual Marketing Blunders based on Pragmatic Label Propagation in Wiktionary
Christian M. Meyer, Judith Eckle-Kohler and Iryna Gurevych

Ambient Search: A Document Retrieval System for Speech Streams
Benjamin Milde, Jonas Wacker, Stefan Radomski, Max Mühlhäuser and Chris Biemann

Semi-supervised Gender Classification with Joint Textual and Social Modeling
Shoushan Li, Bin Dai, Zhengxian Gong and Guodong Zhou

Predicting proficiency levels in learner writings by transferring a linguistic complexity model from expert-written coursebooks
Ildikó Pilán, Elena Volodina and Torsten Zesch

User Classification with Multiple Textual Perspectives
Dong Zhang, Shoushan Li, Hongling Wang and Guodong Zhou

Says Who…? Identification of Expert versus Layman Critics' Reviews of Documentary Films
Ming Jiang and Jana Diesner

Knowledge-Driven Event Embedding for Stock Prediction
Xiao Ding, Yue Zhang, Ting Liu and Junwen Duan

Distributed Representations for Building Profiles of Users and Items from Text Reviews
Wenliang Chen, Zhenjie Zhang, Zhenghua Li and Min Zhang

16:00–16:30 ***coffee break***

16:30–18:00 Session 7-A: Machine Translation III

Improving Statistical Machine Translation with Selectional Preferences
Haiqing Tang, Deyi Xiong, Min Zhang and Zhengxian Gong

Hierarchical Permutation Complexity for Word Order Evaluation
Miloš Stanojević and Khalil Sima'an

Interactive Attention for Neural Machine Translation
Fandong Meng, Zhengdong Lu, Hang Li and Qun Liu

benoit.crabbe@linguist.univ-paris-diderot.fr

Abstract

We present an efficient model selection method using boosting for transition-based constituency parsing. It is designed for exploring a high-dimensional search space, defined by a large set of feature templates, as for example is typically the case when parsing morphologically rich languages. Our method removes the need to manually define heuristic constraints, which are often imposed in current state-of-the-art selection methods. Our experiments for French show that the method is more efficient and is also capable of producing compact, state-of-the-art models.

1 Introduction

Model selection in feature-based parsing is crucial because features define a parsing model's capacity to predict syntactic structure. Choosing an optimal model is a trade-off between generalisation performance, compactness and parsing speed. Although too rarely mentioned, to this we should also add the speed of the selection method, which can determine how much of the search space can actually be explored. Parsing of languages other than English, and in particular morphologically rich languages, spurred on by initiatives such as the SPMRL (Statistical Parsing of Morphologically Rich Languages) shared tasks (Seddah et al., 2014), has received a heightened interest in recent years. For such languages, it is natural to want to exploit morphologically rich data to improve parsing performance. However the effect of this is an explosion in the number of possible models due to a huge number of potential features.

In this paper we introduce an efficient, language-independent model selection method for transition-based constituency parsing. It is designed for model selection when faced with a large number of possible feature templates, which is typically the case for morphologically rich languages, for which we want to exploit morphological information. The method we propose uses multi-class boosting (Zhu et al., 2006) for iterative selection in constant time, using virtually no *a priori* constraints on the search space. We do however introduce a pre-ranking step before selection in order to guide the selection process. We provide experiments on the adaptation of boosting for model selection in the parsing of high-dimensional data, using the transition-based lexicalised constituency parser presented in (Crabbé, 2015) and illustrating the feasibility of the method for our working language, French. Our results show that it is possible to produce high-performing, compact models much more efficiently than naive methods.

The structure of the paper is as follows. We begin by describing the transition-based parser used throughout the paper (Section 2). In Section 3 we review related work, both in model selection for parsing (Section 3.1) and on the boosting algorithm used (Section 3.2) in our proposal. In Section 4 we present our adaptation of the method for parsing and in Section 5 our experiments and results.

2 Discriminative constituency parsing

We base our experiments on the multilingual discriminative constituency parser described in (Crabbé, 2014; Crabbé, 2015) and inspired by transition-based parsing algorithms (Zhu et al., 2013). The parser

[*] This work was carried out while the first author was a Master's student at Alpage (Univ. Paris-Diderot & Inria).

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1–11, Osaka, Japan, December 11-17 2016.

is an accurate and efficient transition-based lexicalised parser, capable of easily integrating lexical and morphological features. Following standard practice in transition-based parsing, the key structure for parsing is the *configuration* $C = \langle j, \mathbf{S} \rangle$ where j is the index of the parser in the queue of input tokens and $\mathbf{S}$ is a stack of partially constructed tree structures. A derivation $C_{0 \Rightarrow \tau}$ of length τ is represented by a sequence of configurations $C_0 \overset{a_0}{\Rightarrow} \ldots \overset{a_{\tau-1}}{\Rightarrow} C_\tau$ where each $a_i \in A$ is the parser *action* used to move from C_i to C_{i+1}. We use the same set A of actions as described in (Crabbé, 2014). Derivations are scored by a function of the form:

$$W(C_{0 \Rightarrow \tau}) = \sum_{i=0}^{\tau-1} \mathbf{w} \cdot \mathbf{\Phi}(a_i, C_i)$$

where $\mathbf{w} \in \mathbb{R}^D$ is a weight vector and where $\mathbf{\Phi}(a, C) \in \{0, 1\}^D$ denotes a function encoding a boolean-valued feature vector from a pair (a, C).

Let GEN_τ be the set of derivations of length τ. The best derivation in this set is defined as:

$$\hat{C}_{0 \Rightarrow \tau} = \underset{C_{0 \Rightarrow \tau} \in \text{GEN}_\tau}{\text{argmax}} \; W(C_{0 \Rightarrow \tau})$$

Weights for individual features are learnt using an averaged multi-class perceptron (Collins, 2002). They can either be optimised globally (over sequences of derivations) or locally (for each individual action). The first strategy is known to give better results for perceptron-based parsing (Zhang and Nivre, 2012).

2.1 Feature functions

The feature vector $\mathbf{\Phi}(a, C)$ is the result of a sequence of boolean feature functions $\phi_1(a, C) \ldots \phi_D(a, C)$, which have access to the action, to the top elements of the stack in C and to the beginning of the queue from index j. Each function is defined as per the following pattern:

$$\phi_l(a, C) = \begin{cases} 1 & \textbf{if} \quad \text{attr}_0 = a \\ & \textbf{and} \quad \text{attr}_1 = v_1 \\ & (\textbf{and} \quad \text{attr}_2 = v_2)? \\ & (\textbf{and} \quad \text{attr}_3 = v_3)? \\ 0 & \textbf{otherwise} \end{cases}$$

in which attr_0 is valued by the action $a \in A$ and the attributes $\text{attr}_{1 \leq i \leq 3}$ are extracted from configuration C. In practice, feature functions have access to the top three elements of the stack (see Figure 1) and the first four elements of the queue. They can address non-terminal categories, word-forms and morphological features (such as the part-of-speech (PoS), the gender, the number, the mood etc.) from the heads in the stack and from the words in the queue. Their values v_i are extracted from the configuration C, as illustrated in the following example:

$$\phi_l(a, C) = \begin{cases} 1 & \textbf{if} \quad \text{attr}_0 = a \\ & \textbf{and} \quad q_0.\text{word} = \text{“pot”} \\ & \textbf{and} \quad s_2.\text{cat} = \text{VP} \\ 0 & \textbf{otherwise} \end{cases}$$

As shown in the pattern above, a function can contain up to three attribute-value pairs, excluding the action. We refer to each pair as a condition, and refer to features as being uni-, bi- or tri-conditional depending on the number of conditions they contain.

2.2 Feature templates

It is common practice to use feature templates when defining hand-crafted models rather than to specify individual features. Feature templates are abstract feature representations in which only the attributes are specified, such that features with the same attribute types are grouped into sets. In the case of templates, which can also have up to three conditions, a condition refers simply to the attribute. For example, the bi-conditional template ‘q_0(word) & s_1(t, h, tag)’ represents all bi-conditional feature functions related to the word-form of the first queue element and to the PoS tag of the lexical head associated with the top of the second stack element.

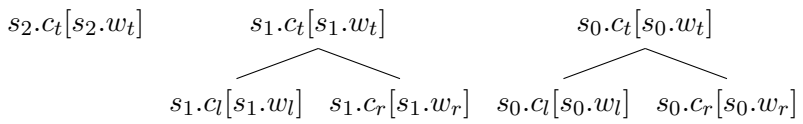

Figure 1: Stack elements for instantiation in feature functions. c_t, c_l and c_r represent non-terminal categories at three positions (top (t), left (l) and right (r)). Lexical information about the head is also available, indicated in squared brackets as $s_i.w_{\{t,l,r\}}$.

Since a feature vector is usually sparse, using templates is an advantage for computational reasons; the values of the feature functions can be dynamically and efficiently bound during parsing. They also enable a more compact and readable representation of models, making models easier to define manually.

When working with parsers that rely on templates, which is the case of most current implementations of existing feature-based parsers (Nilsson and Nugues, 2010; Ballesteros and Nivre, 2014; Crabbé, 2014, etc.), the template seems to be an acceptable level of granularity for specifying models. A selection process at the template-level rather than the feature-level has the advantage of being compatible with these parsers and also reduces the selection time by reducing the combinatorics of the selection process. We therefore focus our work on template selection.

3 Model selection for parsing

3.1 Previous work

For feature-based models, there are two main strategies for model selection. *Filter methods* remove features based on a static analysis, whereas *wrapper methods* iteratively refit the model by forward or backward selection. In the parsing literature, the wrapper method is the most prevalent. While some backward wrappers exist, provided that the template set is small (Attardi et al., 2007), most work focuses on forward wrappers, with a variety of constraints to reduce the search space and thus the time required. Nilsson and Nugues (2010) constrain the search space by imposing an order on stack and queue elements, under the assumption that more local elements are more useful than more distant ones. Ballesteros and Nivre (2014) and Ballesteros and Bohnet (2014) use a combination of forward and backward methods and fix heavy rule-based constraints on the order of templates selected. He et al. (2013) also implement template selection for discriminative parsing. Although applied to graph-based parsing, their work shares a likeness with our own, by their use of a pre-ranking wrapper to order templates prior to selection.

The reason for introducing such constraints is that wrapper methods are computationally intensive and can be known to take weeks to select a model, even with constraints and fully optimised, multi-processed implementations. Take for example the case of the forward wrapper. It starts with an empty model ($M \leftarrow \emptyset$). At each iteration, the template t from the pool of potential templates P that results in the highest overall accuracy gain is added to the model ($M \leftarrow M \cup t$). The process stops when the model's loss ceases to decrease. The most time-consuming part of the process is the training of the possible models, in order to select the template t that results in the highest accuracy gain. In principle, this requires fitting $|P|$ models at each iteration, and the size of the models requiring training grows at each iteration. Given that fitting a single parsing model can take hours (see Section 5.4), it is impractical to perform selection for parsing based on iteratively refitting a series of large and ever-growing models.

3.2 Model selection via boosting

We propose to overcome the limitations of the naive forward wrapper by using sequential additive fitting based on boosting (Freund and Schapire, 1999). Starting with an empty model ($M \leftarrow \emptyset$), additive fitting consists of evaluating the addition of a new template t by fitting t on its own before adding it ($M \leftarrow M \cup t$), without modifying the already fitted content M. At each iteration, as with the naive method, $|P|$ models need to be fit, but they are small and of constant size. As we will show in the

Algorithm 1 SAMME (Zhu et al., 2006)

▷ Data = $\{(x_1, y_1), \ldots, (x_N, y_N)\}$

1: Initialisation of data weights

$$w_i^{(1)} = \frac{1}{N}, \text{ i = 1, 2,..., N}$$

2: **for** iteration t=1 to T **do**

(i) Fit each weak learner $h_j(x)$ in the pool P to data using weights $w_i^{(t)}$

(ii) Calculate the weighted error of each weak learner $h_j(x)$

$$err_{h_j} = \frac{\sum_{i=1}^{N} w_i^{(t)} \mathbb{I}(y_i \neq h_j(x_i))}{\sum_{i=1}^{N} w_i^{(t)}}$$

(iii) Select the $h_j(x)$ with the lowest weighted error err_{h_j} provided that $err_{h_j} > \left(1 - \frac{1}{|Y|}\right)$.

Call the learner $g^{(t)}$ and its weighted error $err^{(t)}$

(iv) Calculate $\alpha^{(t)}$, where Y is the set of classes

$$\alpha^{(t)} = \log\left(\frac{1 - err^{(t)}}{err^{(t)}}\right) + \log\left(|Y| - 1\right)$$

(v) Update data weights using $\alpha^{(t)}$

$$w_i^{(t+1)} = w_i^{(t)} \cdot \exp\left(\alpha^{(t)} \mathbb{I}\left(y_i \neq g^{(t)}(x_i)\right)\right), \text{ i = 1,2,...,N}$$

(vi) Normalise weights such that $\sum_{i=1}^{N} w_i = 1$

end for

3: Prediction is the argmax of a weighted prediction of models $g^{(t)}$, t = 1, 2,..., T

$$f(\text{x}) = \text{argmax}_y \sum_{t=1}^{T} \alpha^{(t)} \mathbb{I}\left(g^{(t)}(x) = y\right)$$

remainder of the paper, this allows for a huge reduction in selection time, meaning that heavy constraints are not needed to reduce the search space.

We use the multi-class AdaBoost variant SAMME (Stagewise Additive Modelling using a Multi-class Exponential loss function) as described in (Zhu et al., 2006) and adapted here in Algorithm 1. The algorithm is designed for predictive modelling and provides the means of combining a set of *weak learners*[1] to produce a strong learner, by additively and iteratively selecting the best weak learner $g^{(t)}$ and calculating its coefficient $\alpha^{(t)}$ (its importance in the final model) until no more weak learners are available. An additive fit is achieved by encoding the exponential loss of already selected learners in a weight distribution over data examples, which is updated at each iteration. The algorithm comes with a theoretical guarantee that as long as the selected learner has a weighted accuracy above chance, the model's boosted accuracy will not decrease.

In the case of parsing, weak learners can be seen as weak parsers, trained each on a very small set of templates. It can be seen as iterative forward selection in that the selection of a weak parser constitutes the selection of the templates on which it is trained. In this paper, we use the term *weak parser* as an alias for the set of templates on which it is trained. Boosting has previously been used for feature selection for automatic face-detection in the domain of imagery (Viola and Jones, 2004) and for a variety of classification tasks by Das (2001). However to our knowledge, boosting methods have not yet been used in the context of template selection for parsing.

4 Adapting boosting for template selection for parsing

Although the algorithm has a theoretical guarantee, certain aspects must be reviewed to adapt it to template selection for parsing. Here we shall review four of these aspects, which prove essential, both in terms of providing a correctly functioning implementation of boosted selection and in terms of the time required for selection: (i) local training during selection, (ii) template grouping for weak parsers, (iii) a user-defined stopping criterion, and (iv) pre-ranking of weak parsers to reduce the pool size at each iteration.

[1] A weak learner (or *weak classifier*, *weak hypothesis*) is a classifier that performs better than random classification.

4.1 Local training of weak parsers

Ensemble methods such as boosting are notoriously problematic when it comes to structured prediction problems such as parsing that require globally optimised training (Cortes et al., 2014). Following Wang et al. (2007), who achieve good results on English and Chinese by boosting locally optimised parsers, we decide to train weak parsers locally during selection. However, unlike Wang et al. (2007), we perform boosting for the unique aim of selecting templates, rather than using the model fitted during boosting. In order to subsequently use the selected templates for parsing, we take the resulting template set, once selection is complete, and fit a globally optimised model. We make the assumption that locally boosted weak parsers provide a good approximation of a template set that can be used to produce a high-performing global model.[2]

4.2 Template grouping for weak parsers

In our approach, the smallest manipulable units for selecting parse models are templates. Instead of considering that each weak parser is trained on a single template, we choose to group templates in order to train larger and stronger weak parsers. The pool of weak parsers is therefore represented by the different template groups available for selection.

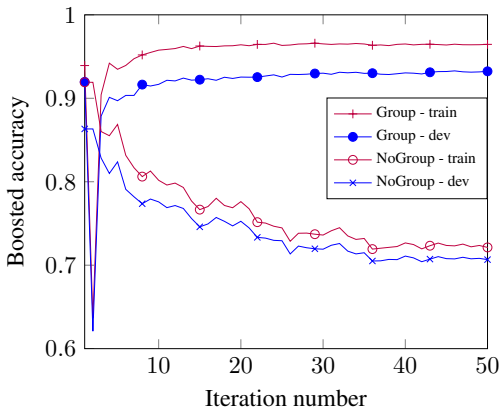

Figure 2: Boosted accuracy with and without grouping

Basis for grouping We use the conditions contained by templates (as defined in Section 2.2) as the basis for grouping. We group templates that share conditions, such that each group contains a single tri-conditional template as well as all the templates with a combination of the three conditions. Each group therefore contains seven templates. Note that uni- and bi-conditional templates necessarily belong to more than one group.

Why group? Grouping templates has several advantages: it allows for cases of co-prediction, it can accelerate model selection by reducing the number of weak parsers trained, and it strengthens the weak parsers. Although in theory handling individual templates would allow for a finer-grained selection, in practice, boosted accuracy does not increase as expected. It has previously been noted by Mukherjee and Schapire (2011) that the guarantee appears to be too weak when the learners perform only just above random. This can be seen in Figure 2, which shows the boosted accuracy for training and development sets with and without grouping. The scores of the resulting models are also significantly lower for individual rather than for grouped templates, and selection is more likely to terminate prematurely due to a lack of sufficiently strong weak parsers, effectively stunting the final model size.

4.3 Stopping criterion

The boosting algorithm has a last-resort stopping criterion, when there are no more weak parsers left. However this is not ideal for a parsing model; time efficiency at parse time is important and, depending on the number of weak parsers available, a model selected with this stopping criterion could be huge, and therefore slow at test time. We observe that the F-score of the retrained model continues to increase (albeit very gradually as the model size increases) as more and more templates are added (tested up to 200 templates), despite the fact that the weighted error during boosting appears to stabilise. We propose a practical stopping criterion, by which the maximum model size (the maximum number of templates) is defined in advance by the user, serving as a second stopping criterion for selection.

4.4 Limiting the pool size by pre-ranking

The size of the weak parser pool is a potential source of problems in terms of efficiency, given the possibility of a very large number of weak parsers. We therefore limit the pool size, by selecting the

[2] Although boosted accuracy is not in strictly perfect correlation with the accuracy of a retrained global model.

parsers from a pool of size k at each iteration, according to a certain criterion. The aim of model selection being to optimise the final performance of the parsing model, we introduce a pre-ranking step, in which all possible weak parsers are globally trained and ranked according to their accuracy. Although this is an approximation of the search space, pre-ranking should be able to guide the search. Weak parsers are not replaced in the pool once selected, which means that the pool is not limited to the original k best-ranked learners; each time a learner is selected, a new one becomes available.[3]

5 Experiments

The aim of our experiments is to investigate the properties of the boosting algorithm in terms of selection time and performance to test the feasibility of the selection method for high-dimensional search spaces. Our working language is French, for which we use a corpus with rich morphological annotations.[4]

5.1 Data

We conduct our experiments for French, using the French TreeBank (FTB) (Abeillé et al., 2003), from the 2014 SPMRL shared task (Seddah et al., 2014), but with automatic predictions of morphological tags[5] by MarMoT (Mueller et al., 2013), trained with ten-fold jackknifing. Templates can refer to the following morphological attributes: word-form, PoS tag, gender, number, mood and multi-word expression tags, as well as the syntactic categories of stack elements. They can access the top two stack elements and the next three queue elements, making a total of 36,050 possible templates and 34,220 possible weak parsers.[6] The corpus is divided into three sets: train, dev and test. Training data is used for pre-ranking and selection, and development data is used for tuning and comparing parameter values. Results on the test set are reported in Section 5.5. For pre-ranking, we use variants of the training set, which vary depending on the maximum length of the sentences they contain. We refer to these variants as FTB-10, FTB-20, FTB-50, where FTB-X contains all sentences from the original with a maximum sentence length of X. To avoid any confusion, we refer to the full set as FTB-all. Data characteristics can be found in Table 1.

Set	#Sents.	#Tokens	Avg. Len.	#(a, C)
FTB-20-train	4,903	63,239	12.90	184,811
FTB-50-train	13,006	330,711	25.43	979,127
FTB-all-train	14,759	443,113	30.02	1,314,580
FTB-all-dev	1235	38,820	31.43	115,225
FTB-all-test	2541	75,216	29.60	223,107

Table 1: Basic data characteristics

5.2 Setup

As described in Section 4, our weak parsers use template groups selected without replacement. During the pre-ranking step, different FTB-X-train variants are evaluated. Weak parsers are trained globally using a single perceptron iteration, a beam size of 4 and early updates (Collins and Roark, 2004). During selection, we also use a single perceptron iteration, but training is done locally. We evaluate the performance of selected models by retraining them globally using FTB-all data, with 30 perceptron iterations, a beam of size 8 and early updates. All experiments were run on an Intel(R) Xeon(R) CPU E5645 @ 2.40GHz. Training is multi-processed but all times reported are approximated for a single processor to enable a rough comparison.

[3] Replacement of learners is common in boosting, especially if they are decision stumps. However we find that with replacement, selection is slower and larger models are unobtainable.

[4] Although not amongst the most morphologically rich languages, the French data contains sufficiently rich morphological annotations to result in a huge number of possible templates, enabling us to test our selection method.

[5] In a realistic scenario where taggers are applied to raw texts before parsing, better parsing results are obtained when training is done on predicted rather than gold tags.

[6] The huge number of templates is due to the large number of morphological attributes available.

5.3 Parameter choices

We investigate the effect on performance and efficiency of selection of varying two parameters: (i) the data used to pre-rank the weak parsers and (ii) the size k of the pool during selection. We also compare against a non-boosted version in which weak learners are simply added in pre-ranking order, which is equivalent to greedy forward selection.

Data	# Sents.	Pre-ranking Time (hours)
FTB-20-train	4,903	63
FTB-50-train	13,006	496
FTB-all-train	14,759	743

Table 2: Pre-ranking times using different data types.

Selection method	Time (mins./iter.)
Pre-rank order	0
Boost, $k = 50$	18.53
Boost, $k = 100$	33.67

Table 3: Selection time per iteration.

Pre-ranking is the most time-consuming step in the process, and the speed is largely determined by training data size (see Table 2). The number of weak parsers is identical for all FTB data, yet there is a stark difference in pre-rank times; FTB-20-train is more than ten times faster than FTB-all-train. Average selection times per iteration, (see Table 3),[7] are directly correlated with the size of the pool k, but are fast compared to the pre-ranking step.

In Figure 3 we study the effect on model performance of varying pre-ranking data and the value of k for two types of model: a small model with a maximum size of 36 templates (for efficient parsing) and a larger model with a maximum size of 120 templates (for higher accuracy but slower parsing).[8]

For the 36-template model, all boosting runs outperform the selection method by pre-ranking only. The effect is greatest when the smaller datasets are used. The crossing pattern seen in the graph for $k = 50$ and $k = 100$ indicates that when the smaller dataset is used for pre-ranking, the larger value for k (of 100) is a better choice, and conversely, when the full dataset is used, the smaller value (of 50) is better. It is therefore possible to achieve almost comparable F-scores as when using full data for pre-ranking and a pool size of 50 by using a smaller dataset (and drastically reducing the time needed to pre-rank) and a larger, less constraining pool size of 100.

F-scores for the larger, 120-template models are higher, but for all methods we observed that the F-score starts to converge at such a large model size. Again, scores are superior when FTB-all-train data is used, but this time, the best model is reached using the simple pre-ranking order of template groups, as long as FTB-all-train is used to pre-rank. For these larger models, it appears that there is less need for the selection process, since a sufficiently large number of reasonably strong templates is all that is required. The disadvantage with this method is that all data is needed for pre-ranking, which, as we have shown above, is more time-consuming. However, as with the smaller models, boosting enables a high-performing model to be selected much faster, by using smaller pre-ranking data.

5.4 Topline model: Naive forward wrapper

We also implemented a naive forward wrapper (see Section 3.1), which we refer to as FWRAP. This method serves as a topline for parsing performance, as the method is a more accurate exploration of the model space, and, as it is very time-consuming, a baseline for selection time. As with the boosting method, templates are added by groups. We change the setup slightly to make the method feasible, using a smaller and less annotated dataset to reduce the number of weak parsers and the time taken to train them. Selection is performed using a variant of FTB-20-train, with the selection criterion being an increased accuracy on FTB-20-dev. We forbid templates from addressing morphological values other than the word-form, the PoS tag and a smoothed version of the word-form,[9] although we allow access to the third stack element and the fourth queue element. Importantly, the total number of weak parsers is far fewer than with the FTB data used above (9,880 vs. 34,220), which means that the initial setup is more

[7] We take the median selection time rather than the mean due to variation due to sporadic differences in machine usage.

[8] For all boosting methods for each parameter combination, an average is calculated over 5 runs to account for random variation due to the use of weighted resampling for training.

[9] Where words of fewer than two occurrences are replaced by a symbol $\$unknown\$$.

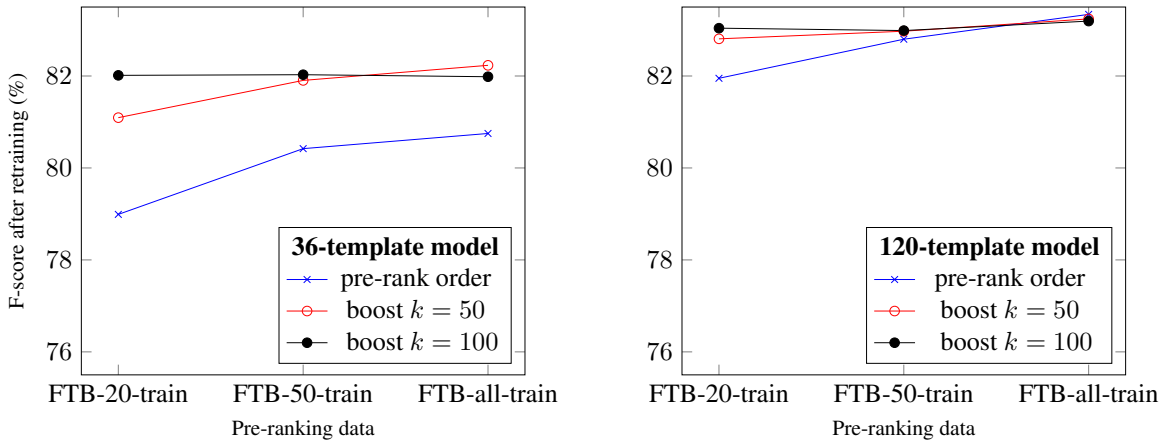

Figure 3: Average F-scores (over 5 separate runs) of selected models with a maximum size of 36 templates (left) and 120 templates (right) for different FTB pre-ranking data and different pool sizes (k).

favourable for FWRAP. Models are trained globally with a beam size of 4 and max-violation updates (Huang et al., 2012) for added speed. Since model sizes vary, the maximum number of perceptron iterations is 35, but we use a test for convergence, enabling training to stop early for smaller models.

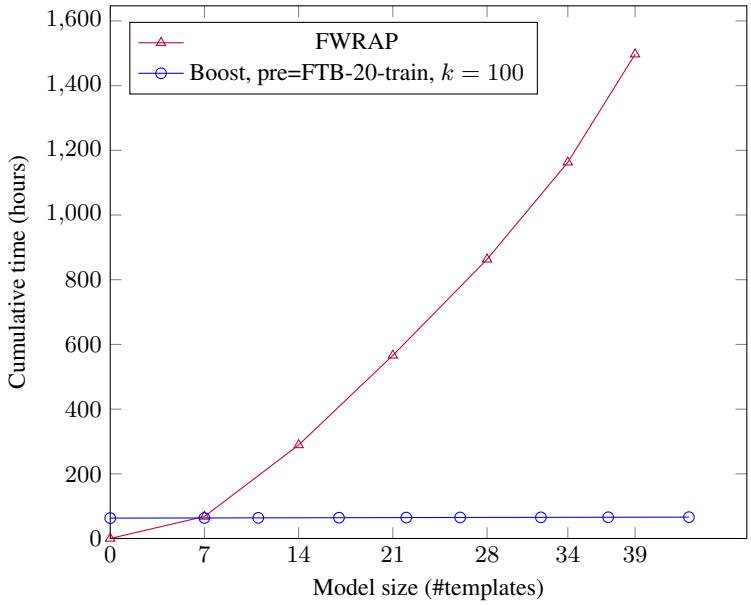

Figure 4: Comparison of cumulative selection time (including pre-ranking) in hours (approximated for a single processor) for FWRAP and a boosted method.

Figure 4 shows selection times for FWRAP and the boosting method (FTB-20-train, $k = 100$). Training an ever-growing model during selection for FWRAP results in an increasing selection time per iteration, whereas the boosting method's selection time is constant and considerably faster overall.

5.5 Results

In Table 4, we provide results for the final selected models on both the development and test sets, evaluated using `evalb`. We provide comparative scores of the Berkeley parser (Petrov et al., 2006), of the current highest performing single parser on French SPMRL data (Durrett and Klein, 2015), of the manually chosen model in (Crabbé, 2014) and of the model selected by FWRAP (Section 5.4). As before, we give our results for two model sizes, using the stopping criterion mentioned in Section 4.3 (a maximum size of 36 templates and of 120 templates).

Model	#tpls.	F-score (%) on FTB-all dev (P)	dev (NoP)	test (P)	test (NoP)	Select. time (hrs)	Parse speed (#Toks./Sec.)
Berkeley (Petrov et al., 2006)	-	79.74	-	80.38	80.73	-	-
Neural CRF (Durrett and Klein, 2015)	-	80.65	-	81.25	-	-	-
Manual (Crabbé, 2014)	68	-	81.79	-	81.43	-	-
FWRAP (Section 5.4)	34	81.80	83.53	**81.52**	83.43	1,163	3,646
FTB-all-train/Pre-rank order	35	79.13	80.75	78.50	80.36	743	3,607
FTB-all-train/$k = 50$	36	**80.73**	**82.42**	79.91	81.69	745	3,478
FTB-20-train/$k = 100$	36	80.58	82.11	**80.34**	**82.23**	**66**	3,426
FTB-all-train/Pre-rank order	117	81.63	83.34	81.14	82.97	743	1,347
FTB-all-train/$k = 100$	119	**81.84**	**83.39**	**81.26**	**83.08**	762	1,328
FTB-20-train/$k = 100$	119	81.59	83.29	80.98	82.71	**80**	1,295

Table 4: Comparison of models. Results are given for evaluation with punctuation (P) and without punctuation (NoP). Selection times include pre-ranking. All times are approximated for a single processor.

The best-performing model is selected using FWRAP, with a higher F-score than the current state-of-the-art single parser (Durrett and Klein, 2015).[10] However the selection time of 1,163 hours means that the method is not very tractable. Our final boosting-based results show the same general pattern as obtained on the development set in the previous section, showing that the approach is robust to a change in dataset, and also to a scaling-up of model training to full optimisation. As in Section 5, the best compromise is the boosted model with pre-ranking on FTB-20-train and $k = 100$. It results in one of the highest scores for the compact model, and the overall selection time is greatly reduced. Importantly, it also outperforms the state-of-the-art manual model (Crabbé, 2014), whilst being almost twice as compact. The results show that for larger models, selection via boosting is less useful, with comparable results between boosted and the "pre-rank only" model. If a large model is needed, simply sequentially adding individually trained weak parsers based on their accuracies can produce a high-performing model.

6 Conclusion

We have successfully performed efficient model selection by using stepwise additive fitting. Experiments on high-dimensional data for French show that compact, state-of-the-art parse models can be achieved, and confirm our hypothesis that locally trained parsers can provide a good approximation for globally trained models. Unlike current template selection methods for parsing (Nilsson and Nugues, 2010; Ballesteros and Nivre, 2014), we use no hand-written heuristic constraints to limit the search space, instead opting for pre-ranking of weak parsers to guide the search. Although pre-ranking is relatively time-consuming, the times are very low compared to standard selection methods. We provide a realistic selection scenario, which involves using only a portion of the training data for pre-ranking, capable of selecting a large model (120 templates) in a couple of hours (when multi-processed), as well as compact models that outperform state-of-the-art manually defined models. A release of all source code is available online at `https://bitbucket.org/rbawden/hyparse-boost-feature-selection`.

In future works, we will extend the approach to a variety of other languages, in particular morphologically rich languages (e.g. Arabic, Hungarian or Korean) and extend the possible templates used to take into account further features. Another interesting perspective would be to study the combination of our approach with constraining heuristics, although language-specific and manual rules would be required.

Abstract

Various treebanks have been released for dependency parsing. Despite that treebanks may belong to different languages or have different annotation schemes, they contain common syntactic knowledge that is potential to benefit each other. This paper presents a universal framework for transfer parsing across multi-typed treebanks with deep multi-task learning. We consider two kinds of treebanks as source: the *multilingual universal treebanks* and the *monolingual heterogeneous treebanks*. Knowledge across the source and target treebanks are effectively transferred through multi-level parameter sharing. Experiments on several benchmark datasets in various languages demonstrate that our approach can make effective use of arbitrary source treebanks to improve target parsing models.

1 Introduction

As a long-standing central problem in natural language processing (NLP), dependency parsing has been dominated by data-driven approaches for decades. The foundation of data-driven parsing is the availability and scale of annotated training data (i.e., *treebanks*). Numerous efforts have been made towards the construction of treebanks which established the benchmark research on dependency parsing, such as the widely-used Penn Treebank (Marcus et al., 1993). However, the heavy cost of treebanking typically limits the existing treebanks in both scale and coverage of languages.

To address the problem, a variety of authors have proposed to exploit existing heterogeneous treebanks with different annotation schemes via grammar conversion (Niu et al., 2009), quasi-synchronous grammar features (Li et al., 2012) or shared feature representations (Johansson, 2013) for the enhancement of parsing models. Despite their effectiveness in specific datasets, these methods typically lack the scalability of exploiting richer source treebanks, such as cross-lingual treebanks.

In this paper, we aim at developing a universal framework for transfer parsing that can exploit multi-typed source treebanks to improve parsing of a target treebank. Specifically, we will consider two kinds of source treebanks, that are *multilingual universal treebanks* and *monolingual heterogeneous treebanks*.

Cross-lingual supervision has proven highly beneficial for parsing low-resource languages (Hwa et al., 2005; McDonald et al., 2011), implying that different languages have a great deal of common ground in grammars. But unfortunately, linguistic inconsistencies also exist in both typologies and lexical representations across languages. Figure 1(a) illustrates two sentences in German and English with universal dependency annotations. The typological differences (*subject-verb-object* order) results in the opposite directions of the *dobj* arcs, while the rest arcs remain consistent.

Similar problems also come with monolingual heterogeneous treebanks. Figure 1(b) shows an English sentence annotated with respectively the universal dependencies which are *content-head* and the CoNLL dependencies which instead take the functional heads. Despite the structural divergences, these treebanks express the syntax of the same language, thereby sharing a large amount of common knowledge that can be effectively transferred.

(a) Multilingual universal dependencies.

(b) Monolingual heterogeneous dependencies.

Figure 1: Comparisons between multilingual universal dependencies (a) and monolingual heterogeneous dependencies (b).

The present paper proposes a simple yet effective framework that aims at making full use of the consistencies while avoiding suffering from the inconsistencies across treebanks. Our framework effectively ties together the deep neural parsing models with multi-task learning, using multi-level parameter sharing to control the information flow across tasks. More specifically, learning with each treebank is maintained as an individual task, and their interactions are achieved through parameter sharing in different abstraction levels on the deep neural network, thus referred to as *deep multi-task learning*. We find that different parameter sharing strategies should be applied for different typed source treebanks adaptively, due to the different types of consistencies and inconsistencies (Figure 1).

We investigate the effect of multilingual transfer parsing using the Universal Dependency Treebanks (UDT) (McDonald et al., 2013). We show that our approach improves significantly over strong supervised baseline systems in six languages. We further study the effect of monolingual heterogeneous transfer parsing using UDT and the CoNLL-X shared task dataset (Buchholz and Marsi, 2006). We consider using UDT and CoNLL-X as source treebanks respectively, to investigate their mutual benefits. Experiment results show significant improvements under both settings. Moreover, indirect comparisons on the Chinese Penn Treebank 5.1 (CTB5) using the Chinese Dependency Treebank (CDT)[1] as source treebank show the merits of our approach over previous work.[2]

2 Related Work

The present work is related to several strands of previous studies.

Monolingual resources for parsing Exploiting heterogeneous treebanks for parsing has been explored in various ways. Niu et al. (2009) automatically convert the dependency-structure CDT into the phrase-structure style of CTB5 using a trained constituency parser on CTB5, and then combine the converted treebanks for constituency parsing. Li et al. (2012) capture the annotation inconsistencies among different treebanks by designing several types of *transformation patterns*, based on which they introduce *quasi-synchronous grammar* features (Smith and Eisner, 2009) to augment the baseline parsing models. Johansson (2013) also adopts the idea of parameter sharing to incorporate multiple treebanks. They focuse on parameter sharing at feature-level with discrete representations, which limits its scalability to multilingual treebanks where feature surfaces might be totally different. On the contrary, our approach is capable of utilizing representation-level parameter sharing, making full use of the multi-level abstractive representations generated by deep neural network. This is the key that makes our framework scalable to multi-typed treebanks and thus more practically useful.

Aside from resource utilization, attempts have also been made to integrate different parsing models through stacking (Torres Martins et al., 2008; Nivre and McDonald, 2008) or joint inference (Zhang and Clark, 2008; Zhang et al., 2014).

[2] Our code is available at: https://github.com/jiangfeng1124/mtl-nndep.

Multilingual resources for parsing Cross-lingual transfer has proven to be a promising way of inducing parsers for low-resource languages, either through *data transfer* (Hwa et al., 2005; Tiedemann, 2014; Rasooli and Collins, 2015) or *model transfer* (McDonald et al., 2011; Täckström et al., 2012; Guo et al., 2015; Zhang and Barzilay, 2015; Guo et al., 2016).

Duong et al. (2015b) and Ammar et al. (2016) both adopt parameter sharing to exploit multilingual treebanks in parsing, but with a few important differences to our work. In both of their models, most of the neural network parameters are shared in two (or multiple) parsers except the feature embeddings,[3] which ignores the important *syntactical inconsistencies* of different languages and is also inapplicable for heterogeneous treebanks that have different transition actions. Besides, Duong et al. (2015b) focus on low resource parsing where the target language has a small treebank of ~3K tokens. Their models may sacrifice accuracy on target languages with a large treebank. Ammar et al. (2016) and Vilares et al. (2016) instead train a single parser on a multilingual set of rich-resource treebanks, which is a more similar setting to ours. We refer to their approach as *shallow multi-task learning* (SMTL) and will include as one of our baseline systems (Section 4.2). Note that SMTL is a special case of our approach in which all tasks use the same set of parameters.

Bilingual parallel data has also proven beneficial in various ways (Chen et al., 2010; Huang et al., 2009; Burkett and Klein, 2008), demonstrating the potential of cross-lingual transfer learning.

Multi-task learning for NLP There has been a line of research on joint modeling pipelined NLP tasks, such as word segmentation, POS tagging and parsing (Hatori et al., 2012; Li et al., 2011; Bohnet and Nivre, 2012). Most multi-task learning or joint training frameworks can be summarized as parameter sharing approaches proposed by Ando and Zhang (2005). In the context of neural models for NLP, the most notable work was proposed by Collobert and Weston (2008), which aims at solving multiple NLP tasks within one framework by sharing common word embeddings. Henderson et al. (2013) present a joint dependency parsing and semantic role labeling model with the Incremental Sigmoid Belief Networks (ISBN) (Henderson and Titov, 2010). More recently, the idea of neural multi-task learning was applied to sequence-to-sequence problems with recurrent neural networks. Dong et al. (2015) use multiple decoders in neural machine translation systems that allows translating one source language to many target languages. Luong et al. (2015) study the ensemble of a wide range of tasks (e.g., syntactic parsing, machine translation, image caption, etc.) with multi-task sequence-to-sequence models.

To the best of our knowledge, we present the first work that successfully integrate both monolingual and multilingual treebanks for parsing, with or without consistent annotation schemes.

3 Approach

This section describes the deep multi-task learning architecture, using a formalism that extends on the transition-based dependency parsing model with LSTM networks (Dyer et al., 2015) which is further enhanced by modeling characters (Ballesteros et al., 2015). We first revisit the parsing approach of Ballesteros et al. (2015), then present our framework for learning with multi-typed source treebanks.

3.1 Transition-based Neural Parsing

Neural models for parsing have gained a lot of interests in recent years, particularly boosted by Chen and Manning (2014). The heart of transition-based parsing is the challenge of representing the *state* (configuration) of a transition system, based on which the most likely transition action is determined. Typically, a state includes three primary components, a *stack*, a *buffer* and a set of *dependency arcs*. Traditional parsing models deal with features extracted from manually defined feature templates in a discrete feature space, which suffers from the problems of *Sparsity*, *Incompleteness* and *Expensive feature computation*. The neural network model proposed by Chen and Manning (2014) instead represents features as continuous, low-dimensional vectors and use a *cube* activation function for implicit feature composition. More recently, this architecture has been improved in several different ways (Dyer et al., 2015; Weiss et al., 2015; Zhou et al., 2015; Andor et al., 2016). Here, we employ the LSTM-based architecture enhanced with character bidirectional LSTMs (Ballesteros et al., 2015) for the following major reasons:

[3] Duong et al. (2015b) used $L2$ regularizers to tie the lexical embeddings with a bilingual dictionary.

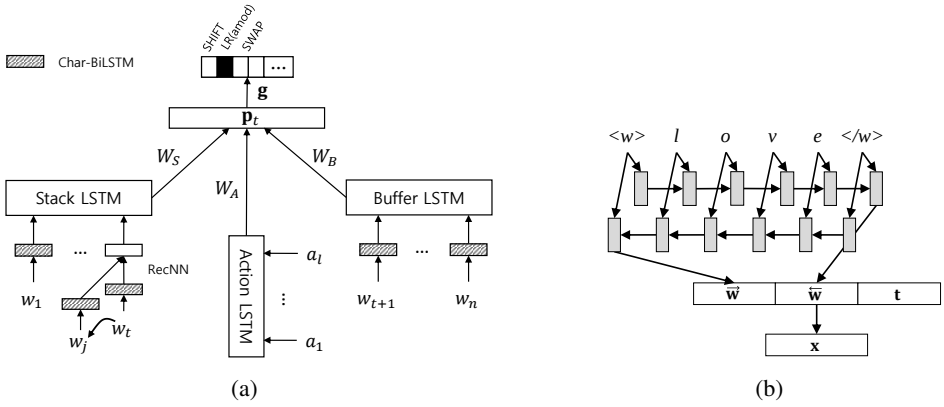

Figure 2: The LSTM-based neural parser (a) and the Char-BiLSTM for modeling words (b).

- Compared with Chen & Manning's architecture, it makes full use of the non-local features by modeling the full history information of a *state* with stack LSTMs.
- By modeling words, stack, buffer and action sequence separately which indicate hierarchical abstractions of representations, we can control the information flow across tasks via parameter sharing with more flexibility (Section 3.2).

Besides, we did not use the earlier ISBN parsing model (Titov and Henderson, 2007) due to its lack of scalability to large vocabulary. Figure 2(a) illustrates the transition-based parsing architecture using LSTMs. Bidirectional LSTMs are used for modeling the word representations (Figure 2(b)), which we refer to as Char-BiLSTMs henceforth. Char-BiLSTMs learn features for each word, and then the representation of each token can be calculated as:

$$\mathbf{x} = \texttt{ReLU}(\mathbf{V}[\overrightarrow{\mathbf{w}}; \overleftarrow{\mathbf{w}}; \mathbf{t}] + \mathbf{b}) \tag{1}$$

where $\mathbf{t}$ is the POS tag embedding. The token embeddings are then fed into subsequent LSTM layers to obtain representations of the *stack*, *buffer* and *action sequence* respectively referred to as $\mathbf{s}_t, \mathbf{b}_t$ and $\mathbf{a}_t$ (The subscript t represents the time step). Note that the subtrees within the stack and buffer are modeled with a *recursive neural network* (RecNN) as described in Dyer et al. (2015). Next, a linear mapping ($\mathbf{W}$) is applied to the concatenation of $\mathbf{s}_t, \mathbf{b}_t$ and $\mathbf{a}_t$, and passed through a component-wise ReLU:

$$\mathbf{p}_t = \texttt{ReLU}(\mathbf{W}[\mathbf{s}_t; \mathbf{b}_t; \mathbf{a}_t] + \mathbf{d}) \tag{2}$$

Finally, the probability of next action $z \in \mathcal{A}(S, B)$ is estimated using a softmax function:

$$p(z|\mathbf{p}_t) = \frac{\exp(\mathbf{g}_z^\top \mathbf{p}_t + \mathbf{q}_z)}{\Sigma_{z' \in \mathcal{A}(S,B)} \exp(\mathbf{g}_{z'}^\top \mathbf{p}_t + \mathbf{q}_{z'})} \tag{3}$$

where $\mathcal{A}(S, B)$ represents the set of valid actions given the current content in the *stack* and *buffer*.

We apply the non-projective transition system originally introduced by Nivre (2009) since most of the treebanks we consider in this study has a noticeable proportion of non-projective trees. In the SWAP-based system, both the *stack* and *buffer* may contain tree fragments, so RecNN is applied both in S and B to obtain representations of each position.

3.2 Deep Multi-task Learning

Multi-task learning (MTL) is the procedure of inductive transfer that improves learning for one task by using the information contained in the training signals of other related tasks. It does this by learning tasks in parallel while using a shared representation. A good overview, especially focusing on neural networks, can be found in Caruana (1997).

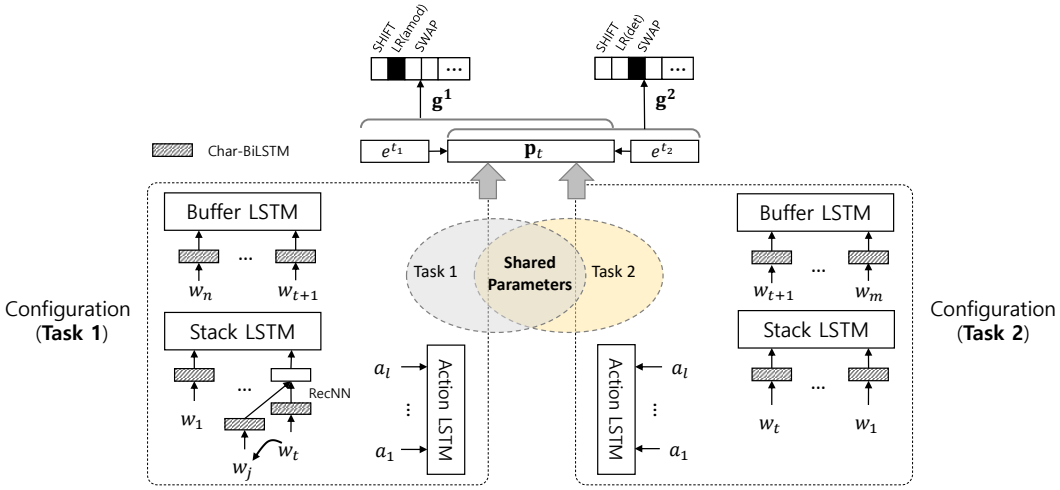

Figure 3: Illustration of the MTL framework.

We illustrate our multi-task learning architecture in Figure 3. As discussed in previous sections, multiple treebanks, either multilingual or monolingual heterogeneous, contain knowledge that can be mutually beneficial. We consider the target treebank processing as the *primary task*, and the source treebank as a *related task*. The two tasks are interacted through multi-level parameter sharing (Section 3.2.1). Inspired by Ammar et al. (2016), we introduce a task-specific vector e^t (*task embedding*) which is first combined with $\mathbf{s}_t, \mathbf{b}_t, \mathbf{a}_t$ to compute $\mathbf{p}_t$, and then further concatenated with $\mathbf{p}_t$ to compute the probability distribution of transition actions. Therefore, Eqn 2, 3 become:

$$\mathbf{p}_t = \texttt{ReLU}(\mathbf{W}[\mathbf{s}_t; \mathbf{b}_t; \mathbf{a}_t; e^t] + \mathbf{d}) \tag{4}$$

$$p(z|\mathbf{p}_t) = \texttt{softmax}(\mathbf{g}_z^\top[\mathbf{p}_t; e^t] + \mathbf{q}_z) \tag{5}$$

The joint cross-entropy is used as the objective function. The key of *multi-task* learning is *parameter sharing*, without which the correlation between tasks will not be exploited. In this work, we design sophisticated parameter sharing strategies according to the linguistic similarities and differences between the tasks.

3.2.1 Parameter Sharing

Deep neural networks automatically learn features for a specific task with hierarchical abstractions, which gives us the flexibility to control parameter sharing in different levels accordingly.

In this study, different parameter sharing strategies are applied according to the source and target treebanks being used. We consider two different scenarios: MTL with multilingual universal treebanks as source (**MULTI-UNIV**) and MTL with monolingual heterogeneous treebanks as source (**MONO-HETERO**). Table 1 presents our parameter sharing strategies for each setting.

MULTI-UNIV Multilingual universal treebanks are annotated with the same set of POS tags (Petrov et al., 2012), dependency relations, and share the same set of transition actions. However, the vocabularies (word, characters) are language-specific. Therefore, it makes sense to share the lookup tables (embeddings) of POS tags (E_{pos}), relations (E_{rel}) and actions (E_{act}), but separate the character embeddings (E_{char}) as well as the Char-BiLSTMs (BiLSTM(chars)). Additionally, linguistic typologies such as the order of *subject-verb-object* and *adjective-noun* (Figure 1(a)) varies across languages, which result in the divergence of inherent grammars of transition action sequences. So we set the action LSTM (LSTM(A)) as *task-specific*.

MONO-HETERO Monolingual heterogeneous treebanks instead share the same lexical representations, but have different POS tags, structures and relations due to the different annotation schemes. Hence the transition actions set varies across treebanks. For simplicity reasons, we convert the language-specific

	MULTI-UNIV	MONO-HETERO
Shared	$E_{pos}, E_{rel}, E_{act}$ LSTM(S), LSTM(B), RecNN W_A, W_S, W_B	E_{pos}, E_{char} LSTM(S), LSTM(B), BiLSTM(chars), RecNN W_A, W_S, W_B
Task-specific	E_{char}, e^t LSTM(A), BiLSTM(chars) $\mathbf{g}$	E_{rel}, E_{act}, e^t LSTM(A) $\mathbf{g}$

Table 1: Parameter sharing strategies for **MULTI-UNIV** and **MONO-HETERO**. LSTM(S) – *stack* LSTM; LSTM(B) – *buffer* LSTM; LSTM(A) – *action* LSTM; BiLSTM(chars) – Char-BiLSTM; RecNN – recursive NN modeling the subtrees; W_A, W_S, W_B – weights from A, S, B to the state ($\mathbf{p}_t$); $\mathbf{g}$ – weights from the state to output layer; E – embeddings.

POS tags of the heterogeneous treebanks into universal POS tags (Petrov et al., 2012). Consequently, E_{char} and BiLSTM(chars), E_{pos} are shared across tasks, but E_{rel}, E_{act}, LSTM(A) are *task-specific*.

Besides, the LSTM parameters for modeling the *stack* and *buffer* (LSTM(S), LSTM(B)), the RecNN for modeling tree compositions, and the weights from S, B, A to the state $\mathbf{p}_t$ (W_A, W_B, W_S) are shared for both MULTI-UNIV and MONO-HETERO. As standard in multi-task learning, the weights at the output layer ($\mathbf{g}$) are *task-specific* in both settings.

3.2.2 Learning

Training is achieved in a stochastic manner by looping over the tasks:

1. Randomly select a task.
2. Select a sentence from the task, and generate instances for classification.
3. Update the corresponding parameters by back-propagation w.r.t. the instances.
4. Go to 1.

We adopt the development data of the target treebank (primary task) for early-stopping.

4 Experiments

We first describe the data and settings in our experiments, then the results and analysis.

4.1 Data and Settings

We conduct experiments on UDT v2.0[4] and the CoNLL-X shared task data. For monolingual heterogeneous source, we also experiment on CTB5 using CDT as the source treebank, to compare with the previous work of Li et al. (2012). Statistics of the datasets are summarized in Table 2. We investigate the following experiment settings:

- MULTILINGUAL (UNIV→UNIV). In this setting, we study the integration of multilingual universal treebanks. Specifically, we consider the DE, ES, FR, PT, IT and SV universal treebanks as target treebanks, and the EN treebank as the common source treebank.
- MONOLINGUAL (CONLL↔UNIV). Here we study the integration of monolingual heterogeneous treebanks. The CoNLL-X corporas (DE, ES, PT, SV) and the UDT treebank of corresponding languages are used as source and target treebanks mutually.
- MONOLINGUAL (CDT→CTB5). We follow the same settings of Li et al. (2012), and consider two scenarios using automatic POS tags and gold-standard POS tags respectively.

Table 3: Parsing accuracies of MULTILINGUAL (UNIV→UNIV). Significance tests with MaltEval yield p-values < 0.01 for (MTL *vs.* SUP) on all languages.

4.2 Baseline Systems

We compare our approach with the following baseline systems.

- Monolingual supervised training (SUP). Models are trained only on the target treebank, with the LSTM-based parser.
- Cascaded training (CAS). This system has two stages. First, models are trained using the source treebank. Then the parameters are used to initialize the neural network for training target parsers. Similar approach was studied in Duong et al. (2015a) and Guo et al. (2016) for low-resource parsing.

For MULTILINGUAL (UNIV→UNIV), we also compare with the *shallow multi-task learning* (SMTL) system, as described in Section 2, which is representative of the approach of Duong et al. (2015b) and Ammar et al. (2016). In SMTL all the parameters are shared except the character embeddings (E_{char}), and task embeddings (e^t) are not used. Unlike Duong et al. (2015b) and Ammar et al. (2016), we don't use external resources such as cross-lingual word clusters, embeddings and dictionaries which is beyond the scope of this work.

4.3 Results

In this section, we present empirical evaluations under different settings.

4.3.1 Multilingual Universal Source Treebanks

Table 3 shows the results under the MULTILINGUAL (UNIV→UNIV) setting. CAS yields slightly better performance than SUP, especially for SV (+1.52% UAS and +2.04% LAS), indicating that *pre-training* with EN training data indeed provides a better initialization of the parameters for cascaded training. SMTL in turn outperforms CAS overall (comparable for IT), which implies that training two treebanks jointly helps even with a unique model.

	DE	ES	FR
SUP	58.93	61.99	60.45
CAS	64.08	**70.45**	**68.72**
SMTL	63.57	69.01	65.04
+ *weighted sampling*	*63.50*	*70.17*	*68.52*
MTL	62.43	66.67	64.23
+ *weighted sampling*	***64.22***	*68.42*	*66.67*
Duong et al.	61.2	69.1	65.3
Duong et al. + Dict	61.8	70.5	67.2

Table 4: Low resource setup (3K tokens), evaluated with LAS.

Furthermore, with appropriate parameter sharing, our deep multi-task learning approach (MTL) outperforms SUP overall and achieves the best performances in five out of six languages. An exception is Swedish. As we can see, both CAS and SMTL outperforms MTL by a significant margin for SV. The underlying reasons we suggest are two-fold.

1. SV morphology is similar to EN with less inflections, encouraging the morphology-related parameters like BiLSTM(chars) to be shared.
2. SV has a much smaller treebank compared with EN (1:9). We suggest that SMTL and CAS work better than MTL in low resource setting. To our intuition, since knowledge contained in the low-resource target treebank is very limited, it is reasonable for us to put more emphasis on the source treebank through SMTL or CAS.

To verify the first issue, we conduct tests on SMTL without sharing Char-BiLSTMs, and observe significant degradation in performance (-0.73 in UAS and -0.81 in LAS). This observation also suggests that MTL has the potential to reach higher performances through *language-specific tuning* of parameter sharing strategies.

To verify the second issue, we consider a low resource setup following Duong et al. (2015b), where the target language has a small treebank (3K tokens). We train our models on identical sampled dataset shared by the authors on DE, ES and FR. As we can find in Table 4, while all the models outperform SUP, both CAS and SMTL work better than MTL, which confirms our assumption. Although not the primary focus of this work, we find that SMTL and MTL can be significantly improved in low resource setting through weighted sampling of tasks during training. Specifically, in the training procedure (Section 3.2.2), we sample from the source language (EN) which has a much richer treebank with larger probability of 0.9, while sample from the target language with probability of 0.1. In this way, the two tasks are encouraged to converge at a similar rate. As shown in Table 4, both SMTL and MTL benefit from weighted task sampling.

4.3.2 Monolingual Heterogeneous Source Treebanks

Among the four languages here, the SV universal treebank is mainly converted from the Talbanken part of the Swedish bank (Nivre and Megyesi, 2007), thus has a large overlap with the CONLL-X Swedish treebank. Therefore, we exclude the sentences in SV test set that appear in the source treebank for evaluation. Table 5 shows the results of MONOLINGUAL (CONLL↔UNIV). Overall MTL systems outperforms the supervised baselines by significant margins in both conditions, showing the mutual benefits of UDT and CONLL-X treebanks.[5]

To show the merit of our approach against previous approaches, we further conduct experiments on CTB5 using CDT as heterogeneous source treebank (Table 2). For CTB5, we follow (Li et al., 2012) and consider two scenarios which use automatic POS tags and gold-standard POS tags respectively. To compare with their results, we run SUP, CAS and MTL on CTB5. Table 6 presents the results.

[5] An exception is PT in MONOLINGUAL (UNIV→CONLL). This may be due to the low quality of the PT universal treebank caused by the automatic construction process. We discussed and verified this with the author of UDT v2.0.

		SUP	with QG		SUP	with QG	
LI12-O2	UAS	79.67	81.04 (+1.37)		86.13	86.44 (+0.31)	
LI12-O2SIB		79.25	80.45 (+1.20)		85.63	86.17 (+0.54)	

Table 6: Parsing accuracy comparisons of MONOLINGUAL (CDT→CTB5). LI12-O2 use the O2 graph-based parser with both sibling and grandparent structures, while LI12-O2SIB only use the sibling parts.

The indirect comparison indicates that our approach can achieve larger improvement than their method in both scenarios. Beside the empirical comparison, our method has the additional advantages in its scalability to multi-typed source treebanks without the painful human efforts of feature design.

5 Conclusion

This paper propose a universal framework based on deep multi-task learning that can integrate arbitrary-typed source treebanks to enhance the parsing models on target treebanks. We study two scenarios, respectively using multilingual universal source treebanks and monolingual heterogeneous source treebanks, and design effective parameter sharing strategies for each scenario.

We conduct extensive experiments on benchmark treebanks in various languages. Results demonstrate that our approach significantly improves over baseline systems under various experiment settings.

Acknowledgments

We thank Ryan McDonald for helpful discussions, and thank Dr. Zhenghua Li for sharing the processed CTB and CDT dataset. We also thank the anonymous reviewers for their insightful comments and suggestions. This work was supported by the National Key Basic Research Program of China via grant 2014CB340503 and the National Natural Science Foundation of China (NSFC) via grant 61300113 and 61370164.

Abstract

Grammar induction is the task of learning syntactic structure in a setting where that structure is hidden. Grammar induction from words alone is interesting because it is similiar to the problem that a child learning a language faces. Previous work has typically assumed richer but cognitively implausible input, such as POS tag annotated data, which makes that work less relevant to human language acquisition. We show that grammar induction from words alone is in fact feasible when the model is provided with sufficient training data, and present two new streaming or mini-batch algorithms for PCFG inference that can learn from millions of words of training data. We compare the performance of these algorithms to a batch algorithm that learns from less data. The minibatch algorithms outperform the batch algorithm, showing that cheap inference with more data is better than intensive inference with less data. Additionally, we show that the harmonic initialiser, which previous work identified as essential when learning from small POS-tag annotated corpora (Klein and Manning, 2004), is not superior to a uniform initialisation.

1 Introduction

How children acquire the syntax of the languages they ultimately speak is a deep scientific question of fundamental importance to linguistics and cognitive science (Chomsky, 1986). The natural language processing task of grammar induction in principle should provide models for how children do this. However, previous work on grammar induction has learned from small datasets, and has dealt with the resulting data sparsity by modifying the input and using careful search heuristics. While these techniques are useful from an engineering perspective, they make the models less relevant to human language acquisition.

In this paper, we use scalable algorithms for Probabilistic Context Free Grammar (PCFG) inference to perform grammar induction from millions of words of speech transcripts, and show that grammar induction from words alone is both feasible and insensitive to initialization. To ensure the robustness of our results, we use two algorithms for Variational Bayesian PCFG inference, and adapt two algorithms that have been proposed for Latent Dirichlet Allocation (LDA) topic models. Most importantly, we find that the three algorithms that scale to large datasets improve steadily over training to about the same predictive probability and parsing performance.

Moreover, while grammar induction from small datasets of POS-tagged newswire text fails without careful 'harmonic' initialization, we find that initialization is much less important when learning directly from larger datasets consisting of words alone. Of the algorithms in this paper, one does 2.5% better with harmonic initialization, another does 5% worse, and the other two are insensitive to initialization.

The rest of the paper is organized as follows. In Section 2, we discuss previous grammar induction research, in Section 3 we present the particular model grammar we will use, in Section 4 we describe the inference algorithms, and in Section 5 we present our experimental results.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 23–32, Osaka, Japan, December 11-17 2016.

2 Background

Previous grammar induction work has used datasets with at most $50,000$ sentences. Fully-lexicalized models would struggle with data sparsity on such small datasets, so previous work has assumed input in either the form of part-of-speech (POS) tags (Klein and Manning, 2004; Headden III et al., 2009) or word representations trained on a large external corpus (Spitkovsky et al., 2011; Le and Zuidema, 2015).

Some previous work has moved towards learning from word strings directly. Bisk and Hockenmaier (2013) used combinatory categorial grammar (CCG) to learn syntactic dependencies from word strings. However, they initialise their model by annotating nouns, verbs, and conjunctions in the training set with atomic CCG categories using a dictionary, and so do not learn from words alone. Pate and Goldwater (2013) learned syntactic dependencies from word strings alone, but used sentences from the Switchboard corpus of telephone speech that had been selected for prosodic annotation and so were unusually fluent.

Kim and Mooney (2010), Börschinger et al. (2011), and Kwiatkowski et al. (2012), learned from word strings together with logical form representations of sentence meanings. While children have situational cues to sentence meaning, these cues are ambiguous, and it is difficult to represent these cues in a way that is not biased towards the actual sentences under consideration. We focus on the evidence for syntactic structure that can be obtained from word strings themselves.

Grammar induction directly from word strings is interesting for two reasons. First, this problem setting more closely matches the language acquisition task faced by an infant, who will not have access to POS tags or a corpus external to her experience. Second, this setting allows us to attribute behavior of grammar induction systems to the underlying model itself, rather than additional annotations made to the input. Approaches to grammar induction that involve replacing words with POS tags or other lexical or syntactic observed labels make the process significantly more difficult to understand or compare across genres or languages, as the results will depend on exactly how these labels are assigned. Models that only require words alone as input do not suffer from this weakness.

3 PCFGs and the Dependency Model with Valence

3.1 Probabilistic Context Free Grammars

A Probabilistic Context Free Grammar is a tuple $(\boldsymbol{W}, \boldsymbol{N}, S, \boldsymbol{R}, \boldsymbol{\theta})$, where $\boldsymbol{W}$ and $\boldsymbol{N}$ are sets of terminal and non-terminal symbols, $S \in \boldsymbol{N}$ is a distinguished start symbol, and $\boldsymbol{R}$ is a set of production rules. $\boldsymbol{\theta}$ is a vector of multinomial parameters of length $|\boldsymbol{R}|$ indexed by production rules $A \rightarrow \beta$, so $\boldsymbol{\theta}_{A\rightarrow\beta}$ is the probability of the production $A \rightarrow \beta$. We use $\boldsymbol{R}_A$ to denote all rules with left-hand side A, and use $\boldsymbol{\theta}_A$ to denote the subvector of $\boldsymbol{\theta}$ indexed by the rules in $\boldsymbol{R}_A$. We require for all rules, $\theta_{A\rightarrow\beta} \geq 0$, and for all $A \in \boldsymbol{N}$, $\sum_{A\rightarrow\beta\in\boldsymbol{R}_A} \theta_{A\rightarrow\beta} = 1$, and use Δ to denote the probability simplex satisfying these constraints. The *yield* $\mathrm{y}(t)$ of a tree t is the string of terminals of t, and the yield of a vector of trees $\boldsymbol{T} = (t_1, \ldots, t_{|\boldsymbol{T}|})$ is the vector of yields of each tree: $\mathrm{y}(\boldsymbol{T}) = (\mathrm{y}(t_1), \ldots, \mathrm{y}(t_{|\boldsymbol{T}|}))$. The probability of generating a tree t given parameters $\boldsymbol{\theta}$ is:

$$P_G(t|\boldsymbol{\theta}) = \prod_{A\rightarrow\beta\in\boldsymbol{R}} \theta_r^{f(t,A\rightarrow\beta)}$$

where $f(t, A \rightarrow \beta)$ is the number of times rule $A \rightarrow \beta$ is used in the derivation of t.

To model uncertainty in the parameters, we draw the parameters of each multinomial $\boldsymbol{\theta}_A$ from a prior distribution $P(\boldsymbol{\theta}_A|\boldsymbol{\alpha}_A)$, where the vector of hyperparameters $\boldsymbol{\alpha}_A$ defines the shape of this prior distribution (and $\boldsymbol{\alpha}$ is just the concatenation of each $\boldsymbol{\alpha}_A$). The joint probability of a vector of trees $\boldsymbol{T}$ with one tree t_i for each sentence s_i, and parameters $\boldsymbol{\theta}$ is then:

$$P(\boldsymbol{T}, \boldsymbol{\theta}|\boldsymbol{\alpha}) = P(\boldsymbol{T}|\boldsymbol{\theta})P(\boldsymbol{\theta}|\boldsymbol{\alpha}) = \prod_{A\rightarrow\beta\in\boldsymbol{R}} \theta_{A\rightarrow\beta}^{f(\boldsymbol{T},A\rightarrow\beta)} \left[\prod_{A\in\boldsymbol{N}} P(\boldsymbol{\theta}_A|\boldsymbol{\alpha}_A)\right]$$

where $f(\boldsymbol{T}, r)$ is the number of times rule r is used in the derivation of the trees in $\boldsymbol{T}$.

Dirichlet priors for these multinomials are both standard and convenient:

$$P_D(\boldsymbol{\theta}_A|\boldsymbol{\alpha}_A) = \frac{\Gamma\left(\sum_{A\to\beta\in\boldsymbol{R}_A}\alpha_{A\to\beta}\right)}{\prod_{A\to\beta\in\boldsymbol{R}_A}\Gamma(\alpha_{A\to\beta})}\prod_{A\to\beta\in\boldsymbol{R}_A}\theta_{A\to\beta}^{\alpha_{A\to\beta}-1}$$

where the Gamma function Γ generalizes the factorial function from integers to real numbers. Dirichlet distributions are convenient priors because they are *conjugate* to multinomial distributions: the product of a Dirichlet distribution and a multinomial distribution is itself a Dirichlet distribution:

$$P(\boldsymbol{T},\boldsymbol{\theta}|\boldsymbol{\alpha}) = P_G(\boldsymbol{T}|\boldsymbol{\theta})P_D(\boldsymbol{\theta}|\boldsymbol{\alpha}) \propto \prod_{A\to\beta\in\boldsymbol{R}}\theta_{A\to\beta}^{f(\boldsymbol{T},A\to\beta)+\alpha_{A\to\beta}-1} \tag{1}$$

For grammar induction, we observe only the corpus of sentences $\boldsymbol{C}$, and modify Equation 1 to marginalize over trees and rule probabilities.

$$P(\boldsymbol{C}|\boldsymbol{\alpha}) = \sum_{\boldsymbol{T}:\mathrm{y}(\boldsymbol{T})=\boldsymbol{C}}\int_{\Delta}P(\boldsymbol{T},\boldsymbol{\theta}|\boldsymbol{\alpha})d\boldsymbol{\theta} \tag{2}$$

This sum over trees introduces dependencies that make exact inference intractable.

We assessed grammar induction from words alone using the Dependency Model with Valence (DMV) (Klein and Manning, 2004). In the original presentation, it first draws the root of the sentence from a P_{root} distribution over words, and then generates the dependents of head h in each direction $dir \in \{\leftarrow,\rightarrow\}$ in a recursive two-step process. First, it decides whether to stop generating (a Stop decision) according to $P_{stop}(\cdot|h, dir, v)$, where v indicates whether or not h has any dependents in the direction of dir. If it does not stop (a $\neg$Stop decision), it draws the dependent word d from $P_{choose}(d|h, dir)$. Generation ceases when all words stop in both directions.

Johnson (2007) and Headden III et al. (2009) reformulated this generative process as a *split-head bilexical PCFG* (Eisner and Satta, 2001) so that the rule probabilities are DMV parameters. Such a PCFG represents each token of the string with two 'directed' terminals that handle leftward and rightward decisions independently, and defines rules and non-terminal symbols schematically in terms of terminals. Minimally, we need rightward-looking R_w, leftward-looking L_w, and undirected Y_w non-terminal labels for each word w. The grammar has a rule for each dependent word d of a head word h from the left ($L_h \rightarrow Y_d\ \ L_h$) and from the right ($R_h \rightarrow R_h\ \ Y_d$), a rule for each a word w to be the sentence root ($S \rightarrow Y_w$), and a rule for each undirected symbol to split into directed symbols ($Y_w \rightarrow L_w\ \ R_w$).

To incorporate Stop decisions into the grammar, we distinguished non-terminals that dominate a Stop decision from those that dominate a Choose decision by decorating Choose non-terminals with $'$ (so a left attachment rule is $L'_h \rightarrow Y_d\ \ L_h$), and introduced unary rules that rewrite to terminals ($L_h \rightarrow h_l$) for Stop decisions, and to Choose non-terminals ($L_h \rightarrow L'_h$) for $\neg$Stop decisions. We implemented valence with a superscript decoration on each non-terminal label: L_h^0 indicates h has no dependents to the left, and L_h indicates that h has at least one dependent to the left. Figure 1 presents PCFG rule schemas with their DMV parameters, and dependency and split-head PCFG trees for "dogs bark." We use several inference algorithms to learn production weights for this PCFG, and study how the parsing accuracy varies with algorithm and computational effort.

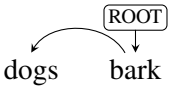
4 Inference[1]

One central challenge of learning from words alone is data sparsity. Data sparsity is most naturally addressed by learning from large amounts of data, which is easily available when learning from words alone, so we use algorithms that scale to large datasets. To ensure that our system reflects the underlying relationship between the model and the data, we explore three such algorithms. These algorithms are extensions of the batch algorithm for variational Bayesian (batch VB) inference of PCFGs due to Kurihara

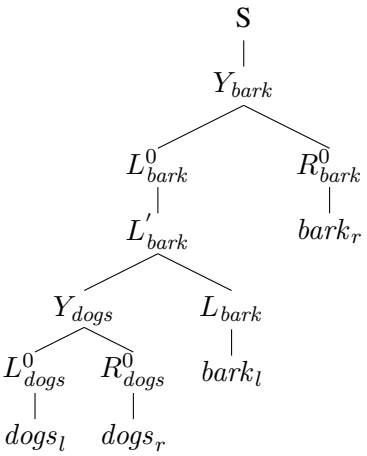
[1]Implementations and pre-processing software are available at `http://github.com/jkpate/streamingDMV`

PCFG Rule	DMV parameter
$S \rightarrow Y_h$	$P_{root}(h)$
$Y_h \rightarrow L_h^0 \ R_h^0$	1
$L_h^0 \rightarrow h_l$	$P_{stop}(\text{Stop}\|h, \leftarrow, \text{no\_dep})$
$L_h^0 \rightarrow L_h^{'}$	$P_{stop}(\neg\text{Stop}\|h, \leftarrow, \text{no\_dep})$
$L_h^{'} \rightarrow Y_d \ L_h$	$P_{choose}(d\|h, \leftarrow)$
$L_h \rightarrow h_l$	$P_{stop}(\text{Stop}\|h, \leftarrow, \text{one\_dep})$
$L_h \rightarrow L_h^{'}$	$P_{stop}(\neg\text{Stop}\|h, \leftarrow, \text{one\_dep})$

(a) Split-head rule schemas and corresponding probabilities for the DMV. The rules expanding L_h^0 and L_h symbols encode Stop decisions with no dependents and at least one dependent, respectively, and the the rules expanding L_h' symbols encode Choose decisions.



(c) Example dependency tree with one root and left arc.



(b) Tree for "dogs bark" using the grammar in Figure 1a.

Figure 1: The DMV as a PCFG, and dependency and split-head bilexical CFG trees for "dogs bark."

and Sato (2004), so we first review batch VB. Inspired by the reduction of LDA inference to PCFG inference presented in Johnson (2010), we then develop new streaming on-line PCFG inference algorithms by generalising the streaming VB (Broderick et al., 2013) and stochastic VB (Hoffman et al., 2010) algorithms for Latent Dirichlet Allocation (LDA) to PCFG inference. We finally review the collapsed VB algorithm due to Wang and Blunsom (2013) for PCFGs that we compare to the other algorithms.

Figure 2 summarizes the four algorithms for PCFG inference.

4.1 Batch VB

Kurihara and Sato's (2004) batch algorithm for variational Bayesian inference approximates the posterior $P(\boldsymbol{T}, \boldsymbol{\theta}|\boldsymbol{C}, \boldsymbol{\alpha})$ by maximizing a lower bound on the log marginal likelihood of the observations $\ln P(\boldsymbol{C}|\boldsymbol{\alpha})$. This lower bound $\mathcal{L}$ involves a variational distribution $Q(\boldsymbol{T}, \boldsymbol{\theta})$ over unobserved variables $\boldsymbol{T}$ and $\boldsymbol{\theta}$. By Jensen's inequality, for any distribution $Q(\boldsymbol{T}, \boldsymbol{\theta})$, we have:

$$\ln P(\boldsymbol{C}|\boldsymbol{\alpha}) = \ln \sum_{\boldsymbol{T}} \int Q(\boldsymbol{T}, \boldsymbol{\theta}) \frac{P(\boldsymbol{C}, \boldsymbol{T}, \boldsymbol{\theta}|\boldsymbol{\alpha})}{Q(\boldsymbol{T}, \boldsymbol{\theta})} d\boldsymbol{\theta} \geq \sum_{\boldsymbol{T}} \int Q(\boldsymbol{T}, \boldsymbol{\theta}) \ln \frac{P(\boldsymbol{C}, \boldsymbol{T}, \boldsymbol{\theta}|\boldsymbol{\alpha})}{Q(\boldsymbol{T}, \boldsymbol{\theta})} d\boldsymbol{\theta} = \mathcal{L}$$

$\ln P(\boldsymbol{C}|\boldsymbol{\alpha}) - \mathcal{L}$ is the Kullback-Leibler divergence $\text{KL}\left(Q(\boldsymbol{T}, \boldsymbol{\theta}) || P(\boldsymbol{T}, \boldsymbol{\theta}|\boldsymbol{C}, \boldsymbol{\alpha})\right)$. Variational inference adjusts the parameters of the variational distribution to maximize $\mathcal{L}$, which minimizes the KL divergence.

VB makes inference tractable by factorizing the variational posterior. The mean-field factorization assumes parameters and trees are independent: $Q(\boldsymbol{T}, \boldsymbol{\theta}) = Q_{\boldsymbol{\theta}}(\boldsymbol{\theta}) \prod_{i=1}^{|\boldsymbol{T}|} Q_{\boldsymbol{T}}(t_i)$. Kurihara and Sato showed that $Q_{\boldsymbol{\theta}}(\boldsymbol{\theta})$ is also a product of Dirichlet distributions, whose hyperparameters $\hat{\boldsymbol{\alpha}}_A$ are a sum of the prior hyperparameters $\alpha_{A \rightarrow \beta}$ and the expected count of $A \rightarrow \beta$ across the corpus under $Q_{\boldsymbol{T}}$:

$$\hat{\alpha}_{A \rightarrow \beta} = \alpha_{A \rightarrow \beta} + \sum_{i=1}^{|\boldsymbol{C}|} \hat{f}(s_i, A \rightarrow \beta)$$

$$\hat{f}(s, A \rightarrow \beta) = \mathbb{E}_{Q_{\boldsymbol{T}}}\left[f(t, A \rightarrow \beta)\right]$$

$f(t, A \rightarrow \beta)$ is the number of times rule $A \rightarrow \beta$ is used in the derivation of tree t. $\hat{f}(s_i, A \rightarrow \beta)$ is the expected number of times $A \rightarrow \beta$ is used in the derivation of sentence s_i, and can be computed using the Inside Outside algorithm (Lari and Young, 1990). Batch VB alternates between optimizing $Q_{\boldsymbol{\theta}}$, using

expected counts, and $Q_{\boldsymbol{T}}$, using the hyperparameters $\hat{\boldsymbol{\alpha}}$ of $Q_{\boldsymbol{\theta}}$ to compute probability-like ratios $\pi_{A\to\beta}$:

$$Q_{\boldsymbol{T}}(t) = \prod_{A\to\beta\in\boldsymbol{R}} \pi_{A\to\beta}^{f(t,A\to\beta)} \qquad \pi_{A\to\beta} = \frac{\exp\left(\Psi\left(\hat{\alpha}_{A\to\beta}\right)\right)}{\exp\left(\Psi\left(\sum_{A\to\beta'\in\boldsymbol{R}_A}\hat{\alpha}_{A\to\beta'}\right)\right)}$$

where the digamma function $\Psi(\cdot)$ is the derivative of the log Gamma function. Algorithm 1 presents the full algorithm.

4.2 Scalable VB algorithms

Batch VB requires a complete parse of the training data before parameter updates, which is computationally intensive. We explore three algorithms that divide the data into minibatches $\boldsymbol{C} = \left\{\boldsymbol{C}^{(1)}, \ldots, \boldsymbol{C}^{(n)}\right\}$ and update parameters after parsing each minibatch.

Streaming VB: Broderick et al. (2013) proposed a 'streaming VB' algorithm for LDA that approximates Bayesian Belief Updates (BBU) to make a single pass through the training data. A BBU uses the current posterior as a prior to compute the next posterior without reanalyzing previous minibatches:

$$P\left(\boldsymbol{\theta}|\boldsymbol{C}^{(1)}, \ldots, \boldsymbol{C}^{(n)}\right) \propto P\left(\boldsymbol{C}^{(n)}|\boldsymbol{\theta}\right) P\left(\boldsymbol{\theta}|\boldsymbol{C}^{(1)}, \ldots, \boldsymbol{C}^{(n-1)}\right)$$

However, the normalization constant involves an intractable marginalization. Broderick et al. suggested approximating each posterior with some algorithm $\mathcal{A}$ that computes an approximate posterior $Q^{(n)}$ given a minibatch $\boldsymbol{C}^{(n)}$ and the previous posterior $Q^{(n-1)}$:

$$P\left(\boldsymbol{\theta}|\boldsymbol{C}^{(1)}, \ldots, \boldsymbol{C}^{(n)}\right) \approx Q^{(n)}(\boldsymbol{\theta}) = \mathcal{A}\left(\boldsymbol{C}^{(n)}, Q^{(n-1)}(\boldsymbol{\theta})\right)$$

where $Q^{(0)}$ is the true prior. By using a mean-field VB algorithm for LDA inference for $\mathcal{A}$, they approximate each subsequent $Q^{(n)}$ as a product of Dirichlets, whose hyperparameters are a running sum of expected counts from previous minibatches and prior hyperparameters. We used the batch VB algorithm for $\mathcal{A}$ to generalise this algorithm to PCFG inference. Algorithm 2 presents the full algorithm.

Stochastic VB: Hoffman et al. (2010) proposed a 'stochastic VB' algorithm for LDA that uses each minibatch to compute the maximum of an estimate of the natural gradient of $\mathcal{L}$. This maximum is obtained by computing expected counts for $\boldsymbol{C}^{(i)}$, and scaling the counts as though they were gathered from the full dataset. The new hyperparameters are obtained by taking a step toward the maximum:

$$\alpha_{A\to\beta}^{(en+i)} = (1-\eta)\,\alpha_{A\to\beta}^{(en+i-1)} + \eta l_{A\to\beta}^{(i)} \hat{f}^{(en+i)}\left(A\to\beta\right)$$

where η is the step size, $\hat{f}^{(en+i)}\left(A\to\beta\right)$ is the expected count of rule $A\to\beta$ in minibatch i of epoch e, and $l_{A\to\beta}^{(i)}$ is the scaling term for rule $A\to\beta$. In their LDA inference procedure, each word has one topic, so the scaling term is the number of words in the full dataset divided by the number of words in the minibatch. For the DMV, a string s with $|s|$ terminals has one root, $|s|-1$ choose rules, and $2|s| + (|s|-1)$ stop decisions (two Stops and one ¬Stop rule for each arc). The scaling terms are then:

root rules	choose rules	stop rules
$l_{S\to Y_h}^{(i)} = \frac{\lvert\boldsymbol{C}\rvert}{\lvert\boldsymbol{C}^{(i)}\rvert}$	$l_{A\to\beta}^{(i)} = \frac{\sum_{j=1}^{\lvert\boldsymbol{C}\rvert}\lvert s_j\rvert-1}{\sum_{j'=1}^{\lvert\boldsymbol{C}^{(i)}\rvert}\lvert s_{j'}\rvert-1}$	$l_{A\to\beta}^{(i)} = \frac{\sum_{j=1}^{\lvert\boldsymbol{C}\rvert} 2\lvert s_j\rvert+\lvert s_j\rvert-1}{\sum_{j'=1}^{\lvert\boldsymbol{C}^{(i)}\rvert} 2\lvert s_{j'}\rvert+\lvert s_{j'}\rvert-1}$

Collapsed VB: Teh et al. (2007) proposed, and Asuncion et al. (2009) simplified, a 'collapsed VB' algorithm for LDA that integrates out model parameters and so achieves a tighter lower bound on the marginal likelihood. This algorithm cycled through the training set and optimized variational distributions over the topic assignment of each word given all the other words.

Wang and Blunsom (2013) generalized this algorithm to PCFGs. The variational distribution for each sentence is parameterized by expected rule counts for that sentence, and they optimize each sentence-specific distribution by cycling through the corpus and optimizing the distribution over trees for sentence s_i using counts from all the other sentences $\boldsymbol{C}^{(\neg i)}$. The exact optimization, marginalizing over rule probabilities, is intractable, so they instead use the posterior mean. Algorithm 4 presents the full algorithm.

  $\pi_{A\to\beta} = \frac{\exp\left(\Psi\left(\hat{\alpha}_{A\to\beta}^{(j-1)}\right)\right)}{\exp\left(\Psi\left(\sum_{A\to\beta'\in\boldsymbol{R}_A}\hat{\alpha}_{A\to\beta'}^{(j-1)}\right)\right)}$
  for $i = 1$ **to** $|\boldsymbol{C}|$ **do**
    $\hat{f}^{(j)}(s_i, A\to\beta) = \mathbb{E}_{\boldsymbol{\pi}}\left[f(t, A\to\beta)\right]$
  end
  $\hat{\boldsymbol{\alpha}}^{(j)} = \boldsymbol{\alpha} + \hat{\boldsymbol{f}}^{(j)}$
end
output: $\hat{\boldsymbol{\alpha}}^{(m)}$

Algorithm 1: Batch VB. Here, $\hat{\alpha}^{(j)}$ are the posterior counts after iteration j, which define rule weights π for the next iteration.

Data: n minibatches $\left\{\boldsymbol{C}^{(1)}, \ldots, \boldsymbol{C}^{(n)}\right\}$
Initialization: prior hyperparameters $\boldsymbol{\alpha}$, step size schedule parameters τ, κ, epoch count E

$\hat{\boldsymbol{\alpha}}^{(0)} = \boldsymbol{\alpha}$
for $e = 0$ **to** $E-1$ **do**
  for $i = 1$ **to** n **do**
    $\pi_{A\to\beta} = \frac{\exp\left(\Psi\left(\hat{\alpha}_{A\to\beta}^{(en+i-1)}\right)\right)}{\exp\left(\Psi\left(\sum_{A\to\beta'\in\boldsymbol{R}_A}\hat{\alpha}_{A\to\beta'}^{(en+i-1)}\right)\right)}$
    $\hat{f}^{(en+i)}(A\to\beta) = \mathbb{E}_{\boldsymbol{\pi}}\left[f(t, A\to\beta)\right]$
    $\eta = (\tau+i)^{-\kappa}$
    for $A\to\beta \in \boldsymbol{R}$ **do**
      $\hat{\alpha}_{A\to\beta}^{(en+i)} = (1-\eta)\,\hat{\alpha}_{A\to\beta}^{(en+i-1)} + \eta l_{A\to\beta}^{(i)} \hat{f}^{(en+i)}(A\to\beta)$
    end
  end
end
output: $\hat{\boldsymbol{\alpha}}^{(n)}$

Algorithm 3: Stochastic VB. $\hat{f}^{(en+i)}(A\to\beta)$ is the expected count of rule $A\to\beta$ in the i^{th} minibatch in the e^{th} epoch, and $l_{A\to\beta}^{(i)}$ is the scaling parameter for rule $A\to\beta$ for the i^{th} minibatch, as described in the text.

Data: n minibatches $\left\{\boldsymbol{C}^{(1)}, \ldots, \boldsymbol{C}^{(n)}\right\}$
Initialization: prior hyperparameters $\boldsymbol{\alpha}$

$\hat{\boldsymbol{\alpha}}^{(0)} = \boldsymbol{\alpha}$
for $i = 1$ **to** n **do**
  $\forall A\to\beta \in \boldsymbol{R}\ \ \hat{f}^{(0)}(A\to\beta) = 0$
  for $j = 1$ **to** m **do**
    $\pi_{A\to\beta} = \frac{\exp\left(\Psi\left(\hat{f}\left(\boldsymbol{C}^{(i)}, A\to\beta\right)+\hat{\alpha}_{A\to\beta}\right)\right)}{\exp\left(\Psi\left(\sum_{A\to\beta'\in\boldsymbol{R}_A}\hat{f}\left(\boldsymbol{C}^{(i)}, A\to\beta'\right)+\hat{\alpha}_{A\to\beta'}\right)\right)}$
    $\hat{f}^{(i,j)}(A\to\beta) = \mathbb{E}_{\boldsymbol{\pi}}\left[f(t, A\to\beta)\right]$
  end
  $\hat{\boldsymbol{\alpha}}^{(i)} = \hat{\boldsymbol{f}}^{(i,m)} + \hat{\boldsymbol{\alpha}}^{(i-1)}$
end
output: $\hat{\boldsymbol{\alpha}}^{(n)}$

Algorithm 2: Streaming VB with m steps of VB per minibatch. $\hat{f}^{(j)}(A\to\beta)$ is the expected count of rule $A\to\beta$ in the i^{th} minibatch after j iterations.

Data: n single-string minibatches $\left\{\boldsymbol{C}^{(1)}, \ldots, \boldsymbol{C}^{(n)}\right\}$
Initialization: prior hyperparameters $\boldsymbol{\alpha}$, epoch count E, initial sentence-specific expected counts $\hat{\boldsymbol{f}}$

$\hat{\boldsymbol{\alpha}} = \boldsymbol{\alpha} + \sum_{i=1}^{n}\hat{\boldsymbol{f}}^{(i)}$
for $e = 0$ **to** $E-1$ **do**
  for $i = 1$ **to** n **do**
    $\hat{\boldsymbol{\alpha}} = \hat{\boldsymbol{\alpha}} - \hat{\boldsymbol{f}}^{(i)}$
    $\pi_{A\to\beta} = \frac{\hat{\alpha}_{A\to\beta}}{\sum_{A\to\beta'\in\boldsymbol{R}_A}\hat{\alpha}_{A\to\beta'}}$
    $\hat{f}^{(i)}(A\to\beta) = \mathbb{E}_{\boldsymbol{\pi}}\left[f(t, A\to\beta)\right]$
    $\hat{\boldsymbol{\alpha}} = \hat{\boldsymbol{\alpha}} + \hat{\boldsymbol{f}}^{(i)}$
  end
end
output: sentence-specific expected counts $\hat{\boldsymbol{f}}$, global hyperparameters $\hat{\boldsymbol{\alpha}}$

Algorithm 4: Collapsed VB. $\hat{f}^{(i)}(A\to\beta)$ is the expected count of rule $A\to\beta$ for the i^{th} sentence, and the global hyperparameters $\hat{\boldsymbol{\alpha}}$ are the sum of the expected counts for each sentence and prior hyperparameters.

Figure 2: The four variational Bayes algorithms for PCFG inference that are evaluated in this paper. Algorithm 1 is from Kurihara and Sato (2004), and Algorithm 4 is from Wang and Blunsom (2013). Algorithms 2 and 3 are novel PCFG inference algorithms developed here that generalise the LDA inference algorithms of Broderick et al. (2013) and Hoffman et al. (2010).

Fisher	Words	5,576,173	–	–
	Sentences	664,346	–	–

Table 1: Data set sizes. Fisher is only for training.

5 Experiments

We evaluate how millions of words of training data affects grammar induction from words alone by examining learning curves. We ran each algorithm 5 times, each with a different random shuffle of the training data on each run, and evaluated on the test set at logarithmically-spaced numbers of training sentences. Stochastic, collapsed, and batch VB used more than one pass over the training corpus, while streaming VB makes one pass over the training corpus. To obtain a consistent horizontal axis in our learning curves, we plot learning curves as a function of computational effort, which we measure by the number of sentences parsed, since almost all the computational effort of all the algorithms is in parsing.

Stochastic, collapsed, and streaming VB can learn from the full training corpus (although collapsed VB requires more RAM – 60GB rather than 6GB for us – as it stores expected rule counts for each sentence). Batch VB required about 50 iterations for convergence for large training sets, and so cannot be applied to the full training set due to long training times. We used batch VB with training sets of up to $100,000$ strings.

5.1 Hyperparameters and initialization

We use Dirichlet priors with symmetric hyperparameter $\alpha = 1$ for all algorithms (preliminary experiments showed that the algorithms are generally insensitive to hyper-parameter settings). We ran batch VB until the log probability of the training set changed less than 0.001%. For stochastic VB, we used $\kappa = 0.9$, $\tau = 1$, and minibatches of 10,000 sentences. To investigate convergence and overfitting, we ran stochastic and collapsed VB for 15 epochs of random orderings of the training corpus. For streaming VB, the first minibatch had $10,000$ sentences, the rest had 1, and we used one iteration of VB per minibatch.

Klein and Manning (2004) showed that initialization strongly influences the quality of the induced grammar when training from POS-tagged WSJ10 data, and they proposed a harmonic initialization procedure that puts more weight on rules that involve terminals that frequently appear close to each other in the training data. We present results both for a uniform initialization, where the only counts initially are the uninformative Dirichlet priors (plus, for collapsed VB, random sentence-specific counts), and a harmonic initialization. For streaming VB, harmonic counts are gathered from each minibatch, and for the others, harmonic counts are gathered from the entire training set.

5.2 Data

We present experiments on two corpora of words from spontaneous speech transcripts. Our first corpus is drawn from the Switchboard portion of the Penn Treebank (Calhoun et al., 2010; Marcus et al., 1993). We used the version produced by Honnibal and Johnson (2014), who used the Stanford dependency converter to convert the constituency annotations to dependency annotations (Catherine de Marneffe et al., 2006). We used Honnibal and Johnson's train/dev/test partition, and ignored their second dev partition. We discarded sentences shorter than four words from all partitions, as they tend to be formulaic backchannel responses (Bell et al., 2009), and sentences with more than 15 words (long sentences did not improve accuracy on the dev set).

We augmented the Switchboard training set with the Fisher corpus of telephone transcripts. We again used only sentences with 4 to 15 words. Unlike the words-only evaluation of Pate and Goldwater (2013), which used only the fluent sentences from Switchboard that had been prosodically annotated, both of these corpora contain disfluencies. These corpora have a vocabulary of $40,597$ word types. The grammars have one Root rule for each word type, four Stop rules (two directions x two Stop decisions) for

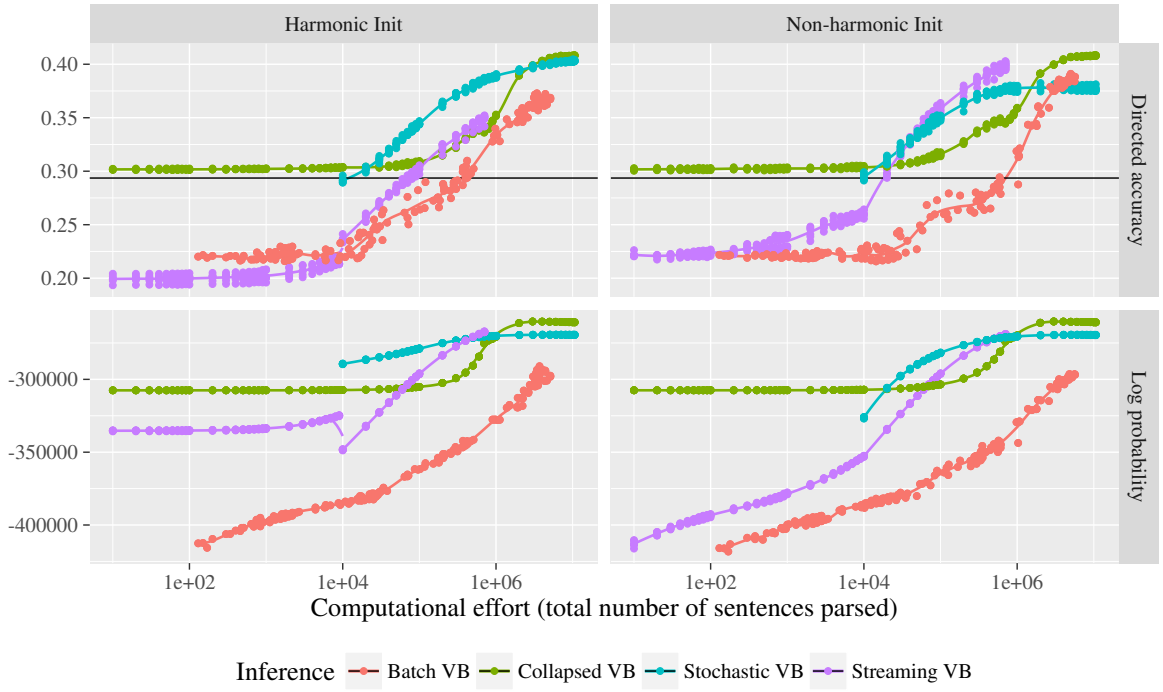

Figure 3: Directed accuracy (top) and predictive log probability (bottom) of test-set sentences from Switchboard with 4-15 words. The horizontal axis is the number of sentences parsed (all algorithms except streaming VB re-parse sentences multiple times). The left column presents inference with a harmonic initialization, and the right column presents inference with a uniform initialization (and, for collapsed VB, random sentence-specific counts). The black line is a uniform-branching baseline.

each word type, and $5,381,644$ Choose rules. Table 1 presents data set sizes.

5.3 Evaluation measures

We evaluated all algorithms in terms of predictive log probability and directed attachment accuracy. We computed the log probability of the evaluation set under posterior mean parameters, obtained by normalizing counts. Directed accuracy is the proportion of arcs in the Viterbi parse that match the gold standard, including the root. We also compared with a left-branching baseline, since it outperformed a right-branching baseline. A left-branching (right-branching) baseline sets the last (first) word of each sentence to be the root, and assigns each word to be the head of the word to its left (right). The left-branching baseline on this dataset is about 0.29, while on the traditional `wsj10` dataset of Klein and Manning (2004) it is 0.336, suggesting our dataset, with longer sentences, is somewhat more difficult.

5.4 Results

The bottom row of Figure 3 presents the predictive log probability of the test set under the posterior mean parameter vector as training proceeds. The figure contains one point per evaluation per run, and a loess-smoothed curve for each inference type. We see among all algorithms that the log probability of the test set constantly increases, regardless of initialization, with one exception. The sole exception is streaming VB with harmonic initialization, where predictive log probability drops after the initial minibatch of 10,000 sentences. Streaming VB with harmonic init parses each sentence of the initial minibatch using prior pseudocounts and harmonic counts. We will return to this drop when we discuss accuracy.

Batch VB learns more slowly (as a function of computational effort) than the online and minibatch algorithms, but the online and minibatch algorithms all ultimately obtain similar performance. Collapsed VB obtains the best predictive log probability, which, as it integrates out parameters and therefore has a tighter bound, is to be expected (Teh et al., 2007). There is no clear advantage to the harmonic initialization except early in training for streaming and stochastic VB, so it may be that earlier results showing

the importance of harmonic initialisation reflect the small training data sets used in those experiments.

The top row of Figure 3 presents directed accuracy on the test set as training proceeds. As in the predictive probability evaluation, there is no clear advantage to a harmonic initialization across algorithms. Batch VB and collapsed VB perform identically with both initializations, and streaming VB ultimately does 5% better while stochastic VB does 2.5% worse. While streaming VB showed a drop in predictive probability after the initial 10,000 sentence minibatch with harmonic initialization, it obtains a small but sharp improvement in parse accuracy at the same point. These two results suggest that the harmonic initialization, applied to words, captures regularities that are not syntactic but still explain data well.

The inference algorithms differ most obviously when they have parsed few sentences, indicating that each algorithm's bias is strongest in the face of small data. Streaming VB learns slowly initially because, throughout the large initial minibatch, it gathers counts using only the uninformative prior or only the uninformative prior plus harmonic counts. Collapsed VB, on the other hand, has sentence-specific counts for the entire training corpus even in the random case. These counts provide a rough estimate of how many opportunities there are for an arc to exist between each word in each direction at each valence, and therefore provide a stronger starting point that takes more time to overcome. Finally, the good performance of stochastic VB with small datasets, compared to streaming VB and batch VB, may reflect the conservatism of only taking a step in the direction of the gradient rather than always maximizing.

Regardless of the details of the different algorithms' performance, we see that they all steadily improve or stabilize as inference proceeds over a large dataset, and that initialization is not important when learning from large numbers of words.

6 Conclusion

Grammar induction from words alone has the potential to address important questions about how children learn and represent linguistic structure, but previous work has struggled to learn from words alone in a principled way. Our experiments show that grammar induction from words alone is feasible with a simple and well-known model if the dataset is large enough, and that heuristic initialization is not necessary (and may even interfere). Future computational work on child language acquisition should take advantage of this finding by applying richer models of syntax to large datasets, and learning distributed word representations jointly with syntactic structure.

Abstract

Existing sentence regression methods for extractive summarization usually model sentence importance and redundancy in two separate processes. They first evaluate the importance $f(s)$ of each sentence s and then select sentences to generate a summary based on both the importance scores and redundancy among sentences. In this paper, we propose to model importance and redundancy simultaneously by directly evaluating the relative importance $f(s|S)$ of a sentence s given a set of selected sentences S. Specifically, we present a new framework to conduct regression with respect to the relative gain of s given S calculated by the ROUGE metric. Besides the single sentence features, additional features derived from the sentence relations are incorporated. Experiments on the DUC 2001, 2002 and 2004 multi-document summarization datasets show that the proposed method outperforms state-of-the-art extractive summarization approaches.

1 Introduction

Sentence regression is one of the branches of extractive summarization methods that achieves state-of-the-art performances (Cao et al., 2015b; Wan et al., 2015) and is commonly used in practical systems (Hu and Wan, 2013; Wan and Zhang, 2014; Hong and Nenkova, 2014). Existing sentence regression methods usually model sentence importance and sentence redundancy in two separate processes, namely sentence ranking and sentence selection. Specifically, in the sentence ranking process, they evaluate the importance $f(s)$ of each sentence s with a ranking model (Osborne, 2002; Conroy et al., 2004; Galley, 2006; Li et al., 2007) through either directly measuring the salience of sentences (Li et al., 2007; Ouyang et al., 2007) or firstly ranking words (or bi-grams) and then combining these scores to rank sentences (Lin and Hovy, 2000; Yih et al., 2007; Gillick and Favre, 2009; Li et al., 2013). Then, in the sentence selection process, they discard the redundant sentences that are similar to the already selected sentences.

In this paper, we propose a novel regression framework to directly model the relative importance $f(s|S)$ of a sentence s given the sentences S. Specifically, we evaluate the relative importance $f(s|S)$ with a regression model where additional features involving the sentence relations are incorporated. Then we generate the summary by greedily selecting the next sentence which maximizes $f(s|S)$ with respect to the current selected sentences S. Our method improves the existing regression framework from three aspects. First, our method is redundancy-aware by considering importance and redundancy simultaneously instead of two separate processes. Second, we treat the scores computed using the official evaluation tool as the groundtruth and find that our method has a higher upper bound. Third, there is no manually tuned parameters, which is more convenient in practice. We carry out experiments on three benchmark datasets from DUC 2001, 2002, and 2004 multi-document summarization tasks. Experimental results show that our method achieves the best performance in terms of ROUGE-2 recall metric and outperforms state-of-the-art extractive summarization approaches on all three datasets.

2 Framework

2.1 Background

Formally, given a sentence set (from one or multiple documents) $D \in C$, extractive summarization tries to select a sentence set S^* as the summary that maximizes an utility function $f(S)$ with respective to the length limit l, Existing sentence regression methods usually model the importance of each sentence independently (Osborne, 2002; Galley, 2006; Li et al., 2007). Then, they use a threshold parameter to control the redundancy (Cao et al., 2015b; Galanis et al., 2012) when selecting sentences with the Greedy algorithm or Integer Linear Programming (ILP) algorithm (Cao et al., 2015a). The framework for these regression methods can be formulated as follows.

$$f(s|S) = \begin{cases} f(s) & 1 - SIM(s,S) \geq t \\ 0 & 1 - SIM(s,S) < t \end{cases} \tag{1}$$

where S is the set of already selected sentences, $f(s)$ models the importance of sentence s. $SIM(s,S)$ evaluates the similarity of sentence s with the current generated summary S. Usually, $SIM(s,S) = \frac{bi\text{-}gram\text{-}overlap(s,S)}{Len(s)}$, which is the bi-gram overlap ratio. $Len(s)$ is the length of s. t is a threshold parameter used to control the redundancy, which is usually set heuristically.

2.2 Our Framework

In this paper, we propose to directly model the relative importance $f(s|S)$ instead of the independent importance of each sentence $f(s)$. Specially, we model the importance of s given the sentences S as follows:

$$f(s|S) = \min_{s' \in S} f(s|s') \tag{2}$$

which considers the minimum relative importance of sentence s with respect to each sentence of S. $f(s|s')$ models the relative importance of sentence s given sentence s', which makes Equation 2 a redundancy-aware framework.

When generating summaries, we select the first sentence by treating $s' = \emptyset$ or using a $f(s)$ model. Then, we select the rest summary sentences with the following greedy algorithm:

$$s^* = \arg \max_{s \subset D \setminus S} \min_{s' \in S} f(s|s') \tag{3}$$

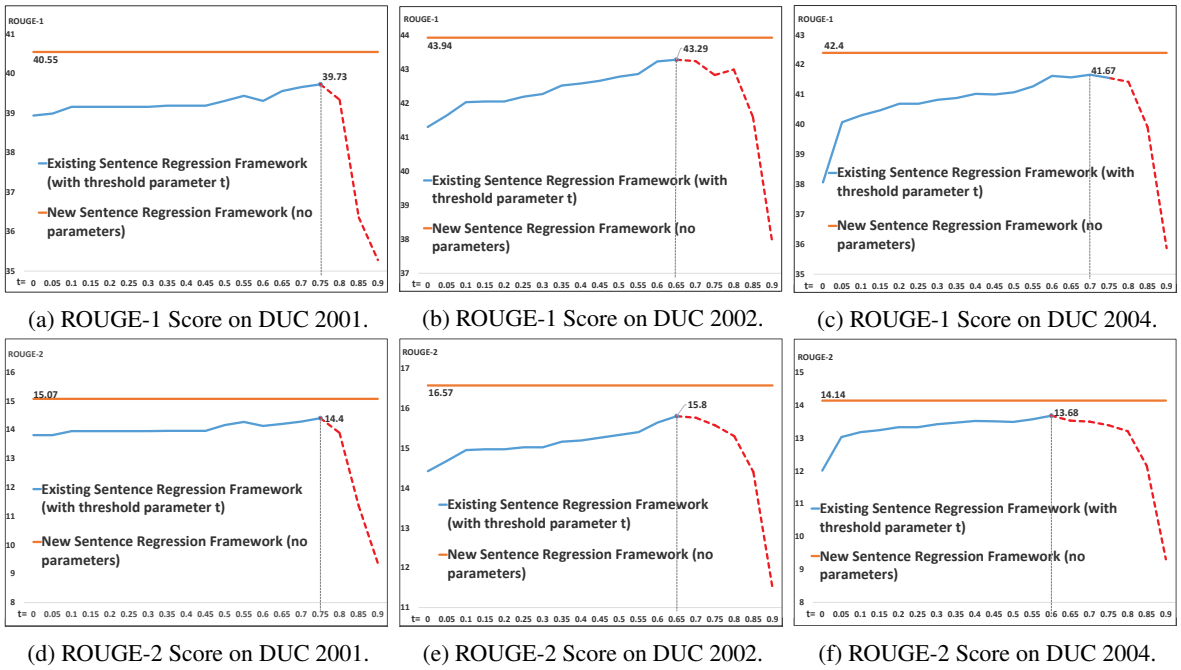
The algorithm starts with the first selected sentence. In each step, a new sentence is added to the summary that results in the maximum relative increase according to Equation 3. The algorithm terminates when the summary length constraint is reached.

Next we conduct experiments to analyze the upper bounds of the new framework compared with the existing framework (Equation 1). To this end, we compute $f(s)$ and $f(s|s')$ as follows:

$$\begin{aligned} &f(s) = ROUGE\text{-}2(s|S_{ref}) \\ &f(s|s') = f(\{s,s'\}) - f(s') = ROUGE\text{-}2(\{s,s'\}|S_{ref}) - ROUGE\text{-}2(s'|S_{ref}) \end{aligned} \tag{4}$$

where S_{ref} is one or several summaries written by people. The ROUGE-2 recall metric gives a score to a set of sentences with respective to the human written summaries. We compute $f(s|s')$ as the total gain of s and s' ($f(\{s,s'\})$) subtracted by the individual gain of s' ($f(s')$). Equation 4 can be seen as the groundtruth computation of $f(s)$ and $f(s|s')$.

The experimental upper bounds of different frameworks are shown in Figure 1. Similar results of ROUGE-1 and ROUGE-2 are achieved on all three benchmark datasets from DUC 2001, 2002 and 2004. The *advantages* of the new framework (Equation 2) are three-fold compared with the framework of Equation 1. First, there is no parameter to be tuned manually. By comparison, Equation 1 has a threshold parameter t, which is very sensitive around the best performance, as shown in the red dashed line parts of Figure 1. Second, the new framework has a higher upper bound, which means there is a bigger potential



(a) ROUGE-1 Score on DUC 2001. (b) ROUGE-1 Score on DUC 2002. (c) ROUGE-1 Score on DUC 2004.

(d) ROUGE-2 Score on DUC 2001. (e) ROUGE-2 Score on DUC 2002. (f) ROUGE-2 Score on DUC 2004.

Figure 1: Experimental Upper bounds of our sentence regression framework and existing sentence regression framework.

for improvement. Finally, besides single sentence features, additional features involving the relations of two sentences can be extracted to improve the regression performance.

The new proposed framework also has some *challenges*. First, the groundtruth of $f(s|s')$ is usually unavailable for many tasks. Fortunately, in the text summarization task, the groundtruth of $f(s|s')$ can be computed according to Equation 4. Second, the number of training instances is $O(|C||D|^2)$ ($O(|C||D|)$ for Equation 1). We come up with two ways to speed up the training process in the next session.

3 Implementation

3.1 Objective Function

We implement $f(s|s')$ with MultiLayer Perceptron (MLP) (Ruck et al., 1990; Gardner and Dorling, 1998).

$$f(s|s') = MLP\left(\Phi(s|s')|\theta\right) \tag{5}$$

where $\Phi(s|s')$ is the set of features and θ is the parameters to be learned.

We use the standard Mean Square Error (MSE) as the loss function as follows:

$$\begin{aligned} L(\theta) &= \frac{1}{|C||D|(|D|-1)} \sum_{D \in C} \sum_{s \in D} \sum_{\substack{s' \in D; \\ s' \neq s}} Err(s|s') \\ Err(s|s') &= \left(MLP\left(\Phi(s|s')|\theta\right) - ROUGE(s|s', S_{ref})\right)^2 \\ ROUGE(s|s', S_{ref}) &= ROUGE\text{-}2(\{s, s'\}|S_{ref}) - ROUGE\text{-}2(s'|S_{ref}) \end{aligned} \tag{6}$$

We use ROUGE-2 recall as the groundtruth score due to its high capability of evaluating automatic summarization systems (Owczarzak et al., 2012).

The s' in $f(s|s')$ should mainly refer to the sentences that have a big potential to be selected into the summary. To this end, we do not have to treat each sentence in D as s' during training. We can accelerate the training process by generating a set of sentences S' from D. We come up with two ways as shown in Algorithm 1. The first way is using the greedy strategy (Line 4 of Algorithm 1). Specifically, for each training episode of sentence s, we use the current model to generate the summary with greedy algorithm

as a part of the S'. We refer to this part as S'_1. The advantage is that S'_1 is adaptively generated with respective to the training status of the model. The second way is randomly sampling a small set of s' with respect to its groundtruth ROUGE score (Line 6 of Algorithm 1). Specifically, for each training episode of sentence s, we sample a small set S'_2 according to the following rule:

$$\begin{cases} NotSelected & rnd(0,1) > 0.05 * ROUGE\text{-}2(s) + 0.05 \\ Selected & Otherwise \end{cases} \tag{7}$$

where $rnd(0,1)$ generates random number from a uniform distribution within the range $[0,1]$. $ROUGE\text{-}2(s)$ is normalized to $[0,1]$. Each sentence is selected with at least 5% probability and sentences with higher ROUGE scores have higher probabilities. Different probabilities will influence the speed of the training process but will not make much difference in the final results according to our experiments. We use the randomly sampled S'_2 to avoid the premature convergence caused by S'_1. Finally, $S' = S'_1 \bigcup S'_2$. In this way, the number of training instances is $O(|C||D||S'|)$ while originally it is $O(|C||D|^2)$, where C is the set of all D in the training corpus. Note that $|S'|$ is a very small number compared to $|D|$.

3.2 Feature

We employ two groups of features in terms of sentence importance and redundancy, namely Sentence Importance Features and Sentence Relation Features. The former are widely studied by existing methods (Gupta et al., 2007; Li et al., 2007; Aker et al., 2010; Ouyang et al., 2011; Galanis et al., 2012; Hong et al., 2015). However, to our knowledge, the latter are firstly incorporated into a regression model in this paper. Details of used features are listed in Table 1. We use Sentence Importance Features to model the independent sentence importance of s. $Len(s)$, $Position(s)$, $Stop(s)$, $TF(s)$ and $DF(s)$ are commonly used features. Embedding feature $Emb(s)$ is an effective feature that encodes the sentence content which can be seen as summary prior nature of the sentence (Cao et al., 2015b). We use Sentence Relation Features to evaluate the content overlap between s and s'. $Match\text{-}P(s \cap s')$ and $Match\text{-}R(s \cap s')$ evaluate the ratio of the overlap words, while $TF(s \cap s')$, $DF(s \cap s')$ and $Stop(s \cap s')$ evaluate the importance of the overlap words. $Cos(s, s')$ evaluates the exact match similarity while $Emb\text{-}Cos(s, s')$ evaluates the meaning match similarity. All features in Table 1 are basic features commonly used in summarization.

Features	Formulations	Descriptions
Sentence Importance Features	$Len(s)$	Length of s
	$Position(s)$	Position of s in its document
	$Stop(s) = \frac{stop\text{-}count(s)}{Len(s)}$	Stop words ratio of s
	$TF(s) = \frac{\sum_{w \in s} GTF(w)}{Len(s)}$	Average Term Frequency $GTF(w)$ is the Global Term Frequency
	$DF(s) = \frac{\sum_{w \in s} DF(w)}{Len(s)}$	Average Document Frequency
	$Emb(s) \frac{\sum_{w \in s} Emb(w)}{Len(s)}$	Average Word Embedding $Emb(w)$ is the word embedding
Sentence Relation Features	$Match\text{-}P(s, s') = \frac{Match(s,s')}{Len(s)}$	Term match precision $Match\text{-}P(s, s') = 0$ if $s \cap s' = \emptyset$
	$Match\text{-}R(s, s') = \frac{Match(s,s')}{Len(s')}$	Term match recall $Match\text{-}R(s, s') = 0$ if $s \cap s' = \emptyset$
	$TF(s, s') = \frac{Len(s \cap s')}{\sum_{w \in s \cap s'} GTF(w)}$	Average Global Term Frequency of overlap $s \cap s'$ $TF(s, s') = 0$ if $s \cap s' = \emptyset$
	$DF(s, s') = \frac{Len(s \cap s')}{\sum_{w \in s \cap s'} DF(w)}$	Average Document Frequency of overlap $s \cap s'$ $DF(s, s') = 0$ if $s \cap s' = \emptyset$
	$Stop(s, s') = 1 - \frac{Stop\text{-}Count(s \cap s')}{Len(s \cap s')}$	Stop words ratio of overlap $s \cap s'$ $Stop(s, s') = 0$ if $s \cap s' = \emptyset$
	$Cos(s, s')$ $= Cosine(GTF(s), GTF(s'))$	Cosine of Global Term Frequency vector
	$Emb\text{-}Cos(s, s')$ $= Cosine(Emb(s), Emb(s'))$	Cosine of average embedding vector

Table 1: Summary of features

4 Experiment

4.1 Experimental Setup

Datasets. The benchmark evaluation corpora for summarization are the ones published by the Document Understanding Conferences (DUC[1]). We focus on the generic multi-document summarization task, so we carried out all our experiments on DUC 2001, 2002 and 2004 datasets. The documents are all from the news domain and are grouped into various thematic clusters. For each document set, we concatenated all the articles and split them into sentences using the tool provided with the DUC 2003 dataset. We train the model on two years' data and test it on the other year.

Evaluation Metric. ROUGE metrics are the official metrics of the DUC extractive summarization tasks (Rankel et al., 2013). We use the official ROUGE tool[2] to evaluate the performance of the baselines as well as our approach (Lin, 2004). The parameter of length constraint is "-l 100" for DUC 2001/2002, and "-b 665" for DUC 2004. We take ROUGE-2 recall as the main metric for comparison because Owczarzak et al. prove its high capability of evaluating automatic summarization systems (Owczarzak et al., 2012).

Comparison Methods. The comparison methods used in the experiments are listed as follows.

- LexRank: State-of-the-art summarization model (Erkan and Radev, 2004).
- ClusterHITS: State-of-the-art results on DUC 2001 (Wan and Yang, 2008).
- ClusterCMRW: State-of-the-art results on DUC 2002 (Wan and Yang, 2008).
- REGSUM[3]: State-of-the-art results on DUC 2004 (Hong and Nenkova, 2014).
- R2N2_GA/R2N2_ILP: State-of-the-art results on DUC 2001/2002/2004 (Cao et al., 2015a) with a neural network regression model.
- PriorSum: To our knowledge, the best results on DUC 2001, 2002 and 2004 using regression approaches (Cao et al., 2015b).
- SR (Sentence Regression): Evaluate sentence importance with MLP and the Sentence Importance Features in Table 1 and select the top ranks as the summary (without handling redundancy).

[1] http://duc.nist.gov/

[2] ROUGE-1.5.5 with options: -n 2 -m -u -c 95 -x -r 1000 -f A -p 0.5 -t 0

[3] REGSUM truncates a summary to 100 words.

	DUC 2001		DUC 2002		DUC 2004	
	ROUGE-1	ROUGE-2	ROUGE-1	ROUGE-2	ROUGE-1	ROUGE-2
BestSentence	37.32	10.44	39.75	11.60	40.36	11.68
Strategy 1	36.31	8.49	37.80	9.61	39.60	10.57
Strategy 2	36.32	8.52	37.82	9.26	38.75	10.19

Table 2: First sentence selection strategies

- t-SR (threshold t based Sentence Regression): Evaluate sentence importance with MLP and the Sentence Importance Features in Table 1 and generate the summary with greedy by directly discarding the redundant sentence according to Equation 1.
- RASR (**R**edundancy-**A**ware **S**entence **R**egression): The proposed method in this paper.

Note that for the methods with the parameter t, we tried all values of ranging from 0 to 1 with a step size of 0.05. The final value of t on each dataset is decided by 3-fold cross validation on the training datasets.

Model Configuration. The word embedding used in this paper is trained on the English Wikipedia Corpus[4] with Google's Word2Vec tool[5]. The dimension is 300. We use 4 hidden layers MLP with tanh activation function and the sizes of the layers are $[300, 200, 100, 1]$. To update the weights of MLP, we apply the diagonal variant of AdaGrad with mini-batches. We set the mini-batch size to 20.

4.2 Results and Analysis

First Sentence Selection. Remember that when generating a summary, our method first selects the first sentence then greedily selects the rest sentences with respective to $f(s|S)$. We tried two strategies to select the first sentence with RASR. Strategy 1: treating RASR as an united model by setting the Sentence Relation Features to zero when fitting $f(s)$ during training period or selecting the first sentence during test period. Strategy 2: treating RASR as two models that fit $f(s)$ and $f(s|S)$ respectively. The former is used to select the first sentence and the latter is used to select the rest sentences. We also use the sentence that gets the highest ROUGE-2 score as the first sentence as a comparison, namely BestSentence. The results are shown in Table 2. As expected, BestSentence is much better than Strategy 1 and Strategy 2, which means selecting a better first sentence will greatly improve the performance of RASR. It does not make too much difference whether using Strategy 1 or Strategy 2. We report the results of Strategy 1 to compare with the baseline methods in Table 3.

Performance Analysis. As shown in Table 3, the bold face indicates the best performance. Generally, our method RASR achieves the best performance in terms of ROUGE-2 metric on all three datasets. The improvement of ROUGE-2 on DUC 2001 is significant with p-value < 0.05 compared with LexRank, SR and t-SR. Although ClusterHITS and ClusterCMRW get higher ROUGE-1 scores, their ROUGE-2 scores are much lower. In contrast, our method works quite stably.

The improvements of our method come from two aspects. First, it is effective to model sentence importance and redundancy simultaneously with multiple nonlinear function transformations. This can be reflected by the following comparison experiments. SR does not handle redundancy at all, so it achieves bad performance especially on the DUC 2004 corpus. The other methods in Table 3 model sentence importance and redundancy in two separate processes by first ranking the sentences and then discarding the redundant ones whose bi-gram overlap ratio is larger than a threshold parameter. Although we tune the threshold parameter carefully, RASR still outperforms them. Second, effective features involving the sentence relations (i.e., Sentence Relation Features) are considered which cannot be incorporated by the baseline methods.

Table 3: Comparison results (%) on DUC datasets

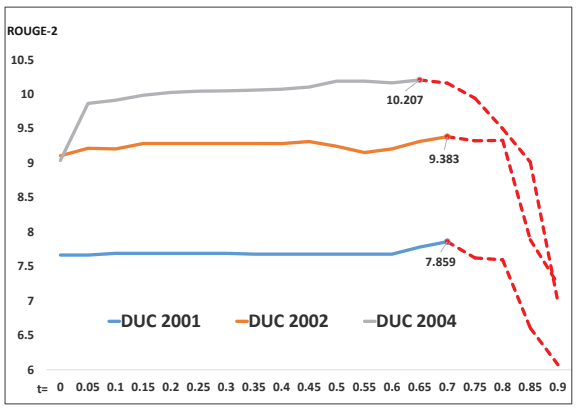
Parameter Sensitiveness. We present the ROUGE-2 performance of t-SR with the threshold parameter t ranging from 0 to 0.9 with a step size of 0.05 shown in Figure 1 and 2a. The best achieved performances of the groundtruth implementation are around 0.75, 0.65, 0.6 (Figure 1) while the best achieved performances in practice are around 0.7, 0.7, 0.65 (Figure 2a). t is still very sensitive around the best performance, as shown in the red dashed line in both Figure 1 and 2a.

Training Convergence. In order to speed up the training process of RASR, we randomly sample some pairwise training instances with Equation 7 for training of RASR. We want to know whether this will influence the convergence of RASR, so we present the decrease of loss with respect to training iterations in Figure 2b. We find that the random sampling has little influence on the convergence of RASR with t-SR as a comparison.

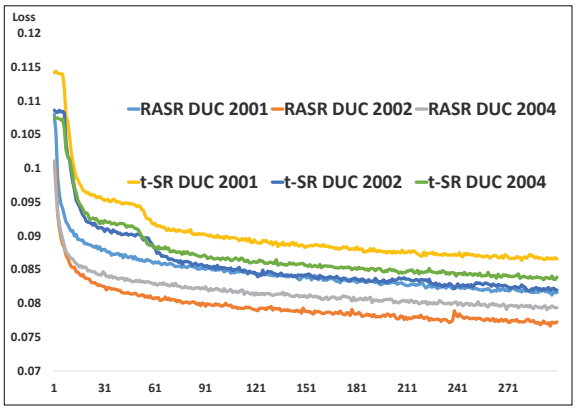
5 Related Work

Existing work on extractive summarization can be divided into two categories: unsupervised and supervised.

Two most famous unsupervised frameworks are Centroid based and Maximum Marginal Relevance based. Centroid-based methods evaluate the sentence centrality as its importance (Mihalcea, 2004). Radev et al. first propose to model cluster centroids in their summarization system, MEAD (Radev et al., 2000; Radev et al., 2004). Then LexRank (or TextRank) is proposed to compute sentence importance



(a) Sensitiveness of the parameter t of t-SR.



(b) Loss decrease with respect to training iterations.

based on the concept of eigenvector centrality in a graph of sentence similarities (Erkan and Radev, 2004; Mihalcea and Tarau, 2004). Due to its expansibility and flexibility, centroid-based methods have a lot of extensions. Wan et al. propose several centroid-based approaches for different summarization tasks, e.g., cross-language summarization, etc (Wan, 2008; Wan and Xiao, 2009; Wan, 2011). Maximum Marginal Relevance (MMR) based methods consider the linear trade-off between relevance and redundancy (Carbonell and Goldstein, 1998). Goldstein et al. first extend MMR to support extractive summarization by incorporating additional information (Goldstein et al., 2000). McDonald achieves good results by reformulating this as a knapsack packing problem and solving it using ILP (McDonald, 2007). Later Lin and Bilmes propose a variant of MMR framework which maximizes an objective function that considers the linear trade-off between coverage and redundancy terms (Lin and Bilmes, 2010; Lin and Bilmes, 2011).

Supervised methods model the extractive summarization task from various perspectives. Kupiec et al. train a naive-Bayes classifier to decide whether to include a particular sentence in the summary or not. (Kupiec et al., 1995). Li et al. evaluate the sentence importance with support vector regression, then a simple rule-based method is applied for removing redundant phrases (Li et al., 2007). Gillick and Favre evaluate bi-grams importance and then use these scores to evaluate sentence importance and redundancy with a linear combination (Gillick and Favre, 2009). Sipos et al. propose a structural SVM learning approach to learn the weights of feature combination using the MMR-like submodularity function proposed by Lin and Bilmes (Lin and Bilmes, 2010). Cao et al. evaluate the sentence importance with a neural regression model, then they remove the redundant sentence larger than a threshold parameter during greedy algorithm (Cao et al., 2015b). In another paper, they remove the redundant sentence by adding a redundancy constraint to the ILP objective which restricts the bi-gram redundancy of the selected sentences smaller than a threshold (Cao et al., 2015a).

In all above extractive summarization methods, redundancy is mainly considered in two ways. The first way is measuring the importance of each sentence then explicitly removing the redundant sentence larger than a threshold parameter during the sentence selection process. Another way is linearly substracting the sentence redundancy score or scoring the redundant parts with low weights. To the best of our knowledge, none of them studies the summarization task and models redundancy from the perspective of this paper.

6 Conclusion and Future Work

This paper presents a novel sentence regression framework to conduct regression with respect to the relative importance $f(s|S)$ of sentence s given a set of sentences S. Additional features involving the sentence relations are incorporated. We conduct experiments on three DUC benchmark datasets. Generally, our approach achieves the best performance in terms of ROUGE metrics compared with state-of-the-art approaches.

We believe our work can be advanced and extended from many different perspectives. First, more features can be designed especially those involving the relations of two sentences. Second, the results

can be further improved by exploring better strategies to select the first sentence. Third, the framework can be extended to other tasks, e.g., query-focused summarization, which can be achieved by introducing query-related features.

Abstract

Automatic video description generation has recently been getting attention after rapid advancement in image caption generation. Automatically generating description for a video is more challenging than for an image due to its temporal dynamics of frames. Most of the work relied on Recurrent Neural Network (RNN) and recently attentional mechanisms have also been applied to make the model learn to focus on some frames of the video while generating each word in a describing sentence. In this paper, we focus on a sequence-to-sequence approach with temporal attention mechanism. We analyze and compare the results from different attention model configuration. By applying the temporal attention mechanism to the system, we can achieve a METEOR score of 0.310 on Microsoft Video Description dataset, which outperformed the state-of-the-art system so far.

1 Introduction

Since the recent breakthrough in machine learning, generating description for static images has been intensively researched and high-quality image description can be achieved in the past few years by many research groups (Vinyals et al., 2014; Karpathy and Fei-Fei, 2015; Fang et al., 2015; Xu et al., 2015; You et al., 2016). However, video description generation is a much more challenging task, which requires understanding temporal relationship between video frames. Automatically generating video description can be useful in many aspects. It can help visually-impaired people to understand the content of videos. More importantly, it will enable computers to understand videos, rather than just working at pixel levels, because the generated descriptions contain objects appearing the videos along with their attributes, locations, actions, and relations with other objects. Though considered very challenging, being able to understand videos can have great impact and will be useful to many other applications, such as human-robot interaction, video indexing and query, and video classification.

This paper focuses on generating video description using a encoder-decoder sequence-to-sequence model with temporal attention mechanism. We perform a set of experiments using different configurations of attention mechanisms and also can achieve state-of-the-art results. Our main contributions are as follows: First, we apply temporal attention mechanism to the encoder-decoder sequence-to-sequence model and are able to outperform the state-of-the-art system on Microsoft Video Description dataset (MSVD) (Chen and Dolan, 2011) in terms of the METEOR (Denkowski and Lavie, 2014), CIDEr (Vedantam et al., 2014), and ROUGE-L (Lin, 2004) scores. Second, we analyze and compare the results from different model configurations, and show how temporal attention works in generating sentences. We also performed the experiments on a large movie dataset, Montreal Movie Annotation Dataset (M-VAD) collected by Torabi et al. (2015).

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 44–52, Osaka, Japan, December 11-17 2016.

2 Related Work

There exist many works in the image captioning task inspired by recent advances in machine translation using encoder-decoder Recurrent Neural Network (RNN) (Bahdanau et al., 2014). Vinyals et al. (2014) replaced the RNN encoder with a Convolutional Neural Network (CNN) which was pre-trained for an image classification task. Then, the last hidden layer of the pre-trained CNN can be used to produce a meaningful representation of an image, which they used as an input to the RNN decoder that generates sentences.

Karpathy and Fei-Fei (2015) used a combination of a CNN and a bidirectional RNN to generate natural language sentences from an image as well as their corresponding regions. Fang et al. (2015) first trained visual detectors from a dataset of image-caption pairs, and then used the output words from the visual detectors as input to the language model for generating image description. Xu et al. (2015) also used a CNN-RNN encoder-decoder scheme and applied a spatial attention mechanism over an input image, so that the model can attend to a specific region of an image while generating each word of a caption sentence. The model of You et al. (2016) learned to selectively attend to semantic concepts (similar to visual concepts in (Fang et al., 2015)) of an image and input them into the RNN decoder at each time step of generating image description.

After great success in image captioning, researchers are currently moving forward into working on generating sentences that describe videos. Venugopalan et al. (2015b) proposed the first end-to-end system to translate a video into natural language by extending the CNN-RNN encoder-decoder framework for image captioning proposed by Vinyals et al. (2014) to generate description for videos. They performed a mean pooling over CNN feature vectors of frames to generate a single vector representation for a video, and then use the vector as input to the RNN decoder to generate a sentence. Yao et al. (2015) has incorporated an attentional mechanism to video caption generation. They took into account both local and global temporal structures of videos by incorporating a spatial temporal 3D CNN.

A sequence-to-sequence model for generating description of videos has been first proposed by Venugopalan et al. (2015a). They used 2 layers of RNN for both encoding the videos and decoding into sentences, so their model is able to learn both a temporal structure of a sequence of video frames and a sequence model for generating sentences.

3 Sequence-to-sequence Model

This section describes the concept and structure of the sequence-to-sequence model, including Long Short-Term Memory (LSTM), the two-layer encoder-decoder LSTM, and the temporal attention mechanism that we used in this work.

3.1 Long Short-Term Memory

An LSTM network, proposed by Hochreiter and Schmidhuber (1997), is a type of RNN that is commonly used in sequence-to-sequence models. It has been intensively used in machine translation, speech recognition as well as in image/video description generation.

LSTM can help to avoid exploding and vanishing gradient problems by using forget gates to reset memory block when they are out of date. Given an input x_t, at time step t, one unit of an LSTM can be formulated as

$$\begin{aligned} i_t &= sigmoid(W_{xi}x_t + W_{hi}h_{t-1} + b_i) \\ f_t &= sigmoid(W_{xf}x_t + W_{hf}h_{t-1} + b_f) \\ o_t &= sigmoid(W_{xo}x_t + W_{ho}h_{t-1} + b_o) \\ g_t &= tanh(W_{xg}x_t + W_{hg}h_{t-1} + b_g) \\ c_t &= f_t * c_{t-1} + i_t * g_t \\ h_t &= o_t * tanh(c_t) \end{aligned} \tag{1}$$

where i_t, f_t and o_t are input gates, forget gates, and output gates. The symbol $*$ represents the element-wise multiplication. W_{xi}, W_{hi}, W_{xf}, W_{hf}, W_{xo}, W_{ho}, W_{xg}, W_{hg} and b_i, b_f, b_o, b_g are the parameters

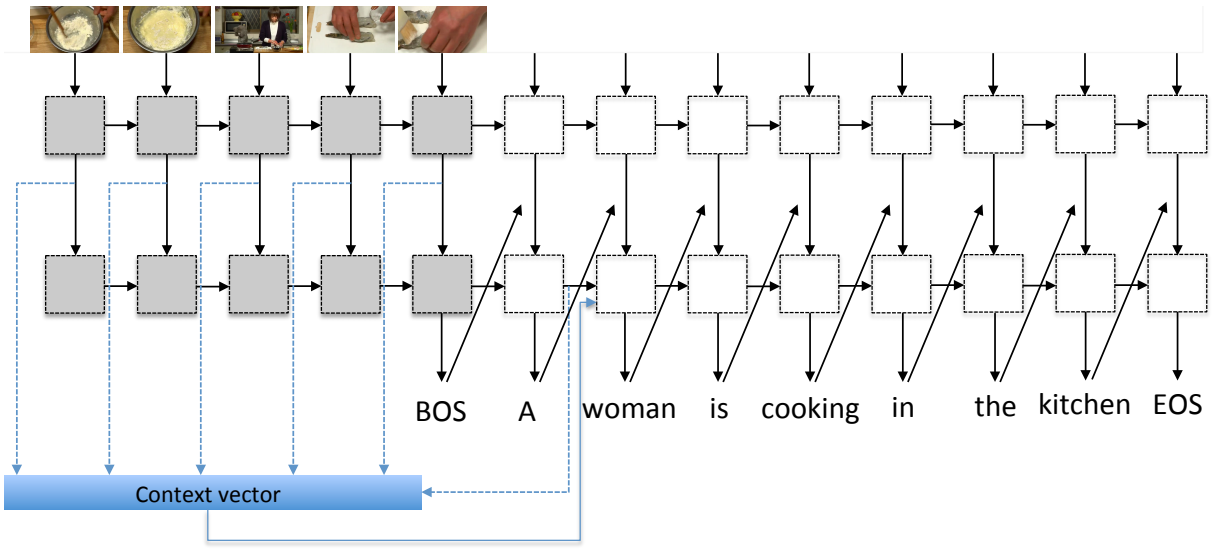

Figure 1: System architecture of the sequence-to-sequence model with temporal attention. In the figure, we omit the image embedding layer, the word embedding layer, and the softmax layer, due to the space constraint.

to be learned during training. h_t is the hidden state at time step t which will be an input to the next time step's LSTM unit.

3.2 Two-layer LSTM for Sequence-to-sequence Model

Figure 1 depicts our two-layer LSTM model for generating sentences from a video, which is based on the sequence-to-sequence model proposed by Venugopalan et al. (2015a). Given a video as a sequence of frames $V = \{v_1, v_2, ..., v_n\}$, where the video V has n frames and v_i is the i^{th} frame of the video, we can formulate our system as

$$h_t^{(1)} = LSTM^{(1)}(x_t, h_{t-1}^{(1)}) \tag{2}$$

where $h_t^{(1)}$ is the hidden state of the first (upper) LSTM layer, defined as $LSTM^{(1)}$, at time step t. In the encoding stage, the input $x_t = v_t$ and, in the decoding stage, $x_t = \vec{0}$.

The input to the second (lower) LSTM layer is the concatenation of the word (represented as word embedding) generated on the previous time step $t-1$ and the hidden state of the first LSTM layer.

$$h_t^{(2)} = LSTM^{(2)}([w_{t-1}; h_t^{(1)}], h_{t-1}^{(2)}) \tag{3}$$

where $h_t^{(2)}$ is the hidden state of the second LSTM layer, defined as $LSTM^{(2)}$, at time step t. In the encoding stage, we fix the word $w_{t-1} = \vec{0}$, since there is no word being generated. Lastly, the distribution over all the words at time step t can be computed by

$$p(w_t|w_1, ..., w_{t-1}, V) = softmax(W_s h_t^{(2)} + b_s) \tag{4}$$

3.3 Temporal Attention Mechanism

Our approach incorporates the previously-proposed sequence-to-sequence model with a temporal attention mechanism. The second-layer LSTM at decoding stage can be formulated as

$$h_t^{(2)} = LSTM^{(2)}([w_{t-1}; h_t^{(1)}], h_{t-1}^{(2)}, c_t) \tag{5}$$

where the context vector c_t, at the time step t in the decoding stage, is the weighted sum of encoder's hidden states $h_i^{(1)}$.

$$c_t = \sum_{i=1}^{n} \alpha_i^{(t)} h_i^{(1)} \tag{6}$$

	videos	sentences	tokens	vocab size	avg. length	captions/video	source
MSVD	1,970	80,827	567,874	12,594	10.2s	≈40	crowd
M-VAD	46,589	55,904	502,926	17,609	6.2s	1	professional

Table 1: Video description dataset statistics. Refer to Venugopalan et al. (2015a) and Torabi et al. (2015) for more details.

The weight $\alpha_i^{(t)}$ is computed at every time step t and can be computed by

$$\alpha_i^{(t)} = \frac{e^{a(h_i^{(1)}, h_{t-1}^{(2)})}}{\sum_{j=1}^{n} e^{a(h_j^{(1)}, h_{t-1}^{(2)})}} \tag{7}$$

where $a(h_i^{(1)}, h_{t-1}^{(2)})$ is the alignment function used to calculate relevance scores between every hidden state $h_i^{(1)}$ in the encoding stage the hidden state $h_{t-1}^{(2)}$ at the previous time step $t-1$.

3.4 Alignment model

To see which alignment functions are suitable for the model, we have used four different alignment functions in this work. Three of them were used in Luong et al. (2015), and we also use summation of hidden states as an alignment function.

$$a(h_i^{(1)}, h_{t-1}^{(2)}) = \begin{cases} {h_i^{(1)}}^\top h_{t-1}^{(2)} & \text{dot} \\ {h_i^{(1)}}^\top W_a h_{t-1}^{(2)} & \text{bilinear} \\ W_a[h_i^{(1)}; h_{t-1}^{(2)}] & \text{concat} \\ W_a h_i^{(1)} + W_b h_{t-1}^{(2)} & \text{sum} \end{cases} \tag{8}$$

The parameters W_a and W_b of the alignment model are jointly learned at training time with all other parameters in the network.

4 Dataset and Experiment Setting

This section describes the video description datasets, the pre-processing steps, the experiment setting, and the evaluation metrics that we used.

4.1 Dataset and pre-processing

In this paper, we trained the models and generated descriptions for two publicly-available video datasets as follows. The summary of the datasets is shown in Table 1.

Microsoft Research Video Description Corpus (MSVD) collected by Chen and Dolan (2011). It is a set of video clips aggregated from Youtube, containing 1,970 short clips with ≈40 captions/per clip. The videos were collected and annotated by crowdsourcing on Amazon Mechanical Turk. The clips mostly contain a single activity and can be described using only one sentence. For fair comparison with other previous work, we split the dataset into train/validation/test sets following Venugopalan et al. (2015b) and Yao et al. (2015). The size of the train, validation, and test sets is 1200, 100, and 670, respectively. We also use the pre-processed sentences and vocabularies from Venugopalan et al. (2015b). The pre-processing includes tokenizing, converting to lower case, and removing punctuations.

Montreal Video Annotation Dataset (M-VAD) M-VAD is a large collection of movie clips provided by Torabi et al. (2015). It was collected from 92 movies, and spitted into 46,589 short clips. Each clip is associated with a description, which can be more than one sentence. The dataset provides an official training/validation/test split, consisting of 36,921, 4,717 and 4,951 video clips respectively. We used all words in the training data as our vocabulary set and only pre-processed the data by tokenizing the sentences.

Table 2: Scores of video description generation results on the MSVD dataset. * marks the top scores of each column.

4.2 Experiment Setting

We down-sample all the video clips by selecting every 8^{th} frame from the original videos and resize them to 224x224. We extract features for each frame using the pre-trained image classification models provided publicly in *Caffe Model Zoo* (Jia et al., 2014). In this work, we performed the experiments using the features extracted from the 4096-dimensional fc7 layer of the 16-layer VGG model (VGG16), proposed by Simonyan and Zisserman (2014), and the 2048-dimensional output from Deep Residual Networks (ResNet), recently proposed by He et al. (2015), who is the winner in the ILSVRC 2015 classification task. We embed input frame features into 512-dimensional embeddings.

For text input, after pre-processing, the word tokens are represented by one-hot vectors. We use the word BOS to mark the beginning of a sentence and EOS to represent the end of the sentence. We also embed the word vectors into 512-dimensional embeddings. The parameters for both image and word embedding layers are jointly learned with other parameters at training time.

We fix the number of encoding and decoding time steps in order to enable batch training. For the MSVD dataset, we constrain the number of encoding and decoding time steps to be 60 and 20, respectively. The M-VAD corpus has longer sentence length, so we set the number time steps to 50 and 30 for encoding and decoding, respectively, to allow the language model to generate longer sentences.

In every experiment, the LSTM hidden layer size is set to 1,000. We use the Adam optimizer (Kingma and Ba, 2014) with the learning rate of 0.0001 and the mini-batch size of 40. We also apply the dropout strategy (Srivastava et al., 2014) with the ratio of 0.3 at the video input layer to avoid overfitting. We implemented our system using *Chainer*, which is a powerful framework for developing neural networks developed by Tokui et al. (2015).

5 Experimental Results and Discussion

This section shows the experimental results in both qualitative and quantitative aspects. We performed a quantitative analysis of results based on four evaluation metrics, including

Our system (VGG16) - *sum*	0.007	0.070	0.074	0.155

Table 3: Scores of video description generation results on the M-VAD dataset. * marks the top scores of each column.

- **BLEU** (Papineni et al., 2002), an evaluation metric widely used in machine translation. BLEU calculates a score based on modified n-gram precision of the generated sentence against a set of human-annotated reference sentences.

- **METEOR** (Denkowski and Lavie, 2014), an automatic metric for machine translation evaluation. It is based on explicit word-to-word matching between the generated sentence and one or more reference sentences. METEOR supports matching between words with simple morphological variants and synonyms.

- **CIDEr** (Vedantam et al., 2014), an automatic consensus metric of image description quality. Consensus-based Image Description Evaluation (CIDEr) measures the similarity of a computer-generated sentence against a set of human-annotated sentences. It gives a higher score to the sentence that is more similar to the majority of human written descriptions.

- **ROUGE-L** (Lin, 2004), a recall-oriented evaluation metric popularly used in summarization community. It measures the number of in-sequence unigram matches between the generated sentence and sentences created by annotators.

We use the caption evaluation package provided by the Microsoft COCO Image Captioning Challenge (Chen et al., 2015).

We compare our results to the results reported by the mean-pooling and sequence-to-sequence approaches reported in (Venugopalan et al., 2015a), and results from the CNN-RNN encoder-decoder model with a temporal attention mechanism reported in (Yao et al., 2015). However, the comparison to (Yao et al., 2015) is probably not a fair comparison, since we used different CNNs for feature extraction, e.g. they used GoogleNet and 3D-CNN but we used VGG16 and ResNet.

5.1 Results on the MSVD dataset

The results on the MSVD dataset are presented in Table 2 and the sample sentences are shown in Figure 2. The attention model plays an important role for both VGG16 and ResNet experiments. We can achieve the BLEU scores of 0.411 with VGG16 features and 0.437 with ResNet features. Our METEOR scores reached 0.310 when using VGG16 and 0.326 when using ResNet. However, in the experiment using VGG16 features, the *bilinear* alignment function seems to work best, while the *dot* alignment function gives the highest performance for the ResNet feature set.

As we can clearly see from the table, ResNet features are very powerful and can achieve the highest scores in all evaluation metrics.

(ground truth)
(1) the man is pouring sauce over the pasta
(2) a man is putting food from pan to a plate
(3) a man is adding sauce to his spaghetti

Figure 2: Generated descriptions from MSVD dataset.

5.2 Results on the M-VAD dataset

The results on the M-VAD dataset are presented in Table 3. For this dataset, we did not perform the experiments using all the model configurations and feature types, due to the time constraints.

Even though the previous experiment on MSVD dataset showed that the result with ResNet were better than those with VGG16, we decided to use image features extracted from VGG16 to make a fair comparison with the previous work. From the table, our non-attention model can outperform the previous work in all evaluation metrics, but the attention model does not work well in this dataset. The reason probably comes from the characteristic of the M-VAD dataset that the videos contain a very high diversity of scenes and descriptions, so our attention models cannot be learned properly.

Some samples of generated sentences are shown in Figure 3.

6 Conclusion

In this paper, we have proposed a framework to automatically generate descriptions for video clips. We have applied the temporal attention mechanism to the sequence-to-sequence LSTM model. The results have proved that our model can generate high-quality short descriptions for videos, and can outperform the previous work. With the temporal attention mechanism, the model can learn to selectively focus on different parts of a video while generating each describing word.

For future work, we would like to use audio features or include a text-to-speech system in our framework since we think that audio is a very important piece of information for video understanding.

Acknowledgements

This paper is based on results obtained from a project commissioned by the New Energy and Industrial Technology Development Organization (NEDO). We also would like to thank the anonymous reviewers for their insightful comments and suggestions, which were helpful in improving the quality of the paper.

An Improved Phrase-based Approach to Annotating and Summarizing Student Course Responses

Abstract

Teaching large classes remains a great challenge, primarily because it is difficult to attend to all the student needs in a timely manner. Automatic text summarization systems can be leveraged to summarize the student feedback, submitted immediately after each lecture, but it is left to be discovered what makes a good summary for student responses. In this work we explore a new methodology that effectively extracts summary phrases from the student responses. Each phrase is tagged with the number of students who raise the issue. The phrases are evaluated along two dimensions: with respect to text content, they should be informative and well-formed, measured by the ROUGE metric; additionally, they shall attend to the most pressing student needs, measured by a newly proposed metric. This work is enabled by a phrase-based annotation and highlighting scheme, which is new to the summarization task. The phrase-based framework allows us to summarize the student responses into a set of bullet points and present to the instructor promptly.

1 Introduction

Effective teachers use student feedback to adjust their teaching strategies. Nowadays, in large classes, there is far too much feedback for a single teacher to manage and attend to. If different perspectives in the student feedback could be summarized and pressing issues identified, it would greatly enhance the teachers' ability to make informed choices. In this work we seek to automatically summarize the student course feedback into a set of bullet points. Each bullet point corresponds to a phrase, tagged with the number of students who raise the issue. Our emphasis is on the textual feedback submitted by students after each lecture in response to two reflective prompts (Boud et al., 2013): 1) "Describe what you found most interesting in today's class" and 2) "Describe what was confusing or needed more detail." Education researchers have demonstrated that asking students to respond to reflection prompts can improve both teaching and learning (Van den Boom et al., 2004; Menekse et al., 2011). However, summarizing these responses for large classes (e.g., introductory STEM, MOOCs) remains costly, time-consuming, and an onerous task for humans (Mosteller, 1989).

In our prior work, **L**uo and **L**itman (2015) (henceforth **L&L**) introduced the task of automatic summarization of student responses. The challenges of this task include 1) high lexical variety, because students tend to use different word expressions to communicate the same or similar meanings (e.g., "bike elements" vs. "bicycle parts"), and 2) high length variety, as the student responses range from a single word to multiple sentences. To tackle the challenges, L&L proposed a *phrase summarization framework* consisting of three stages: phrase extraction, phrase clustering, and phrase ranking. The approach extracts noun phrases from student responses, groups the phrases using a greedy clustering algorithm, and finally selects representative phrases from the clusters using LexRank (Erkan and Radev, 2004).

There are three limitations in the phrase summarization framework. First, noun phrases do not suffice. Other types of phrases such as "how confidence intervals linked with previous topics" are useful and should be allowed. Second, clustering is based on similarity, but similarity of phrases that do not appear in a background corpus (i.e., the corpus used to learn the similarities) cannot be captured in the previous

- sampling distributions [6]
- nothing [6]

Table 1: Example prompt, student responses, and two human summaries. 'S1'–'S10' are student IDs. The summary phrases are each tagged with the number of students who raise the issue (i.e., student supporters). The summary and phrase highlights are manually created by annotators. Phrases that bear the same color belong to the same issue. Each annotator is free to choose his/her color palette. We have only demonstrated the highlights of **Human Summary 1** to avoid overlaying of two sets of colors on student responses. The superscripts of the phrase highlights are imposed by the authors of this paper to differentiate colors when printed in grayscale (y: yellow, g: green, r: red, b: blue, and m: magenta).

setting. Lastly, a greedy clustering algorithm K-medoids (Kaufman and Rousseeuw, 1987) was previously used to group candidate phrases. It ignores global information and may suffer from a "collapsing" effect, which leads to the generation of a large cluster with unrelated items (Basu et al., 2013).

The goal of this work is to explore a phrase-based highlighting scheme, which is new to the summarization task. We aim to improve the phrase summarization framework by exploiting new capabilities that are enabled by the highlighting scheme. In the new scheme, human annotators are instructed to 1) create summary phrases from the student responses, 2) associate a number with each summary phrase which indicates the number of students who raise the issue (henceforth **student supporters**), and 3) highlight the corresponding phrases in both the human summary and student responses. Table 1 illustrates the highlighting scheme and more details are presented in §3. The new highlighting scheme makes it possible to develop a supervised candidate phrase extraction model (§4.1) and estimate pairwise phrase similarity with supervision (§4.2). To solve the third limitation, we explore a community detection algorithm OSLOM (Lancichinetti et al., 2011) that optimizes the statistical significance of clusters with respect to a global null model (§4.3). Experimental results show that the newly developed phrase extraction model is better than noun phrases only, in terms of both intrinsic and extrinsic measures; phrase similarity learning appears to produce marginal improvement; and the community detection approach yields better phrase summaries with more accurate estimation of the number of student supporters.

In summary, the contribution of this work is threefold.

- We introduce a new phrase-based highlighting scheme for automatic summarization, a departure from prior work. It highlights the phrases in the human summary and also the semantically similar phrases in student responses. We create a new dataset annotated with this highlighting scheme[1].
- We push the boundary of a phrase-based summarization framework by using our highlighting scheme to enable identification of candidate phrases as well as estimation of phrase similarities with supervision, and by using community detection to group phrases into clusters.
- We conduct comprehensive evaluations in terms of both summary text quality, measured by ROUGE (Lin, 2004), and how well phrase summaries capture the most pressing student needs, measured by a new evaluation metric based on color matching.

2 Related Work

Work on automatic text summarization involves multiple granularities, ranging from keywords, phrases, to sentences. Traditional approaches have largely focused on sentence extraction (Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011; Li et al., 2013) and document abstraction (Liu et al., 2015; Rush et al., 2015; Durrett et al., 2016; Nallapati et al., 2016). In both cases, the produced summary is expected to be cohesive and coherent. We deviate from this path and seek to directly generate a set of bullet points as a summary. Phrases are easy to search and browse like words but more meaningful, and fit better on the small screen of a mobile device compared to sentences (Ueda et al., 2000; Luo et al., 2015).

Our task setting differs from those of keyphrase extraction (Wu et al., 2005; Liu et al., 2009; Medelyan et al., 2009; Hasan and Ng, 2014; Kan, 2015). Of key importance is that each summary phrase is associated with a numerical value, indicating the number of students who raise the issue. This information is critical to course instructors for making informed choices. Intuitively our task setting bears similarity to word/phrase cloud (Yatani et al., 2011; Brooks et al., 2014), where the cloud gives greater prominence to words or phrases that appear frequently in the source text. The downside is that they do not take lexical variety into account or considering semantically-equivalent words/phrases.

A summarization system is expected to produce high quality summary phrases and accurate estimates of the number of student supporters for each phrase. Luo and Litman (2015) focus on extracting noun phrases from student responses, however there lacks a comprehensive evaluation of the results, taking the number of student supporters into account. Other related work on student responses includes collecting student responses using a mobile application named CourseMIRROR (Luo et al., 2015; Fan et al., 2015), determining the quality of a student reflective response and providing feedback (Luo and Litman, 2016), and extracting informative sentences from the student feedback (Luo et al., 2016).

Traditional approaches to summary annotation have been based on either sentence extracts or document abstracts (Loza et al., 2014; Xiong and Litman, 2014; Wang and Ling, 2016). An effective linkage between the document content and human summary on the micro level have been largely absent. Barker et al.(2016) partially address this challenge by linking a summary back to a group of sentences that support the summary. However, this linkage is weak since it tells only that there is one sentence or more supporting the summary within the group, without explicitly telling which one(s). Approaches such as Pyramid (Nenkova and Passonneau, 2004) have exploited creating Summary Content Units (SCUs) to establish such links and alleviate the challenge. The new highlighting scheme described in this work holds promise for establishing direct links between the phrases in student responses and those in the human summary, allowing us to develop a new evaluation metric based on color matching.

3 New Data and Annotation

When reviewing the student feedback, we observe that not all issues are equally important. Some teaching problems are more prominent than others. Summary phrases should naturally reflect the number of students who raise the issue. But until now a reasonable sized dataset has been missing for this type of summarization setting. In this work we create a new dataset for this purpose. This allows us to develop a class of summarization approaches that learn to extract summary phrases from the student responses and estimate the number of student supporters for each summary phrase.

Our dataset consists of two statistics courses offered in a research university for industrial engineers. After each lecture, the students were asked to respond to two carefully designed reflection prompts using a mobile application named CourseMIRROR[2]: 1) "Describe what you found most interesting in today's class," and 2) "Describe what was confusing or needed more detail." For each course, two independent human annotators (native English speakers) with a statistics/mathematics background were recruited to create summaries for each lecture and prompt. The instructions we provide to the annotators include "*create a summary using 5 phrases and mark how many students semantically mentioned each phrase*." We limit the number of summary phrases to 5 per lecture and prompt in order to provide a concise summary to the instructor. Note that the summary phrases are not limited to extracts; while abstracts

[2] https://play.google.com/store/apps/details?id=edu.pitt.cs.mips.coursemirror

and fusion of phrases are also possible, they are rare. We further ask the annotators to "*highlight the corresponding phrases in the student responses which are semantically the same to the summary phrases using the same highlight colors*." The number of highlights in student responses should match the number of students who semantically mentioned the phrase. An example is illustrated in Table 1.

Note that L&L attempt to annotate the number of student supporters for summary phrases on a small dataset but without the highlighting scheme. We argue that the new highlighting scheme can provide many unique benefits. First, it allows us to track the "source phrases" that humans use to create the summary phrase. For example, the first summary phrase in Human Summary 1 of Table 1 is "central limit theorem." It is created from a collection of phrases in the student responses, including "The central limit", "central limit teorem" (a typo by the student), "CLT" (its abbreviation), and "Central Limit Thm" (another abbreviation). Naturally the highlighted source phrases lend themselves to a supervised approach to candidate phrase extraction. Second, the highlights inform us about the similarity and dissimilarity of phrases. For example, the source phrases that bear the same color are semantically similar to each other, whereas those with different colors are semantically dissimilar. In a similar vein, we develop a supervised approach that learns to predict the phrase similarity using highlights as guidance. Third, we are now able to accurately match the phrases in a system summary to those in a human summary, allowing the development of a novel summarization evaluation metric. For instance, assuming the system summary contains the phrase "Last problem about normalization" from S2 (Table 1), using the color highlights, we know that this phrase matches the human summary phrase "normalization (last example)." Such semantic matching between system and human summaries remains an elusive challenge for traditional summarization evaluation, but highlights make it an easy decision. Finally, the highlights on source texts indicate to what extent the information has been retained in the human summary. Specific to our task, we are interested to know the percentage of students whose responses are covered by the human summary. We define a student coverage score where a student is covered if and only if part of his/her response is highlighted. For example, in Table 1, S9 is considered not covered by Human Summary 1.

Basic statistics of the dataset are presented in Table 2.[3] The student coverage scores (75.9% for Course A and 82.4% for Course B) highlight the effectiveness of the current annotation scheme, with a majority of students covered by the human summaries.

Course	# Students	# Lectures	Averaged by Lecture/Prompt				
			# Responses	# Words	Words Per Res.	# Highlights	Student Coverage
A	66	11	34.1	156.5	4.5	27.8	75.9%
B	74	24	41.9	161.8	3.7	37.2	82.4%

Table 2: Basic statistics of the dataset. Because the student responses and human summaries are created for each lecture and prompt, we take the average of the corresponding statistics.

4 Improved Phrase Summarization

So far we have motivated the need for a new dataset with a highlighting scheme for phrase-based summarization. We proceed by describing three improvements to the phrase-based summmarization framework. Our first improvement involves a supervised approach to candidate phrase extraction (§4.1). Next, we learn to predict the pairwise phrase similarity (§4.2). Further, we explore a community detection algorithm to group the phrases into clusters (§4.3). We use the cluster size as an approximation to the number of student supporters for all the phrases within the cluster. L&L adopt LexRank (Erkan and Radev, 2004) to finally choose one representative phrase from each cluster. We follow the convention in this study. Note that our focus of this paper is not on developing new algorithms but to explore new capabilities that are enabled by the highlighting scheme. We thus perform direct comparisons with approaches described in L&L and leave comparisons to other approaches to future work. We present an intrinsic evaluation of each improvement in this section, followed by a comprehensive extrinsic evaluation in §5.

[3]While there are 22 lectures in total for Course A, unfortunately, only 11 of them have phrase highlighting.

4.1 Candidate Phrase Extraction

The phrase-based highlighting scheme lends itself to a supervised phrase extraction approach. In contrast, L&L used heuristics to extract noun phrases (NPs) only. This limitation has meant that informative non-NP phrases such as "how confidence intervals linked with previous topics" will be excluded from the summary, whereas uninformative NP phrases such as "the most interesting point" may be included.

We attempt to resolve this issue by formulating candidate phrase extraction as a word-level sequence labeling task. Concretely, we aim to assign a label to each word in the student responses. We choose to use the 'BIO' labeling scheme, where 'B' stands for the beginning of a phrase, 'I' for continuation of a phrase, 'O' for outside of a phrase. For example, "The (B) central (I) limit (I) and (O) normal (B) approximations (I)" illustrates the tagging of individual words, where the "The central limit" and "normal approximations" are two phrases highlighted by our annotators.

Local Features	• Word trigram within a 5-word window • Part-of-Speech tag trigram within a 5-word window • Chunk tag trigram within a 5-word window • Whether the word is in the prompt • Whether the word is a stopword • Label bigrams.
Global Features	• Total number of word occurrences (stemmed) • Rank of the word's term frequency

Table 3: Local and global features for supervised phrase extraction. Local features are extracted within one student's response. Global features are extracted using all student responses to a prompt in one lecture.

We choose to use the Conditional Random Fields (CRF) (Lafferty et al., 2001) as our sequence labeler[4] and develop a number of features (Table 3) based on sentence syntactic structure and word importance to signal the likelihood of a word being included in the candidate phrase. During training, we merge the phrase highlights produced by two annotators in order to form a large pool of training instances. When two highlights overlap completely, e.g., "normal approximations" are marked by both annotators using different colors, we keep only one instance of the phrase, resulting in 1,115 and 2,682 instances for Course A and Course B respectively. When the highlights partially overlap, we use each phrase highlight as a separate training instance. In this and all the following experiments, we perform leave-one-lecture-out cross validation on all the lectures and report results averaged across folds. Table 4 presents the intrinsic evaluation results on the phrase extraction task. We calculate Precision (P), Recall (R) and F-measure (F) scores based on the exact match of system phrases to gold-standard phrases. While the sequence labeling approach and the features presented here are straightforward, they do produce a collection of candidate phrases with higher precision. It removes noun phrases that are commonly used by students but uninformative (e.g., "a little bit abstract", "a problem with today's topic") as they were not highlighted by annotators. Phrase well-formedness is highly important to the summary quality, as evaluated in §5.

	Course A			Course B		
Candidate Phrase Extraction	P	R	F	P	R	F
L&L (NPs only)	0.426	**0.633**	0.503	0.538	0.714	0.609
Sequence Labeling with Highlights	**0.692***	0.569*	**0.618***	**0.771***	**0.743**	**0.753***

Table 4: Results of phrase extraction, intrinsically evaluated by comparing the system phrases to gold-standard phrases using exact match. The highest score in each column is shown in bold. $*$ means the difference is significant with $p < 0.05$.

4.2 Similarity Learning

Accurately estimating pairwise phrase similarity plays an essential role in phrase-based summarization. Better similarity learning helps produce better phrase clusters, which in turn leads to more accurate estimation of the number of student supporters for each summary phrase. While a human annotator

[4]We use the implementation of Wapiti (Lavergne et al., 2010) with default parameters.

could distinguish the semantic similarity or dissimilarity of the phrase highlights, it remains unclear if a single similarity metric could fulfill this goal or if we may need an ensemble of different metrics.

L&L calculate the pairwise phrase similarity using SEMILAR (Rus et al., 2013) with the latent semantic analysis (LSA) trained on the Touchstone corpus (Ştefănescu et al., 2014). One drawback of this approach is that the similarity of phrases that do not appear in a background corpus cannot be captured. In this work we develop an ensemble of similarity metrics by feeding them into a supervised classification framework. We use the phrase highlights as supervision, where phrases of the same color are positive examples and those of different colors are negative examples. We experiment with a range of metrics for measuring lexical similarity, including lexical overlap (Rus et al., 2013), cosine similarity, LIN similarity (Miller, 1995), BLEU (Papineni et al., 2002), SimSum (Lin, 2004), Word Embedding (Goldberg and Levy, 2014), and LSA (Deerwester et al., 1990). LIN similarity is based on WordNet definitions. Lexical overlap, cosine similarity, BLEU, and SimSum are related to how many words the two phrases have in common, while Word Embedding and LSA both capture the phrase similarity in a low dimensional semantic space. Therefore, we use an ensemble of the above similarity metrics by feeding them as features in a SVM classification model, assuming it will be better suited for this task than the LSA alone. Table 5 presents the intrinsic evaluation results. LSA has a poor degree of coverage (low recall) with many phrase similarities not being picked up by the metric.

	Course A			Course B		
Pairwise Phrase Similarity	P	R	F	P	R	F
L&L (LSA)	**0.904**	0.665	0.730	0.878	0.506	0.584
Similarity Learning with Highlights	0.895	**0.801***	**0.833***	**0.943***	**0.768***	**0.836***

Table 5: Results of predicting pairwise phrase similarity, measured using classification P/R/F.

4.3 Phrase Clustering

L&L use K-medoids for phrase clustering. It is a greedy iterative clustering algorithm (Kaufman and Rousseeuw, 1987), which may suffer from local minimal. We instead treat phrase clustering as a community detection problem. We define a **community** as a set of phrases that are semantically similar to each other, as compared to the rest of the phrases in student responses (Malliaros and Vazirgiannis, 2013). In our formulation, we consider each candidate phrase as a node in the network graph. We create an edge between two nodes if the two phrases are considered semantically similar to each other using the above similarity learning approach. Our goal is to identify tightly connected phrase communities in the network structure. The community size is used as a proxy for the number of students who semantically mention the phrase. Community detection has seen considerable success in tasks such as word sense disambiguation (Jurgens, 2011), medical query analysis (Campbell et al., 2014), and automatic summarization (Qazvinian and Radev, 2011; Mehdad et al., 2013).

Phrase Clustering	Course A	Course B
L&L (K-medoids)	82.2%	84.0%
Community Detection with OSLOM	**85.2%***	**88.8%***

Table 6: Results of phrase clustering measured by purity: ratio of number of phrases agreeing with the majority color in clusters.

We use OSLOM (Order Statistics Local Optimization Method, Lancichinetti et al., 2011) in this work. It is a widely used community detection algorithm that detects community structures (i.e., clusters of vertices) from a weighted, directed network. It optimizes locally the statistical significance of clusters with respect to a global null model during community expansion. We use an undirected version of OSLOM and set the p-value as 1.0 to encourage more communities to be identified[5] since the number of vertices in the constructed graph is relatively small compared to large complex networks. The key feature of OSLOM is that it supports finding overlapped community structures and orphaned vertices, offering more flexibility in the clustering process than K-medoids. We want to investigate if the unique characteristics of OSLOM allow it to produce better phrase clusters, hence more accurate estimation of

[5]L&L set the number of clusters is to be the square root of the number of extracted phrases.

the number of student supporters. We conduct an intrinsic evaluation using purity, corresponding to the percentage of phrases in the cluster that agree with the majority color. Results are presented in Table 6. While this metric by itself is not thorough enough, it does highlight the strength of the community detection approach in generating cohesive clusters. One advantage of OSLOM we found is that it will treat a phrase different from any other phrase as a singleton, while this phrase must be assigned to one of the clusters in K-medoids, resulting in a noisy cluster.

5 Summary Evaluation

The previous section described three improvements to the phrase summarization framework. Next, we evaluate them on the end task of summarizing student course responses. The phrase summaries are evaluated along two dimensions: we expect ROUGE (Lin, 2004) to measure the informativeness of the summary text content (§5.1); we further propose a new metric to quantify to what extent the most pressing student needs have been captured in the summary (§5.2).

5.1 ROUGE

ROUGE measures the n-gram overlap between system and human summaries. In this work, we report R-1, R-2, and R-SU4 scores, which respectively measure the overlap of unigrams, bigrams, and unigrams plus skip bigrams with a maximum distance of 4 words. These are metrics commonly used in the DUC and TAC competitions (Dang and Owczarzak, 2008). We implement the phrase summarization framework described in (Luo and Litman, 2015), named as **PhraseSum**. Further, we include **LexRank** (Erkan and Radev, 2004) as a competitive baseline. LexRank is a graph-based summarization approach based on eigenvector centrality. It has demonstrated highly competitive performance against the **PhraseSum** on a prior dataset (Luo and Litman, 2015). The summary is limited to 5 phrases or less in all experiments. Note that, the summary length is set independently of the number of clusters. If the number of clusters produced in §4.3 is less than 5, the phrase number is equal to the cluster number.

Course	System	R-1			R-2			R-SU4		
		P	R	F	P	R	F	P	R	F
A	LexRank	.276*	**.511**	.348*	.118*	**.245**	.154	.077*	**.260**	.106*
	PhraseSum	.402	.466	.415	.170	.208	.178	.162	.222	.160
	SequenceSum	.600*	.448	.493*	.307*	.231	.249*	.368*	.225	.244*
	SimSum	.597*	.460	**.504***	.302*	.241	.260*	.355*	.227	.249*
	CDSum	**.634***	.435	.499*	**.335***	.229	**.262***	**.404***	.210	**.250***
B	LexRank	.357*	**.560**	.429*	.187*	**.304***	.227	.129*	**.290**	.168*
	PhraseSum	.492	.545	.508	.231	.258	.239	.234	.283	.241
	SequenceSum	.618*	.485*	.531	.347*	.267	.294*	.385*	.238*	.274
	SimSum	.618*	.500*	.543	.353*	.284	.309*	.379*	.250	.285*
	CDSum	**.702***†	.480*	**.550***	**.433***†	.279	**.324***	**.500***†	.240*	**.293***

Table 7: Summarization Performance. **SequenceSum** means replacing the syntax phrase extraction in the PhraseSum baseline with the supervised sequence labeling phrase extraction. **SimSum** means replacing not only the phrase extraction but also the similarity scores using the supervised models. **CDSum** means using all three proposed techniques including the community detection. * indicates that the difference is statistically significant compared to PhraseSum with $p < 0.05$. † means that the improvement over SequenceSum is statistically significant with $p < 0.05$.

The summarization performance is shown in Table 7 (the caption explains the system names). The PhraseSum baseline, compared to LexRank, gets better P and F scores for all three ROUGE metrics for both courses, and the improvement of P is significant. This is the same as the findings in (Luo and Litman, 2015), and verifies our implementation of their model. For our enhancements of PhraseSum, the proposed supervised phrase extraction (SequenceSum) significantly improves P and thus improves (mostly significantly) F as well. SimSum is slightly better than SequenceSum for R and F, however, it is not significant using a two-tailed paired t-test. It suggests that a supervised method is not necessarily better than an unsupervised model in terms of the end-task performance, and its improvement over the

PhraseSum baseline is mainly due to the supervised phrase extraction step. In fact, the predicted similarity scores using the similarity learning model and the LSA model are highly correlated to each other ($r = 0.852$, $p < 0.01$) although it has a better classification performance (Table 5). Although CDSum is not significantly different from SequenceSum for the Course A, it does improve P significantly for all three ROUGE metrics for Course B. One possible explanation is that the latter course has a larger number of student responses, and thus benefits more from the community detection as the graph is larger.

5.2 A New Metric based on Color Matching

Our goal is to create a comprehensive evaluation metric that takes into account the following two factors.

- **Phrase matching.** While ROUGE is a classic summarization evaluation metric, it trivially compares the system vs. human summaries based on surface text form. In contrast, the phrase highlights allow us to accurately match the phrases in the system summary to those in the human summary based on color matching. This is due to two facts: first, our methods are extractive-based and all candidate phrases are extracted from the student responses; second, in the new highlighting scheme, the annotators are asked to highlight both the human summary phrase and any phrases in the student responses that are semantically the same with the summary phrase using the same color. It thus becomes easy to track the colors of the extracted phrases and verify if they match any of those in the human summary.
- **Student supporters.** Each summary phrase is tagged with the number of students who raise the issue. For human summary, this number is created by human annotators. For system summary, we approximate this number using the size of the cluster, from which the summary phrase is extracted.

Our proposed new metric resembles precision, recall, and F-measure. We define the true positive (TP) as the number of *shared colors* between system and human summaries. Each color is weighted by the number of student supporters, taken as the smaller value between system and human estimates. The *precision* is defined as TP over the total number of colors in the *system* summary, each weighted by system estimates; while *recall* is defined as TP over the total number of colors in the *human* summary, each weighted by human estimates. For example, assuming the phrases in the human summary are colored and tagged with estimates on student support: yellow/12, green/9, red/6, blue/5, magenta/3; similarly the phrases in the system summary are colored and tagged: yellow/11+3, green/17, red/7, blue/7. There are two phrases in the system summary that bear the same color, we thus add up the system estimates into yellow/11+3 (see Human Summary 1 in Table 1 and SequenceSum in Table 9). There are 4 shared colors between system and human summaries. The true positive is calculated as: $12+9+6+5 = 32$. The precision is $32/((11+3)+17+7+7) = 0.711$, and recall is $32/(12+9+6+5+3) = 0.914$. The F-measure is calculated as the harmonic mean of precision and recall scores.

The performance is shown in Table 8. Similar to the ROUGE evaluation, SequenceSum improves the P and F significantly. Now, CDSum not only significantly improves P, but also F for Course B.

	Course A			Course B		
	P	R	F	P	R	F
PhraseSum	.349	.615	.437	.485	.747	.576
SequenceSum	.626*	**.642**	**.614***	.698*	.757	.717*
SimSum	.602*	.636	.595*	.711*	.753	.723*
CDSum	**.643***	.634	.613*	**.777***†	**.762**	**.759***†

Table 8: Evaluation based on the new metric of color matching. P, R, and F are averaged by the annotators.

5.3 Example Summaries

The automatic summaries generated by different systems for the same example in Table 1 are shown in Table 9. The PhraseSum baseline extracts unnecessary content, which could be eliminated by the supervised phrase extraction model. For example, including "the example after" before "central limit theorem" makes it too specific. The "collapse" effect with a large cluster with unrelated items (Basu et al., 2013) can also be illustrated (e.g., the quantitative numbers for the phrase "i" in PhraseSum and

"q-q plot" in "SequenceSum" are much larger than the gold standard). This is solved by the community detection algorithm where such bigger clusters will not be considered as a single community.

PhraseSum	**SequenceSum**	**CDSum**
- i [40]	- q-q plot ^{g} [17]	- central limit theorem ^{y} [11]
- the example after central limit theorem ^{y} [12]	- central limit theorem ^{y} [11]	- q-q plot ^{g} [10]
- q q plot ^{g} [9]	- normal approximation to binomial ^{b} [7]	- sampling distributions ^{r} [7]
- the fact that we can sample as many as we want [9]	- sampling distributions ^{r} [7]	- normal approximation to binomial ^{b} [5]
- last problem about normalization ^{m} [6]	- clt ^{y} [3]	- nothing [4]

Table 9: Example system summaries for the example in Table 1. Note, the highlights in these summaries are NOT annotated by human after they are generated. Instead, they are automatically extracted from the dataset (§5.2).

6 Conclusion and Future Work

In this work, we introduce a new phrase-based highlighting scheme for automatic summarization. It highlights the phrases in the human summary and also the corresponding phrases in student responses. Enabled by the highlighting scheme, we improved the phrase-based summarization framework proposed by Luo and Litman (2015) by developing a supervised candidate phrase extraction, learning to estimate the phrase similarities, and experimenting with different clustering algorithms to group phrases into clusters. We further introduced a new metric that offers a promising direction for making progress on developing automatic summarization evaluation metrics. Experimental results show that our proposed methods not only yield better summarization performance evaluated using ROUGE, but also produce summaries that capture the pressing student needs. Future work includes thorough comparison with other approaches and extending the current research to multiple courses and other summary lengths in order to test the generalizability. We also plan to supplement our ROUGE scores with human evaluations of system summaries.

Abstract

We present CATENA, a sieve-based system to perform temporal and causal relation extraction and classification from English texts, exploiting the interaction between the temporal and the causal model. We evaluate the performance of each sieve, showing that the rule-based, the machine-learned and the reasoning components all contribute to achieving state-of-the-art performance on TempEval-3 and TimeBank-Dense data. Although causal relations are much sparser than temporal ones, the architecture and the selected features are mostly suitable to serve both tasks. The effects of the interaction between the temporal and the causal components, although limited, yield promising results and confirm the tight connection between the temporal and the causal dimension of texts.

1 Introduction

When the Greek government missed its 1.6 billion euro payment to the IMF as its bailout expired on 30 June 2015, people started to look for information, such as *What is going on? Why did it happen and what will happen next?* A compact summary that represents the development of a story over time, highlighting not only the temporal connections between events but also cause-effect chains, would be very beneficial for providing information that the readers need. Besides, this kind of knowledge, derived from structured information about events and their temporal-causal relations, could be used in a number of applications, from tools for automated generation of timelines to question answering and decision support systems.

While temporal relation classification is a well-studied task with a number of systems participating in the TempEval campaigns (Verhagen et al., 2010; UzZaman et al., 2013; Llorens et al., 2015), less attention has been devoted by the NLP community to the detection of causal links between events. Although recent attempts have tried to settle an annotation standard for causality inspired by TimeML (Mirza et al., 2014), the interactions between the temporal and the causal dimension of texts have been scarcely explored, especially from an empirical point of view. In this work, we face this challenge by presenting CATENA (CAusal and TEmporal relation extraction from NAtural language texts),[1] a multi-sieve architecture for the extraction and classification of both relation types from English documents, which are pre-annotated with *temporal entities*, namely *events* and *time expressions*.

2 Related Work

Our proposed approach for relation extraction is inspired by recent works on hybrid approaches for temporal relation extraction (D'Souza and Ng, 2013; Chambers et al., 2014). D'Souza and Ng (2013) introduce 437 hand-coded rules along with supervised classification models using lexical relation, semantic and discourse features. CAEVO, a CAscading EVent Ordering architecture by Chambers et al. (2014), combines rule-based and data-driven classifiers in a *sieve-based architecture* for temporal ordering. The classifiers (sieves) are ordered by their individual precision, and transitive closure is applied after each sieve to ensure consistent temporal graph.

[1] The system is made available at https://github.com/paramitamirza/CATENA.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 64–75, Osaka, Japan, December 11-17 2016.

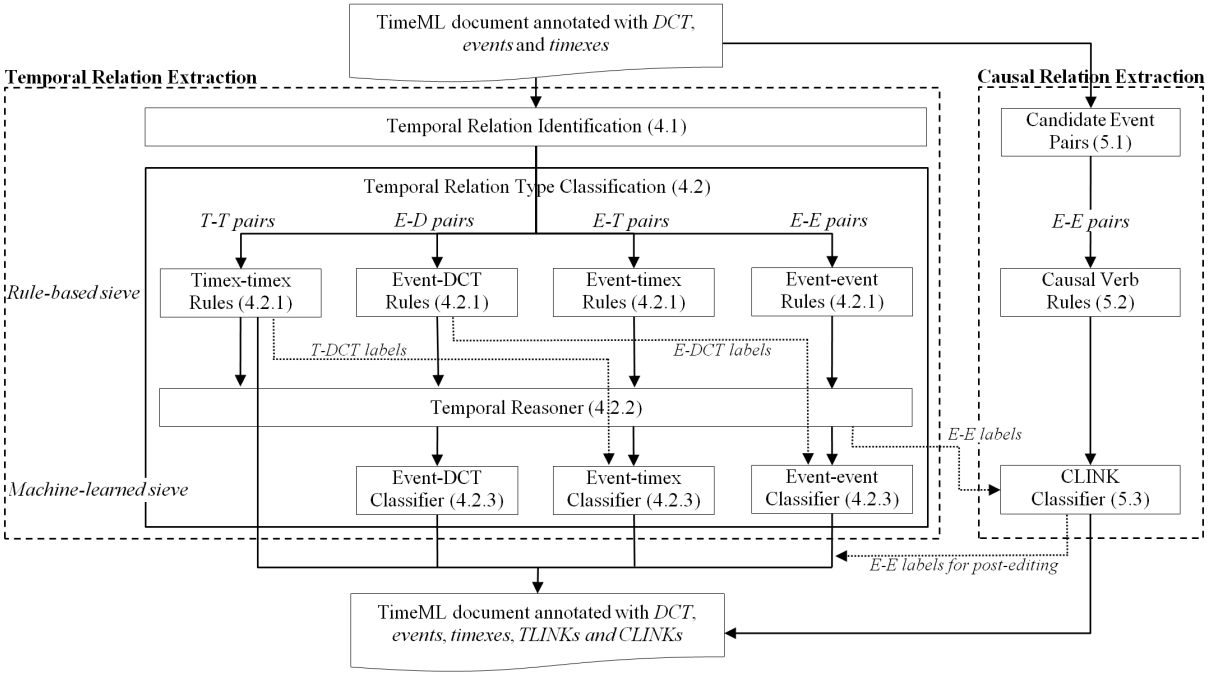

Figure 1: System architecture of CATENA

The problem of detecting causality between events is as challenging as recognizing their temporal order, but less analyzed from an NLP perspective. Besides, previous works have mostly focused on specific types of event pairs and causal expressions in text (Bethard et al., 2008; Do et al., 2011; Riaz and Girju, 2013). Several works, relying on corpus of parallel temporal and causal relations developed with specific connectives in mind (Bethard et al., 2008), have presented analyses on the interaction between temporal and causal relations (Bethard and Martin, 2008; Rink et al., 2010). Exploiting gold temporal labels as features for the causal relation classifier is shown to be beneficial. Mirza et al. (2014) presented some annotation guidelines to capture explicit causality between event pairs, inspired by TimeML. The resulting corpus, Causal-TimeBank, is then used to build supervised classification models for extracting causal relations (Mirza and Tonelli, 2014a). None of the above systems presents a hybrid approach in a sieve-based architecture to deal with this task. CATENA is at present the first integrated system available performing temporal and causal relation extraction.

3 System architecture

The CATENA system includes two main classification modules, one for temporal and the other for causal relations between events. As shown in Figure 1, they both take as input a document annotated with the so-called temporal entities according to TimeML guidelines (Pustejovsky et al., 2003), including the document creation time (DCT), events and time expressions (timexes). The output is the same document with temporal links (TLINKs) set between pairs of temporal entities, each assigned to one of the TimeML temporal relation types, such as BEFORE, INCLUDES or SIMULTANEOUS, which denotes the temporal ordering. The document is also annotated with causal relations (CLINKs) between event pairs.

The modules for temporal and causal relation classification rely both on a sieve-based architecture, in which the remaining unlabelled pairs – after running a rule-based component and/or a transitive reasoner – are fed into a supervised classifier. Although some steps can be run in parallel, the two modules interact, based on the assumption that the notion of causality is tightly connected with the temporal dimension and that information from one module can be used to improve or check the consistency of the other. In particular, (i) TLINK labels for event-event (E-E) pairs, resulting from the rule-based sieve + temporal reasoner modules, are used as features for the CLINK classifier; and (ii) CLINK labels (i.e. CLINK and CLINK-R) are used as a post-editing method for correcting the wrong labelled event pairs by the TLINK

classifier. This step relies on a set of rules based on the temporal constraint of causality, i.e. (i) CLINK(e_1, e_2) → BEFORE(e_1, e_2) and (ii) CLINK-R(e_1, e_2) → AFTER(e_1, e_2). The modules for temporal and causal relation extraction are detailed in Section 4 and 5 respectively.

4 Temporal Relation Extraction System

The module for the extraction of temporal relations contains two main components, one for (i) *temporal relation identification*, which is based on a set of rules, and the other for (ii) *temporal relation type classification*, which is a combination of rule-based and supervised classification modules, with a temporal reasoning component in between. The three steps for temporal relation type classification are ordered based on their individual precisions. This mechanism allows the system to first label few links with high precision using rules, then to infer new links through the reasoner, and finally to increase recall through supervised classification, based on the output of the previous steps.

4.1 Temporal Relation Identification

All pairs of temporal entities satisfying one of the following rules, inspired by the TempEval-3 task description, are considered as having temporal links (TLINKs): (i) two main events of consecutive sentences, (ii) two events in the same sentence, (iii) an event and a timex in the same sentence, (iv) an event and a document creation time and (v) pairs of all possible timexes (including document creation time) linked with each other.[2] These pairs are then grouped together into four different groups: *timex-timex* (T-T), *event-DCT* (E-D), *event-timex* (E-T) and *event-event* (E-E).

4.2 Temporal Relation Type Classification

Our *sieve-based architecture* is inspired by CAEVO (Chambers et al., 2014), although we significantly reduce the system complexity as follows:

- We merge all rule-based classifiers into one sieve component (rule-based sieve), and all Support Vector Machine (SVM) classifiers in the machine-learned sieve.
- Instead of running transitive inference after each classifier, we run our *temporal reasoner* module on the output of the rule-based sieve, only once.

Furthermore, we use the output of the rule-based sieve (Section 4.2.1) as features for the machine-learned sieve (Section 4.2.3), specifically: (i) the timex-DCT link label proposed by the *timex-timex rules* are used as a feature in the *event-timex SVM*, and (ii) the event-DCT link label proposed by the *event-DCT rules* are used as a feature in the *event-event SVM*.

4.2.1 Temporal Rule-Based Sieve

The temporal rule-based sieve relies on specific hand-crafted rules designed for each type of temporal entity pairs, and takes as input the entity pairs identified in the previous step.

Timex-timex Rules For timex-timex relations, we take into account temporal expressions of types DATE and TIME, and determine the relation types based on their *normalized values*. For example, *"7 PM tonight"* (2015-12-12T19:00) IS_INCLUDED in *"today"* (2015-12-12).

Event-DCT Rules The rules for labelling E-D pairs are based on the *tense* and/or *aspect* of the event word. For example, for the event mention *"(had) fallen"*, which is in the past tense with perfective aspect, its relation with the DCT is labelled as BEFORE.

Event-timex Rules As for E-T pairs, we build a set of rules based on the temporal senses of some prepositions (Litkowski and Hargraves, 2006; Litkowski, 2014).[3] In particular we assign a label whenever a temporal preposition establishes a dependency path between an event (E) and a timex (T), in which T acts as the *temporal modifier* of E. For example, if T is introduced by a temporal prepositions expressing a STARTTIME sense such as *from* or *since*, the relation is labelled as BEGUN_BY.

[2]Note that this is not included in the enumerated possible TLINKs in the TempEval-3 task description.

[3]We took the list of temporal prepositions from http://www.clres.com/db/classes/ClassTemporal.php.

In the absence of a temporal preposition, T might simply be a temporal modifier of E, as exemplified in *"Police [confirmed]* $_{\text{E}}$ *[Friday]* $_{\text{T}}$ *that the body was found..."*. In this case, we assume that the E-T label is IS_INCLUDED. Moreover, sometimes events are modified by temporal expressions marking the starting time and ending time in a *duration pattern* such as '*between* TBEGIN *and* TEND' or '*from* TBEGIN *to/until* TEND'. We define additional rules as follows: (i) If T matches TBEGIN then E-T label is BEGUN_BY, and (ii) if T matches TEND then E-T label is ENDED_BY.

Event-event Rules E-E pairs are finally labelled following two sets of rules. The first set is based on the dependency path possibly existing between the first (e_1) and the second event (e_2), and the verb information encoded in e_1. For example, if e_2 is the *logical subject* of e_1 as in *"...the chain reaction [touched]* $_{e_1}$ *off by the [collapse]* $_{e_2}$ *of Lehman Brothers"*, e_1 and e_2 are connected by an AFTER relation.

The other set of rules is taken from CAEVO, including: (i) rules for linking a reporting event and another event syntactically dominated by the first, based on *tense* and *aspect*; and (ii) rules based on the role played by various tenses of English verbs in conveying temporal discourse (Reichenbach, 1947).

Further details on the implemented rules for the temporal rule-based sieve can be found in Appendix A.

4.2.2 Temporal Reasoner

Based on the output of the previous sieve, we run a transitive reasoner layer, similar to CAEVO, in order to infer new temporal links among candidate pairs. This alleviates the issue of high precision and low recall, typical of the rule-based sieve.

An annotated TimeML document can be mapped into a constraint problem according to how TLINKs are mapped into Allen relations (Allen, 1983). We apply the following mapping:

- $<$ and $>$ for BEFORE and AFTER
- o and o^{-1} for DURING and DURING_INV
- d and d^{-1} for IS_INCLUDED and INCLUDES
- s and s^{-1} for BEGINS and BEGUN_BY
- f and f^{-1} for ENDS and ENDED_BY

Once the documents are mapped into constraint problems, they are then processed by an automated temporal reasoner for computing their deductive closure, globally reasoning on them. We rely on the *Generic Qualitative Reasoner* (GQR) (Westphal et al., 2010), a fast solver for generic qualitative constraint problems, such as Allen constraint problems. The rationale of preferring GQR to other solutions, such as fast *Boolean Satisfiability Problem* (SAT) solvers, is due to its scalability, simplicity of use and efficient performances (Westphal and Wölfl, 2009).

4.2.3 Temporal Supervised Classifiers

We build three supervised classification models, one for event-DCT (E-D), one for event-timex (E-T) and one for event-event (E-E) pairs. We use LIBLINEAR (Fan et al., 2008) L2-loss linear SVM (default parameters), and one-vs-rest strategy for multi-class classification.

Tools and Resources Several external tools and resources are used to extract features from each temporal entity pair, including:

- *MorphoPro* (Pianta et al., 2008), to get PoS tags and phrase chunk for each token.
- *Mate tools* (Bjorkelund et al., 2010) to extract the dependency path between words.
- *WordNet similarity module*[4] to compute semantic similarity (Lin, 1998) between words.
- *Temporal signal lists* from Mirza and Tonelli (2014b), further expanded using the Paraphrase Database (Ganitkevitch et al., 2013), and manually clustered e.g. {*before*, *prior to*, *in advance of*}.

Feature Set We implemented a set of features, listed in Table 1, largely inspired by the best performing systems in TempEval-2 (Verhagen et al., 2010) and TempEval-3 (UzZaman et al., 2013) campaigns. We simplified the possible values of some features as follows:

[4] `http://ws4jdemo.appspot.com/`

Feature	TLINK E-D	TLINK E-T	TLINK E-E	CLINK E-E	Rep.	Description
Morphosyntactic information						
PoS	x	x	x	x	one-hot	Part-of-speech tags of e_1 and e_2.
phraseChunk	x	x	x	x	one-hot	Shallow phrase chunk of e_1 and e_2.
samePoS		x	x	x	binary	Whether e_1 and e_2 have the same PoS.
Textual context						
entityOrder		x			binary	Appearance order of e_1 and e_2 in the text.[5]
sentenceDistance		x	x	x	binary	`0` if e_1 and e_2 are in the same sentence, `1` otherwise.
entityDistance		x	x	x	binary	`0` if e_1 and e_2 are adjacent, `1` otherwise.
EVENT attributes						
class	x	x	x	x	one-hot	EVENT attributes as specified in TimeML.
tense	x	x	x	x	one-hot	
aspect	x	x	x	x	one-hot	
polarity	x	x	x	x	one-hot	
sameClass			x	x	binary	Whether e_1 and e_2 have the same EVENT attributes.
sameTenseAspect			x	x	binary	
samePolarity			x	x	binary	
TIMEX3 attributes						
type	x	x			one-hot	TIMEX3 attributes as specified in TimeML.
Dependency information						
dependencyPath			x	x	one-hot	Dependency path between e_1 and e_2.
isMainVerb	x	x	x	x	binary	Whether e_1/e_2 is the main verb of the sentence.
Temporal signals						
tempSignalTokens		x	x	x	one-hot	Tokens (cluster) of temporal signal around e_1 and e_2.
tempSignalPosition		x	x	x	one-hot	Temporal signal position w.r.t e_1/e_2 (BETWEEN, BEFORE, BEGIN, etc.)
tempSignalDependency		x	x	x	one-hot	Temporal signal dependency path between signal tokens and e_1/e_2.
Causal signals						
causSignalTokens				x	one-hot	Tokens (cluster) of causal signal around e_1 and e_2.
causSignalPosition				x	one-hot	Causal signal position w.r.t e_1/e_2 (BETWEEN, BEFORE, BEGIN, etc.)
causSignalDependency			x	x	one-hot	Causal signal dependency path between signal tokens and e_1/e_2.
Lexical semantic information						
wnSim			x	x	one-hot	WordNet similarity computed between the lemmas of e_1 and e_2.
TLINK labels from the rule-based sieve						
timex-DCT label		x			one-hot	The TLINK type of the e_2 (timex) and DCT pair (if any).
event-DCT label			x		one-hot	The TLINK types of the e_1/e_2 and DCT pairs (if any).

Table 1: Feature sets for TLINK classification of event-DCT (E-D), event-timex (E-T) and event-event (E-E) pairs, and for CLINK classifier (E-E pairs), with corresponding feature representation (Rep).

- *dependencyPath* We only consider a dependency path between an event pair if it describes coordination, subordination, subject or object relation.
- *signalTokens* Given a temporal signal, we do not include in the feature set the token but the *clusterID* of the cluster containing synonymous signals, e.g. {*before*, *prior to*, *in advance of*}.
- *wnSim* The value of WordNet similarity measure is discretized as follows: $sim \leq 0.0$, $0.0 < sim \leq 0.5$, $0.5 < sim \leq 1.0$ and $sim > 1.0$.

We exclude lexical features such as *token/lemma* of temporal entities from the feature set in order to increase the classifiers' robustness in dealing with completely new texts with different vocabularies. Instead, we include *WordNet similarity* in the feature set to capture the semantic relations between event words.

Label Simplification For training the classification models, we only consider 10 out of the 14 relation types defined in TimeML by collapsing some types, i.e., IBEFORE into BEFORE, IAFTER into AFTER, DURING and DURING_INV into SIMULTANEOUS, due to the sparse annotation of such labels in the datasets.

5 Causal Relation Extraction System

We propose the same hybrid approach combining rule-based and supervised classifiers for the identification of causal relations. However, while temporal order has a clear formalization in the NLP community, capturing causal relationships in natural language text is more challenging, for they can be expressed by different syntactic and semantic features and involve both situation-specific information and world knowledge. We adopt the notion of causality proposed in the annotation guidelines of the Causal-TimeBank (Mirza et al., 2014; Mirza and Tonelli, 2014a), which accounts for CAUSE, ENABLE and

[5]The order of e_1 and e_2 in E-E pairs is always according to the appearance order in the text, while in E-T pairs, e_2 is always a timex regardless of the appearance order.

PREVENT phenomena (Wolff, 2007; Wolff and Song, 2003) that are overtly expressed in text. In particular, we aim at assigning a causal link to pairs of events when: (i) the causal relation is expressed by *affect*, *link* and *causative verbs* (CAUSE-, ENABLE- and PREVENT-type verbs), hereinafter simply addressed as *causal verbs*; or (ii) the causal relation is marked by a *causal signal* (see e.g. footnote 6).

The two cases require different algorithms: while causal constructions containing causal verbs are quite straightforward to identify, causal signals are very ambiguous and can appear in different syntactic constructions.[6] Therefore, we tackle the first through a rule-based approach, while the second is best covered via supervision, taking advantage of the freely available Causal-TimeBank.

5.1 Causal Relation Identification

Similar to the temporal processing module, the first step towards causal relation classification is the identification of candidate event pairs. Given a document already annotated with events, we take into account every possible combination of events in a sentence in a forward manner as *candidate event pairs*. For example, if we have a sentence "e_1, triggered by e_2, cause them to e_3," the candidate event pairs are (e_1,e_2), (e_1,e_3) and (e_2,e_3). We also include as candidate event pairs the combination of each event in a sentence with events in the following one, to account for inter-sentential causality, under the simplifying assumption that causality may be expressed also between events in two consecutive sentences.

5.2 Causal Rule-Based Sieve

In the rule-based sieve, we classify causal constructions containing causal verbs. These show strong regularities: given a causal verb v, the first event e_1 is usually the *subject* of v and the second event e_2 is either the *object* or the *predicative complement* of v. Such relations between events and causal verbs are usually syntactically expressed, therefore our rules aim at identifying pairs of events being related to a causal verb in a causal construction by looking at their dependency paths.

We take the list of 56 affect, link and causative verbs presented in Mirza et al. (2014) as the causal verb list. We further expand the list using the Paraphrase Database (Ganitkevitch et al., 2013) and original verbs as seeds, resulting in a total of 97 verbs. We then manually cluster the causal verbs sharing the same syntactic behaviour in groups and define a set of rules for each verb group, taking into account the possible existing dependency paths between v and e_1/e_2, as well as the *causal direction sense*[7] conveyed in v. Further details on the implemented rules for the causal rule-based sieve can be found in Appendix B.

5.3 Causal Supervised Classifier

In order to recognize and determine the causal direction of CLINKs that are signalled by a causal signal, we adopt a supervised approach. We build a classification model using LIBLINEAR (Fan et al., 2008) L2-loss linear SVM (default parameters), and one-vs-rest strategy for multi-class classification. The classifier has to label an event pair (e_1, e_2) with CLINK, CLINK-R or O for others.

We take as candidate event pairs only those in which the causal signal is connected via dependency path to either e_1 or e_2, or both. Besides, we exclude event pairs where the two events are directly connected through relations such as subject, object, coordinating or locative adverbial, because a causal relation usually does not hold in these cases.

Tools and Resources The same external tools and resources mentioned in Section 4.2.3 for building the temporal classifiers are used to extract features from each event pair. Additionally, we take the list of causal signals from the annotation guidelines presented in Mirza et al. (2014) as the *causal signal list*. Again we expand the list using the Paraphrase Database (Ganitkevitch et al., 2013), resulting in a total of 200 signals. We also manually cluster some signals together, e.g. {*therefore*, *thereby*, *hence*, *consequently*}, as we did for temporal signals.

[6] *"The building [collapsed]* $_{\text{T}}$ ***because of*** *the [earthquake]* $_{\text{S}}$*"* vs *"**Because of** the [earthquake]* $_{\text{S}}$ *the building [collapsed]* $_{\text{T}}$*"*. S and T denote the *source* (cause) and *target* (effect) of the causal relation.

[7] For example, *result in* and *result from* have different senses affecting the causal direction, i.e. the causing event is the subject of *result in* and the object of *result from*.

Feature Set The implemented features are listed in Table 1. As shown in Figure 1, the event-event labels added by the rule-based sieve and the reasoner in the temporal relation extraction module are also used as features for the CLINK classifier.

6 Evaluation

The purpose of the evaluation is two-fold: (i) to evaluate the quality of extracted temporal and causal links separately; and (ii) to investigate the interaction between temporal and causal relation extraction systems in the integrated architecture.

6.1 Temporal and Causal Relation evaluation

We perform two evaluations, one following *TempEval-3* and the other *TimeBank-Dense* evaluation methodology.

Dataset For the evaluation of the temporal relation extraction module following TempEval-3, we use the same training and test data released for the shared task,[8] i.e. *TBAQ-cleaned* (cleaned and improved version of the TimeBank 1.2 and the AQUAINT corpora) and *TempEval-3-platinum*, respectively. The TimeBank 1.2 corpus contains 183 documents coming from a variety of news report, specifically from the ACE program and PropBank, while the AQUAINT corpus contains 73 news report documents and often referred to as the *Opinion corpus*. The TempEval-3-platinum corpus, containing 20 news articles, was annotated/reviewed by the TempEval-3 organizers.

The *TimeBank-Dense* corpus (Chambers et al., 2014) is created to address the sparsity issue in the existing TimeML corpora. The resulting corpus contains 12,715 temporal relations over 36 documents taken from TimeBank 1.2. For the TimeBank-Dense evaluation, we follow the experimental setup in Chambers et al. (2014), in which the TimeBank-Dense corpus is split into a 22 document training set, a 5 document development set and a 9 document test set.[9]

To evaluate the causal relation extraction module, we use the Causal-TimeBank corpus[10] (Mirza and Tonelli, 2014a) for training. For TimeBank-Dense evaluation, the test set is a subset of TimeBank, so we exclude the 9 test documents from Causal-TimeBank during training. For TempEval-3 evaluation, we manually annotated 20 TempEval-3-platinum documents with causal links following the annotation guidelines of the Causal-TimeBank.[11] Causal relations are much sparser than temporal ones, and we found only 26 CLINKs.

Label Adjustment Since the set of TLINK types used in the TimeBank-Dense corpus is slightly different from the one used in TempEval-3,[12] we map the relation types of TLINKs labelled by the rule-based sieve of CATENA (Section 4.2.1) as follows: (i) BEGINS, ENDED_BY → BEFORE, (ii) BEGUN_BY, ENDS → AFTER, and (iii) DURING, IDENTITY → SIMULTANEOUS. The set of labels for the TLINK classifiers (Section 4.2.3) is also adjusted accordingly following the labels in the TimeBank-Dense training data.

Evaluation Results In Table 2, we compare the performance of CATENA with the two best-performing systems participating in the *Task C* of TempEval-3 (relation annotation given gold entities) and *Task C 'relation type only'* (relation annotation given gold entities and related pairs). We also compare the results on the second task with the results of Laokulrat et al. (2015), who recently presented a state-of-the-art system for relation classification based on timegraphs and stacked learning. In CATENA, Task C 'relation type only' is performed by disabling the module for identifying temporal links described in Section 4.1.

The evaluation shows that CATENA is the best performing system in both tasks, even if in Task C best precision and best recall are yielded by Bethard (2013) and Laokulrat et al. (2013), respectively. The recall drop (from .613 to .595) in Task C is because we remove the timex-timex pairs from the final

[8] Available at `https://www.cs.york.ac.uk/semeval-2013/task1/index.php\%3Fid=data.html`.

[11] Available at `https://github.com/paramitamirza/CATENA/data/`.

[12] Some relation types are not used, and the VAGUE relation introduced in the first TempEval task (Verhagen et al., 2007) is adopted to cope with ambiguous temporal relations, or to indicate pairs for which no clear temporal relation exists. The final set of TLINK types in TimeBank-Dense includes: BEFORE, AFTER, INCLUDES, IS_INCLUDED, SIMULTANEOUS and VAGUE.

Table 3: Analysis of classifier performance per sieve. RB: rule-based sieve, ML: machine-learned sieve and TR: temporal reasoner.

annotated documents in order to avoid a relevant decrease in precision, since only very few of such pairs are annotated in the gold standard. The significant drop in precision shows the difficulty in matching annotators' decision to set TLINKs between entity pairs, although CATENA implements the instructions they had to follow in the annotation guidelines.

We also report in Table 2 the performance of CATENA in the TimeBank-Dense evaluation and compare it with CAEVO. We report only F1-score, since all possible links are labelled, yielding the same P and R values. We achieve a small improvement in the overall F1-score, i.e., .511 vs .507. If we consider the different entity pairs, CATENA performs best on timex-timex and event-timex relations, while CAEVO still achieves the best results on event-DCT and event-event pairs. One of the possible reasons for that is the lack of rules in CATENA to classify VAGUE TLINKs between E-E pairs, a relation type present only in TimeBank-Dense.

In order to measure the contribution of each component to the overall performance of CATENA, we also evaluate the performance of each sieve both in the temporal and in the causal module. Results are reported in Table 3, evaluated on both TempEval-3 and TimeBank-Dense test data. As expected, running a transitive closure module after the temporal rule-based sieve (RB + TR) results in improving recall, but the overall performance is still lacking (less than .30 F1-score).

Combining rule-based and machine-learned sieves (RB + ML) yields a slight improvement compared with enabling only the machine-learned sieve in the system (ML). Introducing the temporal reasoner module between the two sieves (RB + TR + ML) proves to be even more beneficial. This is especially evident in the TimeBank-Dense evaluation. The same phenomena are also observed by CAEVO; Table 3 (right) shows the related numbers reported in Chambers et al. (2014). Note that in CAEVO, the machine-learned sieves are not the last sieves, instead, the *AllVague* sieve is finally activated to label all remaining unlabelled pairs as VAGUE.

For causal relation extraction, the combination of rule-based and machine-learned sieves (RB + ML) achieves .622 F1-score in TempEval-3 evaluation, with the ML component contributing to increase

E-E pair	Sentence	TE3-gold	TE-label	CA-label	Post-editing
(e_{32}, e_{44})	*The [incident]* $_{e_{32}}$ *provoked an international [outcry]* $_{e_{44}}$*...*	-	SIMULTANEOUS	CLINK	BEFORE
(e_{32}, e_{45})	*The [incident]* $_{e_{32}}$ *provoked an international outcry and led to a major [deterioration]* $_{e_{45}}$ *in relations...*	-	AFTER	CLINK	BEFORE
(e_{18}, e_{19})	*...the [inspections]* $_{e_{18}}$ *were directly linked to the new law on NGOs and the targeted groups' [compliance]* $_{e_{19}}$ *with it.*	-	IS_INCLUDED	CLINK-R	AFTER
(e_4, e_6)	*A haze akin to volcanic fumes [cloaked]* $_{e_4}$ *the capital, causing convulsive [coughing]* $_{e_6}$ *and...*	INCLUDES	AFTER	CLINK	BEFORE

Table 4: Examples of E-E pairs in the TempEval-3-platinum dataset with gold annotated labels (TE3-gold), labelled by the temporal module (TE-label) and causal module (CA-label) of CATENA. These examples illustrate how TLINK post-editing using CLINK could improve the labelling quality.

the recall of the highly precise RB component. The low precision of the ML module is mostly due to dependency parsing mistakes and issues in disambiguating signals such as *from*, as in *"...passenger cars in China was on track to hit [400 million]* $_{\text{T}}$ *by 2030, up* ***from*** *[90 million]* $_{\text{S}}$ *now."* Unfortunately, from the total of 5 gold CLINKs in the 20 documents of the TimeBank-Dense test set, none is identified by CATENA.

6.2 Interaction between Temporal and Causal Relations

As shown in Figure 1, E-E labels returned by the temporal reasoner are used by the CLINK classifier as features, whose causal relations are then used to post-edit TLINK labels. We evaluate the impact of the first step through an ablation test, by removing TLINK types from the features used by the CLINK classifier. We only analyse the results of TempEval-3 evaluation, since there are no causal links recognized in the TimeBank-Dense test corpus. Without TLINK types, the F1-score drops from .622 to .571, with a significant recall drop from .538 to .462. This shows that temporal information is beneficial to the classification of causal relations between events, especially in terms of recall.

As for the evaluation of TLINK post-editing using CLINKs, the system identifies 19 causal links in the test set, which are passed to the temporal module. While 15 of them are already consistent with BEFORE/AFTER labels, 3 would add new correct TLINKs that are currently not annotated in the evaluation corpus, and were wrongly labelled by the temporal module of CATENA, as shown in Table 4. The fourth would add a BEFORE relation between *cloaked* and *coughing* in *"A haze akin to volcanic fumes [cloaked]* $_{\text{S}}$ *the capital,* ***causing*** *convulsive [coughing]* $_{\text{T}}$ *..."*. This relation is labelled as INCLUDES in the gold standard, but we believe that BEFORE would be correct as well.

7 Conclusions

We presented CATENA, a hybrid system for the extraction and classification of temporal and causal relations in text, which we make freely available to the research community. We adopt a sieve-based architecture both for the temporal and the causal module, integrating rule-based and machine learning components. The two modules were evaluated separately, showing that they achieve state-of-the-art performance on different tasks. Furthermore, the interaction between temporal and causal components, especially the benefits of passing information from one module to the other, was also analysed.

The system relies on the notion of events as defined in the TimeML standard, making it possible to easily put temporal and causal information in relation. Although the interplay between causality and temporality may seem obvious from a theoretical point of view, CATENA allows a systematic study and a quantification of this phenomenon. The presented approach would probably have more impact if implicit causality was also considered, which we did not take into account because it is not annotated in the Causal-TimeBank corpus. However, we plan to investigate this issue in the near future.

Forecasting Word Model: Twitter-based Influenza Surveillance and Prediction

Hayate ISO, Shoko WAKAMIYA, Eiji ARAMAKI
Nara Institute of Science and Technology
{iso.hayate.id3,wakamiya,aramaki}@is.naist.jp

Abstract

Because of the increasing popularity of social media, much information has been shared on the internet, enabling social media users to understand various real world events. Particularly, social media-based infectious disease surveillance has attracted increasing attention. In this work, we specifically examine influenza: a common topic of communication on social media. The fundamental theory of this work is that several words, such as symptom words (*fever*, *headache*, etc.), appear in advance of flu epidemic occurrence. Consequently, past word occurrence can contribute to estimation of the number of current patients. To employ such forecasting words, one can first estimate the optimal time lag for each word based on their cross correlation. Then one can build a linear model consisting of word frequencies at different time points for nowcasting and for forecasting influenza epidemics. Experimentally obtained results (using 7.7 million tweets of August 2012 – January 2016), the proposed model achieved the best nowcasting performance to date (correlation ratio 0.93) and practically sufficient forecasting performance (correlation ratio 0.91 in 1-week future prediction, and correlation ratio 0.77 in 3-weeks future prediction). This report reveals the effectiveness of the word time shift to predict of future epidemics using Twitter.

1 Introduction

The increased use of social media platforms has led to wide sharing of personal information. Especially Twitter, a micro-blogging platform that enables users to communicate by updating their status using 140 or fewer characters, has attracted great attention of researchers and service developers because Twitter can be a valuable personal information resource. The feasibility of such approaches, known as social sensors, has been demonstrated in various event detection systems such as earthquakes (Sakaki et al., 2010), outbreaks of disease (Chew and Eysenbach, 2010), and stock market fluctuations (Bollen et al., 2011). Among the applications mentioned above, this study particularly examines detection of seasonal influenza epidemics because the influenza detection is a popular application of Twitter. To date, more than 30 Twitter-based influenza detection and prediction systems have been developed worldwide (Charles-Smith et al., 2015).

Although the detailed functions of these systems differ, they share the underlying assumption that the flu spreading in the real world is immediately reflected to the tweets. Therefore, most systems have simply aggregated counts of daily flu-related tweets to obtain the current patient status (Aramaki et al., 2011; Collier et al., 2011; Chew and Eysenbach, 2010; Lampos and Cristianini, 2010; Culotta, 2013; Paul et al., 2014). Their typical materials are presented as shown below.

- *I got a* **flu** 😢 *I can not go to school for the rest of the week*
- *I was diagnosed with a high* **fever**. *Maybe flu :(*

Although the former tweet is described by an actual influenza patient, the latter one merely expresses a suspicion of flu. From a practical (clinical) perspective, these differences have great importance because

(a) "*Fever.*" (b) "*Injection.*"

Figure 1: Motivating examples: The time lag of the frequency of a word enables one to obtain a good approximation to the number of patients. The blue line shows the word frequency. The green line shows the word frequency shifted time lag days. The red line shows the number of patients.

the latter is noise that impedes precise influenza surveillance. Therefore, earlier studies (Aramaki et al., 2011; Kanouchi et al., 2015; SUN et al., 2014) have devoted great efforts to removal of such noise (suspicion, negation, news wired, and so on).

This study employs such noisy tweets. We assume that a word, "*fever*" presents a clue to an upcoming influenza outbreak. Inferring that people are frequently afflicted by symptoms such as "*fever*" and "*headache*" immediately before the onset and diagnosis of influenza, we designate such words as **forecasting words**.

More concrete examples of forecasting words are presented in Figure 1a. The figure reveals that an approximately 16-day time lag exists between the frequency of "*fever*" (blue line) and the number of patients (red line). If this time lag was known in advance, one could obtain a good approximation of the number of patients (red line) by a 16-day time shift operation (green line). Similarly, flu prevention words such as "*shot*" and "*injection*" have previously been used to describe outbreaks.

- *I took a flu* **shot** *today* 💉
- *I don't wanna get a flu* **injection** *cuz it hurts me*

In the latter case as shown in Figure 1b, we can find much longer time lag (55 days) between tweets (frequency of "*injection*") and the reality (number of patients).

Presuming that each word has its own time lag, then the problems to be solved are two-fold: (1) estimating the optimal time lag for each forecasting word and (2) incorporating these time lags into the model.

For the first problem, the suitable time lag for each word is measured by calculating the cross correlation between the word frequency and the patient number. For the second problem, we construct a word frequency matrix that consists of a shifted word frequency timeline (Sec. 3). Next, a linear model called **nowcasting model** is constructed from the modified word matrix, for which the parameters are estimated using several regularization models, Lasso and Elastic Net (Sec. 4).

Moreover, the nowcasting model can be extended easily to a predictive model called a **forecasting model**. In the forecasting model (Δf days future), only forecasting words that have more than n day time lag are used (Sec. 5).

Nowcasting models can dramatically boost the current patient number estimation capability (correlation ratio 0.93; $+0.10$ point). Forecasting models have demonstrated successful prediction performance (the correlation ratio 0.91 in 1-week future prediction, and the correlation ratio 0.77 in 3-weeks future prediction). This performance goes beyond the practical baseline (over 0.75 correlation).

Our contributions are summarized as presented below.

- We discover that **forecasting words** have a time lag between the virtual world (number of tweets in Twitter) and the real world (number of patients).

- We propose a method to build time-shifted features using **cross correlation** measures.
- We realize **nowcasting model** and its extended one, **forecasting model**, based on the time shift with parameter estimation. This report is the first of the relevant literature describing a successful model enabling the prediction of future epidemics over the practical baseline.

We make code and data publicly available. [1]

2 Dataset

2.1 Influenza Corpus

We collected 7.7 million influenza related tweets, starting from August 2012 to January 2016, via Twitter API[2]. Then, we filtered noises (removed retweets including the word, *RT*, and tweets linked to other web pages including the word, *http* from the collected tweet data). In the case of just counting influenza-related tweets, we should only consider unique users to avoid to count more than ones the tweets of the same patients. However, we didn't filter out the users which posted influenza-related tweets multiple times because we provide the different word for the different role even if these tweets were posted by the same patients. For example, the word, "fever" for nowcasting, and the word, "injection" for forecasting. To analyze a word, we applied a Japanese morphological parser (JUMAN[3]) and obtained the stem forms. As a result, 27,588 words were extracted. Then, we investigated the word frequency per day to build a word matrix ($days \times words$) as shown in Figure 2a.

2.2 IDSC report

In Japan, the Infectious Disease Surveillance Center (IDSC) announces the number of influenza patients once a week during an influenza epidemic season (typically during November–May in Japan). In fact, IDSC reports tend to delay around a week likewise the U.S. Centers for Disease Control and Prevention (CDC) (Paul et al., 2014), but even if we consider such time delay, twitter stream attains the peak faster than the real world.

To use the IDSC reports for evaluation, we divided the data into the following three periods: 2012/12/01–2013/05/31 (Season 1), 2013/12/01–2014/05/31 (Season 2), and 2014/12/01–2015/05/24 (Season 3). We prepared a buffer time (60 day maximum time shift) immediately preceding the experimental periods to secure the time shift width.

3 Method

To estimate the current influenza epidemics (nowcast) and forecast the future ones, the number of influenza patients was derived from the following linear model.

$$\hat{y}^{(t)} = x_1^{(t-\hat{\tau}_1)}\hat{\beta}_1 + x_2^{(t-\hat{\tau}_2)}\hat{\beta}_2 + \cdots + x_{|V|}^{(t-\hat{\tau}_{|V|})}\hat{\beta}_{|V|}$$

Therein, $\hat{y}^{(t)}$ shows the estimated number of influenza patients at time t, $x_v^{(t)}$ stands for the count of a word v at time t, and $\hat{\beta}$ represents a weight estimated in the training phase, $\hat{\tau}_v$ denotes a suitable time shift parameter for word v decided in the training phase, and $|V|$ denotes the size of vocabulary.

This section first provides methods to explore the most suitable time shift width $\hat{\tau}_v$ for each word v (Sec. 3.1). Then, the parameter estimation method is described (Sec. 3.2). Finally, the model of future prediction based on the original model is explained (Sec. 3.3).

(a) Ordinary Word Matrix.

(b) Time Shifted Word Matrix.

Figure 2: Word matrix transformation. The Y-axis shows a timeline. The X-axis shows words with the IDSC reports (right side).

3.1 Time Shift Estimation

The first problem to be solved is finding the optimal time shift width that achieves the best fit to the target influenza timeline. Given the IDSC reports and wider range of tweets, **Cross Correlation** is used to search for the most suitable time shift width for each word frequency as

$$r_{\mathbf{x}_v,\mathbf{y}}(\tau) = \frac{\sum_{t=1}^{T}(x_v^{(t-\tau)} - \bar{x}_v^{(t-\tau)})(y^{(t)} - \bar{y})}{\sqrt{\sum_{t=1}^{T}(x_v^{(t-\tau)} - \bar{x}_v^{(t-\tau)})^2 \sum_{t=1}^{T}(y^{(t)} - \bar{y})^2}},$$

where τ is a time shift parameter (time shift width)[4]. The cross correlation $r_{\mathbf{x}_v,\mathbf{y}}(\tau)$ measures the similarity between (τ days) time shift variable $\mathbf{x}_v$ and objective $\mathbf{y}$. In this study, $x_v^{(t-\tau)}$ is the count of word v with time shift width τ days earlier from t and $\mathbf{y} = [y^{(1)}, \ldots, y^{(T)}]^\top$ is the number of patients from the IDSC reports. It is formulated as $\hat{\tau}_v = \underset{\tau}{\operatorname{argmax}}\, r_{\mathbf{x}_v,\mathbf{y}}$.

Next, we construct a matrix, $\mathbf{X} \in \mathbb{N}^{T \times V}$, where T stands for the timeline and V represents the vocabulary, according to the Algorithm 1.

Algorithm 1: Time-shifted word matrix for nowcasting.

Set the maximum shift parameter $\tau_{\max}$
for $v \leftarrow 1$ **to** $|V|$ **do**
  for $\tau \leftarrow 0$ **to** $\tau_{\max}$ **do**
    Calculate Cross Correlation $r_{x_v,y}(\tau)$
  end
  $\hat{\tau}_v = \underset{\tau \in \{0,\ldots,\tau_{\max}\}}{\operatorname{argmax}} r_{x_v,y}(\tau)$
  Shift the word vector to maximize Cross Correlation $\hat{\mathbf{x}}_\mathbf{v} \leftarrow [x_v^{(1-\hat{\tau}_v)}, x_v^{(2-\hat{\tau}_v)}, \ldots, x_v^{(T-\hat{\tau}_v)}]$
end
return *Shifted Word Matrix* $\mathbf{X} = [\hat{\mathbf{x}}_1, \ldots, \hat{\mathbf{x}}_{|V|}]$

The algorithm decides the optimal time shift width ($\hat{\tau}_{\mathbf{x}_v,\mathbf{y}}$) based on the cross correlation for each word. After time shifts for all words, a shifted word matrix $\mathbf{X}$ is constructed.

Figure 2a presents the initial (original) word matrix ($\tau = 0$ for all words) of 50 words (randomly selected). This matrix includes several low-correlated words, making several vertically irregular lines. In contrast, the time shift operation arranges the irregular words to match the IDSC reports, producing a beautiful horizontal line, as shown in Figure 2b.

3.2 Nowcasting

To construct the linear model (called **nowcasting model**), the parameter $\boldsymbol{\beta}$ is estimated as minimizing the squared error. For this study, the vocabulary size $|V|$ is of much larger order than sample size T

[4]The cross correlation is exactly the same as the Pearson's correlation when $\tau = 0$.

so that the ordinary least squares estimator is not unique. It heavily overfits the data. According to the previous study's manner, parameters with a penalty are estimated as shown below.

$$\hat{\boldsymbol{\beta}} = \underset{\boldsymbol{\beta}}{\operatorname{argmax}} \|\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\|_2^2 + \mathbf{P}(\boldsymbol{\beta}, \boldsymbol{\lambda})$$

In that equation, $\mathbf{P}(\boldsymbol{\beta}, \boldsymbol{\lambda})$ is the penalty term.

In the case of $\mathbf{P}_{lasso}(\boldsymbol{\beta}, \boldsymbol{\lambda}) = \lambda\|\boldsymbol{\beta}\|_1$, the regularization method called the Least Absolute Shrinkage and Selection Operator (Lasso) is a well-known method for selecting and estimating the parameters simultaneously (Tibshirani, 1994). In earlier studies, Lasso was employed to model influenza epidemics by Lampos and Cristianini (2010). However, in the case of vocabulary size $|V|$, which is much larger order than sample size T, it has been observed empirically that the prediction performance of l_1-penalized regression, the Lasso is dominated by the l_2-penalized one.

Therefore, we employ the Elastic Net (Zou and Hastie, 2005), which combines the l_1-penalty and l_2-penalty $\mathbf{P}_{enet} = \lambda(\alpha\|\boldsymbol{\beta}\|_1 + (1-\alpha)\|\boldsymbol{\beta}\|_2^2)$, where α is called l_1 ratio. The Elastic Net was already employed for nowcasting influenza-like illness rates using search query log, not Twitter (Lampos et al., 2015). In the case of $\alpha = 1$, Elastic Net is exactly the same as Lasso and $\alpha = 0$, Ridge (l_2 regularization). Similarly to Lasso, the Elastic Net simultaneously does automatic variable selection and continuous shrinkage. It has a l-2 regularization advantage that selects groups of correlated variables. Elastic Net, as the generalized method of Lasso and Ridge, estimates with equal or better performance compared to both.

3.3 Forecasting

Our nowcasting model can be extended naturally to **forecasting model**. To predict the number of future patients Δf days after, we force to shift the word frequency at least Δf days. To do so, a setting of the nowcasting model in Algorithm 1 is just changed to $\tau_{\min} = \Delta f$, as shown in Algorithm 2. It enables forecasting of future epidemics, demonstrating a widely applicable methodology of the proposed approach.

Algorithm 2: Time-shifted word matrix for forecasting.

Set the maximum shift parameter $\underline{\boldsymbol{\tau}_{\mathbf{min}}}, \tau_{\max}$
for $v \leftarrow 1$ **to** $|V|$ **do**
  for $\tau \leftarrow \underline{\boldsymbol{\tau}_{\mathbf{min}}}$ **to** $\tau_{\max}$ **do**
    Calculate Cross Correlation $r_{x_v,y}(\tau)$
  end
  $\hat{\tau}_v = \underset{\tau \in \{\underline{\boldsymbol{\tau}_{\mathbf{min}}}, \ldots, \tau_{\max}\}}{\operatorname{argmax}} r_{x_v,y}(\tau)$
  Shift the word vector to maximize Cross Correlation $\hat{\mathbf{x}}_{\mathbf{v}} \leftarrow [x_v^{(1-\hat{\tau}_v)}, x_v^{(2-\hat{\tau}_v)}, \ldots, x_v^{(T-\hat{\tau}_v)}]$
end
return *Shifted Word Matrix* $\mathbf{X} = [\hat{\mathbf{x}}_1, \ldots, \hat{\mathbf{x}}_{|V|}]$

4 Experiment 1: Nowcasting

To assess the nowcasting performance, we used the actual influenza reports provided by the Japanese IDSC.

4.1 Comparable Methods

We compared four linear methods for nowcasting as shown below:

- `Lasso`: l_1-regularization method (Tibshirani, 1994; Lampos and Cristianini, 2010),
- `Lasso+`: Lasso and time shift combined method,
- `ENet`: Elastic-Net, which combines l_1-, l_2-regularization (Zou and Hastie, 2005),
- `ENet+`: Elastic-Net and time shift combined method.

All hyperparameters were tuned via five-fold cross validation in the training dataset.

Train	Season 2	Season 3	Season 1	Season 3	Season 1	Season 2	Avg.
Test	Season 1		Season 2		Season 3		
`Lasso`	0.854	0.916	0.768	0.894	0.770	0.753	0.826
`Enet`	0.900	**0.927**	0.809	**0.914**	0.792	0.805	0.858
`Lasso+`	**0.952**	0.907	0.951	0.888	0.955	**0.963**	**0.936**
`Enet+`	0.944	0.898	**0.960**	0.878	**0.967**	0.959	0.934

Table 1: Correlation between estimated values and the IDSC reports.

Figure 3: Timelines of estimated values obtained using the four methods for nowcasting.

4.2 Dataset and Evaluation Metric

The detailed dataset is described in Sec. 2. To construct the time-shifted word matrix, we set $\tau_{\max} = 60$. Our tweet corpus had a dropout period, so that we did not calculate the cross correlation with more than a 60-day shift. We employed each season's data as training data and others as test data.

The evaluation metric is based on correlation (Pearson correlation) between the estimated value and the value of the IDSC reports.

4.3 Result

Results of modeling accuracy are presented in Table 1. Correlations of our baselines, `Lasso` and `Enet`, were lower than those of previous studies. Results suggest that our dataset is more difficult than those used in earlier studies.

In contrast, time-shifted models (`Lasso+`, `Enet+`) demonstrated about 0.1 point improvement than their baseline models, indicating the contribution of time shift features.

It is noteworthy that `Lasso` type model and `Enet` type one did not differ so much. The whole trained model chose l_1 ratio parameter that is nearly equal to 1, so that the `Enet` type model became almost identical as `Lasso` type model.

Overestimation

Results showed that values in Figure 3a were overestimated in mid-May. One reason is that tweets related to news such as "**Scientists create hybrid flu that can go airborne**"[5] were popular in social media. Although tweets linked to web pages were removed during preprocessing, many tweets without links to web pages were posted by many people worried about the news. An example of such tweets is the following:

[5] `http://go.nature.com/29ATqc9`

- *What? In an attempt to make a vaccine for bird flu and swine flu had created a new strain of influenza virus? 😡 What are you doing? 😡😡😡*

In addition, the model trained in Season 2 included the word "*bird*" as one feature. This word's time shift was 15 days. Consequently, this peak occurred.

In most cases, these kinds of outlier words are not selected through model selection, but preprocessing will play an crucial role to prevent these kinds of outlier.

5 Experiment 2: Forecasting

We evaluate the forecasting performance described in Sec 3.3.

5.1 Comparable methods

`Lasso` and `Enet` have no features for predicting future values. Therefore, we use `Lasso+` and `Enet+` for forecasting. Additionally, we employ the following baseline model of `BaseLine`: $\hat{y}^{(t)}_{\text{test}} = y^{(t)}_{\text{train}}$ for comparison with our proposed models.

5.2 Dataset and Evaluation Metric

To evaluate the forecasting performance, we used the same dataset and evaluation metric as Experiment 1, except that we set the minimum time shift $\tau_{\min}$ from 1 day to 30 days.

5.3 Result

Results of forecasting accuracy are presented in Figure 4. In both models, the accuracy was superior to the baseline until around 3 weeks into the future. In addition, the accuracy for prediction one week into the future was almost identical to that in the case of $\tau_{\min} = 0$. That result might occur because the accuracy about one week future was nearly the same as that for the current state. In addition, there were many highly correlated features by shifting around 10 days into the future. Consequently, our model demonstrated equivalent performance up to 10 days into the future.

Furthermore, the forecasting performance decreased dramatically along with the increase of $\tau_{\min}$, as shown in Figure 4e. We discuss that point further in Sec. 6.

Figure 5 presents timeline plots of examples. From Figure 5a to Figure 5d are shown the values estimated by the forecasting models trained in Season 2 and tested in Season 1 for $\tau_{\min} \in \{7, 14, 21, 28\}$. The estimated values showed a consistently similar shape to that of the IDSC report. In Figure 5c, the same word, "*bird*", occurred as described in Sec. 4.3. In contrast, the weight for "*bird*" decreased in Figure 5d for that reason, the forecasting accuracy increased.

Then, from Figure 5e to Figure 5h show the values estimated by the forecasting models trained in Season 3 and tested in Season 2 for the same $\tau_{\min}$. Our models overestimated before outbreaks and underestimated after the peak of influenza epidemics. For $\tau_{\min} = 28$, this phenomenon was widely evident. We discuss that point further in Sec. 6.

6 Discussion

In general, the proposed approach (time shift operation) fitted the IDSC reports, demonstrating the basic feasibility. However, exceptions were apparent, as for the model trained in Season 3. One reason is that a gap exists in the suitable time shift widths between the train (Season 3) and the other (Seasons 1 and 2). `Lasso+` model trained in Season 3 selected the words, "*fever*" with $\hat{\tau}_{\textit{fever}} = 16$, "*vaccination*" with $\hat{\tau}_{\textit{vaccination}} = 55$, "*absent*" with $\hat{\tau}_{\textit{absent}} = 10$, and others as features. These words have high correlations only in Season 3, with poor correlation in other seasons. The most drastic example is "*vaccination*" with $\hat{\tau}_{\textit{vaccination}}$, (over 0.849 correlation in Season 3). This word is adversely affected by other seasons (0.313 correlation in Season 1 and 0.04 correlation in Season 2). The reason for the lost correlation was that $\hat{\tau}_{\textit{vaccination}}$ in Season 3 differed from that of other seasons. This phenomenon suggests that "*vaccination*" is just an annually cycling word. Neither the cycle of "*vaccination*" nor that of influenza is fixed, bringing us different time lags.

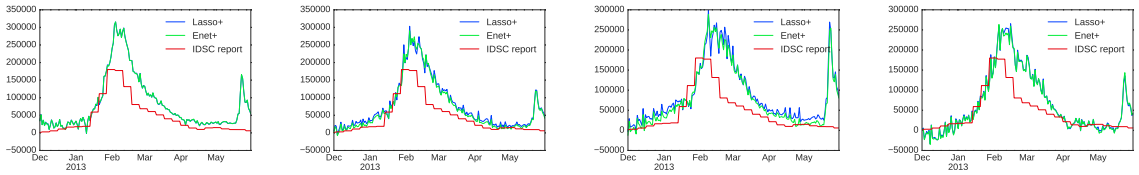
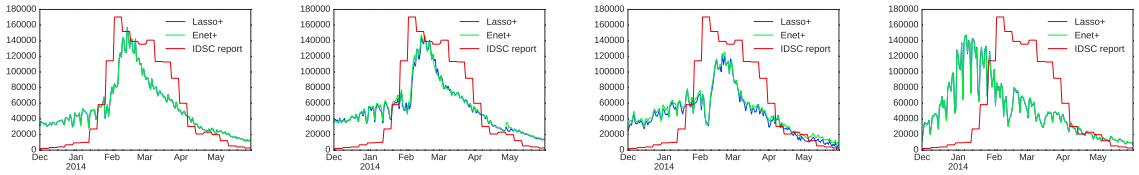
Figure 4: Correlation between estimated values using the two methods for forecasting.



(a) $\tau_{\min} = 7$ in Fig. 4a. (b) $\tau_{\min} = 14$ in Fig. 4a. (c) $\tau_{\min} = 21$ in Fig. 4a. (d) $\tau_{\min} = 28$ in Fig. 4a.



(e) $\tau_{\min} = 7$ in Fig. 4e. (f) $\tau_{\min} = 14$ in Fig. 4e. (g) $\tau_{\min} = 21$ in Fig. 4e. (h) $\tau_{\min} = 28$ in Fig. 4e.

Figure 5: Timelines of values estimated using the two methods for forecasting and the IDSC reports in each $\tau_{\min}$.

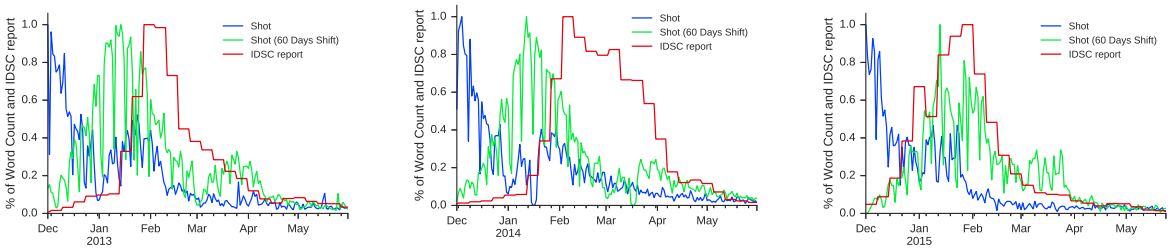
This inconsistency of time shifts also affected the forecasting performance directly. As shown in Figure 4e, the forecasting performance was decreased dramatically against the increase of $\tau_{\min}$. In spite of the word "*shot*" is the largest weighted feature in the case of $\tau_{\min} = 21$ and Train in Season 3, these word correlations were 0.310 in Season 1 and 0.03 in Season 2. Consequently, it caused a considerable decrease of the forecasting accuracy. In contrast, some words, such as "*fever*" and "*symptom*", showed consistently similar time shifts.

A technique to distinguish actual forecasting words such as "*fever*", and noises (simple year cycle words), "*vaccination*" is highly anticipated for use in the near future. If multiple-year training sets were available, one could filter out such noisy words.

Although some room for improvement remains, the basic feasibility of the proposed approach has been demonstrated. The time shift was effective for social media based surveillance. In addition, the model enables prediction.

7 Related Work

To date, numerous web based surveillance systems have been proposed, targeting the common cold (Kitagawa et al., 2015), drug side effects (Bian et al., 2012), cholera (Chunara et al., 2012), *E. Coli* (Diaz-Aviles et al., 2012), problem drinking (MA et al., 2012), smoking (Prier et al., 2011), campylobacteriosis (Chester et al., 2011), dengue fever (Gomide et al., 2011), and HIV/AIDS (Ku et al., 2010). Influenza has especially drawn much attention from earlier studies (Ginsberg et al., 2009; Polgreen et al., 2009;



(a) Season 1. (b) Season 2. (c) Season 3.

Figure 6: Frequencies of "*Shot*" in respective seasons.

Hulth et al., 2009; Corley et al., 2010) to current Twitter-based studies (Aramaki et al., 2011; Collier et al., 2011; Chew and Eysenbach, 2010; Lampos and Cristianini, 2010; Culotta, 2013).

Because of great variance in data resources and evaluation manner (region, year, only winter or all seasons), a precise comparison would be difficult and meaningless, Culotta (Culotta, 2013) and Ginsberg (Ginsberg et al., 2009) are apparently better than the others in US (correlation ratios $= 0.96$ and 0.94, respectively). Aramaki et al. (2011) achieved the best score for Japan (correlation ratio $= 0.89$). This study also examined Twitter data in Japan, and achieved competitive results for nowcasting. Another aspect of reviews of related studies is the manner of tweet counting. In earlier studies, a simple word counting, the direct number of tweets, is considered an index of the degree of disease epidemics. However, such a simple method is adversely affected by the huge numbers of noisy tweets. Currently, counting approaches of two types have been developed: (1) a classification approach (Kanouchi et al., 2015; SUN et al., 2014; Aramaki et al., 2011) aimed at extracting only tweets including patient information, and (2) a regression approach (Lamb et al., 2013; Culotta, 2010; Lampos and Cristianini, 2010; Paul and Dredze, 2011) that handles multiple words to build a precise regression model.

The proposed study fundamentally belongs among regression approaches, which explore optimal weight perimeters for each word. An important difference is that this study handles one more parameter for each word: time shift (days). To handle many parameters, we first ascertain the best time shift widths. Then we explore weight parameters using L1 or elastic net. It is noteworthy that this study does not employ any classification method, engaging a room to improve by incorporation with classification techniques.

8 Conclusions

This study proposed a novel social media based influenza surveillance system using forecasting words that appear in Twitter usage before main epidemics occur. First, for each word, the optimal time lag was explored, which maximized the cross correlation to influenza epidemics. Then, we shifted a matrix consisting of word frequencies at different time points by each optimal time lag. Using the time-shifted word matrix, this study produced and evaluated a nowcasting model and forecasting model designed to predict the number of influenza patients. In the experimentally obtained results, the proposed model achieved the best nowcasting performance to date (correlation ratio 0.93) and practically sufficient forecasting performance (correlation ratio 0.91 in the 1-week future prediction, and correlation ratio 0.77 in 3-week future prediction). This report is the first of the relevant literature describing a model that enables prediction of future epidemics. Furthermore, the model has much room for potential application to prediction of other events.

Abstract

Semantic Textual Similarity (STS) is a foundational NLP task and can be used in a wide range of tasks. To determine the STS of two texts, hundreds of different STS systems exist, however, for an NLP system designer, it is hard to decide which system is the best one. To answer this question, an intrinsic evaluation of the STS systems is conducted by comparing the output of the system to human judgments on semantic similarity. The comparison is usually done using Pearson correlation. In this work, we show that relying on intrinsic evaluations with Pearson correlation can be misleading. In three common STS based tasks we could observe that the Pearson correlation was especially ill-suited to detect the best STS system for the task and other evaluation measures were much better suited. In this work we define how the validity of an intrinsic evaluation can be assessed and compare different intrinsic evaluation methods. Understanding of the properties of the targeted task is crucial and we propose a framework for conducting the intrinsic evaluation which takes the properties of the targeted task into account.

1 Introduction

Semantic Textual Similarity (STS) is the foundational NLP task of determining the degree of semantic similarity between two texts. Most STS systems compute the similarity score between two texts on a fixed scale, for example a scale between 0 and 5, with 0 indicating the semantics are completely independent and 5 indicating semantic equivalence. In recent years, the number and quality of systems that rate the STS between texts have increased, as has the number of tasks where such systems are used.

Textual similarity is an active research field and was part of several shared tasks. In 2012, the pilot *Semantic Textual Similarity (STS) Task* (Agirre et al., 2012) was established at the *Semantic Evaluation (SemEval)* workshop. Further shared tasks on text similarity were part of SemEval 2013 (Agirre et al., 2013), SemEval 2014 (Agirre et al., 2014), SemEval 2015 (Agirre et al., 2015), and SemEval 2016 (Agirre et al., 2016). For the latest shared task on semantic textual similarity at SemEval 2016, 43 teams were submitting 119 different systems, depicting the large interest in this field.

STS is a foundational NLP technique, however, STS systems are seldom used for the sole purpose of measuring the similarity of two texts. Often they are used in a larger context. Examples for such tasks can be found in the field of Automatic Essay Grading (Attali et al., 2006), Plagiarism Detection (Potthast et al., 2012), Automated Text Summarization (Barzilay and Elhadad, 1997), Question Answering (Lin and Pantel, 2001), or Link Discovery (He, 2009). In this paper we call a task that heavily depends on the output of an STS system an *STS based task*. These tasks are often strongly dependent on the quality of the STS system they use, but they might apply further steps as well.

Given this large number of different STS systems, it is hard for an NLP system designer to decide which STS system should be implemented and used for a specific task. As such tasks often strongly depend on the quality of the STS system, the NLP system designer likes to use the most suitable system. To support the NLP system designer in this decision, the quality of STS systems is most often compared in an *intrinsic evaluation*. In the SemEval shared tasks on STS, the participating systems were asked to

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 87–96, Osaka, Japan, December 11-17 2016.

return a continuously valued similarity score given two texts. Performance is assessed by computing the Pearson correlation between machine assigned semantic similarity scores and human judgments (Agirre et al., 2016). Systems with a high Pearson correlation coefficient are considered as "good" STS systems and would often be the first choice for the system designer of an STS based task.

Usage of the Pearson correlation is common practice despite the fact that Agirre et al. (2013) state in the discussion of the results of the SemEval 2013 task about STS: "Evaluation of STS is still an open issue" and that beside the Pearson correlation "... other alternatives need to be considered, depending on the requirements of the target application." Up to our knowledge, no one published so far results whether Pearson correlation is a good method to evaluate the performance of different STS systems.

There are two factors defining the quality of intrinsic evaluations: The used dataset with the human judgments on similarity and the used evaluation measure to compare system outputs with the judgments. In this work, we will concentrate on the used evaluation measure. We studied three STS based tasks with different properties and evaluated 14 different STS systems. As the first task, we selected a classification task on text reuse using the Wikipedia Rewrite Corpus (Clough and Stevenson, 2011), as the second task a binary classification task of news article pairs on their relatedness, and as the third task one on detecting a related news article in a large corpus.

In our three examined tasks, we noticed that the Pearson correlation was misleading and especially ill-suited to predict the best STS system for the task. The performance of the STS systems in the intrinsic evaluation using Pearson correlation had no resemblance to their performance in the three different STS based tasks, i.e. for an NLP system designer the results of the intrinsic evaluation could be discarded. Other evaluation measures were much better in predicting which STS systems will perform well. In our experiments we could not observe that a single evaluation measure consistently produced the best predictions. The requirements on the STS systems for different tasks are too distinct, that a single evaluation measure could cope with all those. We thus claim that understanding the properties of the task and mapping them to the desired properties of the evaluation measure is crucial when selecting a measure for an intrinsic evaluation. Therefore, we propose in section 4 a new framework on the intrinsic evaluation of STS systems by taking the requirements of the target task into account.

This publication is based on the thesis of Beyer (2015). Some details in this paper are ommited for brevity and can be found online.[1]

2 Limitations of the Pearson Correlation and Alternative Evaluation Measures

Figure 1 depicts the output of four hypothetical STS systems in comparison to the gold standard derived from human judgment. These four distributions, also known as Anscombe's quartet, all have the same Pearson correlation coefficient of 0.816. By comparing only the Pearson correlation, all systems would be judged as equally good.

Pearson correlation is especially sensitive to non-linear relations, for example as depicted in the upper-right scatter plot, and to outliers, as depicted in the bottom scatter plots. In the scatter plot in the down-left corner, a single outlier is sufficient to disturb an otherwise perfect correlation. In the down-right corner the opposite is the case, a single outlier is sufficient to produce a high correlation of 0.816 even though there is no relationship between all other outputs and the human judgments. It is obvious that a human would judge the quality of these four STS systems quite differently, even though all four systems achieve the same Pearson correlation coefficient of 0.816.

2.1 Different STS Based Tasks Require Different Evaluation Measures

The usage of the Pearson correlation for the evaluation of STS systems has been questioned before. Zesch (2010) lists the limitations that the Pearson correlation is sensitive to outliers, that it can only measure a linear relationship, and that the two variables need to be approximately normally distributed. To overcome these limitations, Zesch recommends to use Spearman's rank correlation coefficient. The Spearman's rank correlation does not use the actual values to compute a correlation, but the ranking of

[1] https://www.ukp.tu-darmstadt.de/publications/details/?no_cache=1&tx_bibtex_pi1[pub_id]=TUD-CS-2015-12076

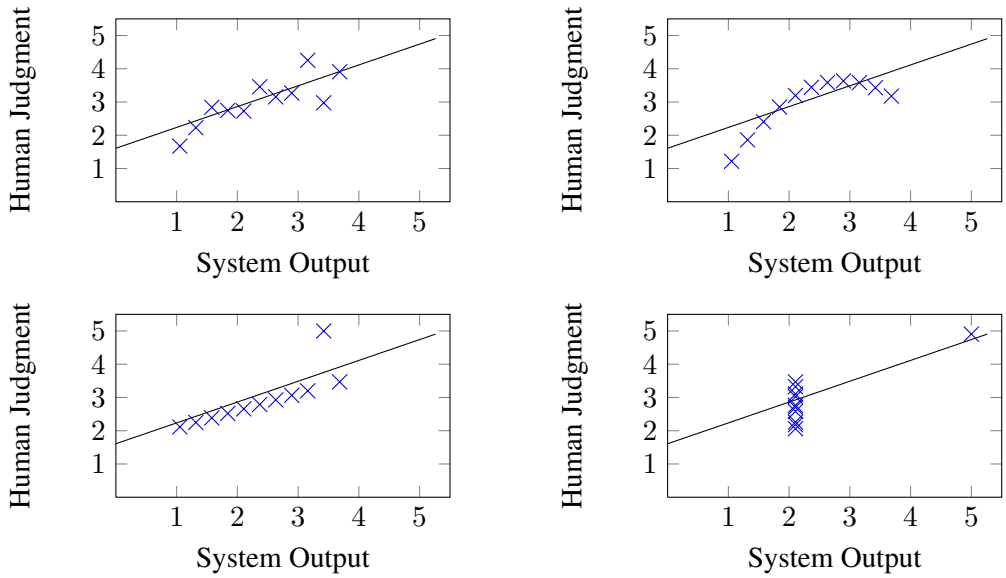

Figure 1: Anscombe's quartet with four different distributions. All distributions have a Pearson correlation coefficient of 0.816. All four STS systems would therefore be considered equally good.

the values. It is therefore not sensitive to outliers, non-linear relationships, or non-normally distributed data. However, most intrinsic evaluations of STS systems only report the Pearson correlation.

Depending on the STS based task, only some characteristics of the STS systems are important. For plagiarism detection, documents are often pre-filtered using an STS system and only documents with a score larger a certain threshold are passed for further inspection. For this task, only the decision whether the score is above the threshold is of importance, less the precise value. For the task of finding the top 10 most similar documents in a corpus for a search query, it is important that the STS system works well in distinguishing similar from dissimilar documents and is able to spot the most similar documents. Working perfectly on dissimilar documents and achieving the gold standard ranking for those is far less important than being able to find the few documents with high similarity. On the other hand, selecting semantically different sentences is important in automatic text summarization, therefore the STS system should work well to detect dissimilar text pairs.

It is unlikely that one evaluation measure can cope well with these different requirements. For Pearson and Spearman's rank correlation for example, all system outputs contribute equally, even though that for several tasks only some scores are relevant, often pairs that are especially similar or especially dissimilar. Using Pearson or Spearman's rank correlation therefore bears the risk that systems working especially well for the desired properties are missed. Hence, we study the following alternative evaluation measures for the intrinsic evaluation:

- The **normalized Cumulative Gain (nCG)** can be used to evaluate the ranking quality of STS scores (Järvelin and Kekäläinen, 2000). Let $\vec{m}$ be the vector with the gold STS values ranked by the STS system highest to lowest, i.e. at position 1 is the most similar pair according to the STS system and m_1 is the human judgment of this pair. The Cumulative Gain at k is defined as $CG_k = \sum_{i=1}^{k} m_i$. To normalize this value, it is divided by the so called ideal Cumulative Gain iCG_k which is the maximal value of CG_k for a perfect system. The normalized Cumulative Gain (nCG) is then defined as $nCG_k = \frac{CG_k}{iCG_k}$. Note that nCG is always equal 1 when k is equal to the number of text pairs.

- The **normalized Discounted Cumulative Gain (nDCG)** applies a discount factor to the normalized Cumulative Gain (Kekäläinen, 2005). It makes the assumption that similar text pairs are more important than less similar text pairs. An STS system which would score well with respect to the nDCG measure is well suited to find the most similar pairs in a corpus while it would be less suited to find the less similar, most distinct pairs. It is defined as $nDCG_k = \frac{DCG_k}{iDCG_k}$ with $DCG_k =$

$m_1 + \sum_{i=2}^{k} m_i / \log_2(i)$ and $iDCG_k$ the ideal Discounted Cumulative Gain. We can compute the $nDCG$ either for all text pairs or up to some position making an especially strong emphasis on the most similar pairs. Note: In case dissimilar pairs are more important for the targeted task, nCG and $nDCG$ can simply be modified by reversing the order of vector $\vec{m}$.

- **Accuracy** is a common evaluation measure for many tasks. However, as the STS scores are continuously valued, it is unclear how to compute it. One option is to define arbitrary bins and check whether the human judgments and the computed STS scores fall in the same bin. This requires that the minimal and maximal value of the STS systems is known and that there is a linear relationship between the STS scores and the human judgments. For the SemEval shared tasks, the systems were supposed to produce an output between 0 and 5 identical to the scale for the human judgments. In this work we set arbitrary borders at 1.5 and 3.5 with the intention to detect pairs with high similarity, e.g. for plagiarism detection, or pairs with low similarity, e.g. for detecting distinct sentences to be used in summarization. Accuracy^{low} describes the accuracy for scores below 1.5, and Accuracy^{high} describes the accuracy for scores higher than 3.5.

- Besides accuracy, the **$\mathbf{F_1}$-score** is a commonly used measure in several NLP tasks. Similar to accuracy, we have the challenge to define meaningful bins. As before, we set arbitrary borders at 1.5 and 3.5. F_1^{low} describes the F_1-score for low similarity pairs with a score below 1.5, and F_1^{high} describes the F_1-score for high similarity pairs with a score higher than 3.5.

Besides these evaluation measures, we define further measures by combining those using the harmonic mean $hmean(a, b) = 2ab/(a + b)$ and the unweighted macro average $macro\_avg(a, b) = (a + b)/2$. We also define the measure nDCG$_{AvgRank}$ which is the average of nDCG$_3$, nDCG$_5$, and nDCG$_{10}$ and nCG$_{AvgRank}$ which is the average of nCG$_3$, nCG$_5$, and nCG$_{10}$. These two measures only evaluate the top 3, 5, and 10 most similar text pairs according to the STS systems.

2.2 Impact of the Evaluation Measure on the Ranking

The evaluation measure of the intrinsic evaluation of STS systems can have a huge impact on the ranking of different STS systems. For the SemEval 2012 shared task on Semantic Textual Similarity (Agirre et al., 2012), 88 different STS systems were submitted by the participants. The official evaluation measure of this shared task used the Pearson correlation. We took the predicted STS scores and ranked the systems according to the alternative evaluation measures described in section 2. The results are depicted in Table 1. Using Spearman's rank correlation instead of Pearson correlation changed the positions of the STS systems on average by 6.6. The largest observed difference was 21 positions, i.e. a system that performed quite well according to the Pearson correlation coefficient achieved a mediocre result when the Spearman rank correlation coefficient is used. An even larger difference was observed when comparing Pearson correlation to the other presented evaluation measure like nDCG. The ranking of the STS systems according to the Pearson correlation was on average 19.0 positions different than the ranking according to nDCG.

The results show that the used evaluation measure plays an important role in defining the ranking of different STS systems in the intrinsic evaluation. A system which is assessed to be good using one evaluation measure, for example Pearson correlation, might perform badly according to another evaluation measure, for example Spearman's rank correlation.

3 Evaluation of the Predictiveness of Different Evaluation Measures

When the STS system is a crucial component of an STS based task, we expect that STS systems achieving good results in an intrinsic evaluation should in general lead to better results in the task and STS systems with weak results should in general lead to worse results for the STS based task. This allows us to define how *predictive* an intrinsic evaluation is:

> *Given the ranking of STS systems in an intrinsic evaluation as well as the ranking of the systems in an extrinsic evaluation, we say the intrinsic evaluation has **high predictiveness** when the*

Mean Absolute Difference	Spearman	nDCG$_{all}$	nDCG$_{AvgRank}$	Accuracy	F_1
Pearson	6.6	19.0	29.4	12.5	12.5
Spearman	-	19.6	29.1	12.0	15.2
nDCG$_{all}$		-	20.6	21.1	20.8
nDCG$_{AvgRank}$			-	31.8	26.3
Accuracy				-	14.3

Table 1: Mean Absolut Difference between ranks of submissions for the shared task on Semantic Textual Similarity at SemEval 2012 using different evaluation measures.

> *ranking in the intrinsic evaluation is similar to the ranking in the extrinsic evaluation. We say the **predictiveness** is **low**, when the ranking in the intrinsic evaluation is disconnected from the ranking of the systems in the extrinsic evaluation.*

In an ideal situation, the ranking of the STS systems in the intrinsic evaluation would be identical to the ranking in the extrinsic evaluation. As we cannot expect this, we need to define an objective measure on how similar these two rankings are. We can measure the resemblance of two rankings using the Mean Absolute Difference (MAD), the Mean Squared Difference (MSD), or the Spearman's rank correlation coefficient ρ. Given the rankings IR of the n STS systems in the intrinsic evaluation and the rankings ER in the extrinsic evaluation with IR_i corresponding to the rank of the i-th STS system in the intrinsic evaluation and ER_i corresponding to the rank in the extrinsic evaluation, the values are defined as:

$$\rho(IR, ER) = \frac{\text{cov}(IR, ER)}{\sigma_{IR}\sigma_{ER}}$$

$$\text{MSD}(IR, ER) = \frac{1}{n}\sum_{i=1}^{n}(IR_i - ER_i)^2$$

$$\text{MAD}(IR, ER) = \frac{1}{n}\sum_{i=1}^{n}|IR_i - ER_i|$$

where $\text{cov}(IR, ER)$ is the covariance of the rankings and σ_{IR}, σ_{ER} are the standard deviations of the rank variables. An intrinsic evaluation with high predictiveness would have MAD and MSD values close to 0 and a Spearman's correlation ρ close to 1. We would consider an intrinsic evaluation of STS system useful, when it scores well on MAD, MSD, and ρ values for a large range of STS based tasks.

3.1 Experiments

To assess the predictiveness of different evaluation measures presented in section 2, we chose three STS based tasks and evaluated 14 different STS systems. We used the implementation for these systems from the publically available framework DKPro Similarity[2]. For each STS system, we computed the score in an intrinsic evaluation. For the intrinsic evaluation, we used the datasets provided for the SemEval 2012 task on Semantic Textual Similarity (Agirre et al., 2012). The intrinsic evaluation was performed for 16 different evaluation measures described in section 2. We then compared the ranking of the different STS systems in the intrinsic evaluation with the ranking of those in the STS based task, which allows to compute the *predictiveness* of the (intrinsic) evaluation measure.

As our first STS based task, we chose the task of text reuse detection. Clough and Stevenson (2011) presented the Wikipedia Rewrite Corpus, a dataset with 95 documents, each containing an answer to one

[2] `https://dkpro.github.io/dkpro-similarity/`

of five questions about computer science. The answers employ different levels of reuse of a Wikipedia article. The degree of reuse was split in one of four categories: `near copy`, `light revision`, `heavy revision`, and `non plagiarized`. The performance for this task is evaluated by calculating the accuracy. To map the continuous output of the STS systems to the four categories, we used the One Rule (OneR) classifier (Holte, 1993) with optimized bucket sizes as well as a logistic regression classifier. The OneR classifier chooses a simple decision boundary for the different classes. Both have been evaluated using 10-fold cross-validation and the classifier with the better result was chosen.

The second and third STS based task uses a newly created corpus compiled from the German newspaper DIE ZEIT and ZEIT Online[3]. For most of the articles, the authors added two links to related articles that provide further information on the same news topic. The second task is a binary classification task with the goal to identify whether two articles are related or not. The ground truth is the original choice from the journalist. The OneR classifier was used to map the continuous STS score to the binary decision. Results were evaluated using 10-fold cross-validation.

The third STS based task tries to detect the two articles that are related to the target article in a set of articles from ZEIT Online. For the target article and each article in the set, we compute the STS score. The article in the set with the highest STS score was selected. We compared if this article is one of the related articles chosen by the author. Accuracy was computed for 100 randomly selected documents.

3.2 Results

We evaluated 14 different STS systems for the three presented tasks. For the first STS based task on text reuse detection, the best STS system achieved an accuracy of 70%, while the worst achieved an accuracy of 43%. For the second STS based task on deciding whether two news articles are related, the best STS system achieved an accuracy of 77%, while the worst achieved an accuracy of 48%. And for the third STS based task on finding the related article out of a set of articles, the best STS system achieved an accuracy of 67%, while the worst achieved an accuracy of 6%.

We compared the performance of the different STS systems in the three tasks with their performance in the intrinsic evaluation. We expect that the intrinsic evaluation allows us to distinguish between well performing STS systems and bad performing STS systems. Table 2 shows the Spearman ranking coefficient $\rho(IR, ER)$ between the performance of the STS measures in the intrinsic evaluation versus their performance on the STS based tasks. A coefficient close to 1 indicates that the ranking of the system in the intrinsic evaluation was similar to its performance in the STS based task. The values for the two other predictiveness indicators, *Mean Absolute Difference* and *Mean Squared Difference* can be found are nearly identical to the Spearman rank coefficient. Thus, we omit them for brevity.

3.3 Discussion

In the three studied STS based tasks, there was no correlation between the performance of STS systems on the intrinsic evaluation using Pearson or Spearman rank correlation and their performance in the STS based tasks. In two cases, the correlation $\rho(IR, ER)$ between the intrinsic ranking IR and extrinsic ranking ER was even negative, indicating that STS systems that performed well in the intrinsic evaluation performed especially poorly in STS based tasks. From an engineering perspective this raises serious doubts about the value of an intrinsic evaluation that uses Pearson correlation.

Using other measures than Pearson correlation for the intrinsic evaluation however enabled a much better prediction of the performance of the STS systems for the STS based task. A strong STS system in such an intrinsic evaluation was also able to perform well in the STS based task. It is interesting to note that other STS based tasks were especially good predictors, i.e. an STS system performing well in task 1 was also performing well in task 2 and task 3, even though the characteristics of these tasks were very distinct. In all three tasks, the same STS system achieved the best result. However, in none of the performed intrinsic evaluations achieved this system the best place and was placed on 2nd to 6th place depending on the used evaluation measure. The system that achieved the best place in various intrinsic

Task 3: Related article detection	0.82		0.91			

Table 2: The Spearman rank correlation $\rho(IR, ER)$ between the intrinsic ranking IR and the extrinsic ranking ER for the three evaluated STS based tasks: (1) Text reuse classification, (2) binary classification of article pairs, and (3) related article detection. A ρ-coefficient close to 1 means a large correlation between the performance in the intrinsic evaluation and the performance in the STS based task. The *Rank* depicts the ranking, highest to lowest, of the ρ-coefficients for each task.

evaluations performed quite poorly for the STS based tasks only achieving the 6th, 9th, and 12th place, respectively, out of 14 tested systems.

4 Proposal of an Evaluation Framework for Semantic Textual Similarity

On a well-designed and representative dataset, an STS system should show similar behavior in the intrinsic evaluation as it will show for real world data of STS based tasks. For example, in case the STS system is well suited to find the most similar text pairs in the intrinsic evaluation set, then it will likely also be suitable to find the most similar text pairs for other datasets. This STS system would then be useful for tasks where finding the most similar text pairs is essential.

However, different STS based tasks have different requirements on STS systems and, therefore, different properties of STS systems are important. After studying the most common STS based tasks, we propose the following three dimensions to classify the requirements of an STS based task:

- **Cardinality** describes how many texts are compared to how many others. It consists of two sub categories *1:1* and *1:n*. *1:1* in this context means that exactly one text is compared with exactly one other text and only the result of this single comparison is of interest. *1:n* means that one text will be compared with a whole set of other texts and the results of these comparisons will be used in some way. The third option, *m:n*, would theoretically be possible, but no example of this was found.

- **Set of Interest** describes which of the elements of the result set will be used. It has three sub categories: *All*, *k-best*, and *Threshold*. *All* in this context means that all results of all comparisons will be used in some form. *k-best* describes the case where only the "k" best results will be used in some way. And *Threshold* is used when only results over a certain threshold will be used.

- **Information** describes the type of information from the result set that is of interest. It has three sub categories: *Value*, *Rank*, and *Classification*. The case where the actual value of the result of a comparison is of interest falls in the category *Value*. *Rank* on the other hand is used if only the rank of each comparison is used in some way. *Classification* means that a simple classification, for example texts are similar or not, is used.

The first STS based task in section 3.1 on text reuse is an example for a task with cardinality *1:1*, as one text, the answer, is compared to only one other text, the Wikipedia article. The STS score is classified into one of four categories, hence, the *Information* of interest is *Classification*. Tasks of such type can only tolerate minimal variety in the STS scores, i.e. texts of similar similarity should be mapped to similar scores independent of other factors like text length etc. Otherwise, the classification into categories doesn't work well.

The third STS based task in section 3.1 on detecting the related articles in a set of articles is an example for a task with cardinality *1:n*, set of interest *k-best* and information *Rank*. For this task, one document is compared to a set of other documents and the user is interested in the most similar pair. STS systems for this task should be good at ranking text pairs according to their similarity.

With the three dimensions 18 different combinations are possible. However, some of these combinations can be disregarded because they are not plausible. For any combination that involves a *Cardinality* of *1:1* only a *Set of Interest* of *All* is useful, because the result set contains only one result. In addition, the *Information* can't be *Rank*. Overall, only nine combinations are plausible. All nine possible combinations with examples of STS based tasks are described in detail in (Beyer, 2015).

For these nine plausible combinations, we propose in Table 3 an evaluation measure for the intrinsic evaluation that should capture the requirements of the target task. The proposed evaluation measures take similar characteristics into account that are required for the task. An NLP system designer could use this framework to determine the requirements of his task. Instead of selecting the STS system with the best Pearson correlation, the system designer would use the selected evaluation measure to run his own ranking of the STS systems to spot potentially strong STS systems for his task. The reasoning for the individual choices is given in (Beyer, 2015).

Requirements	**Proposed Evaluation Measure for Intrinsic Evaluation**
(1:1, All, Classification)	harmonic mean of F_1-score for low and high similarity pairs
(1:1, All, Value)	Pearson correlation
(1:n, All, Rank)	nDCG or Spearman rank correlation
(1:n, All, Classification)	harmonic mean of F_1-score for low and high similarity pairs
(1:n, All, Value)	Pearson correlation
(1:n, k-best, Value)	harmonic mean of nCG_k and Pearson correlation
(1:n, k-best, Rank)	nDCG_k
(1:n, Threshold, Value)	harmonic mean of F_1-score for low and high similarity pairs and Pearson correlation
(1:n, Threshold, Rank)	harmonic mean of F_1-score for low and high similarity pairs and Spearman rank correlation

Table 3: This Semantic Textual Similarity Framework proposes an evaluation measure for intrinsic evaluation based on the requirements of the target task.

An extensive evaluation of this framework is topic of our future research. The focus of this paper was establishing the need of alternative evaluation measures besides Pearson correlation and how to assess the quality of intrinsic evaluations. We encourage future work by others on this topic to find an intrinsic evaluation that meets the diverse needs of STS based tasks.

5 Conclusion and Future Work

In this paper we demonstrated the challenges of the intrinsic evaluation of STS systems. We introduced the concept of *predictiveness*: An STS system performing well in an intrinsic evaluation should also perform well for STS based tasks. This notion of predictiveness allows us to compare different evaluation measures besides the commonly used Pearson correlation. For three studied tasks we could observe that the predictiveness of an intrinsic evaluation with Pearson correlation is fairly low or even negative. We presented other evaluation measures which had a much higher predictiveness, i.e. those methods could predict much better which STS systems perform well in the STS based tasks. Based on this, we proposed a framework how to evaluate STS scores that take the requirements of the target task into account.

For future intrinsic evaluations of STS systems we find it crucial that not only the Pearson correlation is published, but additionally the STS scores generated by the systems can be downloaded. This allows to compute other evaluation measures, for example Spearman's ranking correlation, nDCG, or F_1-score. It also allows NLP system designers to select an evaluation measure for the intrinsic evaluation that captures the important characteristics needed by their target task.

In our experiments we could observe that the predictiveness of other extrinsic evaluations is high. Systems performing well on the task of text reuse of English Wikipedia articles also did well for detecting related articles on German news articles despite the fact of a different language, a different text genre and a completely different task. An alternative evaluation method of STS systems could be to test those on a broad range of different STS based tasks. The design of these STS based tasks must be standardized and the impact of components or features besides the STS system should be reduced to a minimum.

Expanding wordnets to new languages with multilingual sense disambiguation

Mihael Arcan **John P. McCrae** **Paul Buitelaar**

Abstract

Princeton WordNet is one of the most important resources for natural language processing, but is only available for English. While it has been translated using the *expand* approach to many other languages, this is an expensive manual process. Therefore it would be beneficial to have a high-quality automatic translation approach that would support NLP techniques, which rely on WordNet in new languages. The translation of wordnets is fundamentally complex because of the need to translate all senses of a word including low frequency senses, which is very challenging for current machine translation approaches. For this reason we leverage existing translations of WordNet in other languages to identify contextual information for wordnet senses from a large set of generic parallel corpora. We evaluate our approach using 10 translated wordnets for European languages. Our experiment shows a significant improvement over translation without any contextual information. Furthermore, we evaluate how the choice of pivot languages affects performance of multilingual word sense disambiguation.

1 Introduction

Princeton WordNet (Fellbaum, 1998) is a manually created resource that has been used in many different tasks and applications across linguistics and natural language processing. WordNet's hierarchical structure makes it a useful tool for many semantic applications and it also plays a vital role in modern deep learning based NLP systems (Rychalska et al., 2016). However, Princeton WordNet is only available for English and huge efforts have been made to extend WordNet with multilingual information in projects, such as EuroWordNet (Vossen, 1998), BalkaNet (Tufiş et al., 2004) and MultiWordNet (Pianta et al., 2002). However, most of the wordnet resources resulting from these efforts have fewer synsets than the Princeton WordNet and there are still many languages for which a wordnet does not exist or is not available to all potential users due to licensing restrictions, impacting applications in information retrieval, word sense disambiguation, sentiment analysis or knowledge management that rely on Princeton WordNet.

Most wordnets in languages other than English have followed an *extend* approach (Vossen, 2005), where the structure of Princeton WordNet is preserved and only the words in each synset are translated and new synsets are added for concepts, which are not lexicalized in English. Since manual multilingual translation and evaluation of wordnets using this approach is a very time consuming and expensive process, we apply statistical machine translation (SMT) to automatically translate WordNet entries. While an SMT system can only return the most frequent translation when given a term by itself, it has been observed that SMT provides strong word sense disambiguation when the word is given in the context of a sentence. As a motivating example, we consider the word *vessel*, which is a member of three synsets in Princeton WordNet, whereby the most frequent translation, e.g., as given by Google Translate, is *Schiff* in German and *nave* in Italian, corresponding to `i60833`[1] 'a craft designed for water transportation'. For the second sense, `i65336` 'a tube in which a body fluid circulates', we assume that we know the

[1] We use the CILI identifiers for synsets (Bond et al., 2016)

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 97–108, Osaka, Japan, December 11-17 2016.

German translation for this sense is *Gefäß*. In our approach we look for sentences in a parallel corpus, where the words *vessel* and *Gefäß* both occur and obtain a context such as 'blood vessel' that allows the SMT system to translate this sense correctly. This alone is not sufficient as *Gefäß* is also a translation of `i60834` 'an object used as a container', however in Italian these two senses are distinct (*vaso* and *recipiente* respectively), thus by using as many languages as possible we maximize our chances of finding a well disambiguated context.

In this work, we propose an approach to select the most relevant sentences from a parallel corpus based on the overlap with existing translations of WordNet in as many pivot languages as possible. The goal is to identify sentences that share the same semantic information in respect to the synset of the WordNet entry that we want to translate. This approach will allow us to provide a large multilingual WordNet in more than 20 different European languages, which we call Polylingual WordNet.[2] We present multiple evaluations of our approach and show that in general at least 4 languages should be used to assist in the selection of contexts and that languages closely related to the target language should be used in preference to more distant languages. We evaluated our approach on translating WordNet entries into Italian, Slovene, Spanish and Italian, showing improvements between 5 and more than 10 BLEU points compared to a generic translation approach. This approach has been used to expand wordnets for many European languages as well as generate the first wordnet for Maltese.

2 Related Work

Princeton WordNet inspired many researchers to create similarly structured wordnets for other languages. The EuroWordNet project (Vossen, 1998) linked wordnets in different languages through a socalled Inter-Lingual-Index (ILI) into a single multilingual lexical resource. Via this index, the languages are aligned between each other, which allows to go from a concept in one language to a concept with a similar meaning in any of the other languages. Further multilingual extensions were generated by the BalkaNet project (Tufiş et al., 2004), focusing on the Balkan languages and MultiWordNet (Pianta et al., 2002), aligning Italian concepts to English equivalents.

Due to the large interest in the multilingual extensions of the Princeton WordNet, several initiatives started with the aim to unifying and making these wordnets easily accessible. The KYOTO project (Fellbaum and Vossen, 2012) focused on the development of a language-independent module to which all existing wordnets can be connected, which would allow a better cross-lingual machine processing of lexical information. Recently this has been realized by a new Global WordNet Grid (Vossen et al., 2016) that takes advantage of the Collaborative Inter-Lingual Index (CILI) (Bond et al., 2016). Since most of the current non-English wordnets use the Princeton WordNet as a pivot resource, concepts, which are not in this English lexical resource cannot not be realized or aligned to it. Therefore the authors support the idea of a central platform of concepts, where new concepts may be added even if they are not represented (yet) in the Princeton WordNet or even lexicalized in English (e.g., many languages have distinct gendered role words, such as 'male teacher' and 'female teacher', but these meanings are not distinguished in English).

Previous studies of generating non-English wordnets combined Wiktionary knowledge with existing wordnets to extend them or to create new ones (de Melo and Weikum, 2009). Bond and Paik (2012) describe in their work the creation of the Open Multilingual Wordnet and its extension with other resources (Bond and Foster, 2013). A different approach to expand English WordNet synsets with lexicalizations in other languages was proposed in de Melo and Weikum (2012). The authors do not directly match concepts in the two different language resources, but demonstrate an approach that learns how to determine the best translation for English synsets by taking bilingual dictionaries, structural information of the English WordNet and corpus frequency information into account. With the growing amount of parallel data, Kazakov and Shahid (2009) show an approach to acquire a set of synsets from parallel corpora. The synsets are obtained by comparing aligned words in parallel corpora in several languages. Similarly, the sloWNet for Slovene (Fišer, 2007) and Wolf for French (Sagot and Fišer, 2008) are constructed using a multilingual corpus and word alignment techniques in combination with other existing lexical resources.

[2]The Polylingual WordNet is available at `http://polylingwn.linguistic-lod.org/`

Since all these approaches use word alignment information, they are not able to generate any translation equivalents for multi-word expressions (MWE). In contrast, our approach use an SMT system trained on a large amount of parallel sentences, which allows us to align possible MWEs, such as *commercial loan* or *take a breath*, between source and target language. Furthermore, we engage the idea of identifying relevant contextual information to support an SMT system translating short expressions, which showed better performance compared to approaches without a context. Arcan et al. (2015) built small domain-specific translation models for ontology translation from relevant sentence pairs that were identified in a parallel corpus based on the ontology labels to be translated. With this approach they improve the translation quality over the usage of large generic translation models. Since the generation of translation models can be computational expensive, Arcan et al. (2016) use large generic translation models to translate ontology labels, which were placed into a disambiguated context. With this approach the authors demonstrate translation quality improvement over commercial systems, like *Microsoft Translator*. Different from this approach, which uses the hierarchical structure of the ontology for disambiguation, we engage a large number of different languages to identify the relevant context.

Oliver and Climent (2012) present a method for WordNet construction and enlargement with the help of sense tagged parallel corpora. Since parallel sense tagged data are not always available, they use *Google Translate* to translate a manually sense tagged corpus. In addition they apply automatic sense tagging of a manually translated parallel corpus, whereby they report worse performance compared to the previous approach. We try to overcome this issue by engaging up to ten languages to improve the performance of the automatic sense tagging. Similarly, BabelNet (Navigli and Ponzetto, 2012) aligns the lexicographic knowledge from WordNet to the encyclopaedic knowledge of Wikipedia. This is done by assigning WordNet synsets to Wikipedia entries, and making these relations multilingual through the interlingual links. For languages, which do not have the corresponding Wikipedia entry, the authors use *Google Translate* to translate English sentences containing the synset in the sense annotated corpus. After that, the most frequent translation is included as a variant for the synset for the given language.

The use of parallel corpora has been previously exploited for word sense disambiguation, for example to construct sense-tagged corpora in another language (Ng et al., 2003) or by using translations as a method to discriminate senses (Ide et al., 2002). It has been shown that the combination of these techniques can improve supervised word sense disambiguation (Chan et al., 2007). A similar approach to the one proposed in this paper is that of Tufiş et al. (2004), where they show that using the interlingual index of WordNet with the help of parallel text can improve word sense disambiguation of a monolingual approach and we generalize this result to generate wordnets for new languages.

3 Methodology

Our approach takes the advantage of the increasing amount of parallel corpora in combination with wordnets in languages other than English for sense disambiguation, which will help us to improve automatic translations of English WordNet entries. We assume that we have a multilingual parallel corpus consisting of sentences, x_i^l in a language l, grouped into parallel translations:

$$\mathcal{X} = \{(x_i^{l_0}, \ldots, x_i^{l_T})\}$$

We also assume that we have a collection of wordnets consisting of a set of senses, w_{ij}^l, grouped into synsets, for each language:

$$\mathcal{S} = \{(\{w_{ij}^{l_0}\}, \ldots, \{w_{ij}^{l_T}\})\}$$

We say that a context $x_i^{l_0}$, in language l_0 (in our case this is always English), is *disambiguated in* n *languages* for a word $w_{jk}^{l_0}$ if:

$$\exists w_{jk_1}^{l_1}, \ldots, w_{jk_n}^{l_n} : w_{jk_1}^{l_1} \in x_i^{l_1} \wedge \ldots \wedge w_{jk_n}^{l_n} \in x_i^{l_n}$$

That is, a context is disambiguated in n languages for a word, if for each of its translations we have a context in the parallel corpus that contains one of the known synset translations. Furthermore, we assume

we have an SMT system that can translate any context in l_0 into our target language, l_T, and produces a phrase alignment such that we know which word in the output corresponds to the input word. We used the following methods to choose contexts for the SMT system:

None The SMT system is given only the word $w_{jk}^{l_0}$ as a single sentence as input, thus the most frequent translation is returned.

Random context A random $x_i \in \mathcal{X}$, such that $w_{jk}^{l_0} \in x_i^{l_0}$, is chosen.

Disambiguated context The contexts are ordered by the number of languages that they are disambiguated in, and the context that is disambiguated in the maximal number of languages is chosen. If there are multiple such languages, one context is chosen at random.

m **Disambiguated contexts** The contexts are ordered, as above, and the m top scoring contexts are used, with ties broken at random. Each of these contexts is given to the SMT system and the most frequent translation across these m contexts is used. The previous mode is the same as this when $m = 1$.

t**-best Translations** The SMT system is configured to return the t highest scoring translations, according to its model, and we select the translation as the most frequent translation of the context among this t-best list. In our experiments, we combined this with m disambiguations to give tm candidate translations from which the candidate is chosen.

Target Side Lookup (TSL) We can also utilize the translation of our context into the target language $x_i^{l_T}$ from the parallel corpus, however this cannot be applied directly as we do not know which word(s) in $x_i^{l_T}$ correspond to the input and previous work (Arcan et al., 2014) has shown that automatic inference of this alignment (e.g., with GIZA++) can seriously affect performance. Instead we filter contexts to those that generate a translation candidate, $w_k^{l_T}$, such that $w_k^{l_T} \in x_i^{l_T}$, i.e., the machine translation agrees with the gold-standard translation for this context.

4 Experimental Setting

This section gives an overview on the multilingual resources and the translation toolkit used in our experiment. Furthermore, we give insights into SMT evaluation techniques, considering the translation direction of the English WordNet entries into Italian, Slovene, Spanish and Croatian.

4.1 Wordnets for Sense Disambiguation in Parallel Corpora

Princeton WordNet is a large, publicly available lexical semantic database of English nouns, verbs, adjectives and adverbs, grouped into synsets ($\approx$ 117,000). We engage further wordnets in a variety of languages, provided by the Open Multilingual Wordnet web page.[3] The individual wordnets have been made by many projects and we use ten wordnets in different languages for our experiments, i.e, Croatian (Oliver et al., 2015), Dutch (Postma et al., 2016), Finnish (Lindén and Carlson., 2010), French (Sagot and Fišer, 2008), Italian (Toral et al., 2010), Polish (Maziarz et al., 2012), Portuguese (de Paiva and Rademaker, 2012), Romanian (Tufiş et al., 2008), Slovene (Fišer et al., 2012) and Spanish (Gonzalez-Agirre et al., 2012) WordNet. Table 1 illustrates the size of the wordnets and their coverage compared to the Princeton WordNet (last row).[4]

4.2 Statistical Machine Translation

Our approach is based on phrase-based SMT (Koehn et al., 2003), where we wish to find the best translation of a string, given by a log-linear model combining a set of features. The translation that maximizes the score of the log-linear model is obtained by searching all possible translations candidates.

[3] `http://compling.hss.ntu.edu.sg/omw/`

[4] Core refers to the percentage of synsets covered from the semi-automatically compiled list of 5000 "core" word senses in Princeton WordNet.

Language	Synsets	Words	Senses	Core	Language	Synsets	Words	Senses	Core
Croatian	23,120	29,008	47,900	100%	Polish	33,826	45,387	52,378	54%
Dutch	30,177	43,077	60,259	67%	Portuguese	43,895	54,071	74,012	84%
Finnish	116,763	129,839	189,227	100%	Romanian	56,026	49,987	84,638	94%
French	59,091	55,373	102,671	92%	Slovene	42,583	40,233	70,947	86%
Italian	35,001	41,855	63,133	83%	Spanish	38,512	36,681	57,764	76%

Table 1: Statistics on used wordnets for sense disambiguation on parallel corpora.

Parallel Corpus (language pair)	Source Words	Target Words	Parallel Sentences	Parallel Corpus (language pair)	Source Words	Target Words	Parallel Sentences
English–Croatian[1,2]	165M	133M	16M	English-Polish[2]	361M	296M	34M

English–French[2]	730M	784M	52M	English–Spanish[1,2]	391M	378M	37M
English–Italian[1,2]	273M	270M	22M	English–Romanian[2]	317M	302M	43M

Table 2: Statistics on parallel data for translation model training and word-sense disambiguation. (parallel resources used for training the translation models[1] and/or word-sense disambiguation[2])

The decoder, which is a search procedure, provides the most probable translation based on a statistical translation model learned from the training data.

For our translation task, we use the statistical translation toolkit Moses (Koehn et al., 2007), where word alignments, necessary for generating translation models, were built with the GIZA++ toolkit (Och and Ney, 2003). The Kenlm toolkit (Heafield, 2011) was used to build a 5-gram language model.

4.3 Parallel Resources for SMT training and Word-Sense-Disambiguation

To ensure a broad lexical and domain coverage of our SMT system we merged the existing parallel corpora for each language pair from the OPUS web page[5] into one parallel data set, i.e., Europarl (Koehn, 2005), DGT - translation memories generated by the *Directorate-General for Translation* (Steinberger et al., 2014), MultiUN corpus (Eisele and Chen, 2010), EMEA, KDE4, OpenOffice (Tiedemann, 2009), OpenSubtitles2012 (Tiedemann, 2012). Similarly, we concatenate parallel corpora for identifying relevant sentences containing WordNet entries, which are then translated into the targeted languages. Table 2 shows the number of parallel sentences used for the ten language pairs.

4.4 Translation Evaluation Metrics

The automatic translation evaluation is based on the correspondence between the SMT output and reference translation (gold standard). For the automatic evaluation we used the BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014) and chrF (Popović, 2015) metrics. **BLEU** (Bilingual Evaluation Understudy) is calculated for individual translated segments (n-grams) by comparing them with a data set of reference translations.[6] The calculated scores, between 0 and 100 (perfect translation), are averaged over the whole *evaluation data set* to reach an estimate of the translation's overall quality. Considering the short length of the terms in WordNet, while we report scores based on the unigram overlap (BLEU-1), this is in most cases only precision, so in addition we also report other metrics. **METEOR** (Metric for Evaluation of Translation with Explicit ORdering) is based on the harmonic mean of precision and recall, whereby recall is weighted higher than precision. Along with exact word (or phrase) matching it has additional features, i.e. stemming, paraphrasing and synonymy matching. In contrast to

[5] `http://opus.lingfil.uu.se/index.php`

[6] Due to the possibility of including multiple references for evaluation within the BLUE metric, we use the set of target words within a synset as our gold standard.

	types		tokens	
	Num.	Perc.	Num.	Perc.
English-Italian	507	6.3	521	4.2
English-Spanish	396	4.9	406	3.3
English-Slovene	633	7.9	656	5.3
English-Croatian	600	7.5	621	5.0

Table 3: Number of Out-Of-Vocabulary words and their percentage between translation models and WordNet senses.

	Number	Percentage
English-Italian	4239	40.35
English-Spanish	4436	42.22
English-Slovene	4523	43.04
English-Croatian	3986	37.94

Table 4: Statistics (actual number and percentage) of identified context for the evaluated WordNet Senses.

BLEU, the metric produces good correlation with human judgement at the sentence or segment level. **chrF3** is a character n-gram metric, which has shown very good correlations with human judgements on the WMT2015 shared metric task (Stanojević et al., 2015), especially when translating from English into morphologically rich(er) languages. As there are multiple translations available for each sense in the target wordnet we use all translations as multiple references for BLEU, for the other two metrics we compare only to the most frequent member of the synset.

The approximate randomization approach in MultEval (Clark et al., 2011) is used to test whether differences among system performances are statistically significant with a p-value < 0.05.

5 Evaluation

In this section we present the evaluation of the translated English WordNet words into Italian, Slovene, Spanish and Croatian. We evaluate the quality of translations of the WordNet entries based on the provided contextual information as well as the impact on the number of languages and their effect on word-sense disambiguation.

5.1 Translation Quality Evaluation Based on Contextual Information

Our main evaluation focuses on the importance of identifying relevant contexts for translation into Spanish, Italian, Slovene and Croatian. For a comparable evaluation we translated only senses within synsets, which exist in all four targeted languages. Due to the large parallel corpora used to build the translation models, only a small percentage of the used senses (10,507) could not be translated (Table 3). For this evaluation, we required contexts to be disambiguated by at least five out of nine[7] other languages. For around 40% of these senses we could identify relevant context, which was used to guide the SMT to translate the WordNet senses in the right domain (Table 4).

Table 5 illustrates the contribution of the provided contextual information, which supports the SMT system in translating the WordNet entries into the correct sense. We observed that translating a WordNet entry without any contextual information, which we consider as our baseline, provides better translations than translating them within a random context, as the most frequent translation is more likely to be correct than a random disambiguation. Once we identify one unambiguous sentence with a WordNet entry to be translated, the translation quality significantly improves in terms of the BLEU metric for all four targeted languages. Due to the large amount of parallel resources (between ≈15 and ≈50 Million sentences) we provide further a set of ten disambiguated sentences to the SMT system and select the most frequent translation of the targeted English WordNet entry. We observed, that the usage of most frequent translation helps us to improve the translation quality for 1.1 (for Slovene) and 0.7 (for Croatian) BLEU score points. In our last setting we provide the most frequent translation out of the set of t-best possible translations provided by the SMT system, however this does not seem to increase the quality of translation. Finally, in all settings we applied the target side lookup (TSL) procedure and found that it improves the quality of translation in nearly all settings.

[7]The target language is not used to help for sense disambiguation.

		English→Spanish			English→Slovene		
Context	TSL	BLEU-1	METEOR	chrF	BLEU-1	METEOR	chrF
None (baseline)	/	65.8	33.0	64.0	49.4	21.2	56.3

Table 5: Evaluation of WordNet translations into Spanish, Slovene, Italian and Croatian with context-aware techniques (TSL = Target Sentence Lookup; number of languages used for disambiguation = 5)

Error Analysis In order to investigate to what extent the automatically generated translations differ from the existing entries in the target wordnets we manually inspected the WordNet translations. We compare results where contextual information was used with the approach where WordNet entries were translated in isolation, hence without context. For Slovene, the contextual information provided a correct translation of the WordNet entry *space* (outer space/location outside the Earth's atmosphere, i81724) as *vesolje*, where the context-less translation approach produced the word *prostor*, in the meaning of place, room or property. Similarly, translating *medicine* (medical science, i38643) without contextual information provided a wrong translation as *zdravilo* (medication, drug, i56119), instead of the Slovene equivalent *medicina*. For Italian, an evident mistake was observed when translating the word *tip* (gratuity, i106560), where the translation of the word in isolation wrongly produced *punta*, meaning "the top or extreme point of something" (i82274). A correct translation in Italian supported by the contextual information was provided as *mancia*. Further, *union*, in the meaning of trade union or brotherhood (i80384), *sindacato* in Italian, was wrongly translated into the most dominant meaning *unione*, with its meaning of combination or cohesion. In Croatian, the word *weed* (i105476) as "any plant that crowds out cultivated plants", was wrongly translated into *trava* (drug street name, i57595), if translated in isolation. The correct translation as *korov* was generated with the disambiguated contextual information. For Spanish, *town* (i82504) was mistranslated into *ciudad* (city or large town), whereby the preferred sense of the translation *pueblo* (small town) was generated by using the contextual information.

5.2 Impact of the Number of Languages for Sense Disambiguation

Even with a very large parallel corpus, as we increase the number of languages, in which we disambiguate the sense, we find that for many senses we cannot find a context that is disambiguated in all languages. Thus, we evaluate the impact of changing the number of languages used to disambiguate an English

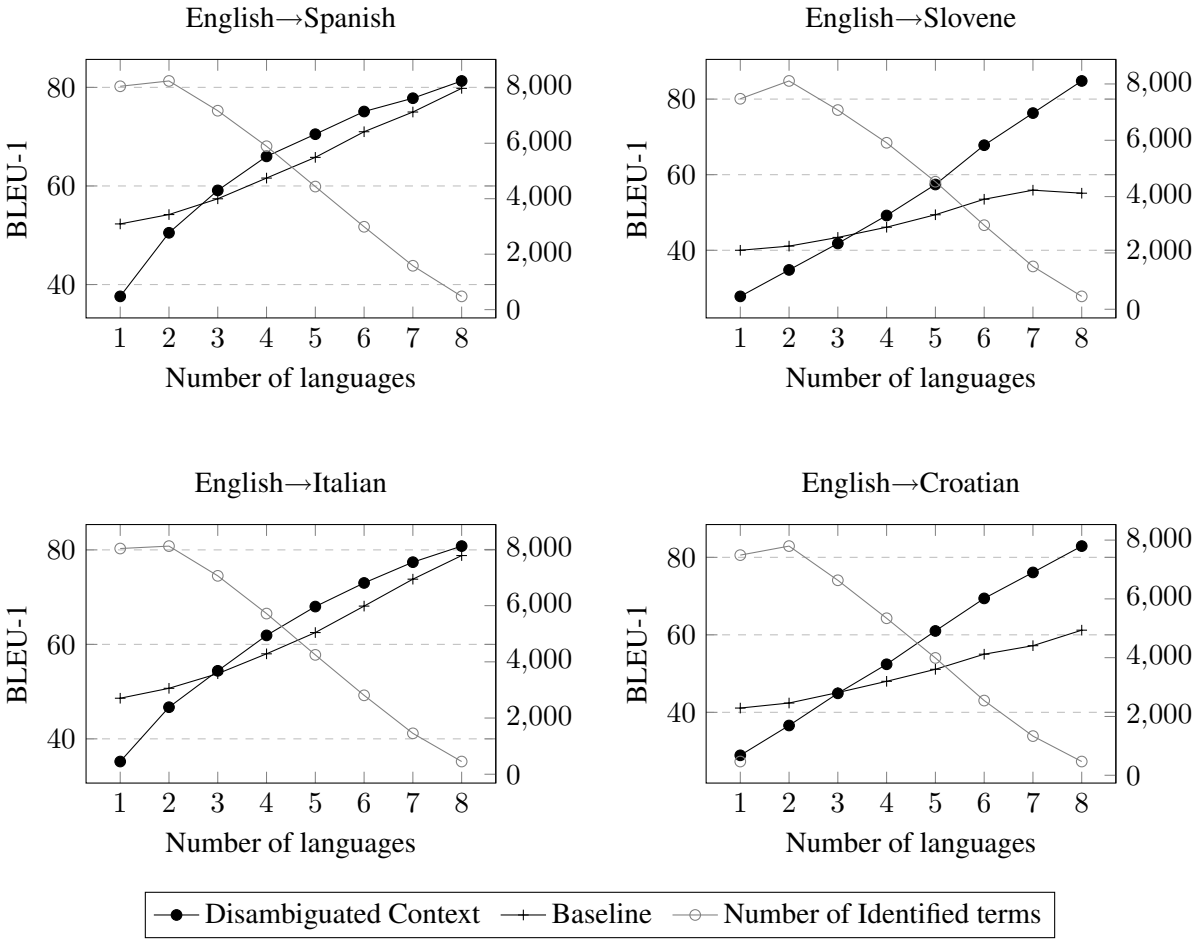

Figure 1: Impact of languages used for disambiguation and translation quality in terms of BLEU.

sentence. For this experiment we report the BLEU scores obtained by the best approach identified in Section 5.1, i.e. *10 disambiguated contexts*. For this evaluation we steadily increase the number of languages that we require a sense to be disambiguated in. We compare these results to the baseline setting, where WordNet entries are translated without any context. As the total number of senses that can be translated decreases, the BLEU score for the baseline does not stay constant and in fact increases, as the senses that our method can disambiguate in many languages are those that are more frequent and less ambiguous. Nevertheless, the disambiguation outperforms the baseline if the context is disambiguated in more than three languages (Figure 1).

For the Romance languages (Italian and Spanish), we outperform the baseline between 3 and 6 BLEU points. The improvement is more evident for the Slavic languages (Slovene and Croatian), where the differences can reach more than 10 BLEU points, if five or more languages are used. For all targeted languages, the observed improvements are statistically significant ($p<0.005$).

5.3 Impact of Language Family for Sense Disambiguation

In addition to the evaluation based on disambiguated contextual information and number of different languages, we were interested in how the similarity of languages affects the disambiguation. Firstly, we focus on the translations of English, a Germanic language, into Slovene, which is a member of the Slavic language family. We considered the cases, where the context is disambiguated in four languages, but looked at two different sets of four languages. Firstly, a group where four languages are of the same family, but different to the source and target language, using four Romance languages: French, Spanish, Romanian and Portuguese. Secondly, we evaluate the sense disambiguation approach using two Romance languages, French and Spanish, and two Slavic languages, Croatian and Polish. As illustrated

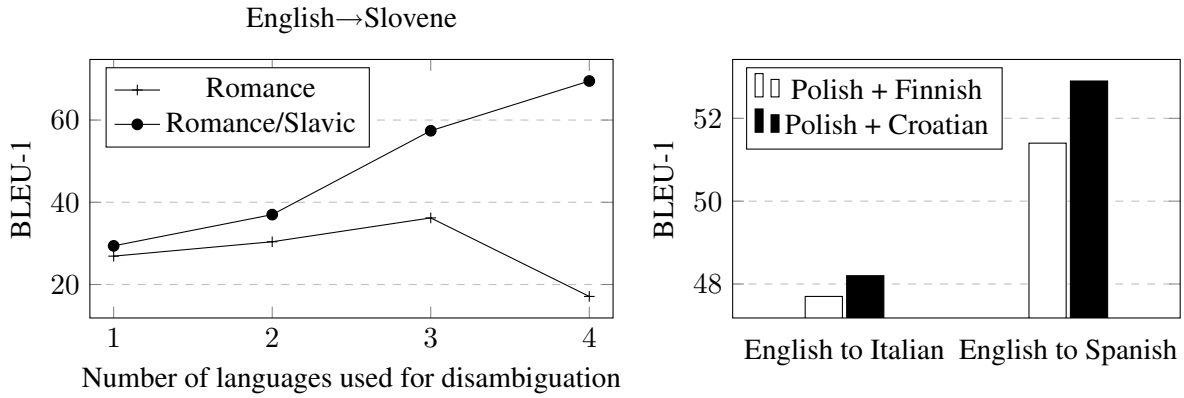

Figure 2: Evaluation on impact of closely-related languages on sense disambiguation for translation quality.

in Figure 2 (left part) the contextual disambiguation approach work significantly better if languages, closely related to the target language – in our case Slovene – are used. In our scenario including the Slavic languages to disambiguate the context yields to better translation quality compared to the usage of only Romance languages.

Secondly, we evaluated our approach if a very distant language is used in the disambiguation, namely Finnish, which is not part of the Indo-European family, the super-family of Romance, Germanic and Slavic languages. We perform disambiguation using Polish and Finnish and compare the results when Finnish is replaced with the Croatian language. The results in Figure 2 (right part) show that Finnish has less disambiguation power than Croatian even though Croatian is similar to Polish. This is because Croatian, even though it is not close to Spanish or Italian is still much closer than Finnish is.

This experiment showed that closely related languages contribute in the disambiguation approach, which yields in our scenario to better translation quality. They also show that using a diverse selection of highly distinct languages does not seem to be advantageous in disambiguating senses.

6 Conclusion and Future Work

We showed an automatic approach to increase the coverage of WordNet into different languages with high-quality translations. By identifying disambiguated context, we demonstrate statistical significant translation improvement for Spanish, Italian, Slovene and Croatian. We demonstrate the importance on closely related languages used for the sense disambiguation approach, which will help us in our ongoing work on generating translations of wordnets beyond the four targeted languages used in this work. This method allows us to release high quality extensions of Princeton WordNet, expanding the coverage for many languages, as well as creating wordnets for languages, where no wordnet has been created or the wordnet is not available to all potential users due to licensing issues.

Abstract

Interlingua based Machine Translation (MT) aims to encode multiple languages into a common linguistic representation and then decode sentences in multiple target languages from this representation. In this work we explore this idea in the context of neural encoder decoder architectures, albeit on a smaller scale and without MT as the end goal. Specifically, we consider the case of three languages or modalities X, Z and Y wherein we are interested in generating sequences in Y starting from information available in X. However, there is no parallel training data available between X and Y but, training data is available between X & Z and Z & Y (as is often the case in many real world applications). Z thus acts as a pivot/bridge. An obvious solution, which is perhaps less elegant but works very well in practice is to train a two stage model which first converts from X to Z and then from Z to Y. Instead we explore an interlingua inspired solution which **jointly learns** to do the following (i) encode X and Z to a common representation and (ii) decode Y from this common representation. We evaluate our model on two tasks: (i) bridge transliteration and (ii) bridge captioning. We report promising results in both these applications and believe that this is a right step towards truly interlingua inspired encoder decoder architectures.

1 Introduction

Interlingua based MT (Nirenburg, 1994; Dorr et al., 2010) relies on the principle that every language in the world can be mapped to a common linguistic representation. Further, given this representation, it should be possible to decode a target sentence in any language. This implies that given n languages we just need n decoders and n encoders to translate between these ${}^nC_2$ language pairs. Note that even though we take inspiration from interlingua based MT, the focus of this work is not on MT. We believe that this idea is not just limited to translation but could be applicable to any kind of conversion involving multiple source and target languages and/or modalities (for example, transliteration, multilingual image captioning, multilingual image Question Answering, *etc.*). Even though this idea has had limited success, it is still fascinating and considered by many as the holy grail of multilingual multimodal processing.

It is interesting to consider the implications of this idea when viewed in the statistical context. For example, current state of the art statistical systems for MT (Koehn et al., 2003; Chiang, 2005; Luong et al., 2015b), transliteration (Finch et al., 2015; Shao et al., 2015; Nicolai et al., 2015), image captioning (Vinyals et al., 2015b; Xu et al., 2015), *etc.* require parallel data between the source and target views (where a view could be a language or some other modality like image). Thus, given n views, we require ${}^nC_2$ parallel datasets to build systems to convert from any source view to any target view. Obviously, this does not scale well in practice because it is hard to find parallel data between all ${}^nC_2$ views. For example, publicly available parallel datasets for transliteration (Zhang et al., 2012) cater to < 20 languages. Similarly, publicly available image caption datasets are available only for English[1] and German[2].

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 109–118, Osaka, Japan, December 11-17 2016.

This problem of resource scarcity could be alleviated if we could learn only n statistical encoders and n statistical decoders wherein (i) the encoded representation is common across languages and (ii) the decoders can decode from this common representation (akin to interlingua based conversion). As a small step in this direction, we consider a scaled down version of this generic ${}^nC_2$ conversion problem. Specifically, we consider the case where we have three views X, Z, Y but parallel data is available only between XZ and ZY (instead of all ${}^3C_2$ parallel datasets). At test time, we are interested in generating natural language sequences in Y starting from information available in X. We refer to this as the bridge setup as the language Z here can be considered to be a bridge/pivot between X and Y.

An obvious solution to the above problem is to train a two-stage system which first converts from X to Z and then from Z to Y. While this solution may work very well in practice (as our experiments indeed suggest) it is perhaps less elegant and becomes tedious as the number of views increases. For example, consider the case of converting from X to Z to R to Y. Instead, we suggest a neural network based model which simultaneously learns the following (i) a common representation for X and Z and (ii) decoding Y from this common representation. In other words, instead of training two independent models using the datasets between XZ and ZY, the model jointly learns from the two datasets. The resulting common representation learned for X and Z can be viewed as a vectorial analogue of the linguistic representation sought by interlingua based approaches. Of course, by no means do we suggest that this vectorial representation is a substitute for the rich linguistic representation but its easier to learn from parallel data (as opposed to a linguistic representation which requires hand crafted resources).

Note that our work should not be confused with the recent work of (Firat et al., 2016), (Zoph and Knight, 2016) and (Elliott et al., 2015). The last two works in fact require 3-way parallel data between X, Z and Y and learn to decode sequences in Y given both X and Z. For example, at test time, (Elliott et al., 2015) generate captions in German, given both (i) the image and (ii) its corresponding English caption. This is indeed very different from the problem addressed in this paper. Similarly, even though (Firat et al., 2016) learn a single encoder per language and a single decoder per language they do not learn shared representations for multiple languages (only the attention mechanism is shared). Further, in all their experiments they require parallel data between the two languages of interest. Specifically, they do not consider the case of generating sentences in Y given a sentence in X when no parallel data is available between X and Y.

We present an empirical comparison of jointly trained models which explicitly aim for shared encoder representations with two-stage architectures. We consider two downstream applications (i) bridge transliteration and (ii) bridge caption generation. We use the standard NEWS 2012 dataset (Zhang et al., 2012) for transliteration. We consider transliteration between 12 languages pairs (XY) using English as the bridge (Z). Bridge caption generation is a new task introduced in this paper where the aim is to generate French captions for an image when no Image-French(XY) parallel data is available for training. Instead training data is available between Image-English (XZ) and English-French (ZY). In both these tasks we report promising results. In fact, in our multilingual transliteration experiments we are able to beat the strong two-stage baseline in many cases. These results show potential for further research in interlingua inspired neural network architectures. We do acknowledge that a successful interlingua based statistical solution requiring only n encoders and n decoders is a much harder task whereas our work is only a small step in that direction.

2 Related Work

Encoder decoder based architectures for sequence to sequence generation were initially proposed in (Cho et al., 2014; Sutskever et al., 2014) in the context of Machine Translation (MT) and have also been successfully used for generating captions for images (Vinyals et al., 2015b). However, such sequence to sequence models are often difficult to train as they aim to encode the entire source sequence using a fixed encoder representation. Bahdanau et al. (2014) introduced attention based models wherein a different representation is fed to the decoder at each time step by focusing the attention on different parts of the input sequence. Such attention based models have been more successful than vanilla encoder-decoder models and have been used successfully for MT (Bahdanau et al., 2014), parsing (Vinyals et

al., 2015a), speech recognition (Chorowski et al., 2015), image captioning (Xu et al., 2015) among other applications. All the above mentioned works focus only on the case when there is one source and one target. The source can be image, text, or speech signal but the target is always a text sequence.

Encoder decoder models in a multi-source, single target setting have been explored by (Elliott et al., 2015) and (Zoph and Knight, 2016). Specifically, Elliott et al. (2015) try to generate a German caption from an image and its corresponding English caption. Similarly, Zoph and Knight (2016) focus on the problem of generating English translations given the same sentence in both French and German. We would like to highlight that both these models require three-way parallel data while we are focusing on situations where such data is not available. Single source, multi-target and multi-source, single target settings have been considered in (Luong et al., 2015a). Recent work by Firat et al. (2016) explores multi-source to multi-target encoder decoder models in the context of MT. However, Firat et al. (2016) focus on multi-task learning with a shared attention mechanism and the goal is to improve the MT performance for a pair of languages for which parallel data is available. This is clearly different from the goal of this paper which is to design encoder decoder models for a pair of languages where no parallel data is available but data is available only between each of these languages and a bridge language.

Of course, in general the idea of pivot/bridge/interlingua based conversion is not new and has been used previously in several non-neural network settings. For example (Khapra et al., 2010) use a bridge language or pivot language to do machine transliteration. Similarly, (Wu and Wang, 2007; Zhu et al., 2014) do pivot based machine translation. Lastly, we would also like to mention the work in interlingua based Machine Translation (Nirenburg, 1994; Dorr et al., 2010) which is clearly the inspiration for this work even though the focus of this work is not on MT.

The main theme explored in this paper is to learn a common representation for two views with the end goal of generating a target sequence in a third view. The idea of learning common representations for multiple views has been explored well in the past (Klementiev et al., 2012; Chandar et al., 2014; Hermann and Blunsom, 2014; Chandar et al., 2016; Rajendran et al., 2015). For example, Andrew et al. (2013) propose Deep CCA for learning a common representation for two views. (Chandar et al., 2014; Chandar et al., 2016) propose correlational neural networks for common representation learning and Rajendran et al. (2015) propose bridge correlational networks for multilingual multimodal representation learning. From the point of view of representation learning, the work of Rajendran et al. (2015) is very similar to our work except that it focuses only on representation learning and does not consider the end goal of generating sequences in a target language.

3 Models

As mentioned earlier, one of the aims of this work is to compare a jointly trained model with a two stage model. We first briefly describe such a two stage encoder decoder architecture and then describe our model which is a correlation based jointly trained encoder decoder model.

3.1 A two stage encoder-decoder model

A two stage encoder-decoder is a straight-forward extension of sequence to sequence models (Cho et al., 2014; Sutskever et al., 2014) to the bridge setup. Given parallel data between XZ and ZY, a two stage model will learn a generative model for each of the pairs independently. For the purpose of this work, the source can be an image or text but the target is always a natural language text. For encoding an image, we simply take its feature representation obtained from one of the fully connected layers of a convolutional neural network and pass it through a feed-forward layer. On the other hand, for encoding the source text sequence, we use a recurrent neural network. The decoder is always a recurrent neural network which generates the text sequence, one token at a time.

Let the two training sets be $\mathcal{D}_1 = \{x_i, z_i\}_{i=1}^{N_1}$ and $\mathcal{D}_2 = \{z_i, y_i\}_{i=1}^{N_2}$ where $x_i \in X$, $y_i \in Y$ and $z_i \in Z$. Given $\mathcal{D}_1$, the first encoder learns to encode x_i and decode the corresponding z_i from this encoded representation. The second encoder is trained independently of the first encoder and uses $\mathcal{D}_2$ to encode $z_i \in Z$ and decode the corresponding $y_i \in Y$ from this encoded representation. These independent training processes are indicated by the dotted arrows in Figure 1. At test time, the two

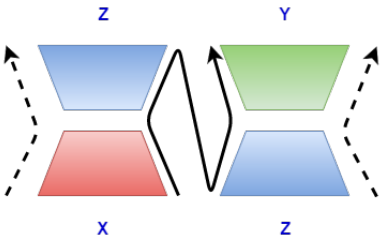

Figure 1: Two stage encoder-decoder model. Dashed lines denote how the model is used during training time and solid line denotes the test time usage. We can see that two encoder-decoders are trained independently but used jointly during testing.

stages are run sequentially. In other words, given x_j, we first encode it and decode z_j from it using the first encoder-decoder model. This decoded z_j is then fed to the second encoder-decoder model to generate y_j. This sequential test process is indicated by solid arrows in Figure 1.

While this two stage encoder-decoder model is a trivial extension of a single encoder-decoder model, it serves as a very strong baseline as we will see later in the experiments section.

3.2 A correlation based joint encoder-decoder model

While the above model works well in practice, it becomes cumbersome when more views are involved (for example, when converting from U to X to Y to Z). We desire a more elegant solution which could scale even when more views are involved (although for the purpose of this work, we restrict ourselves to 3 views only). To this end, we propose a joint model which uses the parallel data $\mathcal{D}_1$ (as defined above) to learn one encoder each for X and Z such that the representations of x_i and z_i are correlated. In addition and simultaneously the model uses $\mathcal{D}_2$ and learns to decode y_j from z_j. Note that this joint training has the advantage that the encoder for Z benefits from instances in $\mathcal{D}_1$ and $\mathcal{D}_2$.

Having given an intuitive explanation of the model, we now formally define the objective functions used during training. Given $\mathcal{D}_1 = \{x_i, z_i\}_{i=1}^{N_1}$, the model tries to maximize the correlation between the encoded representations of x_i and z_i defined as

$$\mathcal{J}_{\text{corr}}(\theta) = -\lambda \, \text{corr}(s(h_X(X)), s(h_Z(Z))) \tag{1}$$

where h_X is the representation computed by the encoder for X and h_Z is the representation computed by the encoder for Z. As mentioned earlier, these encoders could be RNN encoders (in the case of text) and simple feedforward encoders (in the case of images). $s()$ is a standardization function which adjusts the hidden representations h_X and h_Y so that they have zero-mean and unit-variance. Further, λ is a scaling hyperparameter and corr is the correlation function defined as

$$\sum_{i=1}^{N} s(h_X(x_i)) s(h_Z(z_i))^T \tag{2}$$

We would like to emphasize that $s()$ ensures that the representations already have zero mean and unit variance and hence no separate standardization is required while computing the correlation. In addition to the above loss function, given $\mathcal{D}_2 = \{z_i, y_i\}_{i=1}^{N_2}$, the model minimizes the cross entropy loss

$$\mathcal{J}_{\text{ce}}(\theta) = \frac{1}{N_2} \sum_{k=1}^{N_2} P(y_k|z_k); \qquad P(y_k|z_k) = \prod_{i=1}^{L} P(y_{k_i}|y_{k_{<i}}, z_k) \tag{3}$$

where L is the number of tokens in y_k.

The dotted lines in Figure 2 show the joint training process where the model simultaneously learns to compute correlated representations for x_i and z_i and decode y_i from z_i. The testing process is shown by the solid lines wherein the model computes a hidden representation for x_i and then decodes y_i from it directly without transitioning through z_i.

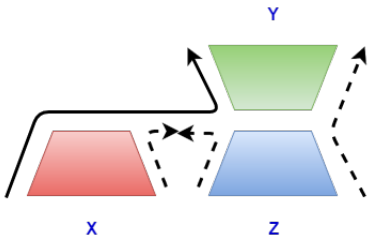

Figure 2: Correlated encoder-decoder model. Dashed lines denote how the model is used during training time and solid line denotes the test time usage. We can see that during training, both the encoders are trained to produce correlated representations and the decoder for Y is trained based on encoder Z. During test time only encoder for X and decoder for Y are used.

While training, we alternately pick mini-batches from $\mathcal{D}_1$ and $\mathcal{D}_2$ and use the corresponding objective function. Means and variances for the representations computed by the two encoders are updated at the end of every epoch based on the hidden representations of all instances in the training data. During the first epoch we assume the mean and variance to be 0 and 1. Note that λ rescales the value of the correlation loss term so that it is in the same range as the value of the cross-entropy loss term.

4 Experiment 1: Bridge Transliteration

We consider the task of transliteration between two languages X and Y when no direct data is available between them but parallel data is available between X & Z and Z & Y. In the following subsections we describe the datasets used for our task, the hyperparameters considered for our experiments and results.

4.1 Datasets

We consider transliteration between 4 languages, *viz.*, Hindi, Kannada, Tamil and Marathi resulting in ${}^4C_2 = 12$ language pairs. However, we do not use any direct parallel data between any of these languages. Instead we use the standard datasets available between English and each of these languages which were released as part of the NEWS 2012 shared task (Zhang et al., 2012). Just to be explicit, for the task of transliterating from Hindi to Kannada, we construct $\mathcal{D}_1$ from the English-Hindi dataset and $\mathcal{D}_2$ from the English-Kannada dataset. The size of the training set (in words) for the four language pairs English-Hindi, English-Kannada, English-Marathi and English-Tamil is 19918, 16556, 8500 and 16857 respectively and the validation and test set sizes (in words) are 500 and 1000 respectively. Fortunately, the English portion of the test set was common across all these four language pairs, thus allowing us to easily create test sets for all the 12 language pairs. For example, if h_i is the transliteration of the English word e_i in the English-Hindi test set and k_i is the transliteration of the same English word e_i in the English-Kannada test set then we add (h_i, k_i) as a transliteration pair in our Hindi-Kannada test set. In this way, we created test sets containing 1000 words for all the 12 language pairs.

4.2 Hyperparameters

For the two stage encoder decoder model, we considered the following hyperparameters: embedding size $\in \{1024, 2048\}$ for characters, rnn hidden unit size $\in \{1024, 2048\}$, initial learning rate $\in \{0.01, 0.001\}$ and batch size $\in \{32, 64\}$. The numbers in bracket indicate the distinct values that we considered for each hyperparameter. Note that the embedding size and rnn size are always kept equal. All these parameters were tuned independently for the two stages using their respective validation sets. For the correlated encoder decoder model, in addition to the above hyperparameters we also had $\lambda \in [0.1, 1.0]$ as a hyperparameter. Here, we tuned the hyperparameters based on the performance on the validation set available between ZY (since the correlated encoder decoder can also decode $y_i \in Y$ from $z_i \in Z$). Note that we do not use any parallel data between XY for tuning the hyperparameters because the general assumption is that no parallel data is available between XY. We used Adam (Kingma and Ba, 2014) as the optimizer for all our experiments.

Two Stage PBSMT

4.3 Results

We compare our model with the following systems:
1. Two Stage PBSMT: Here, we train two PBSMT (Koehn et al., 2003) based transliteration systems using $\mathcal{D}_1$ and $\mathcal{D}_2$. This is an additional baseline to see how well an encoder decoder architecture compares to a conventional PBSMT based system. We used Moses (Koehn et al., 2007) for building our PBSMT systems. The decoder parameters were tuned using the validation sets. Language model was trained on the target portion of the parallel corpus.
2. Two Stage Encoder Decoder: Here, we train two encoder decoder based transliteration systems using $\mathcal{D}_1$ and $\mathcal{D}_2$ as described in Section 3.1.

Table 1 summarizes the accuracy (% of correct transliterations) of the three systems in the bridge setup. We observe that in 6 out of the 12 language pairs our correlated model does better than the 2 stage encoder decoder model. Further, it does better than the two-stage PBSMT baseline in 11 out of the 12 language pairs. This is very encouraging especially because such 2-stage approaches are considered to be very strong baselines for these tasks (Khapra et al., 2010). In general, the encoder decoder based approaches do better than PBSMT based systems. This is indeed the case even when we compare the performance of the PBSMT based system and the Encoder Decoder based system independently on the two stages (Table 2).

5 Experiment 2: Bridge Captioning

We now introduce the task of bridge caption generation. The purpose of introducing this task is two-fold. Firstly, we feel that it is important to put things in perspective and demonstrate that while interlingua inspired encoder decoder architectures are a step in the right direction, much more work is needed when dealing with different modalities in a bridge setup. Secondly, we think that this is an important task which has not received any attention in the past. We would like to formally define and report some initial baselines to motivate further research in this area. The formal task definition is as follows: Generate captions for images in language L_1 (say, French) when no parallel data is available between images and L_1 but parallel data is available between Image-L_2 ($\mathcal{D}_1$) and between L_1-L_2 ($\mathcal{D}_2$) where L_2 is another language (say, English). In the following subsection we describe the datasets used for this task, the hyperparameters considered for our experiments and the results.

5.1 Datasets

Even though we do not have direct training data between Image-French, we need some test data to evaluate our model. For this, we use the Image-French test set recently released by (Rajendran et al.,

Systems	BLEU-4	BLEU-3	BLEU-2	BLEU-1	ROUGE-L	CIDEr
Pseudo Im-Fr	15.5	24.2	37.4	56.5	38.3	41.2
Two Stage	**16.6**	**25.7**	**39.0**	**58.3**	**39.5**	**49.1**
Correlational Encoder Decoder	12.6	19.3	31.1	50.5	34.3	29.8

Table 3: Image Captioning performance in generating French caption for a given image for the three methods: Pseudo Im-Fr, Two Stage and our Correlational Encoder Decoder based model.

2015). To create this data, they first merged the 80K images from the standard train split and 40K images from the standard valid split of MSCOCO data. They then randomly split the merged 120K images into train(118K), validation (1K) and test set (1K). They then collect French translations for all the 5 captions for each image in the test set using crowdsourcing. CrowdFlower (`https://make.crowdflower.com`) was used as the crowdsourcing platform and they solicited one French and one German translation for each of the 5000 captions using native speakers. Note that (Rajendran et al., 2015) report results for cross modal search and do not address the problem of crosslingual image captioning.

In our model, for D_1 we use the same train(118K), validation (1K) and test sets (1K) as defined in (Rajendran et al., 2015) and explained above. Choosing $\mathcal{D}_2$ was a bit more tricky. Initially we considered the corpus released as part of WMT'12 (Callison-Burch et al., 2012) which contains roughly 44M English-French parallel sentences from various sources including News, parliamentary proceedings, etc. However, our initial small scale experiments showed that this does not work well because there is a clear mismatch between the vocabulary of this corpus and the vocabulary that we need for generating captions. Also the vocabulary is much larger (at least an order higher than what we need for image captioning) and it thus hampers training. Further, the average length and structure of these sentences is also very different from captions. Domain shift in MT is itself a challenging problem (not to mention the added complexity in a multimodal bridge setup). It was unrealistic to expect our model to work in the presence of these orthogonal complexities.

To isolate these issues and evaluate our model in a controlled environment, we needed a parallel corpus which had very similar characteristics to that observed in captions. Since we did not have such a corpus at our disposal we decided to follow (Rajendran et al., 2015) and use a pseudo parallel corpus between English-French. Specifically, we take the English captions from the MSCOCO data and translate them to French using the publicly available translation system provided by IBM (`http://www.ibm.com/smarterplanet/us/en/ibmwatson`). Note that our model still does not see direct parallel data between Image and French during training. We acknowledge that this is not the ideal thing to do but it is good enough to do a proof-of-concept evaluation of our model and understand its potential. We, of course, account for the liberty taken here by comparing with equally strong baselines as discussed later in the results section.

5.2 Hyperparameters

Our model has the following hyperparameters: embedding size, batch size, hidden representation size, λ and learning rate. Based on experiments involving direct Image-to-English caption generation we observed that the following parameters work well : embedding size = 512, batch size = 80, rnn hidden unit size = 512, and learning rate = 4e-4 with Adam (Kingma and Ba, 2014) as the optimizer. We just retained these hyperparameters and did not tune them again for the bridge setup. We tuned the value of λ by evaluating the correlation loss on the Image-English validation set. Again, we do not use any Image-French data for tuning any hyperparameters.

5.3 Results

We now present the results of our experiments where we compare with the following strong baselines.
1. Two Stage : Here we use a Show & Tell model (Vinyals et al., 2015b) trained using D_1 to generate an English caption for the image. We then translate this caption into French using IBM's translation system as described above.
2. Pseudo Im-Fr : Here we train an Image-to-French Show & Tell model (Vinyals et al., 2015b) by pairing the images in the MSCOCO dataset with their pseudo French captions generated by translating

MSCOCO Images						
Correlational Encoder Decoder	Un homme est surfer sur une vague dans l'océan	Un skateur est en train de décoller sur un skateboard	Une plaque avec un sandwich et un verre de bière	Une girafe est debout dans la poussière près d'une arborescence	Un bus de transport en commun dans une rue de la ville	Un salon avec un canapé , une table et un téléviseur
Two-Stage	Un homme circonscription une vague sur une planche de surf	Un homme circonscription un skateboard sur une rampe en bois	Une plaque de nourriture sur une table avec un verre de vin	Une girafe debout dans un champ avec des arbres en arrièreplan	Un bus double sandwich au volant dune rue	Un salon avec un canapé fauteuil et une télévision
Pseudo Im-Fr	Un internaute dans une combinaison isothermique est circonscription une vague	Un jeune garçon circonscription un skateboard dans un parc	Une plaque de nourriture sur une table en bois	Une girafe debout à côté d'un autre girafe dans une zone	Un bus ville faire baisser une rue de la ville	Un salon avec un canapé , une table et un canapé

Table 4: Example captions generated by the three methods on a sample set of MSCOCO test images

the English captions into French (using IBM's translation system).

We observe that our model is unable to beat the two strong baselines described above but still comes close to their performance. We believe this reinforces our belief in this line of research and hopefully more powerful models (perhaps attention based) could eventually surpass these two baselines.

As a qualitative evaluation of our model, Table 4 shows the captions generated by our model. It is exciting that even in a complex multimodal bridge setup the model is able to capture correlations between Images and English sentences and further decode relevant French captions from a given image.

The code and datasets used for Experiment 1 and 2 would be made available on request.

6 Conclusion

In this paper, we considered the problem of pivot based sequence generation. Specifically, we are interested in generating sequences in a target language starting from information in a source view. However, no direct training data is available between the source and target views but data is available between each of these views and a pivot view. To this end, we take inspiration from interlingua based MT and propose a neural network based model which explicitly maximizes the correlation between the source and pivot view and simultaneously learns to decode target sequences from this correlated representation. We evaluate our model on the task of bridge transliteration and show that it outperforms a strong two-stage baseline for many language pairs. Finally, we introduce a novel bridge caption generation task and report promising initial results. We hope this new task will fuel further research in this area.

As future work, we would like to go beyond simple encoder decoder based correlational models. For example, we would like to apply the idea of correlation to attention based encoder decoder models. The ideas expressed here can also be applied to other tasks such as bridge translation, bridge Image QA, etc. However, for these tasks, additional issues such as larger vocabulary sizes, complex sentence structures, non-monotonic alignments between source and target language pairs need to be addressed. The model proposed here is just a beginning and much more work is needed to cater to these complex tasks.

Zero-resource Dependency Parsing: Boosting Delexicalized Cross-lingual Transfer with Linguistic Knowledge

Abstract

This paper studies cross-lingual transfer for dependency parsing, focusing on very low-resource settings where delexicalized transfer is the only fully automatic option. We show how to boost parsing performance by rewriting the source sentences so as to better match the linguistic regularities of the target language. We contrast a data-driven approach with an approach relying on linguistically motivated rules automatically extracted from the World Atlas of Language Structures. Our findings are backed up by experiments involving 40 languages. They show that both approaches greatly outperform the baseline, the knowledge-driven method yielding the best accuracies, with average improvements of +2.9 UAS, and up to +90 UAS (absolute) on some frequent PoS configurations.

1 Introduction

The need to automatically process an increasing number of languages has made obvious the extreme dependency of standard development pipelines on in-domain, annotated resources that are required to train efficient statistical models. However, for most languages, annotated corpora only exist for a restricted number of domains, when they exist at all. In response to such low-resource scenario, four main strategies have been considered. The first is to hire experts and handcraft these resources, possibly with the help of active learning techniques: Garrette and Baldridge (2013) show that this strategy can be effective and probably cheaper than expected. An alternative is to use models learned on some resource-rich *source language(s)* to process a low-resource *target language*; note that this is only possible once the source and target data have been mapped into a shared representation space (Zeman and Resnik, 2008). When source-target parallel corpora are available, a third approach projects annotations across languages via alignment links (Yarowsky and Ngai, 2001; Hwa et al., 2005; Lacroix et al., 2016). A variant using *artificial* parallel corpora, obtained via Machine Translation, is suggested and discussed by Tiedemann et al. (2014).

In this work, we focus on the problem of learning dependency parsers for an under-resourced language and consider the *delexicalized transfer* approach of Zeman and Resnik (2008), in which the shared source-target representation is obtained by replacing all tokens by their PoS (assuming a common tagset). Thanks to this language-independent representation, a model trained with annotated sentences in a source language can be readily applied to parse sentences in any other language. Delexicalized techniques are especially useful in very low-resource settings, in which existing parallel corpora are likely to be too small or even non-existing. The development of cross-linguistically homogeneous and consistent schemes for PoS labels (Petrov et al., 2012) and, more recently, for dependency trees (McDonald et al., 2013) has been of great help to improve the applicability and effectiveness of delexicalized transfer methods. We contend, however, that having a universal PoS inventory is only a first step towards making the source and target languages more alike. In particular, these shared representations may hide fundamental differences in word order between source and target languages. As explained in § 2, these

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 119–130, Osaka, Japan, December 11-17 2016.

divergences introduce systematic biases in parsers: since many features rely on word linear sequence, their distribution across languages varies in great proportions, preventing useful generalizations to be effectively transferred cross-linguistically.

In the remaining sections, we study ways to improve the performance of delexicalized techniques by making the source word sequence more similar to target sentences, prior to transferring information. Two extensions are contrasted: a data-driven approach and a knowledge-driven approach (§ 3). The former uses PoS-based statistical language models estimated on target data while the latter relies only on the World Atlas of Language Structures (WALS) (Dryer and Haspelmath, 2013), which contains a series of linguistic typological features documenting 2,679 languages. Experiments on 40 languages exhibiting very different characteristics and covering several language families show that both methods outperform standard delexicalized transfer by a wide margin (§ 4), with the knowledge-based approach having the additional benefit to even dispense with the need of unlabeled target data and consequently to be readily usable for more than thousand languages. Incidentally, our experiments thoroughly re-evaluates previous proposals for improving baseline delexicalized transfer.

2 Motivations

2.1 Principles of Transition-Based Dependency Parsing

Transition-based dependency parsers (Nivre, 2008) are among the most popular methods for computing a syntactic structure. For clarity, we illustrate our work on greedy ARCEAGER parsers which have achieved state-of-the-art performance for many languages. However, our motivations hold regardless of the chosen parsing system, and exploratory experiments with our methods have shown similar improvements with other parsers (including graph-based parsers).

In an ARCEAGER parser, the parse tree is built incrementally while traversing the sentence from left to right, by executing elementary actions that either move words in a buffer and a stack (via SHIFT and REDUCE actions) or create dependency relationships between the word on top of the stack and the leftmost word in the buffer (using the LEFT or RIGHT actions depending whether the head is in the buffer or on the stack).

The actions performed during parsing are predicted by a feature-based classifier, a common choice being the averaged perceptron of Collins and Roark (2004). It is custom to base the classifier decisions on a limited window centered on the two tokens which could be moved or attached; the following features[1] are typically extracted from these neighborhoods and combined together to yield feature tuples: top of the stack (generally denoted s_0) and deeper stack elements (s_1, s_2) to its left, head of the buffer (n_0) and additional tokens (n_1, n_2) on its right.

Transition-based parsers heavily rely on word order: for instance, as shown in Figure 1, in an ARCEAGER system, the dependency between two words will be predicted by two different actions depending whether the head occurs before or after its dependent. More importantly, most features used in a dependency parser (no matter the transition system) are sensitive to the word order, as they encode the position of the word in the stack or in the buffer which, in turn, depends on the position of the word in the sentence.[2]

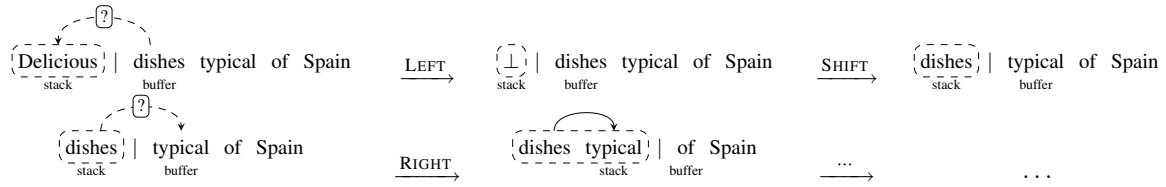

Figure 1: An order-sensitive sequence of transitions computing a dependency tree.

[1] For lexicalized parsers: the word forms and the PoS, for delexicalized: only the PoS.

[2] Graph-based parsing with standard feature templates is slightly less order-dependent, since the classification task and the features of the candidate dependent and head are already abstracted from the linear sequence. However, many features, related for instance to words located *between* these two tokens, remain sensitive to word order and our statement still holds.

2.2 A Waste of Cross-Lingual Knowledge

Delexicalized transfer has proven to be an effective method to transfer parsers between languages (Zeman and Resnik, 2008; McDonald et al., 2013). However, while delexicalized transfer extracts useful language-independent knowledge from training instances in the source language, we claim that this knowledge is often not encoded in the right form to be effectively used to process target sentences, due to divergences in word ordering.[3]

We illustrate this on delexicalized transfer from English to French. Let us assume that we have a delexicalized English parser that is able to perfectly predict the dependency structure of the noun phrase *the following question* and we use it to annotate the corresponding French phrase *la question suivante* (literally, *the question following*[4]). Thanks to recent efforts in defining universal annotation schemes for syntactic information, notably the Universal Dependencies (UD) project (Nivre et al., 2016), these phrases can be represented in a unified manner by mapping word forms into the corresponding PoS, yielding respectively DET ADJ NOUN and DET NOUN ADJ. As the English parser has learned that 'DETs depend on NOUNs' and that 'ADJs depend on NOUNs', the appropriate parse for the French phrase should be obvious, as these rules apply cross-linguistically. PoS sequences thus seem to provide an appropriate level of abstraction for cross-lingual transfer.

However, contrary to what this intuition suggests, the transfer of the ADJ-NOUN dependency often fails in practice. This is because the features underlying the high-level rules stated above are in fact order-dependent. Indeed, when parsing the French phrase, the parser configuration will be mainly described by the feature pair 's_0=NOUN $\wedge$ n_0=ADJ' (as *question* appears before *suivante*, it will be put on the stack first) while for the English phrase the relevant parser configuration would look like 's_0=ADJ $\wedge$ n_0=NOUN'. For lack of connecting these two situations, the parser has no way to predict the correct attachment in French using only English training instances.

Experimentally,[5] and denoting $\mathrm{UAS}\left[\begin{smallmatrix}C_2\\C_1\end{smallmatrix}\right]$ the percentage of C_1 tokens depending on a C_2 token that are correctly attached by the parser, while the English delexicalized model has a $\mathrm{UAS}\left[\begin{smallmatrix}\text{NOUN}\\\text{ADJ}\end{smallmatrix}\right]$ of 91.1% on English, it drops down to 50.8% for French. This decrease results directly from the word order difference between French and English, as English adjectives are almost always preposed[6] while their position in French is less deterministic: in the French UD, 28% of the adjectives occur before their head noun and 72% after it. As a result, the $\mathrm{UAS}\left[\begin{smallmatrix}\text{NOUN}\\\text{ADJ}\end{smallmatrix}\right]$ score on French actually decomposes as 96.8% for $\mathrm{UAS}\left[\begin{smallmatrix}\text{NOUN}\\\text{preposed ADJ}\end{smallmatrix}\right]$ and 34.5% for $\mathrm{UAS}\left[\begin{smallmatrix}\text{NOUN}\\\text{postposed ADJ}\end{smallmatrix}\right]$.[7] These observations highlight the impact of word order on delexicalized transfer: attachment patterns are not robust to variations in word ordering. Note that transfer from French to English is much more successful, with a $\mathrm{UAS}\left[\begin{smallmatrix}\text{NOUN}\\\text{ADJ}\end{smallmatrix}\right]$ of 80.5%. This is because the source language (here French) contains a sufficiently large number of preposed adjectives, which makes it possible to learn the patterns that are useful for English.

The discrepancies in word order can have an even more dramatic effect when transferring parsers between languages in which adjectives have a fixed position. This, for instance, happens when the source is Bulgarian (almost only preposed adjectives) and the target is Hebrew (only postposed): the resulting $\mathrm{UAS}\left[\begin{smallmatrix}\text{NOUN}\\\text{ADJ}\end{smallmatrix}\right]$ is as low as 28.7% (compared to an overall UAS of 60.1%). In the reverse direction, it drops down to 2.8% ($\mathrm{UAS}\left[\begin{smallmatrix}\text{NOUN}\\\text{preposed ADJ}\end{smallmatrix}\right]$ of 0.7%, $\mathrm{UAS}\left[\begin{smallmatrix}\text{NOUN}\\\text{postposed ADJ}\end{smallmatrix}\right]$ of 54.5%, with an overall UAS of 50.6%).[8]

The impact of differences in word order on cross-lingual transfer is not limited to the attachment of adjectives. Consider, for instance, the English phrase *the neighbor's car* (DET NOUN PART NOUN) and

[3]The issues described in this section are at least partially solved by transfer with annotation projection but these techniques require parallel data that are not always available.

[4]Keeping the original order (*la suivante question*) would be wrong in French.

[5]Our experimental data and protocols are presented in Section 4.

[6]In the English UD corpus, 93% of the adjectives come before the noun they depend on.

[7]This observation is consistent with the English monolingual scores (93.2% for the $\mathrm{UAS}\left[\begin{smallmatrix}\text{NOUN}\\\text{preposed ADJ}\end{smallmatrix}\right]$ majority case, and 55.0% for the much rarer $\mathrm{UAS}\left[\begin{smallmatrix}\text{NOUN}\\\text{postposed ADJ}\end{smallmatrix}\right]$ case).

[8]Source data quality cannot be the only cause of such poor results: when delexicalized models apply monolingually, $\mathrm{UAS}\left[\begin{smallmatrix}\text{NOUN}\\\text{ADJ}\end{smallmatrix}\right]$ is 97.4% in Bulgarian and 88.4% in Hebrew.

its French translation *la voiture du voisin* (DET NOUN ADP NOUN). After attaching function words, all that remains for the parser to process is the bigram NOUN NOUN: while the English parser has been trained to predict a left dependency (*car* being the head of *neighbor*), for French it must predict a right dependency (*voiture* being the head of *voisin*). Here the discrepancy of genitives' position across languages does not involve unseen features, but still leads the model to predict a wrong dependency with high confidence.

Our work aims at addressing such scenarios in which knowledge transfer is impeded by the word order of the source language. While current state-of-the-art models learn that 'an ADJ followed by a NOUN depends on that NOUN' and 'the first NOUN depends on the second NOUN', we would like them to transfer more abstract patterns such as 'ADJs depend on NOUNs' and 'genitives depend on NOUNs', leaving it up to the target side to decide which of both NOUNs plays the role of genitive.

3 Boosting Delexicalized Transfer

3.1 Reshaping Training Instances

In this work, we propose to preprocess the source data before they are used to train a delexicalized parser, that will then be directly applied on target sentences. This preprocessing aims at making the source word sequences more similar to target sentences, with the goal to make the cross-lingual knowledge more accessible after transfer. The available information is the same before and after preprocessing (no dependency is ever added), but is presented at training time in a form that should make it more useful at test time.

In the following, we introduce two ways of generating such transformations, by removing or permuting tokens. The first approach uses a language model estimated on target PoS sequences to find the most similar word order between the source and target languages in a lattice containing local reorderings of the source sentence. The second strategy relies on a data bank of linguistic typological features, the WALS (Dryer and Haspelmath, 2013), to generate a series of heuristic transformation operations.

The problem of finding good reorderings of a source sentence is closely related to the problem of word (p)reordering in Statistical Machine Translation (SMT) (Bisazza and Federico, 2016). However, where preordering aims to find an optimal (for SMT) permutation of source words *for each source sentence*, our objective is less ambitious, as we only intend to 'fix' a sufficiently large number of divergent patterns between the source and target languages, so as to increase the effectiveness of transfer *at the model level*.

3.2 Optimally Reordering the Training Corpus with a Language Model

Our first resource-light approach consists of two steps. We first generate a small subset of possible token permutations, compactly encoded in a finite-state graph. In our experiments, we consider all the permutations licensed by the MJ-2 reordering scheme (Kumar and Byrne, 2005), which generates all possible local permutations within a window of three words. Machine Translation experiments have shown that the MJ-2 constraints capture lots of plausible reorderings (Dreyer et al., 2007). In the context of cross-lingual transfer, its local nature allows to correct several important divergences in word order (e.g. the adjective-noun divergence described in § 2.2), while keeping the size of the reordering lattice polynomial with respect to the sentence length (Lopez, 2009).

The permutation lattice is then searched for a reordering that (a) corresponds to a high probability target PoS sequence and (b) preserves the projectivity constraint. In practice, we first generate the lattice of MJ-2 reorderings, score it with a language model estimated on the target PoS sequences, and extract the 1,000-best sequences. After filtering non-projective trees, we retain the one-best sequence (if one projective tree exists), or the original sequence otherwise. We expect the word order of this transformed source to be very close to the word order of a typical target sentence. We then transform the gold dependency tree according to this permutation and use it to train a target-adapted model.

This approach can be viewed as an extension of the data selection technique of Søgaard (2011) in which the delexicalized model is trained only on the source examples that are the most *relevant* for the target at hand. The similarity between the source and target languages is based on the similarity between

their PoS sequences: experimentally, the author retains the 90% sentences with lowest perplexity according to a target PoS language model (PoSLM). We add here an extra degree of freedom by allowing changes in the word order of the source PoS sequence, rather than simply discarding sentences.

3.3 Adapting the Training Corpus with Rewrite Rules

Our second proposal takes advantage of the linguistic knowledge that is now available for many languages. We use here the WALS, which contains a series of linguistic features documenting 2,679 languages. Some of these features are of prime interest for our study, and express general properties related to word order. In this work we focus on the following seven features that describe whether some PoS classes exist in a language and their relative position (preposed or postposed to the noun, or no dominant order): 37A (definite articles), 38A (indefinite articles), 85A (order of adposition and noun), 86A (order of genitive and noun), 87A (order of adjective and noun), 88A (order of demonstrative and noun) and 89A (order of numeral and noun).[9]

We first extract the relevant features for each language considered in our study, quantify their value and automatically transform them to relate to the raw PoS sequences found in our corpora. We extrapolate the order of DET and NOUN from feature 88A and identify the genitives mentioned by feature 86A as NOUNs or PROPNs depending on a NOUN. With an otherwise straightforward mapping, this results in the following set of properties: no definite DET, no indefinite DET (including the affix cases), and a precedence rate (denoted PR) of 0% (postposed), 50% (no dominant order) or 100% (preposed) for ADPs (resp. genitives, ADJs, DETs, NUMs) depending on a NOUN.[10]

The 'No dominant order' feature value of WALS provides very useful quantitative information: contrary to the PoSLM-based approach, which puts hard constraints on each phenomenon by choosing a reordering even when several choices would be almost equally likely, WALS features indicate when and how to balance our transformed treebanks.

By comparing two languages based on their feature values, it is then possible to define actionable transformation rules that remove or permute tokens and their associated subtrees. Table 1 lists the transformation rules derived from each pair of features. We preferred smooth transformations (with mean PR objectives and error margins) to prevent a full transformation of the corpus and a risk of information losses if the child position is less deterministic than expected. For instance, in the case of transfer from English (ADP-NOUN) to Japanese (NOUN-ADP) and according to the fourth transformation rule, we target a precedence rate of ADPs to NOUNs between 45% and 55%. This means that during source treebank traversal, while the precedence rate in previous sentences is above 55% (resp. below 45%), any encountered ADP-NOUN (resp. NOUN-ADP) bigram holding a dependency is switched, along with their dependents to preserve projectivity. According to first rule, for transfer to Czech (no definite article) from any source, all definite articles are systematically removed from source data.

Source feature	Target feature	Transformation rule
any	no DEF-DET	remove all definite DETs
any	no IND-DET	remove all indefinite DETs
$\mathrm{PR} = 0\%$	$\mathrm{PR} \geq 50\%$	switch subtrees to reach $\mathrm{PR} = 50\%$ (with 5% error margin)
$\mathrm{PR} = 100\%$	$\mathrm{PR} \leq 50\%$	switch subtrees to reach $\mathrm{PR} = 50\%$ (with 5% error margin)
$\mathrm{PR} = 50\%$	$\mathrm{PR} = 100\%$	switch subtrees to reach $\mathrm{PR} = 75\%$ (with 5% error margin)
$\mathrm{PR} = 50\%$	$\mathrm{PR} = 0\%$	switch subtrees to reach $\mathrm{PR} = 25\%$ (with 5% error margin)

Table 1: Transformation rules extracted from the comparison of the feature values of a language pair. All other feature pairs result in a no-op.

For each sentence, we apply each rule on the whole sequence (and then iterate 3 times to capture recur-

[9] We do not consider here features (81A, 82A, etc.) describing the relative position of a head VERB and its dependents. Their use would require us to condition our preprocessing patterns on labeled dependency relationship in the source, a task we leave for future work.

[10] For ADPs, and for resilience to annotation inconsistencies, we also include ADPs that are heads of NOUNs.

sive phenomena). Such heuristic rule application strategy is undoubtedly sensitive to the rule ordering, but we have not yet investigated this aspect and simply apply rules according to the lexicographic order of the child tag, breaking ties using word position.

In comparison to the PoSLM-based approach, the WALS-based approach suffers from a lack of exhaustivity regarding word order; by design, less phenomena will be captured. However, since the objective is not the best possible reordering but only more compatible PoS sequences, exhaustivity is probably not a big issue. Besides, working with a discrete and reduced set of transformation operations gives us a better control on the rewriting of dependencies. It also allows us to use extra operations such as word deletion, a transformation that may be difficult to control in the approach described in § 3.2.

Altogether, this linguistically rich method presents a notable upside: since all the required information is available in WALS, it is readily usable for more than thousand languages. Provided that PoS tags can be generated for the target data to parse, no extra resource is required, while estimating a PoSLM requires a sufficiently large corpus of reliably PoS-tagged target data.

4 Experiments

4.1 Experimental Setup

We evaluate our proposals on the Universal Dependencies corpus[11] (Nivre et al., 2016) and compare them with three baselines: (a) standard delexicalized transfer, (b) the data point selection method of Søgaard (2011) and (c) the weighted multi-source combination of Rosa and Zabokrtsky (2015), that weights and combines the hypotheses of several delexicalized source models using KL_{cpos^3} (Kullback-Leibler divergence of coarse PoS trigram distributions) as a syntactic similarity metric between languages. We also include the UAS of KL_{cpos^3} multi-source combination built on top of our knowledge-based model.

In all our experiments, we consider 3-gram PoS language models estimated on the training sets of UD. The KL_{cpos^3} metric is estimated on the same PoS sequences. From WALS, we extract and use the 37A, 38A and 85A to 89A features. For some languages, this information was incomplete. We completed missing features with a majority vote of the languages of same genus if available in the database; otherwise (i.e. for ancient languages, all absent from WALS) we assumed that there were separate article tokens and that there was no dominant order for word order features.

For each component of the algorithms, we use the universal PoS tagset and gold PoS tags. While this scenario is probably unrealistic, it allows us to get a clearer picture of the net effect of a better syntactic knowledge transfer, since possible sources of discrepancies between languages (e.g. more or less noisy tag labels) have been removed. The parser is a greedy ARCEAGER transition-based parser trained with a dynamic oracle (Goldberg and Nivre, 2012), an averaged perceptron classifier (Collins and Roark, 2004) and Zhang and Nivre (2011)'s feature templates (assuming fully delexicalized representations and unlabeled arcs). We use the PanParser implementation (Aufrant and Wisniewski, 2016) and all the code used in this work is available at `https://perso.limsi.fr/aufrant/`.

4.2 Results

Table 2 presents UAS results for the various transfer methods considered. As these experiments amount to 6,320 evaluated parsers, we provide the results in a compacted form as follows. For each target language, for mono-source transfer, we report the scores of the worst, median, best sources and the average score (or average gain) over all sources.

Overall, both preprocessing techniques outperform the direct transfer method of Zeman and Resnik (2008) as well as the selection strategy of Søgaard (2011). The WALS-based rewriting approach yields higher improvements (+2.9 UAS on average) than the PoSLM-based reordering strategy (+2.3 UAS on average). Thanks to the variety and the large number of sources, the multi-source methods have here much higher accuracies, often better than the best source; even in this setting, using WALS provides us with a slight improvement over the baseline multi-source parser.

[11] We consider the version 1.3 of the UD treebank. In order to present only fair sources, for languages where several treebanks are available, we retain only the *main* treebank. This is the case for the following languages: cs, en, es, fi, grc, la, nl, pt, ru, sl and sv.

Table 2: UAS of the various mono-source and multi-source transfer methods, on each UD target language (using UD language codes).
The first line reads as follows: for delexicalized transfer to Arabic, the worst, median and best sources yield UAS scores of 5.1, 43.2 and 56.9, and the average score over all 39 sources is 36.1, which the WALS-based method improves by 5.7 points.

Our experiments also show that the selection baseline method does not perform as well on Universal Dependencies (Nivre et al., 2016) as it did on the CoNLL 2006 Shared Task. Those differences can be explained in two ways. First, we experiment with cleaner treebanks and benefit from the availability of unified tagsets and annotation schemes. This is in contrast with previous experiments, which were using a tagset mapping as a preprocessing step, making the net effect of data selection more difficult to single out and evaluate precisely. Second, the data selection method was primarily intended for distantly related languages, whereas the UD corpus now offers a wide language diversity and often a few good sources for which data size reduction is only detrimental.

In general, our methods do not improve the best source but have a large effect on bad and average sources, often turning them into competitive sources. This is particularly true with PoSLM reordering, which improves the worst sources by 8.1 points and degrades the best ones by 2.6 points. By contrast, the WALS-based method is more conservative and offers lower but more reliable improvements, which in average proves successful.

Table 3 reports the average over some language families[12] of the UAS of the baseline, reordered and WALS-based mono-source models. It shows that accuracies of related sources are only marginally mod-

[12]While the considered ancient languages belong to some of those families, we chose to gather them into a separate category, since they rely on the same WALS completion heuristic, instead of their actual typological features.

Source language	Target language: Romance	Germanic	Slavic	Finno-Ugric	Semitic	Ancient

Table 3: Delexicalized, PoSLM-based reordered and WALS-based UAS aggregated over language family pairs.
The first column reads as follows: the average UAS over all pairs of two Romance languages is 67.1 for mono-source delexicalized transfer; it is slightly improved (67.2) by the WALS-based method. Over all pairs of a Germanic source and a Romance target, the average mono-source UAS raises from 61.2 (delexicalized baseline) to 63.5 (PoSLM-based reordering) and 65.8 (WALS-based rules).

ified when source sentences are transformed according to WALS, which could be expected as related languages share most of their typological features. On the contrary, large gains are obtained for distantly related languages. Such languages are typically poor sources in direct delexicalized transfer due to systematic labeling errors that mostly concern few frequent word classes (in correlation with their typological features). We have found that such errors can often be corrected by transforming the source sentences. With those errors handled, the now competitive sources can in turn contribute with valuable knowledge in multi-source settings.

4.3 A Fine-grained Analysis

We have also investigated the improvements made over the baseline by our best method, the WALS-based rewriting rules, by analyzing the gain in accuracy separately for various PoS. It appears that, in most cases, improvements mostly concern PoS classes covered by the WALS features. For instance, the issue mentioned in § 2.2 for the English-French pair is almost solved with source reordering: 90.4% of the postposed ADJs are correctly predicted by the WALS-based method (34.5% in the baseline), without any detrimental impact on the preposed ones. The same holds for the Hebrew-Bulgarian textbook case, where the UAS $\left[\substack{\text{NOUN}\\\text{ADJ}}\right]$ raises from 0.7% to 95.1%.

We observe similar behaviors across the board for all the classes targeted by transformations: transfer from Czech to Danish had UAS $\left[\substack{\text{NOUN}\\\text{preposed NOUN}}\right]$ and UAS $\left[\substack{\text{NOUN}\\\text{postposed NOUN}}\right]$ scores of 2.8% and 78.4%, with WALS-based preprocessing they are respectively 61.1% and 80.4%. In Finnish-Arabic, scores of 6.3% and 30.9% on ADJs and ADPs become 65.8% and 61.4%, etc. In whole, 21% of the considered language pairs present very large gains (over +50 points) for at least one frequent tag pair (over 30 dependency occurrences in test data).

Careful comparison of results for both PoSLM-based methods shows that reordering improves ADJs' attachment for instance, when data selection does not. This can be explained in two ways. First, if the source corpus contains a very limited number of preposed ADJs, even with perfect selection the ADJs in final data cannot be mostly preposed. Second, data selection mostly targets sequences very far from the target syntax: sentences that only disrespect a local preference of child position are less fluent, and consequently have a lower rank, than their hypothetical counterpart with switched positions; but they are not ungrammatical enough to be pushed into the 10% worst territory. On the other hand, the data transformation approach is not restricted to preexisting n-grams, and it directly confronts the given sequence with its counterpart to keep only the most fluent, thus acknowledging local preferences. These key differences are confirmed experimentally on English-French data: PoSLM-based reordering lowers the precedence rate of ADJs to NOUNs from 93% to 60%, while the rate varies by less than 1% in Søgaard (2011)'s approach, leaving the majority case adjectives still under-trained.

Finally, detailed analyses reveal that the PoSLM reordering approach has lower improvements than the WALS-based one on *easy reorderings* such as the nearly deterministic Hebrew-Bulgarian adjectives

(UAS $\left[\begin{smallmatrix}\text{NOUN}\\ \text{ADJ}\end{smallmatrix}\right]$ of 93.2% with WALS, versus 86.1% with the PoSLM). This suggests that the data-driven technique still wastes part of the available knowledge: indeed, the use of a probabilistic model to rank reorderings does not guarantee that any interesting reordering is in fact selected. Another advantage of the knowledge-rich approach is that the distribution of *local* word orderings is easier to control, since it explicitly regulates the balance between co-existing word orders. Indeed, when two structures are possible and fluent, the PoSLM-based method will always prefer the majority class. While the projectivity requirement generally softens this hard constraint by discarding many reordering candidates, the effect holds for instance on typologically close languages: during transfer from French ($\mathrm{PR} = 28\%$ for ADJ-NOUN) to Italian ($\mathrm{PR} = 32\%$), PoSLM-based reorderings harden the preference down to $\mathrm{PR} = 16\%$, and end up under-training the ADJ-NOUN minority class.

In spite of this, the PoSLM reordering is still competitive, since it covers more diverse phenomena. For instance, when transferring from English to Tamil, the $\mathrm{UAS}\left[\begin{smallmatrix}\text{VERB}\\ \text{AUX}\end{smallmatrix}\right]$ only raises from 31.4% to 35.0% with the WALS-based method, but achieves a nice 91.2% with the PoSLM. Such improvements are however less predictable and unexplained losses also occur, as for the $\mathrm{UAS}\left[\begin{smallmatrix}\text{VERB}\\ \text{AUX}\end{smallmatrix}\right]$ in Hungarian-Tamil (98.5% for the baseline and WALS, 66.4% with PoSLM reordering).

These results suggest that both approaches have their upsides and downsides, which remain to be combined.

5 Related Work

The observation that cross-lingual transfer works better with typologically close or related languages has been already made by many. Indeed, several works have already pointed out that unified annotation schemes cannot compensate for syntactic divergences between source and target languages and that reducing these divergences was likely to improve the performance of transfer.

When several sources are available, a natural approach is to give more weight to the instances observed in related languages, where relatedness can be measured either based on linguistic description (Berg-Kirkpatrick and Klein, 2010) or empirically (Cohen et al., 2011).

Søgaard (2011) follows similar intuitions but binarizes the weights to apply instance selection. Thus, the delexicalized model is trained only on the source examples that are the most *relevant* for the target at hand, using PoSLM perplexity as a relevance metric. Note that this strategy can be applied both in mono-source and multi-source settings.

In Rosa and Zabokrtsky (2015)'s work, the syntactic similarity between languages is also based on the similarity between their PoS sequences. They show how the KL_{cpos^3} measure can be used to improve cross-lingual transfer either by selecting the best source language, or by weighting the source contribution to the output in a multi-source setting.

Both multi-source combination and data selection follow the same intuition that any source sentence or part of it can provide useful information on the syntax of the target language, even when the divergence between the source and the target is large. Indeed, a language is subject to many influences throughout its evolution and can borrow a phenomenon from a very distant language. This is for instance the case of Romanian, which belongs to the Romance family but has also strong Slavic influences.

As a result, both works aim at extracting useful knowledge even from poor sources, and our proposal can be viewed as an extension that pushes further this intuition, to a finer grain: Rosa and Zabokrtsky (2015) reward good source languages, Søgaard (2011) rewards target-relevant sentences, and our method rewards relevant local patterns, by performing a local reordering of target-irrelevant parse subtrees rather than ignoring the whole sentence. This has the effect of using the knowledge embedded in these subtrees as well as in the rest of the sentence more effectively. To see this, consider the case of transferring an English parser to a language in which no verb is labeled as auxiliary.[13] In this case, the method of (Søgaard, 2011) is likely to discard all the English sentences containing auxiliaries and the parser will hardly see, in training, sentences involving passive constructions or past participles; by contrast, methods based on data transformation would not remove the full sentence, but just the auxiliary – all the other dependencies, e.g. the by-agent, can still contribute to learning.

[13] In the UD treebank this is, for instance, the case for Greek, Latvian or Galician.

Thus, in comparison to previous works favoring close word orders at the cost of discarding some training examples or reducing source contribution, our method differs by improving cross-lingual transfer without knowledge loss.

In another line of work, Naseem et al. (2012) also distinguish the knowledge 'ADJs depend on NOUNs' from the ordering of both tokens, and use WALS to predict the latter. However, where our methods compensate for word order divergences at the data level, their work aims at abstracting the dependency prediction from word order, by designing a new parsing algorithm from scratch: their parser decomposes as a dependent selection component, shared among languages, and an ordering component that is specific to the target language. Even though it does not provide full order abstraction, our approach has the double advantage of wrapping any state-of-the-art parsing system, and allowing an extra degree of flexibility by manipulating the data, e.g. to handle PoS classes existing in only one language.

6 Conclusion

The contribution of this work is twofold. First, we have updated earlier results on delexicalized cross-lingual model transfer by reproducing them on the recent Universal Dependencies treebank. This collection of treebanks contains more languages than were previously available. Furthermore, the consistency of annotation schemes makes the analysis of results more reliable and enables to draw firmer conclusions. Second, based on a thorough analysis of the weaknesses of delexicalized transfer, we have proposed two strategies that aim to compensate for word sequence biases when transferring models across languages: a data-driven method using PoSLMs for reordering and a knowledge-based method exploiting heuristic rewrite rules extracted from WALS. The latter method proved to be the most effective of the two, with the additional benefit of being entirely resource-free and thus readily usable for the over thousand languages whose word order is specified in WALS. For the frequent PoS classes targeted by this method, we were able to obtain huge improvements, often 30 and up to 90 points.

A first natural continuation of this work will be to complete our repertoire of preprocessing rules with article insertions, PoS substitutions and patterns involving verbs, which were not considered so far. Another direction we would like to investigate is to contrast our techniques with annotation projection, which is another way to compensate for word order biases in cross-lingual transfer: by analyzing the pros and cons of each method we might find ways to combine them so that we can also use parallel data when available. We finally also aim at generalizing our WALS approach to other order-dependent tasks. Indeed, from a higher-level point of view, the aforementioned issues are not specific to dependency parsing, but occur theoretically with all data-driven NLP methods: however general it is, the linguistic knowledge is always only available as instantiated on a given word sequence and through the proxy of a particular data.

Abstract

Natural-language processing of historical documents is complicated by the abundance of variant spellings and lack of annotated data. A common approach is to normalize the spelling of historical words to modern forms. We explore the suitability of a deep neural network architecture for this task, particularly a deep bi-LSTM network applied on a character level. Our model compares well to previously established normalization algorithms when evaluated on a diverse set of texts from Early New High German. We show that multi-task learning with additional normalization data can improve our model's performance further.

1 Introduction

Interest in computational processing of historical documents is on the rise, as evidenced by the growing field of digital humanities and the increasing number of digitally available resources of historical data. Spelling normalization, i.e. the mapping of historical spelling variants to standardized/modernized forms, is often employed as a pre-processing step to allow the utilization of existing tools for the respective modern target language (Piotrowski, 2012).

Training data for supervised learning of spelling normalization is typically scarce in the historical domain. Furthermore, dialectal influences and even individual preferences of an author can have a huge impact on the spelling characteristics in a particular text, meaning that even training data from other corpora of the same language and time period cannot always be reliably used.

Algorithms have often been developed with this fact in mind, e.g. by being based on some form of phonetic, graphematic, or semantic similarity measure (Jurish, 2010; Bollmann, 2012; Amoia and Martinez, 2013). On the other hand, neural networks – and particularly deep networks with several hidden layers – are assumed to work best when trained on large amounts of data. It is therefore not clear whether neural networks are a good choice for this particular domain.

We frame spelling normalization as a character-based sequence labeling task, and explore the suitability of a deep bi-directional long short-term memory model (bi-LSTM) in this setting. By basing our model on individual characters as input, along with performing some basic preprocessing (e.g., downcasing all characters), we keep the vocabulary size small, which in turn reduces the model's complexity and the amount of data required to train it effectively. We show that this model outperforms both the existing normalization tool Norma (Bollmann, 2012) and a CRF-based tagger when evaluated on a diverse dataset from Early New High German.

Furthermore, we experiment with a multi-task learning setup using auxiliary data that has similar, but not identical spelling characteristics to the target text. We show that using bi-LSTMs with this multi-task learning setup can improve normalization accuracy further, while Norma and CRF do not profit much from the additional data in a traditional setup.

2 Datasets

We use a total of 44 texts from the Anselm corpus (Dipper and Schultz-Balluff, 2013) of Early New High German.[1] The corpus is a collection of several manuscripts and prints of the same core text, a religious treatise. Although the texts are semi-parallel and share some vocabulary, they were written in different time periods (between the 14th and 16th century) as well as different dialectal regions, and show quite diverse spelling characteristics. For example, the modern German word *Frau* 'woman' can be spelled as *fraw/vraw* (Me), *frawe* (N2), *frauwe* (St), *fraüwe* (B2), *frow* (Stu), *vrowe* (Ka), *vorwe* (Sa), or *vrouwe* (B), among others.[2]

All texts in the Anselm corpus are manually annotated with gold-standard normalizations following guidelines described in Krasselt et al. (2015). For our experiments, we excluded texts from the corpus that are shorter than 4,000 tokens, as well as a few texts for which annotations were not yet available at the time of writing (mostly Low German and Dutch versions). Nonetheless, the remaining 44 texts are still quite short for machine-learning standards, ranging from about 4,200 to 13,200 tokens, with an average length of 7,353 tokens.

For all texts, we removed tokens that consisted solely of punctuation characters. We also lowercase all characters, since it helps keep the size of the vocabulary low, and uppercasing of words is usually not very consistent in historical texts.

2.1 Conversion to labeled character sequences

Normalization is annotated on a word level; to reframe the problem as a character-based sequence labeling task, we need to align the historical wordforms and their normalizations on a character level. Ideally, we would like these alignments to be linguistically plausible, i.e., characters that most likely correspond to each other (e.g., historical *j* and modern *i*, as in *jn – ihn* 'him') should be aligned whenever possible.

The Levenshtein algorithm (Levenshtein, 1966) can be used to produce alignments that preferably align identical characters, but is ambiguous when multiple alignments with the same Levenshtein distance exist. We therefore use iterated Levenshtein distance alignment (Wieling et al., 2009), which uses pointwise mutual information on aligned segments to estimate statistical dependence, and favors alignments of characters that tend to cooccur often within the dataset. Since different texts can use the same characters in different ways, we perform this iterated alignment separately for each text.

A difficulty of these alignments is that the two wordforms can be of different lengths. We introduce a special epsilon label (ϵ) whenever a historical character is not aligned to any character in the normalization. We cannot do that for the inverse case, since the historical characters are our units of annotation and therefore need to be fixed, so we choose to perform a leftward merging of normalized characters whenever they are not aligned to any character in the historical wordform. For the word-initial case, we introduce a special "start of word" symbol (_). This symbol is prepended to each word during both training and testing, and is assigned the epsilon label during training when there is no word-initial insertion.

Here is an example of the final character sequence representation for the word pair *vsfuret – ausführt* '(he) leads out':

(1) _ v s f u r e t
a u s f üh r ϵ t

A consequence of this approach is that our labels cannot only be characters, but also combinations of characters (such as *üh* in the example above); our label set is therefore potentially unbounded. However, we found that this is not much of a problem in practice, since these cases tend to be comparatively rare.

3 Model

Our model architecture consists of: (i) an embedding layer for the input characters; (ii) a stack of bi-directional long short-term memory units (bi-LSTMs); and (iii) a final dense layer with a softmax activation to

[1] https://www.linguistics.rub.de/anselm/

[2] Abbreviations in brackets refer to individual texts using the same internal IDs that are found in the Anselm corpus.

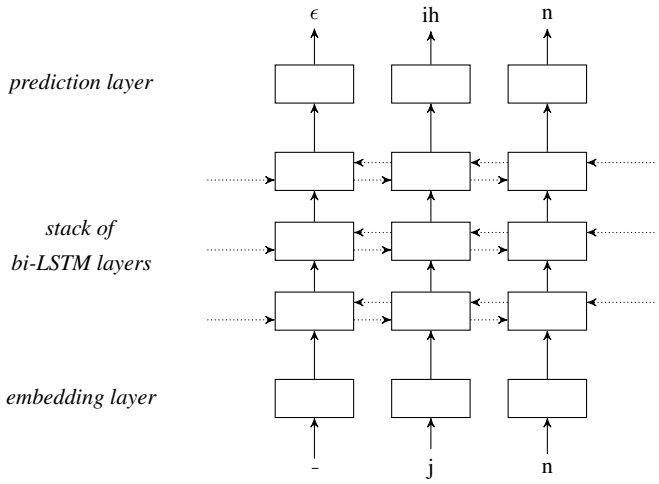

Figure 1: Flow diagram of the bi-LSTM character sequence labeling model, unrolled for time, for the word pair *jn – ihn* 'him'.

generate a probability distribution over the output classes at each timestep. An illustration of the model can be found in Figure 1.

The embedding layer maps one-hot input vectors (representing historical characters) to dense vectors. We did not use pre-trained embeddings; the embeddings are initialized randomly and learned as part of the regular network training process.

LSTMs (Hochreiter and Schmidhuber, 1997) are a form of recurrent neural network (RNN) designed to better learn long-term dependencies, and have proven advantageous to plain RNNs on many tasks. Bi-directional LSTMs read their input in both normal and reversed order, allowing the model to learn from both left and right context at each input timestep. A stack of bi-LSTMs, or a deep bi-LSTM, is a configuration of several bi-LSTM units so that the output of the ith unit is the input of the $(i+1)$th unit. In our model, we use a stack of three bi-LSTM layers.

The final dense layer is used to generate the output predictions, based on a linear transformation of the bi-LSTM outputs for each timestep followed by a softmax activation. We train the model by minimizing the cross-entropy loss across all output characters, and using backpropagation to update the weights in all layers (including the embedding layer). During prediction, we generate output labels in a greedy fashion, choosing the label with the highest probability for each timestep.

3.1 Multi-task learning setup

In multi-task learning (MTL), the performance of a model on a given task is improved by additionally training it on one or more auxiliary tasks (Caruana, 1993). For our bi-LSTM model, this means that all layers of the model are shared between the tasks apart from the final prediction layer, which is kept separate for the main and auxiliary tasks. This way, errors in an auxiliary task that are backpropagated through the network also affect the prediction of the main task, helping to regularize the network's weights and prevent overfitting.

Multi-task learning with (deep) neural network architectures was shown to be effective for a variety of NLP tasks, such as part-of-speech tagging, chunking, named entity recognition (Collobert et al., 2011); sentence compression (Klerke et al., 2016); or machine translation (Luong et al., 2016).

In our experiments, we regard spelling normalization within a target domain (i.e., a given historical text) as our main task, while using normalization within related domains (i.e., texts from a similar time period, but with distinct spelling characteristics) as our auxiliary task. During training, we alternate between training on a random instance from the main and the auxiliary tasks.

3.2 Hyperparameters

We set aside one of the texts (B) from the Anselm corpus for testing different hyperparameter configurations. On this text, we achieved the best results with a dimensionality of 128 for the embedding and bi-LSTM layers, using a dropout of 0.1, and training the model for 30 iterations. These settings were subsequently used for all further experiments.

3.3 Other models used for comparison

For comparison, we also train and evaluate with the Norma tool described by Bollmann (2012), since it was originally developed for the Anselm corpus and the implementation is publicly available.[3] However, Norma actually consists of a combination of three different normalization methods, one of which is a simple wordlist mapping of historical tokens to normalized forms. Since this wordlist mapping is conceptually very simple and could easily be added to our (or any other) normalization method, we exclude it for the comparison, and only use Norma's remaining two algorithms (which we denote Norma*).

Additionally, since we frame the problem as a sequence labeling task, we compare our results to a simple sequence labeling model using conditional random fields (CRF). The CRF model gets the same input/output sequences as our bi-LSTM model (cf. Sec. 2.1), and uses the two preceding and following characters from the historical wordform as additional features. Implementation was done with CRFsuite (Okazaki, 2007) using the averaged perceptron algorithm for training.

4 Evaluation

We evaluate our model separately for each text in our dataset. From each text, we use 1,000 tokens as our evaluation set, set aside another 1,000 tokens as a development set (which was not currently used), and train on the remaining tokens (between 2,000 and 11,000, depending on the text). Both CRF and our bi-LSTM model get their input as character sequences (as described in Sec. 2.1), while Norma requires full words as input.

For the multi-task learning setup, we randomly sample from all Anselm texts and regard each text as its own task. Effectively, we are learning a joint model over all Anselm texts with shared parameters but distinct prediction layers, while viewing the text we are currently evaluating on as our main task and the others as auxiliary tasks. The MTL setup is only applicable to our bi-LSTM model; however, since the auxiliary task consists of spelling normalization with data from the same corpus (although with a higher variety of different spelling characteristics compared to the target text), it is possible that the other methods could also profit from this additional training data. We therefore also evaluate Norma and CRF when the training sets have been augmented by 10,000 randomly sampled training examples from all texts.

4.1 Word accuracy

Evaluation results in terms of word-level accuracy are presented in Table 1.

Columns "S" show results for the traditional setup without multi-task learning. The basic bi-LSTM model performs better than Norma on 34 of the 44 texts. On average, there is an increase of 2.1 percentage points (pp), although the differences on individual texts vary wildly, from -2.9 pp (M5) to $+9.6$ pp (M), giving a standard deviation of 2.7 pp. The CRF model, on the other hand, is almost always worse than Norma, averaging a difference of -2.1 pp (± 2.0). This indicates that the reformulation of the task as character-based sequence labeling cannot alone be responsible for the bi-LSTM results, but the choice of a neural network architecture is crucial, too.

Columns "S+A" present the results when using the augmented training set. For bi-LSTM, this is the multi-task learning setup—using MTL improves the results by $+0.7$ pp (± 2.8) on average, but again there is a high variance within the individual scores. However, for the other methods, adding the 10,000 randomly selected samples to the training set actually decreases the average accuracy, by -0.4 pp for Norma and -2.0 pp for CRF. This is likely due to the fact that this additional training set introduces a variety of spelling characteristics that are not found in the target text. While Norma and

Table 1: Word accuracy on the Anselm dataset, evaluated on the first 1,000 tokens; S = training set from the same text, S+A = like S, but augmented with 10,000 tokens randomly sampled from the other texts; † = Bi-LSTM (S+A) is the multi-task learning setup. Best results shown in bold.

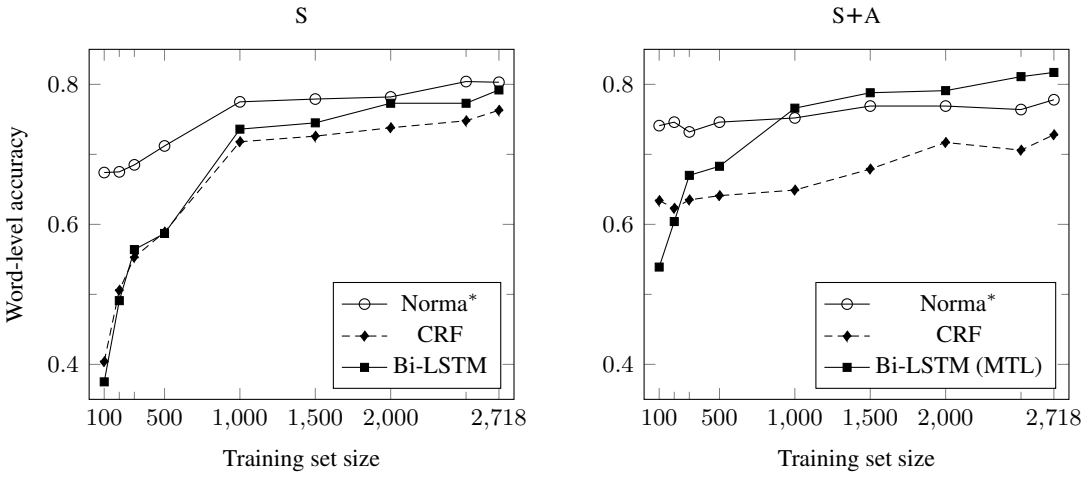

Figure 2: Word accuracy on the 'B' text for different sizes of the training set; left = train only on the training set from 'B' (S); right = use augmented training set/multi-task learning (S+A).

CRF cannot handle this out-of-domain training data well, the MTL setup can actually profit from it in many cases.

Table 1 also shows a rough classification of the dialectal regions from which the texts originate. There is a slight trend for multi-task learning to be advantageous on texts from the East and North Upper German regions, while for the Central and West Upper German texts, there are more instances of the standard bi-LSTM model (S) being better than the MTL model (S+A). This could either be due to linguistic properties of these dialectal regions, or due to the fact that East/North Upper German texts make up the majority of the dataset, thereby also featuring more prominently in the "S+A" settings.

The latter hypothesis is supported by the case of the 'Le' text, which is the only Dutch text in the sample (but which was nonetheless normalized to modern German in the corpus). Here, the "S+A" settings of the experiments all show a dramatic decrease in accuracy (up to -9.2 pp), suggesting that it is disadvantageous to augment the training set with samples that are too different from the target domain, even for the MTL setup.

In general, however, one of the bi-LSTM models is always best; there is only one text (We) for which Norma achieves an equal accuracy. This indicates that deep neural networks can be applied successfully to the spelling normalization task even with a comparatively small amount of training data. Also, we note that Norma always requires a lexical resource which it uses to filter results, while we do not.

4.2 Effect of training set size

In our evaluation, we use all but the first 2,000 tokens from a text for training (cf. the beginning of Sec. 4). Consequently, the training sets for each text are of different sizes. We calculate Spearman's rank correlation coefficient (ρ) between the size of the training sets and the normalization accuracy for each column in Table 1. We find no significant correlation for the CRF and bi-LSTM models ($|\rho| < 0.25$), although there seems to be a moderate *inverse* correlation for the Norma results ($\rho \approx -0.48$ on Norma "S"). The reasons for this are beyond the scope of this paper, though.

The question of how much training data is needed to effectively train a model is particularly relevant for historical spelling normalization, since training data can be very sparse in this domain. We therefore choose to evaluate each method in a scenario where we consider a single text, but vary the size of the training set, to estimate how well they perform with fewer data.

Figure 2 shows the results for different training set sizes on the 'B' text. Not surprisingly, when training on only 100 tokens, accuracy is bad ($< 41\%$) for CRF and bi-LSTM. Norma, on the other hand, already achieves 67.4% in this scenario. The biggest gains for all three methods can be seen for training set sizes between 100 and 1,000 tokens—for larger set sizes, the gains become less, and all three methods

are within close range of each other.

For the "S+A" scenario, all models have noticeably higher accuracy even with only 100 tokens from the 'B' text. However, the increases for Norma and CRF are not as high as in the "S" scenario; this is not surprising, since the total training set for these methods always contains at least 10,000 tokens (from the auxiliary set), and it is only the proportion of tokens coming from the 'B' text that increases. The bi-LSTM model with multi-task learning behaves differently, though: while it starts off as the weakest model (on 100 tokens), it is the best model when training on 1,000 tokens or more.

These learning curves illustrate that the MTL setup is fundamentally different from adding the auxiliary data to the training set normally, as is the case with CRF and the Norma tool. They also show that our bi-LSTM models can be better than or at least competitive with CRF/Norma for training set sizes as low as 1,000 tokens.

4.3 Multi-task learning with grapheme-to-phoneme mappings

It is conceivable to use different tasks than historical spelling normalization as the auxiliary task in a multi-task learning setup. In particular, we also experimented with grapheme-to-phoneme mapping as the auxiliary task, since it can be seen as a similar form of character-based sequence transduction.

For our dataset, we used the German part of the CELEX lexical database (Baayen et al., 1995), particularly the database of phonetic transcriptions of German wordforms. The database contains a total of 365,530 wordforms with transcriptions in DISC format, which assigns one character to each distinct phonological segment (including affricates and diphthongs). For example, the word *Jungfrau* 'virgin' is represented as `'jUN-frB`. We randomly sampled 4,000 tokens from this dataset for our experiment, and used the same algorithm as for the historical data to convert these mappings to a character-based sequence representation (cf. Sec. 2.1).

The evaluation, however, showed no real benefit of this MTL setup compared to the bi-LSTM model without MTL. While accuracy increased for some texts by up to 2.6 pp, it decreased slightly for the majority of texts, averaging to a -0.4 pp difference to the basic model.

5 Related Work

Various methods have been proposed to perform spelling normalization on historical texts; for an overview, see Piotrowski (2012). Many approaches use edit distance calculations or some form of character-level rewrite rules, but require either hand-crafting of the rules (Baron and Rayson, 2008) or a lexical resource to filter their output (Bollmann, 2012; Porta et al., 2013).

A newer approach is the application of character-based statistical machine translation (Pettersson et al., 2013; Sánchez-Martínez et al., 2013; Scherrer and Erjavec, 2013). In contrast to our sequence labeling approach, these methods do not require a fixed character alignment between wordforms, but it is not clear whether this is actually an advantage. To our knowledge, a comparative evaluation between these methods and other approaches has not yet been done.

Azawi et al. (2013) present the only other approach we are aware of that applies neural networks to normalization of historical data. They also use bi-directional LSTMs, but differ from our approach in the way they perform alignment between historical and modern wordforms. More importantly, they evaluate their model on a single dataset, the Luther bible, which has much more regular spelling than the texts in the Anselm corpus and is also significantly longer: they use about 200,000 tokens for their training set.

6 Conclusion and Future Work

We presented an approach to historical spelling normalization using bi-directional long short-term memory networks and showed that it outperforms a CRF baseline and the Norma tool by Bollmann (2012) for almost all of the texts in our dataset, a diverse corpus of Early New High German, despite using a relatively low amount of training data (about 2,000 to 11,000 tokens) and not making use of a lexical resource (like Norma does). We showed further that multi-task learning with additional normalization data can improve accuracy with bi-LSTMs, while adding the same data to the training set of Norma and CRF does not help on average, and can even be detrimental.

Many improvements to this approach are conceivable. Character-based statistical machine translation has been successfully applied to spelling normalization (cf. Sec. 5), but we are not aware of any experiments with neural machine translation (Cho et al., 2014) on this domain. Using an encoder–decoder architecture, e.g. similar to Sutskever et al. (2014), would remove the need for an explicit character alignment (cf. Sec. 2.1) but could also make the model more complex and potentially more difficult to train, so it is unclear whether this would be an improvement to our approach.

With regard to multi-task learning, our results seem to indicate that for the auxiliary task, it is preferable to use data with similar characteristics to the data in the main task. On the other hand, depending on the language variety to be annotated, such data might not always be readily available. We would therefore like to do further experiments with auxiliary data from different corpora or even different string transduction tasks, to see if and under which conditions they can have a beneficial effect on the spelling normalization task.

Deceptive Opinion Spam Detection Using Neural Network

Yafeng Ren and Yue Zhang
Singapore University of Technology and Design, Singapore
renyafeng@whu.edu.cn, yue_zhang@sutd.edu.sg

Abstract

Deceptive opinion spam detection has attracted significant attention from both business and research communities. Existing approaches are based on manual discrete features, which can capture linguistic and psychological cues. However, such features fail to encode the semantic meaning of a document from the discourse perspective, which limits the performance. In this paper, we empirically explore a neural network model to learn document-level representation for detecting deceptive opinion spam. In particular, given a document, the model learns sentence representations with a convolutional neural network, which are combined using a gated recurrent neural network with attention mechanism to model discourse information and yield a document vector. Finally, the document representation is used directly as features to identify deceptive opinion spam. Experimental results on three domains (*Hotel*, *Restaurant*, and *Doctor*) show that our proposed method outperforms state-of-the-art methods.

1 Introduction

Online reviews on products and services are extensively used by consumers and businesses for conducting decisive purchase, making product design and altering marketing strategies. As a result, deceptive opinion spam (e.g. deceptive reviews) arouses increasing attention (Streitfeld, 2012). Opinion spam is a type of review with fictitious opinions, deliberately written to sound authentic (Jindal and Liu, 2008; Ott et al., 2011). It can be difficult for human readers to distinguish them from truthful reviews. In a test by Ott et al. (2011), the average accuracy of three human judges is only 57.33%. It can be expensive to detect opinion spam manually over large user-generated texts. Hence, machine learning methods for automatically detecting deceptive opinion spam can be useful.

The objective of the task is to identify whether a given document is a spam or not. The majority of existing approaches follow the seminal work of Jindal and Liu (2008), employing classifiers with supervised learning. Most studies focus on designing effective features to enhance the classification performance. Typical features represent linguistic and psychological cues, but fail to effectively represent a document from the viewpoint of global discourse structures. For example, Ott et al. (2011) and Li et al. (2014) represent documents with Unigram, POS and LIWC (Linguistic Inquiry and Word Count) (Newman et al., 2003) features. Although such features give the strong performance, their sparsity makes it difficult to capture non-local semantic information over a sentence or discourse.

Recently, neural network models have been used to learn semantic representations for NLP tasks (Le and Mikolov, 2014; Tang et al., 2015), achieving highly competitive results. Potential advantages of using neural networks for spam detection are three-fold. First, neural models use dense hidden layers for automatic feature combinations, which can capture complex global semantic information that is difficult to express using traditional discrete manual features. This can be useful in addressing the limitation of discrete models mentioned above. Second, neural networks take distributed word embeddings as inputs, which can be trained from a large-scale raw text, thus alleviating the sparsity of annotated data to some

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 140–150, Osaka, Japan, December 11-17 2016.

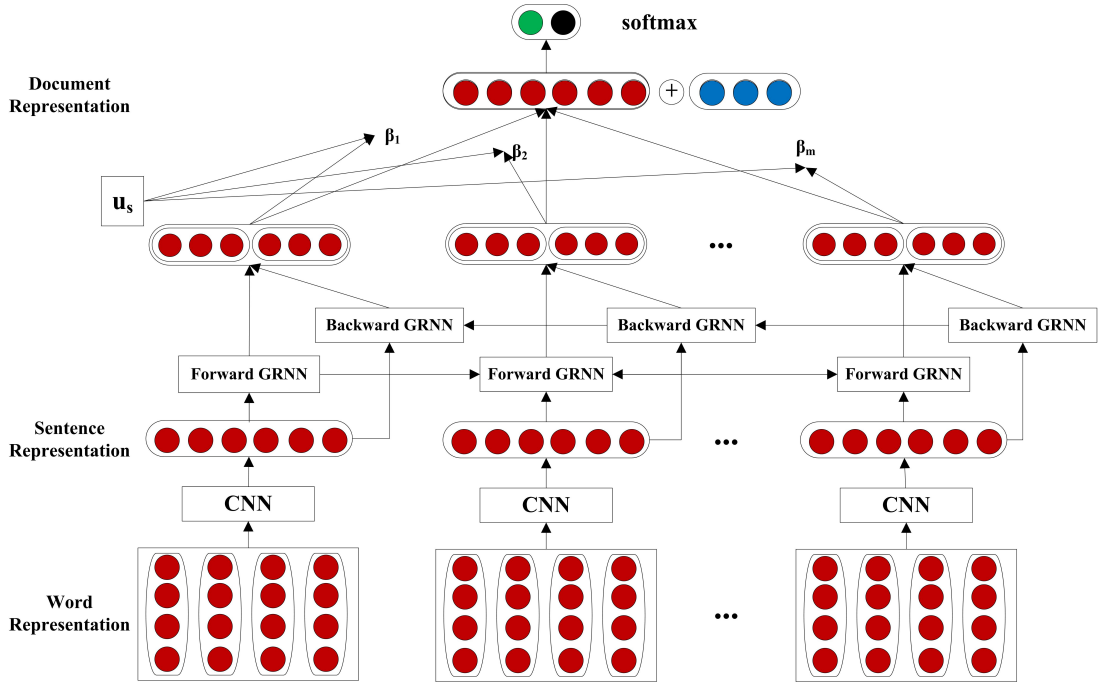

Figure 1: Neural network model structure for deceptive opinion spam detection, red nodes represent neural features, and blue nodes represent discrete features.

extent. Third, neural network models can be used to induce document representations from sentence representations, leveraging sentence and discourse information.

In this paper, we empirically investigate the effectiveness of learning dense document representations for opinion spam detection. In particular, we propose a three-stage neural network system, as shown in Figure 1. In the first stage, a convolutional neural network is used to produce sentence representations from word representations. Second, a bi-directional gated recurrent neural network with attention mechanism is used to construct a document representation from the sentence vectors. Finally, the document representation is used as features to identify deceptive opinion spam. Such automatically induced dense document representation is compared with traditional manually-designed features for the task.

We compare the proposed models on a standard benchmark (Li et al., 2014), which consists of data from three domains (*Hotel*, *Restaurant*, and *Doctor*). Results on in-domain and cross-domain experiments show that the dense neural features significantly outperforms the previous state-of-the-art methods, demonstrating the advantage of neural models in capturing semantic characteristics. In addition, automatic neural features and manual discrete features are complementary sources of information, and a combination leads to further improvements.

2 Related Work

2.1 Deceptive Opinion Spam Detection

Spam detection has been extensively investigated in the Web-page and E-mail domains (Gyöngyi et al., 2004; Ntoulas et al., 2006), while research has recently been extended to the customer review domain (Ott et al., 2011; Mukherjee et al., 2013; Li et al., 2014). Various types of indicator features have been investigated. For examples, Jindal and Liu (2008) trained models using features based on the review content, the reviewer, and the product itself. Yoo and Gretzel (2009) gathered 40 truthful and 42 deceptive hotel reviews and manually compared the linguistic differences between them.

Ott et al. (2011) created a benchmark dataset by employing *Turkers* to write fake reviews. Their data were adopted by a line of subsequent work (Ott et al., 2012; Feng et al., 2012; Feng and Hirst, 2013). For example, Feng et al. (2012) looked into syntactic features from Context Free Grammar (CFG) parse trees to improve the performance. Feng and Hirst (2013) built profiles of hotels from collections of

reviews, measuring the compatibility of customer reviews to the hotel profile, and using it as a feature for opinion spam detection. Recently, Li et al. (2014) created a wider-coverage benchmark, which comprises of data from three domains (*Hotel*, *Restaurant*, and *Doctor*), and explored generalized approaches for identifying online deceptive opinion spam. We adopt this dataset for our experiments due to its larger size and coverage.

Existing methods use traditional discrete features, which can be sparse and fail to effectively encode the semantic information from the overall discourse. In this paper, we propose to learn document-level neural representation for better detecting deceptive opinion spam. To our knowledge, we are the first to investigate deep learning for deceptive opinion spam detection.

There has been work that exploits features outside the review content itself. In addition to Jindal and Liu (2008), Mukherjee et al. (2013) explored the features from customer's behavior to identify deception. Based on some truthful reviews and a lot of unlabeled reviews, Ren et al. (2014) proposed a semi-supervised learning method, and built an accurate classifier to identify deceptive reviews. Kim et al. (2015) introduced a frame-based semantic feature based on FrameNet. Experimental results show that semantic frame features can improve the classification accuracy. We focus on the review content in this paper, but their features can be used to extend our model.

2.2 Neural Network Models for Representation Learning

Neural network models have been exploited to learn dense feature representation for a variety of NLP tasks (Collobert et al., 2011; Kalchbrenner et al., 2014; Ren et al., 2016b). Distributed word representations (Mikolov et al., 2013) have been used as the basic building block by most models for NLP. Numerous methods have been proposed to learn representations of phrases and larger text segments from distributed word representations. For example, Le and Mikolov (2014) introduced paragraph vector to learn document representations, extending to word embedding methods of Mikolov et al. (2013). Socher et al. (2013) introduced a family of recursive neural networks to represent sentence-level semantic composition. Follow-up research includes recursive neural network with global feed backward mechanisms (Paulus et al., 2014), deep recursive layers (Irsoy and Cardie, 2014), and adaptive composition functions (Dong et al., 2014).

Convolutional neural networks have been widely used for semantic composition (Kalchbrenner et al., 2014; Johnson and Zhang, 2014), automatically capturing n-gram information. Sequential models such as recurrent neural network or long short-term memory (LSTM) (Li et al., 2015a; Tang et al., 2015) have also been used for recurrent semantic composition. The attention mechanism was first proposed in machine translation (Bahdanau et al., 2014). Further uses of the attention mechanism include parsing (Vinyals et al., 2014), natural language question answering (Sukhbaatar et al., 2015; Kumar et al., 2015; Hermann et al., 2015), and image question answering (Yang et al., 2015). We explore CNN and recurrent neural networks with attention mechanism to learn document representation for detecting deceptive opinion spam, comparing their effect with bag-of-word and paragraph vector baselines.

3 Approach

The proposed neural network model learns real-valued dense vector representations for documents of variable lengths, which is used as the feature to classify each document. Shown in Figure 1, it consists of two main components, The first produces distributed vector sentence representations from word representations, and the second gives dense vector document representations from the sentence vectors.

Structurally, the composition of words in forming sentences is similar to the composition of sentences in forming documents, both tracking sequences of inputs with long range dependencies. Both CNN and RNN are typically used for representing sequences in NLP, giving state-of-the-art accuracies in various tasks. For example, for modeling sentences, CNN gives the best results for sentiment analysis (Johnson and Zhang, 2014; Ren et al., 2016a), while LSTM gives the best results for question answering (Wang and Nyberg, 2015). For modeling discourse structures, LSTM has been used more frequently (Li et al., 2015b; Tang et al., 2015). We experimented with both CNN and RNN for both sentence and document modeling, finding that the best development accuracies are obtained when CNN is used for sentence

modeling and RNN is used for document modeling. Therefore, we choose this structure in Figure 1. Note, however, that our main goal is to empirically study the effectiveness of neural features in contrast to manual discrete features, rather than find a most accurate neural model variation for this task.

3.1 Sentence Model

We represent words using embeddings (Bengio et al., 2003), which are low-dimensional dense real-valued vectors. For each word w, we use a look-up matrix E to obtain its embedding $e(w) \in R^D$, where $E \in R^{D \times V}$ is a model parameter, D is the word vector dimension size and V is the vocabulary size. E can be randomly initialized from a uniform distribution (Socher et al., 2013), or pre-trained from a large raw corpus (Mikolov et al., 2013).

As shown in the bottom of Figure 1, a convolutional neural network (CNN) (Kim, 2014; Kalchbrenner et al., 2014; Johnson and Zhang, 2014) is used to learn dense representations of a sentence. We use three convolutional filters to capture the local semantics of n-grams of various granularities. Formally, denote a sentence consisting of n words as $\{w_1, w_2, .., w_i, ..w_n\}$. Each word w_i is mapped to the embedding representation $e(w_i) \in R^D$. A convolutional filter is a list of linear layers with shared parameters. Let D_1, D_2, D_3 be the width of the three convolutional filters, respectively. We set $D_1 = 1$, $D_2 = 2$ and $D_3 = 3$ for representing unigrams, bigrams and trigrams, respectively. Taking D_2 for example, W_2 and b_2 are the shared parameters of linear layers for this filter. The input of a linear layer is the concatenation of word embeddings in a fixed-length window size D_2, which is denoted as $I_{2,i} = [e(w_i); e(w_{i+1}); ...; e(w_{i+D_2-1})] \in R^{D \times D_2}$. The output of a linear layer is calculated as

$$H_{2,i} = W_2 \cdot I_{2,i} + b_2, \tag{1}$$

where $W_2 \in R^{l_{oc} \times D \times D_2}$, l_{oc} is the output size of the linear layer. We use an average pooling layer to merge the varying number of outputs $\{H_{2,1}, H_{2,2}, .., H_{2,n}\}$ from the convolution layer into a vector with fixed dimensions.

$$H_2 = \frac{1}{n} \sum_{i=1}^{n} H_{2,i} \tag{2}$$

To incorporate nonlinearity, a activation function $tanh$ is used to obtain the output O_2 of this filter.

$$O_2 = tanh(H_2) \tag{3}$$

Similarly, we obtain the O_1 and O_3 for the other two convolutional filters with width 1 and 3, respectively. The outputs of three filters are lastly averaged to generate sentence representation.

3.2 Document Model

Given a document with m sentences, we use the sentence vectors $s_1, s_2, .., s_m$ obtained by the CNN model as inputs, and learn document composition with a gated recurrent neural network (GRNN). Standard recurrent neural networks (RNN) map sentence vectors of variable lengths to a fixed-length vector, by starting with an initial vector, and recurrently transforming the current sentence vector s_t together with the previous state vector h_{t-1} into a new state vector h_t. The transition function is typically a linear layer followed by a non-linear activation function such as *tanh*

$$h_t = tanh(W_r \cdot [h_{t-1}; s_t] + b_r), \tag{4}$$

where $W_r \in R^{l_h \times (l_h + l_{oc})}$, $b_r \in R^{l_h}$, l_h and l_{oc} are dimensions of state vectors and sentence vectors, respectively. Unfortunately, the standard RNN suffers the problem of vanishing gradients (Bengio et al., 1994; Hochreiter and Schmidhuber, 1997). This makes it difficult to model long-distance correlation in a sequence. We explore a gated recurrent neural network (GRNN) to address this, which is similar in spirit to LSTM (Cho et al., 2014; Chung et al., 2015), but empirically runs faster. Specifically, the transition function of the GRNN used in the work is calculated as follows

$$i_t = sigmoid(W_i \cdot [h_{t-1}; s_t] + b_i) \tag{5}$$

$$f_t = sigmoid(W_f \cdot [h_{t-1}; s_t] + b_f) \tag{6}$$

$$g_t = tanh(W_r \cdot [h_{t-1}; s_t] + b_r) \tag{7}$$

$$h_t = tanh(i_t \odot g_t + f_t \odot h_{t-1}) \tag{8}$$

where $\odot$ stands for element-wise multiplication, i_t and f_t represent the reset gate and update gate, respectively. W_i, W_f, b_i, b_f adaptively select and remove history state vectors and input vectors for semantic composition.

To better capture discourse relations, we apply the GRNN structure over sentence representation vectors in the left-to-right and right-to-left directions, respectively, resulting in a forward state sequence $h_1, h_2, .., h_n$ and a backward state sequence $h_n^{'}, h_{n-1}^{'}, .., h_1^{'}$, respectively. For each sentence vector node s_i, a combination of h_i and $h_i^{'}$ is used as its bi-directional state vector. Here, if all bi-directional state vectors are treated equally, the noisy or irrelevant part may degrade the classification performance. Meanwhile, Vrij et al. (2009) and Ott et al. (2011) find that different topics have different importance in deceptive opinion detection. For example, spatial information can usually be a strong indicator of non-spam for hotel reviews. So we introduce a simple attention mechanism to consider the importance of different state vectors. Specifically, for each sentence s_i in one document d, which contains the sentences vectors $s_1, s_2, .., s_m$, we integrate the weights into bi-directional state vector h_i and $h_i^{'}$. Specifically, we use the context vector to measure the importance of the sentences. This yields

$$u_i = tanh(W_s(h_i \oplus h_i^{'}) + b_s), \tag{9}$$

$$\beta_i = \frac{exp({u_i}^{\mathrm{T}} u_s)}{\sum_i exp({u_i}^{\mathrm{T}} u_s)} \tag{10}$$

The document vector d is represented as

$$d = \sum_i \beta_i (h_i \oplus h_i^{'}), \tag{11}$$

where $\sum_{i=1}^{m} \beta_i = 1$, and $\oplus$ is the vector concatenation function. The context vector u_s has been used in previous memory networks (Kumar et al., 2015; Sukhbaatar et al., 2015), and it can been randomly initialized and jointly learned during the training process.

3.3 The Classification Model

We use the document representation as features for identifying deceptive opinion spam. Specifically, a linear layer is added to transform the document vector into a real-valued vector, whose length is class number *C*. A *softmax* function is added to convert real vector to conditional probability for document classification.

Our training objective is to minimize the cross-entropy loss over a set of training examples $(x_i, y_i)|_{i=1}^{N}$, plus a l_2-regularization term,

$$L(\theta) = -\sum_{i=1}^{N} \log \frac{e^{\vec{o}(y_i)}}{e^{\vec{o}(0)} + e^{\vec{o}(1)}} + \frac{\lambda}{2} \parallel \theta \parallel^2, \tag{12}$$

where θ is the set of model parameters.

We use online AdaGrad to minimize the training objective. At step t, the parameters are updated by:

$$\theta_{t,i} = \theta_{t-1,i} - \frac{\alpha}{\sqrt{\sum_{t'=1}^{t} g_{t',i}^2}} g_{t,i}, \tag{13}$$

where α is the initial learning rate, and $g_{t,i}$ is the gradient of the *i*th dimension at step *t*.

We initialize all the matrix and vector parameters with uniform samples in $(-\sqrt{6/(r+c)}, -\sqrt{6/(r+c)})$, where r and c are the numbers of rows and columns of the matrixes, respectively. We learn word embeddings of 100-dimensions using the CBOW model of Mikolov

et al. (2013) from a large-scale Amazon reviews corpus [1]. During training, we use the average of all the pre-trained embeddings vectors to initialize unknown words. We set the output length of the convolutional filter as 50. The initial learning rate of Adagrad is set as 0.01.

4 Experiments

4.1 Experimental Setup

We use the dataset of Li et al. (2014), which consists of truthful and deceptive reviews in three domains, namely *Hotel*, *Restaurant* and *Doctor*. For each domain, a set of *Customer* reviews are collected as truthful reviews, and a set of deceptive reviews are collected from *Turkers* and *Employees*, respectively. We follow Li et al. (2014) in designing the evaluation metrics. For the *Hotel* domain, we perform both three-way (*Customer*/*Employee*/*Turker*) and two-way classification between *Customer* reviews and *Employee*/*Turker* reviews. This is because deceptive reviews from *Employee* and *Turker* can reflect different levels of domain knowledge. For the *Restaurant* and *Doctor* domains, we perform only two-way *Customer*/*Turker* classification because *Employee* reviews are relatively too few. Table 1 shows the statistics of the dataset. For each experiment, we measure both the per-instance accuracy and the macro-F1 score across different classes.

4.2 Development Experiments

To compare the effectiveness of various neural document models, we conduct a set of development experiments using the mixed dataset of all three domains. Only *Turker* and *Customer* reviews are used, and the total of 2600 reviews are split randomly into training/tuning/testing sets with a ratio of 80/10/10. The tuning set is used for optimizing the hyper-parameters for each neural network structure.

We compare a set of methods for document modeling, which include a single averaging method, tracking a document as a bag of sentences (Average), a CNN, a naive RNN, and our gated RNN in single- and bi-directional method. In addition, we compare the bi-directional RNN without attention and with attention being used.

Table 2 show the results. Without modeling discourse relations, the averaging method gives a baseline accuracy of 73.0%. CNN gives better results by capturing relationships between local sentences. Though modeling global sequential relations, RNN does not give better results compared with the averaging baseline, and the main reason is vanishing gradients in its training. By using gates, the results of GRNN is significantly better than both the baseline and the CNN document model. Both averaging and the bi-directional extension further increased the accuracies. By introducing the attention mechanism into the bi-directional GRNN, the best development result is 84.1%.

We also compare our methods with the paragraph vector model of Le and Mikolov (2014), which builds a document representation without considering sentence vectors. It gives results comparable to

Table 3: In-domain results.

the CNN model, but much lower compared with the GRNN models, which leverage non-local discourse structures.

4.3 In-Domain Results

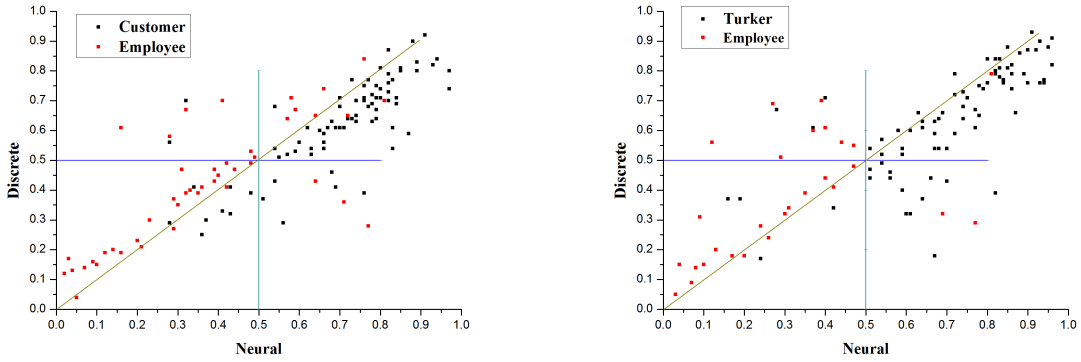
We choose the best neural model, namely the bi-directional GRNN (Attention), according to the development test results. A set of in-domain test are conducted according to Li et al. (2014)'s settings, in order to compare the neural model with the state-of-the-art discrete model with SVM. In particular, all results are reported by using ten-fold cross-validation. As mentioned in the introduction, Li et al. (2014) use hand-crafted features that contain the word, POS and other linguistic clues.

The results are shown in Table 3, in the Li et al. rows and the left items of the Neural/Logistic rows, respectively. For the *Hotel* domain, the neural model outperforms the discrete model of Li et al. (2014) on both three-way *Customer*/*Employee*/*Turker* classification and two-way classification tasks. While Li et al. (2014)'s method gives about around 80% accuracies on *Customer*/*Turker* and *Customer*/*Employee* classifications, which distinguish truthful and deceptive reviews. The accuracies drop to below 66.4% when all the three classes are involved. In contrast, our method gives an accuracy of 78.9% for the three-way task, demonstrating the power of the neural model in distinguishing deceptive reviews from different types of authors. The contrast on the two-way *Employee*/*Turker* classification task is consistent. This shows the power of the neural model in capturing subtle semantic features, which are difficult to express using manual indicator features.

The results on the *Restaurant* domain is similar to those on the *Hotel* domain, where the neural model significantly outperforms the discrete model. However, the neural model gives similar results compared with the discrete model on the *Doctor* domain. One possible reason is that number of reviews in this dataset is relatively lower, which leads to relatively lower accuracies by both models. The other reason is a relatively high OOV rate, and 7.02% of the test words in the *Doctor* domain are out of the embedding dictionary (in contrast to 3.25% in the *Hotel* domain and 3.43% in the *Restaurant* domain).

4.3.1 Analysis

In order to contrast the effect on discrete and neural features, we build a discrete model using logistic regression with the same discrete feature as Li et al. (2014). The main advantage of using this model is a direct comparison on features, because a logistic regression classifier is the same as the *softmax* output layer of our neural network model in mathematic form. The only difference is that the logistic regression method uses discrete features, while the neural model uses continuous features from the deep neural network. The results of the logistic regression model are shown in the right items of the Neural/Logistic rows in Table 3, which are slightly lower but comparable to Li et al. (2014)'s SVM results.



(a) Hotel (Customer/Employee)

(b) Hotel (Turker/Employee)

Figure 2: Output probability comparisons.

Figure 2 shows the output probabilities of the *Customer* and *Turker* classes by both the neural and the logistic discrete models, respectively. Results on the *Hotel* (*Customer*/*Employee*) and *Hotel* (*Turker*/*Employee*) datasets are shown in Figure 2(a) and 2(b), respectively. The x-axis shows the probability by the neural model and the y-axis shows the probability by the discrete model. Taking Figure 2(a) for example, true *Customer* reviews in the test set are shown in black, where false reviews by *Employee* are shown in red. As a result, black dots on the top of the figure and red dots on the bottom show cases which the discrete model predicted correctly, while black dots on the right and red dots on the left show cases which the neural model predicted correctly.

As shown in the figure, most black dots are on the top-right of the figure and most red dots are on the bottom-left, showing that both models are correct in most cases. However, the dots are relatively more disperse in the x-axis, showing that the neural model is more confident in scoring the inputs. This demonstrates the effectiveness of neural features. Observation in Figure 2(b) is similar. For the more challenging task, the neural model shows large advantages.

Figure 2 also shows that the errors by using neural and discrete features can be complementary, which suggests that integrating both types of features in a single model can further improve the results. We make a feature integration by directly concatenating the discrete feature vector (the blue nodes in Figure 1) to the neural features vector before the *softmax* layer. The results of the combined model are shown in the Integrated rows in Table 3. In all the test sets, the model gives significantly better results compared with both the neural and logistic models[2].

4.4 Cross-Domain Results

For the task of deceptive opinion spam detection, the sample numbers of the dataset are relatively small, and the collection of labeled data is time-consuming and expensive. We investigate two important questions. First, it is interesting to know whether the relatively more richly annotated *Hotel* domain dataset can be used to train effective deception detection models on the *Restaurant* or *Doctor* domain. Second, we study the generalization ability of our neural model. We frame the problems as a domain adaptation task, training a classifier on *Hotel* reviews, and evaluate the performance on the other domains. For simplicity, we focus on two-way *Customer*/*Turker* classification.

The results are shown in Table 4. First, the classifiers trained on *Hotel* reviews apply well to the *Restaurant* domain, which is reasonable due to the many shared properties among *Restaurant* and *Hotel*, such as the environment and location. However, the performance on the *Doctor* domain is much worse, largely due to the difference in vocabulary. Second, compared with the method of Li et al. (2014), our neural model gives better performance. For the *Doctor* domain, both models trained on the *Hotel* domain do not generalize well. Our neural model gives a higher F1 (66.3%) compared with the SVM classifier

(61.7%), which shows some relative effectiveness of neural model. Similar to the in-domain results, the integrated model outperforms both the discrete and neural models.

5 Conclusion

We investigated a gated recurrent neural network model with attention mechanism for deceptive opinion spam detection. By capturing non-local discourse information over sentence vectors, the neural network model outperforms a state-of-the-art discrete baseline, and also simple neural document models such as paragraph vectors. Further experiments show that the accuracies can be improved by integrating discrete and neural features.

Abstract

Gaussian LDA integrates topic modeling with word embeddings by replacing discrete topic distribution over word types with multivariate Gaussian distribution on the embedding space. This can take semantic information of words into account. However, the Euclidean similarity used in Gaussian topics is not an optimal semantic measure for word embeddings. Acknowledgedly, the cosine similarity better describes the semantic relatedness between word embeddings. To employ the cosine measure and capture complex topic structure, we use von Mises-Fisher (vMF) mixture models to represent topics, and then develop a novel mix-vMF topic model (MvTM). Using public pre-trained word embeddings, we evaluate MvTM on three real-world data sets. Experimental results show that our model can discover more coherent topics than the state-of-the-art baseline models, and achieve competitive classification performance.

1 Introduction

Topic models such as latent Dirichlet allocation (LDA) (Blei et al., 2003) are hierarchical probabilistic models of document collections. They can effectively uncover the main themes of corpora by using latent topics learnt from observed collections (Blei, 2012), however, they neglect semantic information of words. In topic modeling, a "topic" is a multinomial distribution over a fixed vocabulary, i.e., a word type proportion. Because words are represented by unordered indexes, with statistical inference algorithms, related words are grouped into topics mainly by using document-level word co-occurrence information (Wang and McCallum, 2006), rather than semantics of words. That is why LDA often outputs many low-quality topics, and views in (Das et al., 2015) even suggest that any such observation of semantically coherent topics in topic models is, in some sense, accidental.

To mix with semantics of words, a recent Gaussian LDA (G-LDA) (Das et al., 2015) model integrates topic modeling with word embeddings, which can effectively capture lexico-semantic regularities in language from a large unlabeled corpus (Mikolov et al., 2013). This hot technique transforms words into vectors (i.e., word vector). To model documents of word vectors, G-LDA replaces the discrete topic distributions over word types with multivariate Gaussian distributions on the word embedding space. Because words with similar semantic properties are closer to each other in the embedding space, semantic information of words can be taken into consideration by using Gaussian distributions to describe semantic centrality location of topics.

An issue of G-LDA is that the word weights in Gaussian topics are measured by the Euclidean similarity between word embeddings. However, the Euclidean similarity is not an optimal semantic measure, since most of word embedding algorithms use exponentiated cosine similarity as the link function (Li et al., 2016a). The cosine similarity may be a better choice to describe the semantic relatedness between word embeddings. Following this idea, in this paper we use von Mises-Fisher (vMF) distributions on the embedding space to represent topics, replacing Gaussian topics in G-LDA. The vMF distribution defines a probability density over vectors on a unit sphere, parameterized by mean μ and concentration

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 151–160, Osaka, Japan, December 11-17 2016.

parameter κ. Its density function for $x \in \mathcal{R}^M$, $\|x\| = 1$, $\|\mu\| = 1$, $\kappa \geq 0$ is given by:

$$p\left(x|\mu,\kappa\right) = c_p\left(\kappa\right)\exp\left(\kappa\mu^T x\right) \tag{1}$$

where $c_p\left(\kappa\right)$ is the normalization constant. Note that vMF concerns the cosine similarity defined by $\mu^T x$. It is a better way to represent topics of word embeddings.

Another issue we face is that topics often contain many words that are far away from each other in the embedding space. That is, the true distributions of topics often form two or more dominant clumps. However, a simple vMF distribution is unable to capture such structure. For example, the topic $\langle software, user, net, feedback, grade\rangle$ contains some "dissimilar" words, such as *net* and *grade*[1]. In this case, a simple vMF topic distribution can not simultaneously place high probabilities on these "dissimilar" words.

To address the problem mentioned above, we further use mixtures of vMFs to describe topics, rather than a single vMF. We then develop a novel mix-vMF topic model (MvTM). Mixtures of vMFs can help us capture complex topic structure that forms more dominant clumps. In MvTM, we consider two settings with respect to the topic, i.e., disjoint setting and overlapping setting. Naturally, in disjoint settings all mixtures of vMFs use disjoint vMF bases; and in overlapping setting some mixtures of vMFs share the same vMF bases. An advantages of the overlapping setting is that it can describe topic correlation in some degree. We have conducted a number of experiments on three real-world data sets. Experimental results show that our MvTM can discover more coherent topics than the state-of-the-art baseline topic models, and achieve competitive performance on the classification task.

2 Model

In this section, we simply review LDA and G-LDA.

2.1 LDA

LDA (Blei et al., 2003) is a representative probabilistic topic model of document collections. In LDA, the main themes of corpora are described by topics, where each topic is a multinomial distribution ϕ over a fixed vocabulary (i.e., a word type proportion). Each document is a multinomial distribution θ over topics (i.e., a topic proportion). For simplification, distributions ϕ and θ are designed to be sampled from the conjugate Dirichlet priors parameterized by β and α, respectively. Suppose that *D*, *K* and *V* denote the number of documents, topics and word types. The generative process of LDA is as follows:

1. For each topic $k \in \{1, 2, \cdots, K\}$
   (a) Sample a topic $\phi_k \sim Dir\left(\beta\right)$
2. For each document $d \in \{1, 2, \cdots, D\}$
   (a) Sample a topic proportion: $\theta_d \sim Dir\left(\alpha\right)$
   (b) For each of the N_d words embeddings
      i. Sample a topic indicator $z_{dn} \sim Multinomial\left(\theta_d\right)$
      ii. Sample a word $w_{dn} \sim Multinomial\left(\phi_{z_{dn}}\right)$

Reviewing the definition above, we note that a topic in LDA is a discrete distribution over observable word types (i.e., word indexes). In this sense, LDA neglects semantic information of words and precludes new word types to be added into topics.

2.2 G-LDA

G-LDA (Das et al., 2015) integrates topic modeling with word embeddings. This model replaces the discrete topic distributions over word types with multivariate Gaussian distributions on an *M*-dimensional

[1]This means that the cosine similarity between word embeddings of *net* and *grade* is small.

embedding space, and concurrently replaces the Dirichlet priors with the conjugate Normal-Inverse-Wishart (NIW) priors on Gaussian topics. Because word embeddings learnt from large unlabeled corpora effectively capture semantic information of words (Bengio et al., 2003), G-LDA can handle, in some sense, words' semantics and new word types. Let $\mathcal{N}(\mu_k, \Sigma_k)$ be the Gaussian topic *k* with mean μ_k and covariance matrix Σ_k. The generative process of G-LDA is as follows:

1. For each topic $k \in \{1, 2, \cdots, K\}$
   (a) Sample a Gaussian topic $\mathcal{N}(\mu_k, \Sigma_k) \sim NIW(\mu_0, \kappa_0, \Psi_0, \nu_0)$
2. For each document $d \in \{1, 2, \cdots, D\}$
   (a) Sample a topic proportion: $\theta_d \sim Dir(\alpha)$
   (b) For each of the N_d word embeddings
      i. Sample a Gaussian topic indicator $z_{dn} \sim Multinomial(\theta_d)$
      ii. Sample a word embedding $w_{dn} \sim \mathcal{N}(\mu_{z_{dn}}, \Sigma_{z_{dn}})$

3 MvTM

G-LDA defines Gaussian topics, which measure word weights in topics by the Euclidean similarity between word embeddings. However, the Euclidean similarity is not an optimal semantic measure of word embeddings. People often prefer the cosine similarity (Li et al., 2016a). To upgrade G-LDA, a novel mix-vMF topic model (MvTM) is proposed, where we replace the Gaussian topic in G-LDA with mixture of vMFs. In this work, we use mixture of vMFs with *C* mixture components (Banerjee et al., 2005) described by:

$$p(x|\pi_{1:C}, \mu_{1:C}, \kappa) = \sum_{c=1}^{C} \pi_c p_c(x|\mu_c, \kappa) \tag{2}$$

where $p_c(x|\mu_c, \kappa)$ is the mixture vMF component (i.e., base); π_c is the mixture weight and such that $\sum_{c=1}^{C} \pi_c = 1$. The design of MvTM has two advantages. First, the vMF distribution defines a probability density over normalized vectors on a unit sphere. Reviewing Eq.1, it can be seen that vMF concerns the cosine similarity. Second, using linear vMF mixture model can help us capture complex topic structure, which forms two or more dominant clumps.

Formally, MvTM models documents consisting of normalized word embeddings w in an *M*-dimensional space, i.e., $\|w\| = 1$ and $w \in R^M$. Suppose that there are *K* topics in total. We characterize each topic *k* as a mixture of vMFs with parameter $\Delta_k = \left\{\pi_{k|_{1:C}}, \mu_{k|1:C}, \kappa_k\right\}$. Besides the topic design, again suppose that each document is a topic proportion θ, drawn from a Dirichlet prior α. Let *D* and N_d be the number of documents and the number of words in document *d*, respectively. The generative process of MvTM is given by:

1. For each document $d \in \{1, 2, \cdots, D\}$
   (a) Sample a topic proportion: $\theta_d \sim Dir(\alpha)$
   (b) For each of the N_d word embeddings
      i. Sample a vMF mixture topic indicator $z_{dn} \sim Multinomial(\theta_d)$
      ii. Sample a word vector $w_{dn} \sim v\mathcal{MF}(\Delta_{z_{dn}})$

In MvTM, the vMF bases of different topics can be either disjoint or overlapping. For disjoint MvTM (abbr. MvTM$_d$), the vMF bases of different topics are disjoint. In MvTM$_d$, the total number of vMF bases is $C \times K$. For overlapping MvTM (abbr. MvTM$_o$), vMF bases are allowed to be shared by different topics. An advantage is that the overlapping setting can describe topic correlation in some degree. For example, if two topics share a same vMF base and their corresponding mixture weights are close to each other, they may be semantically correlated. In previous study, we have examined several overlapping patterns, e.g., all topics share a same set of vMF bases. However, an issue is that such patterns often

output many twinborn topics. In this work, we use the following overlapping scheme: suppose that there are *G* groups of K' topics. In a group, each topic consists of C' personal vMF bases, and all topics in this group share *P* public vMF bases, where $C' + P = C$. In this setting, the total number of vMF bases is $G \times (K' \times C' + P)$, and topics in a group $\mathcal{G}_g$ use a same κ_g, i.e., $\kappa_g = \kappa_k = \cdots = \kappa_{k'}$ if $k \cdots k' \in \mathcal{G}_g$. The intuition behind overlapping by topic groups is that only a small set of topics may be semantically correlated. Besides, the personal vMF base design can effectively avoid the outputs of twinborn topics.

3.1 Inference

For MvTM, the topic proportions $\{\theta_d\}_{d=1}^{d=D}$ and the topic assignments $\{z_{dn}\}_{d=1,n=1}^{d=D,n=N_d}$ are hidden variables; and the topics $\{v\mathcal{MF}\left(\Delta_k\right)\}_{k=1}^{k=K}$ are model parameters. Given an observable document collection *W* consisting of word embeddings, we wish to compute the posterior distribution over θ and *z*, and to estimate $v\mathcal{MF}\left(\Delta\right)$.

Because the exact posterior distribution $p(\theta, z|W, \alpha, \Delta)$ is intractable to be computed, we must resort approximation inference algorithms. Due to the multinomial-Dirichlet design, the topic proportion θ can be analytically integrated out. We then use hybrid variational-Gibbs (HVG) (Mimno et al., 2012) to approximate a posterior over the topic assignment *z*: $p(z|W, \alpha, \Delta)$. A variational distribution of the following form is used:

$$q(z) = \prod_{d=1}^{D} q(z_d) \tag{3}$$

where $q(z_d)$ is a single distribution over the K^{N_d} possible topic configurations, rather than a product of N_d distributions. By using this variational distribution, we obtain an Evidence Lower BOund (ELBO) $\mathcal{L}$ as follows :

$$\log p(z|W, \alpha, \Delta) \geq \mathcal{L}(z_d, \Delta) \triangleq \mathrm{E}_q\left[\log p(W, z|\alpha, \Delta)\right] - \mathrm{E}_q\left[\log q(z)\right] \tag{4}$$

We then develop an expectation maximization (EM) process to optimize this ELBO, where in the E-step we maximize $\mathcal{L}$ with respect to the variational distribution $q(z)$, and in the M-step we maximize $\mathcal{L}$ with respect to the model parameter Δ, holding $q(z)$ fixed. Optimizing $q(z)$ directly is expensive because for each document *d* it needs to enumerate all K^{N_d} possible topic configurations. We therefore apply Monte-Carlo approximation to this ELBO $\mathcal{L}$ in Eq.4 by:

$$\begin{aligned}\mathcal{L}(z_d, \Delta) &\triangleq \mathrm{E}_q\left[\log p(W, z|\alpha, \Delta)\right] - \mathrm{E}_q\left[\log q(z)\right] \\ &\approx \frac{1}{B}\sum_{b=1}^{B}\left(\log p(W, z^{(b)}|\alpha, \Delta) - \log q\left(z^{(b)}\right)\right)\end{aligned} \tag{5}$$

where $\left\{z^{(b)}\right\}_{b=1}^{b=B}$ are samples drawn from $q(z)$. Because the variational distributions $q(z_d)$ are independent from each other, reviewing Eq.3, each document *d* drives a personal sampling process with respect to $q(z_d)$.

In the **E-step**, for each document *d* we use Gibbs sampling to draw *B* samples from $q(z_d)$. This sequentially samples topic assignment to each word embedding from the posterior distribution conditioned on all other variables and the data. The sampling equation is given by:

$$p(z_{dn} = k|z_d^{-n}, \alpha, \Delta) \propto (N_{dk}^{-n} + \alpha) \times v\mathcal{MF}(w_{dn}|\Delta_k) \tag{6}$$

where N_{dk} is the number of word embeddings assigned to topic *k* in document *d*; the superscript "-n" is a quantity that excludes the word embedding w_{dn}. During per-document Gibbs sampling, we iteratively run the MCMC chain a fixed number of times and save the last *B* samples.

In the **M-step**, we optimize Δ given all samples of *z* obtained in E-step. This is achieved by maximizing the following approximate ELBO $\mathcal{L}'$:

$$\mathcal{L}' \triangleq \frac{1}{B}\sum_{b=1}^{B}\left(\log p(W, z^{(b)}|\alpha, \Delta) + const\right) \tag{7}$$

For the disjoint setting, i.e., MvTM$_d$, the optimization of $\mathcal{L}'$ is equivalent to independently estimate Δ_k for each topic k. Due to space limit, we omit the derivation details (Gopal and Yang, 2014). Extracting all N_k word embeddings assigned to topic k, for each word embedding w_i we compute its weights for all C vMF bases by:

$$weight_{ic} = \frac{\pi_{k|c} v\mathcal{MF}(w_i|\mu_{k|c}, \kappa_k)}{\sum_{j=1}^{C} \pi_{k|j} v\mathcal{MF}(w_i|\mu_{k|j}, \kappa_k)} \tag{8}$$

and then update Δ_k by:

$$\begin{aligned} R_{k|c} &= \sum_{i=1}^{N_k} weight_{ic} \times w_i, \quad r_k = \sum_{c=1}^{C} \frac{\left\|R_{k|c}\right\|}{N_k} \\ \mu_{k|c} &= \frac{R_{k|c}}{\left\|R_{k|c}\right\|}, \quad \pi_{k|c} = \sum_{i=1}^{N_k} \frac{weight_{ic}}{N_k}, \quad \kappa_k = \frac{r_k M - r_k^3}{1 - r_k^2} \end{aligned} \tag{9}$$

For the overlapping setting, i.e., MvTM$_o$, there are a few changes to the optimization of $\mathcal{L}'$. In each topic group $\mathcal{G}_g$, the updates of π and μ of personal vMF bases remain unchanged, whereas the mean μ of public vMF bases and κ of this group are updated by:

$$r_g = \sum_{c=1}^{C} \frac{\left\|\sum_{k\in\mathcal{G}_g} R_{k|c}\right\|}{\sum_{k\in\mathcal{G}_g} N_k}, \quad \mu_{k|p} = \frac{\sum_{k\in\mathcal{G}_g} R_{k|p}}{\left\|\sum_{k\in\mathcal{G}_g} R_{k|p}\right\|}, \quad \kappa_g = \frac{r_g M - r_g^3}{1 - r_g^2} \tag{10}$$

where $\mu_{k|p}$ is the mean of the pth public vMF base for topic k and note that $\mu_{k|p} = \mu_{k'|p}$ if $k, k' \in \mathcal{G}_g$.

For clarity, the overall EM inference algorithm for MvTM is outlined in *Algorithm 1*.

Algorithm 1 Inference for MvTM

    For MvTM$_0$, optimize Δ using Eq.8, 9 and 10.
End for

3.2 Time Complexity

We first analyze the time complexities of E-step and M-step, and then present the overall time cost of MvTM.

In the **E-step**, the main time cost is the topic assignment sampling of each word embedding over K topics. Reviewing Eq.6, one sampling process needs to compute the probabilities of the current word embedding, i.e., $v\mathcal{MF}(w_{dn}|\Delta_k)$, in all K topics, which requires $O(KCM)$ time. Fortunately, the topics are fixed in the E-step, thus we only need to compute the value of $v\mathcal{MF}(w|\Delta_k)$ for each word embedding at the beginning of each EM sweep, and save them in the memory. This requires $O(VKCM)$ time, where V is the number of word embeddings. Consequently, the topic sampling process of MvTM is equivalent to the sampling of Gibbs sampling LDA, requiring $O(K)$ time. We present that the per-iteration time complexity of E-step is given by $O(VKCM + \zeta N_V K)$, where ζ is the iteration number in per-document Gibbs sampling and N_V is the total number of word embeddings occurred in a corpus. Recently, sparse sampling algorithms (Yao et al., 2009; Li et al., 2014) effectively accelerate the sampling

Table 1: Summarization of data sets used in our experiments. N_V is the total number of word tokens; N_V/D is the average document length; "label" denotes the number of pre-assigned classes.

Data set	V	D	N_V	N_V/D	label
NG	18,127	18,768	1,946,487	104	20
NIPS	4,805	1,740	2,097,746	1,206	–
Wiki	7,702	44,819	6,851,615	153	–

of topic models. Inspired by (Li et al., 2016b), we employ the Alias method (Walker, 1977; Marsaglia et al., 2004) to reduce the per-word sampling cost from $O(K)$ to $O(K_d)$, where K_d is the number of instantiated topics in document d and commonly $K_d \ll K$. The per-iteration time complexity of E-step now is $O(VKCM + \zeta N_V K_d)$.

In the **M-step**, the time cost of MvTM$_d$ and that of MvTM$_o$ are almost the same. We only present the time complexity of MvTM$_d$. Reviewing the M-step, we see that the most expensive updates include Eq.8, the first and the fourth equations in Eq.9. They require $O(VCM)$, $O(VCM)$ and $O(VC)$. Thus we present that the (per-iteration) time complexity of M-step is $O(VCM)$.

Overall, we see that in each EM sweep the E-step dominates the run-time, giving an approximate total per-iteration time complexity $O(VKCM + \zeta N_V K_d)$. Clearly, MvTM is much efficient than Gibbs sampling G-LDA (Das et al., 2015), because G-LDA needs to repeatedly compute the determinant and inverse of the covariance matrix in Gaussian topics. For each word occurring, this spends $O(M^2)$ time, even using Cholesky decomposition.

4 Experiment

In this section, we evaluate MvTM qualitatively and quantitatively.

4.1 Experimental Setting

Data set Three data sets were used in our experiments, including Newsgroup (NG), NIPS and Wikipedia (Wiki). The NG data set is a collection of newsgroup documents, consisting of 20 classes. We will use NG to examine the classification performance of MvTM in Section 4.3. The NIPS data set is a collection of papers in the NIPS conference. The processed versions of these two data sets were downloaded from the open source of G-LDA[2]. For the Wiki data set, we downloaded a number of documents from online English Wikipedia, and processed these documents using a standard vocabulary[3]. The statistics of the three data sets are listed in Table 1.

Baseline model: In the experiments, we used two baseline models, including LDA[4] and G-LDA[2]. For both baseline models, we use their open source codes publicly available on the net. A pre-trained 50-dimensional word embeddings[5] were used. Especially for MvTM, we normalized the word embeddings.

4.2 Evaluation on Topics

We use the PMI score (Newman et al., 2010) to evaluate the quality of topics learnt by topic models. This metric is based on the pointwise mutual information of a power-law reference corpus. For a topic k, given T most probable words the PMI score is computed by:

$$PMI\,(k) = \frac{1}{T\,(T-1)} \sum_{1 \le i \le j \le T} \log \frac{p\,(w_i, w_j)}{p\,(w_i)\,p\,(w_j)} \tag{11}$$

where $p\,(w_i)$ and $p\,(w_i, w_j)$ are the probabilities of occurring word w_i and co-occurring word pattern (w_i, w_j) estimated by the reference corpus, respectively. In the experiments, we use the Palmetto[6] tool

to compute PMI scores of the top 15 words.

We train baseline models and our MvTM with 50 topics, and evaluate the average PMI score of all topics. For MvTM$_d$, the number of vMF bases is set to 2, i.e., $C = 2$. For MvTM$_o$, topics are organized into ten groups, where each group consists of five topics; and the numbers of personal vMF bases and public vMF bases are set to 2 and 3, respectively[7].

The experimental PMI results on three data sets are shown in Figure 1. It is clearly seen that MvTM performs better than LDA and G-LDA. This implies that MvTM outputs more coherent topics. Some examples of top topic words are listed in Table 2. Overall, we see that the topics of MvTM seem more coherent than those of baseline models. The topics of LDA contain some noise words, e,g., "mr" and "don"; and G-LDA contains some less relevant words, e.g., the second topic of G-LDA is incoherent. In contrast, the topics of MvTM are more precise and clean. Besides, for MvTM$_o$ we measure topic correlation by computing the cosine between vMF weights of topics in the same group. Some topic pairs with high cosine similarity scores, such as $\langle patients, treatments, therapy, treatment, diabetes\rangle$ and $\langle blood, skin, heart, stomach, breathing\rangle$, seem semantically correlated.

[7]In previous experiments, we found that using mixtures of vMFs with 2 bases is able to better represent topics.

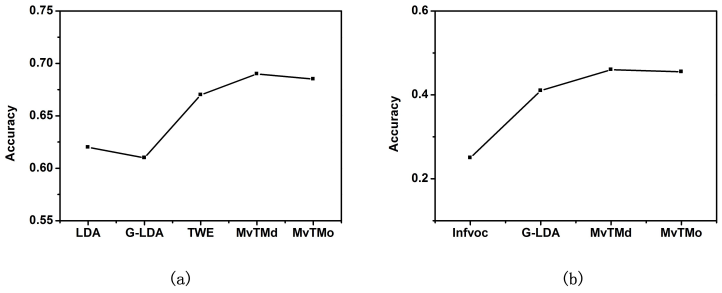

Figure 2: Classification performance on NG: (a) original test documents and (b) test documents with new words.

4.3 Evaluation on Classification

We compare the classification performance of MvTM with baseline topic models across NG. Two new baselines are used, i.e., topical word embedding (TWE) (Liu et al., 2015) and infvoc (Zhai and Boyd-Graber, 2013). For all models, we learn the topic proportions (K=50) as features of documents, and then use the SVM classifier implemented by LibSVM[8].

The results of original test documents are shown in Figure 2(a). Clearly, MvTM achieves better performance than LDA, G-LDA and TWE. MvTM can handle absent words in training data. To examine this ability, we compare MvTM with G-LDA and infvoc[9], where the two also can handle unseen words. We replace a number of words in test documents with synonyms by using WordNet as in (Das et al., 2015). The classification results are shown in Figure 2(b). It can be seen that MvTM outperforms G-LDA and infvoc. The results imply that MvTM works well even future documents containing new words. This may be insignificant in practice.

5 Related Work

Some early works have attempted to combine topic modeling with embeddings. (Hu et al., 2012) proposed a model to describe indexing representations for audio retrieval, which is similar with G-LDA. Another work (Wan et al., 2012) jointly estimates parameters of a topic model and a neural network to represent topics of images.

Recently, (Liu et al., 2015) proposed a straightforward TWE model. This model separately trains a topic model and word embeddings on the same corpus, and then uses the average of embeddings assigned to the same topic as the topic embedding. A limitation of TWE is that it lacks statistical foundations. Another modification latent feature topic modeling (LFTM) (Nguyen et al., 2015) extends LDA and Dirichlet multinomial mixture by incorporating word embeddings as latent features. However, LFTM may be infeasible for large-scale data sets, since it, i.e., the code provided by its authors, is time-consuming. A most recent nonparametric model (Batmanghelich et al., 2016) also uses vMF to describe the topic over word embeddings, where a topic is represented by a single vMF on the embedding space. By contrast, it may be less effective to capture complex topic structure.

6 Conclusion and Discussion

In this paper, we investigate how to improve topic modeling with word embeddings. A previous art G-LDA defines Gaussian topics over word embeddings, however, the word weights of topics are measured by the Euclidean similarity. To address this problem and further capture complex topic structure, we use mixtures of vMFs to model topics, and then propose a novel MvTM algorithm. The vMF bases of topics in MvTM can be either disjoint or overlapping, leading to two versions of MvTM. The overlapping MvTM can describe topic correlation in some degree. In empirical evaluations, we use the per-trained GloVe word embeddings, and then compare MvTM with LDA and G-LDA on three real-world data

[9]For fair comparison, we train infvoc by a batch optimization procedure.

sets. The experimental results indicate that compared to the state-of-the-art baseline models MvTM can discover more coherent topics measured by PMI, and achieve competitive classification performance. In the future, we are interested in supervised versions of MvTM, directly applying to basic document tasks such as sentiment analysis.

Bayesian Language Model based on Mixture of Segmental Contexts for Spontaneous Utterances with Unexpected Words

Abstract

This paper describes a Bayesian language model for predicting spontaneous utterances. People sometimes say unexpected words, such as fillers or hesitations, that cause the miss-prediction of words in normal N-gram models. Our proposed model considers mixtures of possible segmental contexts, that is, a kind of context-word selection. It can reduce negative effects caused by unexpected words because it represents conditional occurrence probabilities of a word as weighted mixtures of possible segmental contexts. The tuning of mixture weights is the key issue in this approach as the segment patterns becomes numerous, thus we resolve it by using Bayesian model. The generative process is achieved by combining the stick-breaking process and the process used in the variable order Pitman-Yor language model. Experimental evaluations revealed that our model outperformed contiguous N-gram models in terms of perplexity for noisy text including hesitations.

1 Introduction

1.1 Background

Language models (LMs) are widely used for text analysis, word segmentation and word prediction in automatic speech recognition (ASR). The basic LM is a conventional N-gram model that predicts a word depending on the patterns of the previous N words (*context*). The probability of a word is usually calculated by counting the words that match the context in text data as maximum likelihood estimation. Therefore, the model easily predicts frequent words or set expressions but not rare words or phrases.

Various N-gram language models have been proposed to prevent the incorrect probability assignment caused by the increase of the context length N. Since the number of combinations of N becomes $O(V^N)$ for vocabulary size V, there are a lot of patterns that do not appear in training data (data sparseness). Using an N-gram model based on a Bayesian framework is a promising approach for data sparseness. Because it is based on a Bayesian framework, an LM based on hierarchical Pitman-Yor process (HPYLM) has two main differences from previous language models (Teh, 2006), such as Witten-bell (WB) (Witten and Bell, 1991) and Kneser-ney (KN) smoothing (Kneser and Ney, 1995): 1) a Bayesian model expressing conventional smoothing methods and 2) automatic tuning of parameters from data. Since HPYLM is based on a Bayesian framework, we can integrate other probabilistic models theoretically for other problems and apply optimization methods in accordance with a Bayesian framework. In contrast, other smoothing methods has several parameters that need to be tuned manually.

Human utterances contain various fillers and hesitations (left in Fig. 1), and these cause the misprediction of words because they rarely appear in the training data, that is, another type of sparsity. This will affect 1) the word prediction accuracy in ASR and 2) the precision of word segmentation (Mochihashi et al., 2009) or lexicon acquisition from speech signal (Elsner et al., 2013; Kamper et al., 2016; Taniguchi et al., 2016), which are our main interest. Since such hesitations are usually not registered

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 161–170, Osaka, Japan, December 11-17 2016.

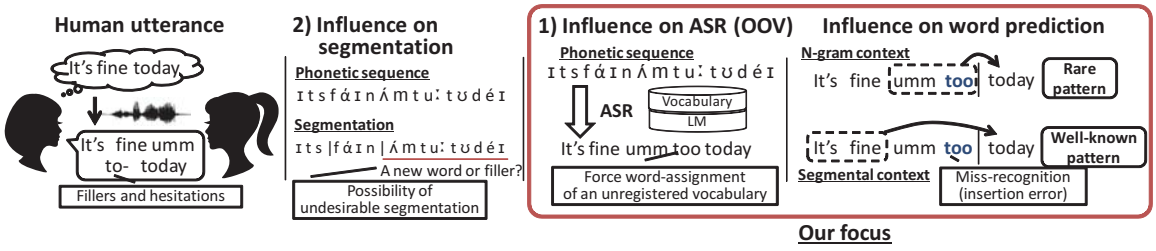

Figure 1: Problem caused by unexpected and inserted words

to an ASR vocabulary (out-of-vocabulary; OOV), they are recognized as the most similar and likely word in the vocabulary set in terms of pronunciation and context (middle-right in Fig. 1). Moreover, mis-recognized words may also affect the subsequent word prediction based on N-gram auto-regression. Such mis-recognition is a kind of insertion error caused by fillers, hesitations and other noise signals, such as coughs. For example, the hesitation "to-" is recognized as "too", and the filler "umm" and hesitation "too" are used for the prediction of the next word if we use normal N-gram model (right upper in Fig. 1). Note that hesitations are hard to eliminate by using only a filler-word list because their complete patterns cannot be prepared in advance. As for word segmentation and lexicon acquisition, the language model is trained from character/phoneme sequences or raw speech signal in an *unsupervised* manner. The Bayesian nonparametrics is often applied to this problem because it enables us to control the number of words/symbols dynamically according to the amount of data. Since the lexicon acquisition includes a kind of segmentation problem, fillers and hesitations may cause mis-segmentations. A nonparametric generative model that can deal with hesitations and fillers will help to recognize words sequence and segment words from phoneme sequence.

We propose using a Bayesian language model in which probability consists of a mixture of conditioned probabilities of segmental contexts for the word prediction problem. Since the lexicon acquisition from phonetic sequence or raw *conversational* speech signal is also our scope, Bayesian approach is necessary in terms of scalability. Our model removes (ignores) some words, such as fillers and hesitations in the ideal case, from the context in predicting words. For example, given the text "It's fine umm too today," the probability $p(\text{today}|\text{It's}, \text{fine}, \text{umm}, \text{too})$ is defined as a mixture of $\hat{p}(\text{today}|\text{It's}, \text{fine}, \text{umm}, \text{too})$, $\hat{p}(\text{today}|\text{fine}, \text{umm})$, $\hat{p}(\text{today}|\text{It's}, \text{fine})$ and so on (right lower Fig. 1). The risk of mis-prediction caused by the unknown context is reduced by other differently conditioned probabilities. Since the given term includes many patterns of segmental context, we constrain the pattern to one "contiguous" segment. That is, the probabilities of a discontiguous segment, such as $p(\text{today}|\text{It's}, \text{umm})$, are not included in the mixture. Since the generative process can be expressed by combining the stick-breaking process (Sethuraman, 1994) and the process used in the variable order Pitman-Yor language model (VPYLM) (Mochihashi and Sumita, 2007), the parameters can be estimated by Gibbs sampling (Christopher Michael Bishop, 2006) the same as they are for VPYLM.

1.2 Related Work on Mixture Models

The main differences between our work and previous studies are 1) assumed context patterns in the mixture and their purpose (text-level or utterance-level), and 2) whether the model is Bayesian or not. Our proposed model is one of various mixture language models and there are several language mixture models that consider word dependency. Again, we stochastically *ignore* some contiguous words in the context in accordance with the appearance of fillers, hesitations and noises (right in Fig. 1) at the utterance-level. Since other LM models correspond to the process for text generation in our framework, we can embed them in our process as mixture components if necessary. As shown in the right half of Fig. 2, our current model is based on the mixture of VPYLM which is based on the mixture of HPYLM. Note that VPYLM and HPYLM have no mechanism to select words in the context for prediction.

Previous studies used all combinations or syntactic structure of N words in context, and their methods are complex to deal with our filler/hesitation problems. The left half of Fig.2 shows a generalized lan-

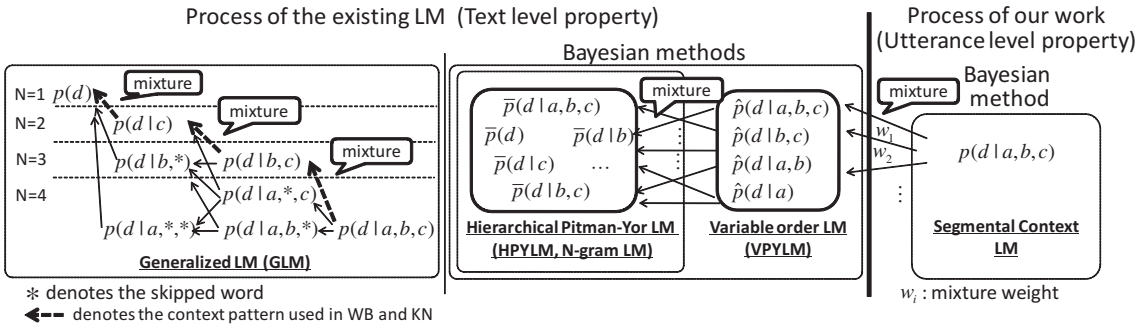

Figure 2: Language model structures: GLM (left), HPYLM/VPYLM (middle) and our model (right)

guage model (GLM) that mixes all probabilities of possible context patterns of N-grams hierarchically (Pickhardt et al., 2014). At each context depth, a word is *skipped* in the context (skip N-gram (Goodman, 2001; Guthrie et al., 2006)), and the probability is smoothed by shallow contexts. The relative position in the context remains, and the skipped word is denoted by the asterisk $*$. WB and KN use only the contiguous contexts for smoothing as shown in the Figure. Wu and Matsumoto (2015) proposed a hierarchical word sequence language model using directional information. The most frequently used word in the sentence is selected for splitting a sentence into two substrings, and a binary-tree is constructed by a recursive split. If a directional structure is assumed, the context patterns decrease in size and the processing time is shortened.

Running a language model on a recurrent neural network (RNN) (Mikolov et al., 2010) is, of course, a reasonable choice because of the good prediction performance for closed-vocabulary task. However, a neural network LM usually does not include a generative process, so it is difficult to apply to *unsupervised* training of a language model or lexicon acquisition from speech signals. In that sense, the LM based on generative model is still important. Of course, the combination method of Bayesian model and neural networks should be investigated for practical use.

Our work is the extension of VPYLM based on mixture of segmental contexts to deal with hesitations and fillers. And our mixture pattern is designed for hesitation and fillers, and it is simpler than that of others in terms of the number of context patterns.

2 Hierarchical Bayesian Language Model based on Pitman-Yor Process

This section explains the fundamental mechanism of a language model based on Bayesian nonparametrics. HPYLM should predict words more accurately than KN-smoothing because KN-smoothing is an approximation of this model.

2.1 Generative Model

The N-gram LM approximates the distribution over sentences $w_T, ..., w_1$ using the conditional distribution of each word w_t given a context $\boldsymbol{h}$ consisting of only the previous $N-1$ words $\boldsymbol{w}_{N-1}^{t-1} = \{w_{t-1}, ..., w_{t-N+1}\}$,

$$p(w_T, ..., w_1) = \prod_t^T p(w_t | \boldsymbol{w}_{N-1}^{t-1}). \tag{1}$$

The trigram model ($N = 3$) is typically used. Since the number of parameters increases exponentially as N becomes larger, the maximum-likelihood estimation severely overfits the training data. Therefore, smoothing methods are required if vocabulary V is large.

The probabilistic generative process of sentences based on HPY is explained by the Hierarchical Chinese restaurant process (CRP). In the CRP, there are tree-structured restaurants with tables and customers that are regarded as latent variables of words. When a customer enters the leaf restaurant $\boldsymbol{h}$, which corresponds to context, he/she sits down at an existing table or a new table depending on some probabilities.

If he/she selects a new table, an agent of the customer recursively enters the parent restaurant $\boldsymbol{h}'$ as a new customer. Here, we represent the depth of $\boldsymbol{h}$ as $|\boldsymbol{h}|$, and there is the relationship $|\boldsymbol{h}'| = |\boldsymbol{h}| - 1$. Given the seating arrangement of customers $\boldsymbol{s}$, the conditional probability of word w with the context $\boldsymbol{h}$ is defined as follows

$$p(w_t|\boldsymbol{s}, \boldsymbol{h}) = \frac{c_{\boldsymbol{h}w} - d_{|\boldsymbol{h}|}t_{\boldsymbol{h}w}}{c_{\boldsymbol{h}*} + \theta_{|\boldsymbol{h}|}} + \frac{\theta_{\boldsymbol{h}} + d_{|\boldsymbol{h}|}t_{\boldsymbol{h}*}}{c_{\boldsymbol{h}*} + \theta_{|\boldsymbol{h}|}} p(w_t|\boldsymbol{s}, \boldsymbol{h}'), \tag{2}$$

where $c_{\boldsymbol{h}w}$ is the count of word w at context $\boldsymbol{h}$, and $c_{\boldsymbol{h}*} = \sum_w c_{\boldsymbol{h}w}$ is its sum. $t_{\boldsymbol{h}w}$ is the number of table at context $\boldsymbol{h}$, and $t_{\boldsymbol{h}*}$ is also its sum. $\theta_{|\boldsymbol{h}|}$ and $d_{|\boldsymbol{h}|}$ are the common parameters of $\boldsymbol{h}$ with the same depth $|\boldsymbol{h}|$. The distribution over the current word given the empty context ϕ is assumed to be uniform over the vocabulary w of V words. The variable order PYLM integrates out the context length (depth) N, thus we need not determine the length in advance.

The predictive probability of word w is approximated by averaging Eq. (2) over sampled seating arrangement $\boldsymbol{s}_n (n = 1, ..., N)$.

$$p(w|\boldsymbol{h}) = \frac{1}{N} \sum_n p(w|\boldsymbol{s}_n, \boldsymbol{h}) \tag{3}$$

2.2 Inference of Parameters

The latent variable $\boldsymbol{s}$ and other parameters d and θ are obtained through simulations on the basis of Gibbs sampling given training text $\bar{w}_i (i = 1, ..., N_{train})$. The procedure for sampling a customer is as follows:

1. Add all customers to the restaurants
2. Select a certain customer $\bar{w}_i$
3. Remove the customer from the restaurant. If a table becomes null, also remove the agent from the parent restaurant recursively.
4. Add the customer to the leaf restaurant. He chooses a table with probabilities proportional to the number of customers at each table. If the table is null, also add an agent to the parent restaurant recursively. (Go back to Step 2).

The parameters are sampled using auxiliary variables from their posterior probability. Please see the work of Teh (Teh, 2006) for the detailed sampling algorithm.

2.3 Problem of Contiguous Context Model

The N-gram model is modeled as a series of words, and has an advantage in expressing common phrases. The Bayesian nonparametrics enables the N-gram model to tune the smoothing parameters automatically. This improves the accuracy of predicting rare words in a large context.

Unexpected words degrade the prediction accuracy of the N-gram model. The unexpected words include noises, fillers, and hesitations in actual utterances. For example, the probability of $p(\text{sing}|\text{he}, \text{will})$ is estimated reliably. However, the probability of $p(\text{sing}|\text{will}, \text{sh..})$, which includes a hesitation ("sh.."), is estimated unreliably because the hesitation does not appear in the corpus. The patterns of insertion location and bursty are also not determined in advance.

3 Bayesian Language Model based on Mixture of Segmental Contexts

This section explains the segmental context model for utterances. First, we explain the generative model and then its parameter inference. Note that the aim of this model is to improve the accuracy of word prediction under noisy context condition, not to detect fillers and hesitations.

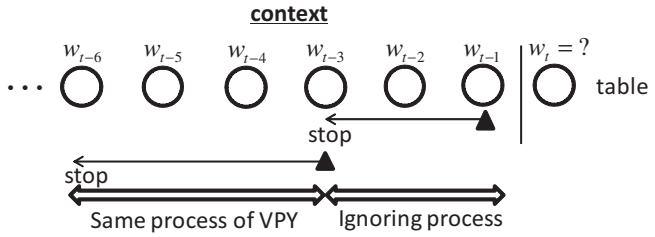

Figure 3: Process for segmental context model

3.1 Generative Model

We assume that the conditional distribution of each word w_t given a context is a mixture of the segmental N-gram context. The segmental N-gram is a part of context $w_{t-i}, .., w_{t-j}$, which begins at w_{t-i} and ends at w_{t-j}.

$$p(w|\boldsymbol{w}_{N-1}^{t-1}) = \sum_i \sum_{j>i} p(w|\boldsymbol{w}_{N-1}^{t-1}, i, j)p(i, j) = \sum_i \sum_{j>i} p(w|\boldsymbol{w}_j^{t-i})p(j|i)p(i) \tag{4}$$

If we consider the $N \to \infty$, the possible segmental patterns are also considered. Setting the start index i of N-gram appropriately can eliminate the influence of the sequential unexpected words for predicting the next word. The word probability term $p(w_t|\boldsymbol{w}_j^{t-i})$ is determined by HPYLM.

The stick-breaking process (SBP) represents the generative process of Eq. (4) as the same way of VPYLM (Mochihashi and Sumita, 2007). The process consists of two parts; 1) decide the start index i of N-gram and then 2) decide the end index j of N-gram. Each index is determined probabilistically using SBP (Fig. 3).

Step1 - Process for start index i: First, the customer walks along the tables (word) from the start, w_{t-1}. The customer stops at the i-th table with probability η_i, and passes it with probability $1 - \eta_i$. Therefore, the probability that the customer stops at the i-th table is given by

$$p(i|\boldsymbol{\eta}) = \eta_i \prod_{l=1}^{i-1}(1 - \eta_l). \tag{5}$$

This probability decreases exponentially. We assume that the prior of parameters $\boldsymbol{\eta}$ is Beta distribution Beta(α_1, β_1).

Step2 - Process for end index j: The end index j is also determined using the same process i. The customer walks along the tables from the i-th table, and stops at or passes the j-th table with probability ζ_j or $1 - \zeta_j$, respectively.

$$p(j|i, \boldsymbol{\zeta}) = \zeta_j \prod_{l=1}^{j-1}(1 - \zeta_l). \tag{6}$$

The prior of parameters $\boldsymbol{\zeta}$ is also assumed to be the Beta distribution Beta(α_2, β_2).

In fact, the whole process can be considered to be the combination of VPYLM and the start index determination process. We thus can describe the probability as

$$p(w_t|\boldsymbol{w}_\infty^{t-1}) = \sum_i P_{\text{vpy}}(w|\boldsymbol{w}_\infty^{t-i-1})p(i). \tag{7}$$

If we determine from which element, $P_{\text{vpy}}(w|\boldsymbol{w}_\infty^{t-i-1})$, the word comes in step 1, the latter process is the same as the VPYLM. In practice, we set a maximum length of context for parameter estimation.

Table 1: Parameters of experiment

	Artificial noisy data		Actual hesitation data
	English	Japanese	Japanese
Target text	War and Peace	CSJ	CSJ
Training	27876 sentences 479585 words	110566 sentences 2828499 words	114372 sentences 3084592 words
Test for clean	5128 sentences 88552 words	7134 sentences 199100 words	20440 sentences 184145 words
Test for noisy	5128 sentences 97373 words	7134 sentences 218945 words	2296 sentences 32342 words
Vocabulary size	10717	18357	19703
(α_1, β_1)	(9, 1)		(1, 1)
(α_2, β_2)	(1, 9)		(1, 8)

3.2 Inference of Start Index

We assume that all words in training data $\bar{\boldsymbol{w}}$ have the start index i_t as a latent variable, and are estimated stochastically by Gibbs sampling. The start index i_t of the word $\bar{w}_t$ is sampled given data $\bar{\boldsymbol{w}}$, seating arrangement $\boldsymbol{s}$, and start and end indexes of other words $\boldsymbol{i}_{-t}$ and $\boldsymbol{j}_{-t}$ as

$$i_t \sim p(i_t|\bar{\boldsymbol{w}}, \boldsymbol{s}_{-t}, \boldsymbol{j}_{-t}, \boldsymbol{i}_{-t}) \tag{8}$$

$$\propto p(w_t|\bar{\boldsymbol{w}}_{-t}, \boldsymbol{j}_{-t}, \boldsymbol{i}) p(i_t|\bar{\boldsymbol{w}}_{-t}, \boldsymbol{s}_{-t}, \boldsymbol{i}_{-t}, \boldsymbol{j}_{-t}) \tag{9}$$

where the notation $-t$ means that the t-th element corresponding to $\bar{w}_t$ is excluded. Here, the first term, $p(\bar{w}_t|\bar{\boldsymbol{w}}_{-t}, \boldsymbol{j}_{-t}, \boldsymbol{i})$, is calculated using VPYLM because the start index i_t is given. The second term is a prior probability to select the start index. It can be calculated in the same way used in the VPYLM:

$$p(i_t = l|\boldsymbol{w}_{-t}, \boldsymbol{s}_{-t}, \boldsymbol{i}_{-t}, \boldsymbol{j}_{-t}) = \frac{a_l + \alpha_1}{a_l + b_l + \alpha_1 + \beta_1} \prod_{k=1}^{l} \frac{b_k + \beta_1}{a_k + b_k + \alpha_1 + \beta_1}, \tag{10}$$

where α_1 and β_1 are hyper-parameters of the Beta distribution. The a_l and b_l are the count of customers who stopped at and those who passed table $\bar{w}_l$. This probability is assumed to depend only on $\bar{w}_l$, not whole context $\boldsymbol{h}$. Since the probability of the word corresponding to $\bar{w}_l$ is not important for the prediction is low, the effect of an unexpected word on this index is reduced.

Once the start index is set, we can also draw the end index j_t and the seating arrangement s_t through VPYLM process. The j_t is first drawn from its posterior distribution, and then seating s_t is also drawn from its posterior distribution. After sampling, the average word probability is used for prediction.

The computational cost of our model is proportional to $O(N)$ while the cost of the generalized language model is roughly proportional to $O(2^N)$. The enumeration of all combinations of words that should be used is computationally heavy for models based on Bayesian nonparametrics when N becomes larger and we optimize parameters of the model. Moreover, the context pattern of the generalized model is complex to deal with fillers and hesitations (insertion errors).

4 Experimental Evaluations

4.1 Experimental Setup

We used two kinds of text for evaluation: 1) artificial noisy text and 2) actual hesitation text (Japanese only). The former is for the validation of our method with model-matched data, and the latter is for the performance measurement with real utterances.

We used two languages English and Japanese text data for training and test dataset for the artificial noisy text. The English text was "War and Peace" from project Gutenberg[1], and the Japanese text was the Corpus of Spontaneous Japanese (CSJ[2]), consists of transcriptions of Japanese speech. For the English

[1] http://www.gutenberg.org/

[2] https://www.ninjal.ac.jp/english/products/csj/

text, we randomly selected 27,876 sentences from the entire of "War and Peace" for training data, and used the remaining 5,128 sentences for test data. For Japanese text, we used 110,566 sentences in the "non-core" set for training data and 7,134 sentences in the "core" set for test data. All hesitations and fillers were eliminated from the Japanese corpus to make it formal text data [3]. The utterances in the CSJ that have 0.5-second short-pauses were separated into sub-utterances, and each sub-utterance was treated as a sentence. The words that appeared more than once were selected for the vocabularies. The sizes of vocabularies were 10,717 words for English text and 18,357 words for Japanese text. To simulate the artificial noisy text, we added words randomly selected from vocabularies into the test data at a rate of 10 %. The OOVs in the test set were treated as a symbol, "<unk>".

The raw CSJ Japanese transcription text was used for the actual hesitation text. In this experiment, hesitations and fillers in the training set are *not* eliminated. The utterances that have 0.2-second short-pauses were separated into sub-utterance, and each sub-utterance was treated as a sentence. The 0.2-second is selected to make a rate of hesitation in noisy text about 8.0%. The test transcription data ("core" set) were divided into two categories: hesitation-included noisy text (2,296 sentences) and clean text (20,440 sentences). The number of hesitations in the test dataset was 2649 (about $2649/32342 = 8.1\%$). The hesitation-included noisy text included hesitations, so its vocabulary was 19,703. The out of vocabulary (OOV) words in the hesitation test data were replaced by words randomly selected from the vocabulary set that had a phoneme distance to the OOV word of less than 2. This is because *such OOV words including unknown hesitations are actually mis-recognized and assigned similar-sounding words in the ASR vocabulary*. Therefore, the vocabulary set was closed. Note that *frequent fillers and hesitations remained in both the test and training sets*. These settings are listed in Tab. 1.

We compared our model with other models: WB, KN, Modified KN (MKN) (Chen and Goodman, 1999), HPYLM, and VPYLM. The hyper-parameters, α_2 and β_2 of the Beta distribution used in VPYLM were set to 1 and 9 for the artificial data, and 1 and 8 for the actual hesitation data. Additionally, those of the start index process, α_1 and β_1, were set to 9 and 1 for the artificial data, and 1 and 1 for the actual hesitation data. These parameters were selected to perform best for each test set to evaluate the limitation of methods. For the English and Japanese text, N was set to 3, 4, 6, 10. For the Japanese transcription, it was set to 3, 6, 8, 10. The predictive probability was averaged over 30 seating arrangements after 90 iterations of Gibbs sampling. We also investigate the performance of RNN language model [4] as a reference. We tried several parameter set of RNN, such as the number of hidden layers and classes, and they are also tuned for each test set. Note that the main interest of our experiments is the performance comparison among Bayesian methods.

Perplexity (PP) was used as the evaluation criterion.

$$\text{PP} = 2^{P(\boldsymbol{w}_{\text{test}})}, \quad P(\boldsymbol{w}_{\text{test}}) = -\frac{1}{N_{\text{test}}} \sum_{s \in w_{\text{test}}} \log P(s), \tag{11}$$

where s is a sentence in the test data and N_{test} is the number of words in the test dataset. The PP was calculated under the assumption that each sentence was independent. Smaller PP values mean better word prediction accuracy. The prediction of OOVs, which are denoted by "<unk>", in the artificial test set is eliminated in calculating perplexity.

4.2 Results and Discussion

4.2.1 Artificial Noisy Data

The perplexity values for the two data sets and the four N-gram lengths can be seen in Tabs. 2 and 3 for English and Japanese text, respectively. The clean text denotes the raw formatted text, and the noisy text denotes the ones with randomly-added words. There is no noteworthy difference between the English and Japanese text other than the range of PP.

The differences among methods for clean text data with $N = 3$ are clear. Like in the results of previous studies, HPYLM and MKN had the lowest PP, followed by VPYLM and WB. Our model had worse PP

[3] All words were tagged by hand. The tags of fillers and hesitations were included.

	RNN	83.1			

than MKN, HPYLM and VPYLM. Since our model stochastically ignores some contiguous words in the context, the prediction accuracy for formatted text was worse than those of other methods. This can be reduced by using more text data or an improved model discussed in the next subsection. Using a longer context improved the PPs of HPYLM and our model. Therefore, a longer context is useful for word prediction. The perplexity of RNN was smallest, and RNN outperformed others by 15 and 4 points for English and Japanese text.

The ranking were different for the noisy text data. The relative performances of WB, KN, MKN, HPYLM, and VPYLM were almost the same as those for the clean text, but our model had the lowest PP. Its performance improved with the context length $N = 6$ or 10. The perplexity of RNN is also higher than that of our model. This indicates that the segmental context mixture works as intended, i.e. reducing the negative effect of unknown context. The improvement with a longer context means that Bayesian smoothing works well.

4.2.2 Actual Hesitation Data

The perplexity values for the four N-gram lengths can be seen in Tab. 4 for clean sentences and hesitation included sentences. The perplexity was much higher for all four models with the noisy text mainly due to hesitations and substitution errors caused by OOVs. Therefore, the word-prediction for actual utterance is more difficult than written text.

The relative performances were almost the same as those for artificial noisy data although the improvement of perplexity seems to be slight. That indicates that our model is effective for the actual transcription. The differences of perplexity among models are smaller than with artificial noisy data due to a) the difference in the hesitation-word ratio (about 8 %) , b) the appearance of patterns of fillers or hesitations in the training text, and c) the substitution of hesitations to pre-defined vocabularies (closed vocabulary set). The substitution suffers the estimation of true skip probability Eq. (6) and (9) of hesitations and true vocabulary. This means that we need to handle hesitation problem in raw-level symbol sequence, such as phoneme sequence. The reason the RNN outperformed our model might be due to the closed vocabulary set in this experiment. On the other hand, the context information in RNN might be

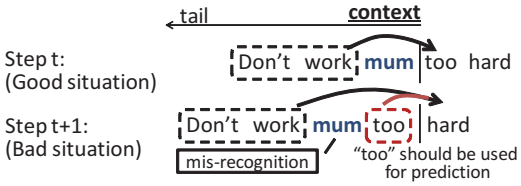

Figure 4: Weakness of segmental context model

suffered from the contiguous noisy words that were caused by the combination of the noise word and OOVs, "<unk>", in the artificial noisy data, and RNN degraded prediction accuracy for artificial noisy data. This indicated that RNN is unfamiliar to open-vocabulary tasks, such as lexicon acquisition.

The model validation with these text-level experiments provides us important knowledge and significant results for the next-level research step. Our method will be more effective for the word/phoneme segmentation problem because the substitution of hesitations to OOVs does not happen and we have to handle raw hesitation symbols. For example, the hesitation "to-" will be treated as itself "to-" or a phonetic expression "t u:", and the skip prior/posterior probability Eq. (6) and (9) of a hesitation symbol will be estimated properly. Our model will provide criteria for which words or symbols should be skipped. Therefore, the model integration of ours and the OOV-free model (Mochihashi et al., 2009) is required to process actual conversational utterances.

4.2.3 Remaining Problem on Model

The main problem of our model is clear from these results: it completely ignores neighbor context and does not use it for prediction, as illustrated in Figure 4. Since the neighbor words are usually useful for prediction, ignoring such words will degrade perplexity, especially that of clean text. The actual fillers/hesitations and mis-recognized words move from head to tail in the context in predicting words sequentially. Therefore, if the unknown segment is away from the context root, we can use the neighbor context without risk. For example, the probability $\hat{p}(\text{hard}|\text{work}, \text{mum}, \text{too})$ should be a mixture of $p(\text{hard}|\text{work}, \text{mum})$, $p(\text{hard}|\text{work}, \text{too})$, $p(\text{hard}|\text{too})$ and so on. The probability $p(\text{hard}|\text{work}, \text{too})$ is not considered in our current model. By modeling this property, our model will perform the same as HPYLM and VPYLM for clean text.

The future work also includes the fundamental modification of our model and the application to word/phoneme segmentation problem of actual utterances. Since hesitation is often a part of phoneme sequence of a word, it also depends on the currently or previously uttered word. A new generative process modeling above properties is required to deal with conversational utterances.

5 Conclusion

We proposed a segmental context mixture model to reduce the prediction error caused by noises, fillers, and hesitations in utterances, which rarely appear in the training text. Although hesitations or fillers will appear for speech transcriptions, they vary according to a speaker and topic. The model's probability consists of a mixture of conditioned probabilities of part of context words. The generative process can be expressed by combining the stick-breaking process and the process used in the variable order Pitman-Yor Language model (VPYLM). Experimental results revealed our model had better perplexity for noisy text than hierarchical PYLM, VPYLM, Witten-Bell and Kneser-ney smoothing.

The remaining challenges include building a more specific process for fillers and mis-recognitions for the language model and evaluation using text obtained by automatic speech recognition. For recognized text, we can use the re-scoring technique to apply our model. As mentioned in the discussion, our model can be improved by considering the movement property of filler and hesitations. Since our further interest is to acquire lexicons and meaning from conversational speech signals through spoken dialogue, the impact of our model on word segmentation should be evaluated.

Abstract

Named entity typing is the task of detecting the types of a named entity in context. For instance, given "Eric is giving a presentation", our goal is to infer that 'Eric' is a speaker or a presenter and a person. Existing approaches to named entity typing cannot work with a growing type set and fails to recognize entity mentions of unseen types. In this paper, we present a label embedding method that incorporates prototypical and hierarchical information to learn pre-trained label embeddings. In addition, we adapt a zero-shot framework that can predict both seen and previously unseen entity types. We perform evaluation on three benchmark datasets with two settings: 1) few-shots recognition where all types are covered by the training set; and 2) zero-shot recognition where fine-grained types are assumed absent from training set. Results show that prior knowledge encoded using our label embedding methods can significantly boost the performance of classification for both cases.

1 Introduction

Named entity typing (NET) is the task of inferring types of named entity mentions in text. NET is a useful pre-processing step for many natural language processing (NLP) tasks, e.g., auto-categorization and sentiment analysis. Named entity linking, for instance, can use NET to refine entity candidates of a given mention (Ling and Weld, 2012). Besides, NET is capable of supporting applications based on a deeper understanding of natural language, e.g., knowledge completion (Dong et al., 2014) and question answering (Lin et al., 2012; Fader et al., 2014). Standard NET approaches or sometime known as named entity recognition (Chinchor and Robinson, 1997; Tjong Kim Sang and De Meulder, 2003; Doddington et al., 2004) are concerned with coarse-grained types (e.g, person, location, organization) that are flat in structure. In comparison, fine-grained named entity typing (FNET) (Ling and Weld, 2012), which has been studied as an extension of standard NET task, uses a tree-structured taxonomy including not only coarse-grained types but also fine-grained types of named entities. For instance, given "[*Intel*] *said that over the past decade*", standard NET only classifies *Intel* as *organization*, whereas FNET further classifies it as *organization/corporation*.

FNET is faced with two major challenges: growing type set and label noises. Since the type hierarchy of entities is typically built from knowledge bases such as DBpedia, which is regularly updated with new types (especially fine-grained types) and entities, it is natural to assume that the type hierarchy is growing rather than fixed over time. However, current FNET systems are impeded from handling a growing type set for that information learned from training set cannot be transferred to unseen types. Another problem with FNET is that the weakly supervised tagging process used for automatically generating labeled data inevitably introduces label noises. Current solutions rely on heuristic rules (Gillick et al., 2014) or embedding method (Ren et al., 2016) to remove noises prior to training the multi-label classifier. In order to address these two problems at the same time, we propose a simple yet effective method for learning prototype-driven label embeddings that works for both seen and unseen types and is robust to the label

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers,
pages 171–180, Osaka, Japan, December 11-17 2016.

noises. Another contribution of this work is that we combine prototypical and hierarchical information for learning label embeddings.

The remainder of this paper is organized as follows: Section 2 proposes a survey of prior works related to FNET; Section 3 introduces the embedding-based FNET method and its zero-shot extension; Section 4 describes our label embedding method; Section 5 illustrates experiments and analysis for both few-shot and zero-shot settings; finally, Section 6 concludes the paper and discusses future work.

2 Related Work

There is little related work specifically on zero-shot FNET but several research lines are considered related to this work: fine-grained named entity recognition, prototype-driven learning, and multi-label classification models based on embeddings. As FNET works with a much larger type set as compared with standard NET, it becomes difficult to have a sufficient training set for every type when relying on manual annotation. Instead, training data can be automatically generated from semi-structural data such as Wikipedia pages (Ling and Weld, 2012). Consequently, a single supervised classifier (Ling and Weld, 2012; Yogatama et al., 2015) or a series of classifiers (Yosef et al., 2012) are trained on this auto-annotated training set. This auto-annotating practice has been followed by later works on FNET (Yosef et al., 2012; Yogatama et al., 2015; Ren et al., 2016). However, since the automated tagging process is not accurate all the time, a number of noisy labels are then propagated to supervised training and affect the performance negatively.

The starting point of this work is the embedding method, WSABIE (Weston et al., 2011), adapted by (Yogatama et al., 2015) to FNET. WSABIE maps input features and labels to a joint space, where information is shared among correlated labels. However, the joint embedding method still suffers from label noises which have negative impacts on the learning of joint embeddings. In addition, since the labeled training set is the only source used for learning label embeddings, WSABIE cannot learn label embeddings for unseen types. DeViSE (Frome et al., 2013) is proposed for annotating image with words or phrases. As in such case, labels are natural words, e.g., fruit, that can be found in textual data, Skip-gram word embeddings (Mikolov et al., 2013) learned from a large text corpus are directly used for representing labels. In addition to label itself, prior works have also tried to learn label embeddings from side information such as attributes (Akata et al., 2013), manually-written descriptions (Larochelle et al., 2008), taxonomy of types (Weinberger and Chapelle, 2009; Akata et al., 2013; Akata et al., 2015), and so on.

Another related line of research is prototype-driven learning. (Haghighi and Klein, 2006) presented a sequence labeling model using prototypes as features and has tested the model on NLP tasks such as part-of-speech (POS) tagging. Prototype-based features (Guo et al., 2014) are then adapted for coarse-grained named entity recognition task. Even though we select prototypes in the same way as (Guo et al., 2014), we use prototypes in a very different manner: we consider prototypes as the basis for representing labels, whereas prototypes are mainly used as additional features in prior works (Haghighi and Klein, 2006; Guo et al., 2014). In other words, prototypes are previously used on the input side, while we use them on the label side.

3 Embedding Methods for FNET

In this section, we introduce the embedding method for FNET proposed by (Yogatama et al., 2015) and its extension to zero-shot entity typing.

3.1 Joint Embedding Model

Each entity mention m is represented as a feature vector $x \in \mathbb{R}^V$; and each label $y \in Y$ is a one-hot vector, where Y is the set of true labels associated with x. $\bar{Y}$ denotes the set of false labels of the given entity mention. The bi-linear scoring function for a given pair of x and y is defined as follows:

$$f(x, y, W) = x'Wy,$$

where $W \in \mathbb{R}^{M \times N}$ matrix with M the dimension of feature vector and N the number of types.

Instead of using a single compatibility matrix, WSABIE (Weston et al., 2011; Yogatama et al., 2015) considers an alternate low-rank decomposition of W, i.e., $W = A^\top B$, in order to reduce the number of parameters. WSABIE rewrites the scoring function as

$$f(x, y, A, B) = \phi(x, A) \cdot \theta(y, B) = x' A^\top B y,$$

which maps feature vector x and label vector y to a joint space. Note that it actually defines feature embeddings and label embeddings as

$$\phi(x, A) : x \rightarrow Ax,$$
$$\theta(y, B) : y \rightarrow By,$$

where $A \in \mathbb{R}^{D \times M}$ and $B \in \mathbb{R}^{D \times N}$ are matrices corresponding to lookup tables of feature embeddings and label embeddings, respectively. The embedding matrices A and B are the only parameters to be learned from supervised training process. In (Weston et al., 2011), the learning is formulated as a learning-to-rank problem using weighted approximate-rank pairwise (WARP) loss,

$$\sum_{y \in Y} \sum_{y' \in \bar{Y}} L(rank(x, y)) \max(1 - f(x, y, A, B) + f(x, y', A, B), 0),$$

where the ranking function $rank(x, y) = \sum_{y' \in \bar{Y}} \mathbb{I}(1 + f(x, y', A, B) > f(x, y, A, B))$, and $L(k) = \sum_{i=1}^{k} \frac{1}{i}$ which maps the ranking to a floating-point weight.

3.2 Zero-shot FNET Extension

A zero-shot extension of above WSABIE method can be done by introducing pre-trained label embeddings into the framework. The pre-trained label embeddings are learned from additional resources, e.g., text corpora, to encode semantic relation and dependency between labels. Similar to (Akata et al., 2013), we use two different methods for incorporating pre-trained label embeddings. The first one is to fully trust pre-trained label embeddings. Namely, we fix B as the pre-trained $\tilde{B}$ and only learn A in an iterative process. The second method is to use pre-trained label embedding as prior knowledge while adjusting both A and B according to the labeled data, i.e., adding a regularizer to the WARP loss function,

$$\sum_{y \in Y} \sum_{y' \in \bar{Y}} L(rank(x, y)) \max(1 - f(x, y, A, B) + f(x, y', A, B), 0) + \lambda ||B - \tilde{B}||_F^2,$$

where $|| \cdot ||_F$ is the Frobenius norm, and λ is the trade-off parameter.

4 Methods

4.1 Prototype-driven Label Embedding

Joint embedding methods such as WSABIE learn label embeddings from the whole training set including noisy labeled instances resulting from weak supervision. It is inevitable that the resulting label embeddings are affected by noisy labels and fail to accurately capture the semantic correlation between types. Another issue is that zero-shot frameworks such as DeViSE are not directly applicable to FNET as conceptually complex types, e.g, *GPE* (Geo-political Entity) cannot be simply mapped to a single natural word or phrase.

To address this issue, we propose a simple yet effective solution which is referred to as prototype-driven label embedding (ProtoLE), and henceforth we use $\tilde{B}^P$ to denote the label embedding matrix learned by ProtoLE. The first step is to learn a set of prototypes for each type in the type set. ProtoLE does not fully rely on training data to generate label embeddings. Instead, it selects a subset of entity mentions as the prototypes of each type. These prototypes are less ambiguous and noisy compared to the rest of the full set.

Even though it is already far less labor-intensive to manually select prototypes than annotating entity mentions one by one, we consider an alternative automated process using Normalized Point-wise Mutual Information (NPMI) as the particular criterion for prototype selection. The NPMI between a label and an entity mention is computed as:

$$\texttt{NPMI}(y, m) = \frac{\texttt{PMI}(y, m)}{-\ln p(y, m)},$$

where $\texttt{NPMI}(\cdot, \cdot)$ is the point-wise mutual information computed as follows:

$$\texttt{PMI}(y, m) = \log \frac{p(y, m)}{p(y)p(m)},$$

where $p(y)$, $p(m)$ and $p(y, m)$ are the probability of entity mention m, label y and their joint probability. For each label, NPMI is computed for all the entity mentions and only a list of top k mentions are selected as prototypes. Note that NPMI is not applicable to unseen labels. In such case, it is necessary to combine manual selection and NPMI.

Word embeddings methods such as Skip-gram model (Mikolov et al., 2013) are shown capable of learning distributional semantics of words from unlabeled text corpora. To further avoid affected by label noises, we use pre-trained word embeddings as the source to compute prototype-driven label embeddings. For each label y_i, we compute its label embedding as the average of pre-trained word embeddings of the head words of prototypes, i.e.,

$$\tilde{B}_i^P = \frac{1}{k} \sum_{j=1}^{k} v_{m_{ik}},$$

where $v_{m_{ik}}$ denotes the word embedding of kth word in the prototype list of label y_i. In the case of using phrase embeddings, the full strings of multi-word prototypes could be used directly.

4.2 Hierarchical Label Embedding

Another side information that is available for generating label embeddings is the label hierarchy. We adapt the Hierarchical Label Embeddings (HLE) (Akata et al., 2013) to FNET task. Unlike (Akata et al., 2013), which uses the WordNet hierarchy, FNET systems typically have direct access to predefined tree hierarchy of type set. We denote the label embedding matrix resulting from label hierarchy as $\tilde{B}^H$. Each row in $\tilde{B}^H$ corresponds to a binary label embedding and has a dimension equal to the size of label set. For each label, the sets $\tilde{B}_{ij}^H$ to 1 when y_j is the parent of y_i or $i = j$, and 0 to the remainder,

$$\tilde{B}_{ij}^H = \begin{cases} 1 & \text{if } i = j \text{ or } y_j \in Parent(y_i) \\ 0 & \text{otherwise} \end{cases}.$$

HLE explicitly encodes the hierarchical dependency between labels by scoring a type y_i given m using not only y_i but also its parent type $Parent(y_i)$. The underlying intuition is that recognition of a child type should be also based on the recognition of its parent.

4.3 Prototype-driven Hierarchical Label Embedding

One shortcoming of HLE is that it is too sparse. A natural solution is combining HLE with ProtoLE, which is denoted as Proto-HLE. Since $\tilde{B}^H \in \mathbb{R}^{N \times N}$ and $\tilde{B}^P \in \mathbb{R}^{D \times N}$, the combined embedding matrix $\tilde{B}^{HP}$ can be obtained by simply multiplying $\tilde{B}^H$ by $\tilde{B}^P$, i.e.,

$$\tilde{B}^{HP} = \tilde{B}^P \tilde{B}^{H\top}.$$

Note that $\tilde{B}^{HP}$ has the same shape as $\tilde{B}^P$, and it is actually representing the child label as a linear combination of the ProtoLE vectors of its parent and itself.

4.4 Type Inference

Having computed the scoring function for each label given a feature vector of the mention, we conduct type inference to refine the top k type candidates. In the setting of few-shots FNET, k is typically set to the maximum depth of type hierarchy, while different values for k may be used for a better prediction of unseen labels in zero-shot typing. For top k type candidates, we greedily remove the labels that conflict with others. However, unlike (Yogatama et al., 2015), we use a relative threshold t to decide whether the selected type should remain in the final results, which is more consistent with the margin-infused objective function than a global threshold. Namely, a type candidate will be passed to type inference only if the difference of score from the 1-best is less than a threshold.

5 Experiments

5.1 Experiment Setup

Our method uses feature templates similar to what have been used by state-of-the-art FNET methods (Ling and Weld, 2012; Gillick et al., 2014; Yogatama et al., 2015; Xiang Ren, 2015). Table 1 illustrates the full set of feature templates used in this work. We evaluate the performance of our methods on three benchmark datasets that have been used for the FNET task: BBN dataset (Weischedel and Brunstein, 2005), OntoNotes dataset (Weischedel et al., 2011) and Wikipedia dataset (Ling and Weld, 2012). (Xiang Ren, 2015) has pre-processed the training sets of BBN and OntoNotes using DBpedia Spotlight[1]. Entity mentions in the training set are automatically linked to a named entity in Freebase and assigned with the Freebase types of induced named entity. As shown in Table 2, BBN dataset contains 2.3K news articles of Wall Street Journal, which includes 109K entity mentions belonging to 47 types. OntoNotes contains 13.1K news articles and 223.3K entity mentions belonging to 89 entity types. The size of Wikipedia dataset is much larger than the other two with 2.69M entity mentions of 113 types extracted from 780.5K Wikipedia articles. Each data set has a test set that is manually annotated for purpose of evaluation. To tune parameters such as the type inference threshold t and trade-off parameter λ, we randomly sample 10% instances from each testing set as the development sets and use the rest as evaluation sets.

Feature	Description	Example
Tokens	Unigram words in the mentions	"White", "House"
Head	Head word of the mention	"House"
Cluster	Brown Cluster IDs of the head word	"4_1111", .. ,"8_11111101"
POS Tag	POS tag of the mention	"NNP"
Character	Lower-cased character trigrams in the head word	"hou","ous","use"
Word Shape	The word shape of words in the mention	"Aa","Aa"
Context	Unigram/bigram words in context of the mention	"Bennett","the", "Bennett_the"
Dependency	Dependency relations involving the head word	"gov_nn_director"

Table 1: Features extracted for context "*William Bennet, the [White House] drug-policy director....*"

Dataset		Types	Documents	Sentences	Mentions
BBN	train	47	2.3K	48.8K	109K
	test		459	6.4K	13.8K
OntoNotes	train	89	13.1K	147.7K	223.3K
	test		76	1.3K	9.6K
Wikipedia	train	113	780.5K	1.15M	2.69M
	test		-	434	563

Table 2: Statistics of datasets

[1] http://github.com/dbpedia-spotlight/dbpedia-spotlight

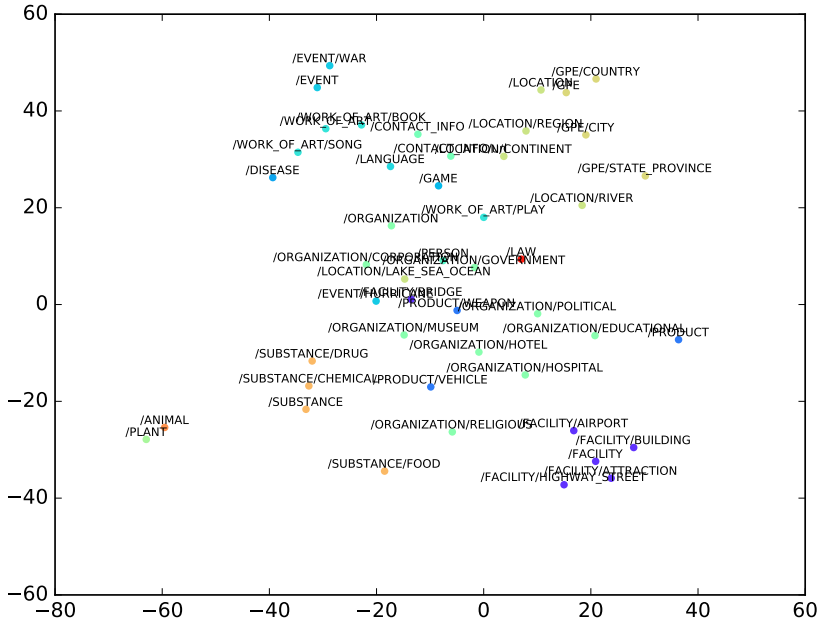

Figure 1: t-SNE visualization of the prototype-driven label embeddings for BBN dataset

Following prior works (Ling and Weld, 2012), we evaluate our methods and baseline systems using both loose and strict metrics, i.e., Macro-F1, Micro-F1, and strict Accuracy (Acc.). Given the evaluation set D, we denote Y_m as the ground truth types for entity mention $m \in D$ and $\widehat{Y}_m$ as the predicted labels. Strict accuracy (Acc) can be computed as:Acc= $\frac{1}{D}\sum_{m\in D}\sigma(Y_m = \widehat{Y}_m)$, where $\sigma(\cdot)$ is an indicator function. Macro-F1 is based on Macro-Precision (Ma-P) and Micro-Recall (Ma-R), where Ma-P = $\frac{1}{|D|}\sum_{m\in D}\frac{|Y_m\cap\widehat{Y}_m|}{Y_m}$, and Ma-R= $\frac{1}{|D|}\sum_{m\in D}\frac{|Y_m\cap\widehat{Y}_m|}{Y_m}$. And Micro-F1 is based on Micro-Precision (Mi-P) and Micro-Recall (Mi-R), where Mi-P= $\frac{\sum_{m\in D}|Y_m\cap\widehat{Y}_m|}{\sum_{m\in D}\widehat{Y}_m}$, and Mi-R= $\frac{\sum_{m\in D}|Y_m\cap\widehat{Y}_m|}{\sum_{m\in D}Y_m}$.

5.2 Generating ProtoLE

Our ProtoLE embeddings use Continuous-Bag-of-Words (CBOW) word embedding model (Mikolov et al., 2013) trained on Wikipedia dump using a window of 2 words to both directions. We use 300 dimensions for all embedding methods except HLE. Table 3 illustrates examples of prototypes learned for types in BBN dataset. It can be observed that most of the top ranked mentions are correctly linked to types, even though there are still some noises, e.g., north_american for `/LOCATION/CONTINENT`. It also shows that prototypes of related types such as `/LOCATION` and `/GPE` are also semantically related. Figure1 visualizes the prototype-driven label embeddings for BBN dataset using -Distributed Stochastic Neighbor Embedding (t-SNE)(Maaten and Hinton, 2008). It can be easily observed that semantic related types are close to each other in the new space, which proves that prototype-driven label embeddings can capture the semantic correlation between labels.

Figure 2 shows the Micro-F1 score of FNET with regard to the number of PMI prototypes used by ProtoLE. It shows that the Micro-F1 score does not change significantly on BBN and Wikipedia dataset, whereas using fewer prototypes per type (≤ 40) results in a drop of Micro-F1. Since the definitions of several types, especially the coarse-grained types, are actually very general, it may introduce bias into the label embeddings if using too few prototypes. We use $K = 60$ for all our experiments for that it achieves decent performance on all three datasets. Our pre-trained label embeddings and manually-selected prototypes (zero-shot typing) are available for download[2].

5.3 Few-shots Fine-grained Entity Typing

In this section, we compare performances of FNET methods in the setting of few-shots FNET where the training set covers all types. Methods compared in this section are trained using the entire type set. We use evaluation metrics for our experiments: macro-F1, micro-F1 and accuracy. As in section 3.2, we train our label embeddings in two different ways: 1) non-adaptive training where label embeddings are fixed during training; and 2) adaptive training where label embeddings are also updated. Table 4 shows the comparison with state-of-the-art FNET methods: FIGER(Ling and Weld, 2012), HYENA(Yosef et al., 2012) and WSABIE (Yogatama et al., 2015). We make several findings from the results.

Firstly, embedding methods with WARP loss function consistently outperform non-embedding methods (i.e., FIGER and HYENA) on all three datasets. The performance gaps are huge for BBN and OntoNotes, where the best embedding method achieves 10%-20% absolute improvement over the best non-embedding method (FIGER). However, the gap is much smaller on Wikipedia dataset whose size is significantly larger than the other two.

Secondly, non-adaptive embedding methods always outperform their adaptive versions except HLE on Wikipedia dataset. Performance of adaptive label embeddings are all close to WSABIE, which suggests that adaptive label embeddings might suffer from same label noise problem as WSABIE does.

Thirdly, our ProtoLE and its combination with HLE consistently outperform both non-embedding and embedding baselines. Using the prototype information and non-adaptive framework results in absolute 3%-5% improvement with both loose and strict evaluation metrics. Non-adaptive HLE performs poorer than other embedding methods, which is most likely due to its sparsity in representing labels. However, Proto-HLE performs very close to ProtoLE on BBN and Wiki, while it improves all three measures by another absolute ≈2.5% on OntoNotes .

Method	Adapt	BBN			OntoNotes			Wiki		
		Ma-F1	Mi-F1	Acc.	Ma-F1	Mi-F1	Acc.	Ma-F1	Mi-F1	Acc.
FIGER	NA	67.28	60.70	46.92	58.77	52.37	38.01	**68.28**	64.71	47.37
HYENA	NA	51.38	52.85	45.01	47.65	43.97	26.56	45.51	43.80	30.67
WSABIE	NA	71.28	72.08	66.22	62.03	55.83	43.61	67.97	64.49	48.28
HLE	Y	70.84	71.61	65.74	61.54	49.16	43.25	67.09	65.65	47.01
	N	68.86	70.00	63.32	59.52	54.01	41.60	65.29	62.53	45.19
ProtoLE	Y	72.67	73.54	67.58	60.90	54.68	42.82	66.96	65.78	49.18
	N	**75.78**	**76.50**	**70.43**	65.91	59.08	46.94	68.06	**66.53**	**53.54**
Proto-HLE	Y	71.97	72.89	67.05	62.71	56.64	44.81	67.85	65.74	50.27
	N	74.54	74.38	69.46	**68.23**	**61.27**	**49.30**	66.61	65.29	50.45

Table 4: Performance of FNET in a few-shots learning on 3 benchmark datasets

5.4 Zero-shot Fine-grained Entity Typing

In this section, we evaluate our method's capability recognizing mentions of unseen fine-grained types. We assume that the training set contains only coarse-grained types (i.e., Level-1), and Level-2 types are unseen types to be removed from the training set. Table 5 shows the Micro-Precision for Level-1 and Level-2 types using top k type candidates for type inference. NPMI is computed for Level-1 types. We manually build prototype lists for unseen types by choosing from a randomly sampled list of entity mentions. Level-3 types are ignored for OntoNotes as Level-3 types never show in top-10 list produced by all methods. As the prediction for coarse-grained types are the same with regard to k, we only list the results using $k = 3$.

One interesting finding on all three datasets is that combining hierarchical and prototypical information results in better classification of coarse-grained types. It suggests that embeddings of unseen fine-grained types contains information complementary to the embeddings of coarse-grained types. Since HLE actually produces random prediction on Level-2 types due to its sparse representation, HLE perform poorly on Level-2 types.

Data Set	Method	Micro-Precision @k Level 1	Micro-Precision @k Level 2		
		3	3	5	10
BBN	ProtoLE	76.71	**42.95**	**36.61**	**42.34**
	HLE	70.44	13.08	13.16	12.82
	Proto-HLE	**76.89**	42.35	35.18	30.16
OntoNotes	ProtoLE	73.26	**21.01**	**13.72**	**12.22**
	HLE	66.96	7.13	6.14	6.23
	Proto-HLE	**76.33**	7.09	11.43	9.91
Wiki	ProtoLE	65.52	12.50	21.28	17.91
	HLE	65.13	0.00	8.82	8.99
	Proto-HLE	**67.41**	**20.01**	**31.25**	**24.24**

Table 5: Performance of zero-shot entity typing

ProtoLE outperforms HLE by 100%-300% in terms of Micro-Precision. However, again the combination of prototypes and hierarchy achieves similar or better results than ProtoLE on BBN and Wikipedia dataset. The drop of precision of Proto-HLE on OntoNotes is likely due to a different nature of annotation. It is more prevalent in test set of OntoNotes that one entity mention is annotated with multiple Level-1 types, and the presence of fine-grained types are less constrained by the label hierarchy. In such case, hierarchical constrains enforced by Proto-HLE might have negative impacts on type inference.

6 Conclusion

In this paper, we presented a prototype-driven label embedding method for fine-grained named entity typing (FNET). It shows that our method outperforms state-of-the-art embedding-based FNET methods in both few-shots and zero-shots settings. It also shows that combining prototype-driven label embeddings and type hierarchy can improve the prediction on coarse-grained types. In the near future, we plan to integrate our method with other types of side information such as definition sentences as well as label noise reduction framework (Ren et al., 2016) to further boost the robustness of FNET.

The Role of Context in Neural Morphological Disambiguation

Qinlan Shen, Daniel Clothiaux, Emily Tagtow, Patrick Littell, Chris Dyer

{qinlans, dclothia, etagtow, plittell, cdyer}@cs.cmu.edu

Abstract

Languages with rich morphology often introduce sparsity in language processing tasks. While morphological analyzers can reduce this sparsity by providing morpheme-level analyses for words, they will often introduce ambiguity by returning multiple analyses for the same surface form. The problem of disambiguating between these morphological parses is further complicated by the fact that a correct parse for a word is not only dependent on the surface form but also on other words in its context. In this paper, we present a language-agnostic approach to morphological disambiguation. We address the problem of using context in morphological disambiguation by presenting several LSTM-based neural architectures that encode long-range surface-level and analysis-level contextual dependencies. We applied our approach to Turkish, Russian, and Arabic to compare effectiveness across languages, matching state-of-the-art in two of the three languages. Our results also demonstrate that while context plays a role in learning how to disambiguate, the type and amount of context needed varies between languages based on their morphological and syntactic properties.

1 Introduction

Morphologically rich languages introduce sparsity in language processing tasks, as different surface variants over the same root are often taken as independent entities. Using a morphological analyzer can decompose inflected words into known tags that encode syntactic and semantic information about the word. However, finding the correct morphological parse is a non-trivial task. Functionally different morphemes may have similar forms, and long strings of potentially ambiguous morphemes compound the problem of ambiguity. As a result, analyzers for morphologically complex languages often return several parses for the same surface word. Table 1, for example, shows the resulting candidate parses for the surface form "alın" returned by Oflazer's (1994) morphological analyzer for Turkish.

```
alın+Noun+A3sg+Pnon+Nom (forehead)
al+Adj^DB+Noun+Zero+A3sg+P2sg+Nom (your red)
al+Adj^DB+Noun+Zero+A3sg+Pnon+Gen (of red)
al+Verb+Pos+Imp+A2pl ((you) take)
al+Verb^DB+Verb+Pass+Pos+Imp+A2sg ((you) be taken)
alın+Verb+Pos+Imp+A2sg ((you) be offended)
```

Table 1: Possible morphological parses for surface form "alın"

The surrounding context of the word being disambiguated plays a major part in determining the role of a word in a sentence and thus its correct morphological parse. For example, the surface form "evi" in Turkish can be interpreted as either accusative or third-person singular possessive, as shown in Table 2 (Yildiz et al., 2016); this determination cannot reliably be made without further context. Moreover, the disambiguation of a word can in turn disambiguate other words; if we have determined that "evi" is

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 181–191, Osaka, Japan, December 11-17 2016.

accusative, we can infer that a transitive verb must follow and that other ambiguous forms in a sentence are not accusative.

Sentence and translation	Analysis of `evi`
Evi bulabildiniz mi? – Did you find the house?	`ev+Noun+3sg +Pnon+Acc`
Evi gerçekten güzelmiş. – His/Her house is really beautiful	`ev+Noun+3sg +P3sg+Nom`

Table 2: Possible interpretations for "`evi`" based on context

The problem of disambiguating over the candidate morphological parses generated by a morphological analyzer has been tackled in many languages and with different strategies. These systems primarily rely on methods for capturing the structure of a target word and its candidate tag sequences (Yuret and Türe, 2006; Habash and Rambow, 2005; Daybelge and Cicekli, 2007; Daoud, 2009) and/or the surrounding context of a target word (Hakkani-Tür et al., 2002; Smith et al., 2005; Sak et al., 2008; Lee et al., 2011) to choose the best candidate analysis. Despite the breadth of work on this problem, there is little work on disambiguation using neural network models. Based on previous work, it is not clear whether neural models are able to disambiguate only using surface forms or how context plays a role in a neural disambugation model. Models that disambiguate jointly over tokens incorporate more information about the surrounding context of a word, but models that make decisions at the word level are often simpler to train.

In this paper, we present a language-agnostic LSTM-based approach for morphological disambiguation that takes into account both the structure of a word, including its candidate tag sequences, and the surrounding context of a target word. We propose a neural architecture for generating vector embeddings of the candidate analyses of a target word using character-based LSTMs to generate representations for the stems and surface forms, as well as an LSTM over the tag sequences to embed analyses.

We then describe several model architectures that operate over these vector representations, differing according to the window of context used and whether the context tokens have themselves been disambiguated. Because our architecture relies on character- and tag-level embeddings, the models can be adapted into other languages and handle unknown words at test time. Experiments on Turkish, Russian, and Arabic show that different languages benefit from different types and windows of context.

2 Models

The problem of morphological disambiguation involves selecting among a list of possible parses returned by an analyzer. Given the output of a morphological analyzer for tokens in a sentence, we use several LSTM architectures to predict the correct analysis for a word based on its context. These architectures vary based on the amount and type of context taken into account when choosing the best analysis.

Our approach to disambiguation relies on two embeddings: vector representations for each possible analysis for a word (expressed as matrix $\mathbf{R}$), which encode the stem and all of the morpheme tags for each analysis, and a vector embedding $\mathbf{h}$ of the relevant context of the target word. Using these embeddings, we can define a compatibility function between the representation of each candidate analysis and the representation of the context by taking the product of $\mathbf{R}$ and $\mathbf{h}$. Taking the softmax of this compatibility function will give us a probability distribution over possible parses given the relevant context.

$$p(y_t = a|x) = \text{softmax}(\mathbf{R}_{x_t} \times \mathbf{h}_t) \quad (1)$$

We describe a general architecture for embedding the possible parses of a target word, as well as the different architectural and objective variants for different models of context.

2.1 Analysis Embeddings

Given a morphological analysis of the form

$$stem_i + tag_{i,1} + tag_{i,2} + ... + tag_{i,L}$$

where $stem_i = (stem_{i,1}, stem_{i,2}...stem_{i,K})$ is the K character long stem of the i-th parse and each $tag_{i,j}$ is the j-th tag in the i-th parse (containing L tags), we use a bidirectional character-based LSTM to embed the stem, and a separate bidirectional LSTM over tags to embed the morphemes. A bidirectional LSTM creates a representation g_x of an input sequence $x = (x_1, x_2, ..., x_T)$ by computing a forward sequence $\overrightarrow{g}$ and a reverse sequence $\overleftarrow{g}$ over the input sequence, concatenating the results of the two sequences, and applying a rectified linear unit (ReLU) activation

$$\overrightarrow{g}_t = f(x_t, \overrightarrow{g}_{t-1}) \tag{2}$$

$$\overleftarrow{g}_t = f(x_t, \overleftarrow{g}_{t+1}) \tag{3}$$

$$g = \text{ReLU}([\overrightarrow{g}_T, \overleftarrow{g}_0]) \tag{4}$$

where $f(x, y)$ is the output of an LSTM unit with inputs x and y.

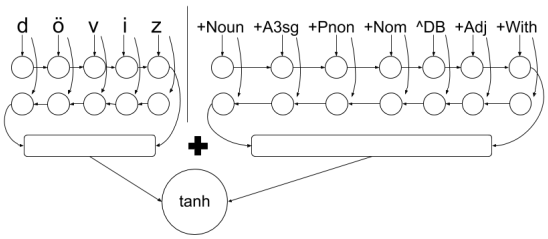

Figure 1: Neural architecture for analysis embedding

Thus, we create a representation of the stem by taking the characters of $(stem_{i,1}, stem_{i,2}, ..., stem_{i,K})$ as the input sequence for a "stem" LSTM and a representation of the tags by taking $(tag_{i,1}, tag_{i,2}, ..., tag_{i,L})$ as the input sequence for a separate "tag" LSTM. We then add these two representations and apply a $\tanh$ nonlinearity to create an embedding, r_i, for the i-th potential analysis a of the word (Figure 1).

$$r_i = \tanh(g_{stem_i} + g_{tag_i}) \tag{5}$$

These vectors of parse options r_i are concatenated to form matrix $\mathbf{R}$ for a word with N analyses, where each row in the matrix corresponds to a possible parse for a given word.

$$\mathbf{R} = [r_1; r_2; ...; r_N] \tag{6}$$

As a baseline model, we use matrix $\mathbf{R}$ without leveraging any of the surrounding context of the target word. To obtain the probability distribution of the possible parses from $\mathbf{R}$, we take the softmax of the product of $\mathbf{R}$ and a learned parameter vector $\mathbf{h}$. We then take the analysis a with the highest probability as the predicted analysis for the word.

$$p(y_t = a|x_t) = \text{softmax}(\mathbf{R}_{x_t} \times \mathbf{h}) \tag{7}$$

2.2 Surface Model

One method of integrating the context around a target word for morphological disambiguation is to leverage the surface forms of the words surrounding the target word. To capture the surface-level context of a target word, we first use another bidirectional character LSTM to embed the surface forms of each word x_i surrounding the current target word, creating a vector representation for each surrounding word.

We then use the embeddings for the relevant context words to the left of the target word as input to a left-to-right LSTM and the embeddings of the relevant context words to the right as input to a right-to-left LSTM over words to create vectors representing the left ($\overrightarrow{c}_t$) and right ($\overleftarrow{c}_t$) contexts of the target word at position t.

$$\overrightarrow{c}_t = f(x_t, \overrightarrow{c}_{t-1}) \tag{8}$$

$$\overleftarrow{c}_t = f(x_t, \overleftarrow{c}_{t+1}) \tag{9}$$

We add the left and right context vectors, then apply a tanh non-linearity to get $\mathbf{h}_t$ representing the surrounding surface context of the target word at position t.

$$\mathbf{h}_t = \tanh(\overrightarrow{c}_t + \overleftarrow{c}_t) \tag{10}$$

To combine this surface context representation with the possible parse embeddings matrix $\mathbf{R}$, we take a softmax over the product of $\mathbf{R}$ and $\mathbf{h}_t$ to return a probability distribution over possible parses given surface-level context.

$$p(y_t = a|x) = \text{softmax}(\mathbf{R}_{x_t} \times \mathbf{h}_t) \tag{11}$$

We compare two models that leverage the surface context of a word. The full context model uses all the words to the left of the target word and all the words to the right of the target word to build context vector $\mathbf{h}_t$ (Figure 2). The local context model uses a one word window to the left and right of its target word to build context vector $\mathbf{h}_t$.

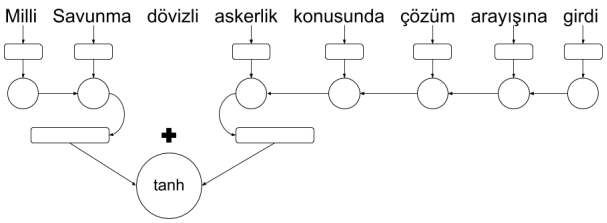

Figure 2: Neural architecture for full surface context embedding

2.3 Left-To-Right Analysis

A further question regarding the use of context in morphological disambiguation is whether the contextual tokens themselves need to be disambiguated, or whether their surface forms alone suffice to guide further disambiguation. For example, in a language like Russian with subject-verb agreement, having disambiguated a word as being third-person singular in the nominative case can help us predict that the verb should have third-person agreement.

To explore this question, we also consider models that take previously-disambiguated tokens as context. A simple way of leveraging information about the parses of surrounding words is to disambiguate the words in the sentence sequentially and use the previously selected parses to inform our decision at the current position. We use an LSTM over the selected parses of previously disambiguated words to create m_t, a representation of the decisions that were made up until position t. To build m_t, we take the representation of chosen parse $\tilde{r}^t$ from $\mathbf{R}_{x_t}$, and feed it into the LSTM encoding the sequence of previously chosen parses.

$$m_t = f(\tilde{r}_i^t, m_{t-1}) \tag{12}$$

Then, when choosing the next parse at position $t+1$, we also add m_t to the stem and morpheme representations $g_{stem_i}^{t+1}$ and $g_{tag_i}^{t+1}$ and apply a tanh nonlinearity when creating parse embeddings r_i^{t+1}.

$$r_i^{t+1} = \tanh(g_{stem_i}^{t+1} + g_{tag_i}^{t+1} + m_t) \tag{13}$$

$$\mathbf{R}_{x_{t+1}} = [r_1^{t+1}; r_2^{t+1}; ...; r_N^{t+1}] \tag{14}$$

Intuitively, the goal of this operation is to learn interactions between the previous parses and each candidate parse at the current position. We can then calculate a probability distribution over the candidates given both surface context and the previous parses in a manner similar to the process in Section 2.2.

$$p(y_t = a|x, y_1, y_2, ..., y_{t-1}) = \text{softmax}(\mathbf{R}_{x_t} \times \mathbf{h}_t) \tag{15}$$

When decoding, we use a greedy approach to select the parse to add to the previous parse LSTM. Thus, our objective is to predict the output sequence

$$\hat{y} = \text{argmax}_{\tilde{y} \in Y_X} \prod_{i=1}^{T} p(\tilde{y}_t|x, \tilde{y}_1, \tilde{y}_2, ..., \tilde{y}_{t-1}) \tag{16}$$

2.4 Conditional Random Field Joint Decoding

Locally normalized models suffer from the label bias problem (Andor et al., 2016), meaning that they have little to no ability to revise previous decisions. Conditional Random Fields (CRFs) have been shown to be effective at modeling sequences in tasks like part of speech tagging and named entity recognition (Lample et al., 2016). In this approach, we attempt to find the best sequence of parses that takes the entire sentence into account.

The CRF model is built on top of our full-context surface model, using the same process for embedding the parses and the surface context. Rather than taking the softmax over the combined representation of the surface context vector and the parse matrix, we use the product directly as a vector $\mathbf{u}_t$ of emission scores between each word x_t and its possible parses.

$$\mathbf{u}_t = \mathbf{R}_{x_t} \times \mathbf{h}_t \tag{17}$$

To model the transition scores between the j-th parse of word at position p and the i-th analysis of the previous word, we concatenate the embeddings of the two analyses and input the resulting vector to a feed-forward layer to give a transition score between the two parses, $\mathbf{v}(r_i^{t-1}, r_j^t)$.

$$\mathbf{v}(r_i^{t-1}, r_j^t) = \tanh(\mathbf{W}_{trans}[r_i^{t-1}, r_j^t]) \tag{18}$$

We can then produce a trellis of possible parses for each word and their transitions to use for picking the best parse sequence for a given sentence x of length N. We score sequences using the function

$$S(x, y) = \sum_{i=1}^{N} \mathbf{v}(y_{i-1}, y_i) + \mathbf{u}_i^{y_i} \tag{19}$$

To find the best parse sequence, we predict the output sequence

$$\hat{y} = \text{argmax}_{\tilde{y} \in Y_X} S(x, \tilde{y}) \tag{20}$$

We learned the parameters of the CRF as part of our neural architecture, then decode using the Viterbi algorithm to compute the best analysis sequence.

3 Experimental Setup

To demonstrate the language-agnostic nature of our disambiguation model, we applied our approach to Turkish, Russian, and Arabic, three morphologically-complex but typologically-distinct languages with well-established morphological analyzers (Oflazer, 1994; Korobov, 2015; Maamouri et al., 2010).

	Turkish		Russian		Arabic	
	Ambiguous	All	Ambiguous	All	Ambiguous	All
Training	332,457	783,209	830,055	1,815,414	253,058	318,821
Development	16,327	38,744	22,344	49,773	13,915	17,387
Annotated Test	379	946	16,340	50,083	14,231	18,021
Generated Test	18,022	42,000	-	-	-	-

Table 3: Token counts for data sets

3.1 Turkish

We used the same dataset for Turkish as in Sak et al. (2007) and Yildiz et al. (2016). The datasets were extracted from a corpus of approximately 1 million words of semi-automatically disambiguated Turkish (Yuret and Türe, 2006), which were split into training, development, and test sets. To limit the effect of noise from using semi-automatically disambiguated data in our training and evaluation, we also evaluated over the small test set of human disambiguated tokens in context that was provided with the data.

Preliminary analysis of the training set found that the average number of parses per word was 1.60 (std=1.304, max=24) for all tokens and 2.81 (std=1.208) for only ambiguous tokens. The average length of a Turkish sentence within our training set was 16 tokens (std=20.231).

3.2 Russian

Data for Russian was extracted from OpenCorpora, a freely available treebank for Russian (Bocharov et al., 2011). OpenCorpora provides a large corpus of approximately 1.7 million tokens, as well as a strict, manually disambiguated subset of approximately 50,000 tokens. Due to the relatively small amount of manually disambiguated data for training, we used the parse scores returned by the pymorphy2 morphological analyzer (Korobov, 2015) to semi-automatically disambiguate the full corpus, sampling the "gold" parse based on its parse score. One previous work in Russian morphology (Muzychka et al., 2014) used the SynTagRus dataset. However, this dataset used a different tagset than the pymorphy2 analyzer (Oflazer, 1994), which is based on OpenCorpora data.

The average number of parses per word in the training set was 3.10 (std=5.329, max=69) for all tokens and 5.81 (std=6.961) for only ambiguous tokens. The average length of a Russian sentence within our training set was 19.87 tokens (std=22.974).

We took the manually disambiguated data as our test set and randomly split the remaining data from the full corpus into a training set and development set.

3.3 Arabic

Data for Arabic was extracted from the Arabic Penn Treebank (ATB) part 3 version 3.2 (catalog number LDC2010T08) (Maamouri et al., 2004), a corpus containing approximately 370,000 annotated tokens. Analyses for the tokens were generated using the Buckwalter Morphological Analyzer Version 1.0 (Buckwalter, 2002), with human annotators selecting the correct parse. Previous approaches used different versions and subsets of the ATB. Here, we used a comparable subset to previous work, split into training, development, and test sets.

Each token had 9.11 possible parses (std=8.5932, max=86) on average, with each ambiguous token having 11.31 possible parses (std=8.301). The average length of a sentence was 26.13 (std=30.78) tokens.

3.4 Training

We considered each sentence to be a minibatch for training. The objective function used for training was the total cross-entropy loss between the selected parse and the correct parse for every token in the sentence. Stochastic gradient descent and backpropagation were used to adjust the parameters for our model. To prevent overfitting on the training set, we used validation-based early-stopping, saving the model parameters based on a periodic accuracy evaluation step over the development set. All LSTMs in

our models were trained with a single hidden layer. We used a hidden dimension size of 100 for the tag, stem, and surface form LSTMs and 200 for the context and previous parse LSTMs.

4 Discussion

4.1 Results

In all cases, using some contextual information improved accuracy over the no-context baseline, but there is noticeable variation between languages regarding what kinds of context were most valuable. We report accuracy over ambiguous tokens, as well as all tokens for sake of comparison with other systems.

	Ambiguous Tokens		All Tokens	
	Annotated Test	Generated Test	Annotated Test	Generated Test
No Context	88.65	90.72	95.45	96.08
Local Context	89.18	92.65	95.67	96.90
Full Context	**91.03**	**93.46**	**96.41**	**97.24**
Left-to-Right	90.50	93.42	96.19	97.23
CRF	90.24	93.06	96.09	97.07

Table 4: Disambiguation results for Turkish

Table 4 shows the performance of all models in Turkish on a hand-annotated test set, as well as the generated test set. We see that each of the models with some form of context is able to beat the no context baseline. The best-performing model on both the generated and annotated datasets is the full surface context model, followed closely by the left-to-right and CRF models. This shows that some form of long-range contextual information is useful for disambiguation for Turkish. Our full context model is comparable to the previous state of the art of 96.28% on annotated test and 96.80% on generated test established in Sak et al. (2007).

As we will see below, of the languages considered here, Turkish is the only one in which the full surface context model approached (and slightly exceeded) other models, which may stem from the typological character of Turkish. Turkish is a strongly head-final subject-object-verb (SOV) language, and so the best disambiguating evidence for a token often follows it. For example, in disambiguating "evi" (cf. Table 2), the best evidence for its case (nominative or accusative) will lie in whether a transitive or intransitive verb follows, and in a verb-final language the verb can follow at some distance from its arguments. Meanwhile, as seen in Section 3.1, Turkish is the least ambiguous of these languages (with a mean of 1.60 parses per word compared to 3.10 for Russian and 9.11 for Arabic), so surface context is not much less informative than disambiguated context. In other words, Turkish combines the greatest need for full context with higher relative informativeness of the surface context.

	Ambiguous Tokens	All Tokens
No Context	64.97	88.58
Local Context	71.56	90.72
Full Context	69.49	90.05
Left-to-Right	68.55	89.75
CRF	**72.78**	**91.13**

Table 5: Disambiguation results for Russian

The results for Russian are detailed in Table 5. Again, each of the contextual models perform much better than the no context baseline. However, we see an interesting pattern when comparing the four contextual models; unlike in Turkish, the CRF model performs the best. Many words in Russian are required to agree in gender, case, and number to their heads. We argue that a model that takes the parse information of neighboring words into account is more suited to capturing agreement than one that only uses the surface form information. The CRF model over parse sequences would be able to capture this

phenomenon, whereas the left-to-right decoding model, which also operates over neighboring parses, may fail due to making locally but not globally optimal decisions near the beginning of the sentence.

Muzychka et al. (2014) reported an accuracy of 91.06% in their CRF-based disambiguation model. In comparison, our neural CRF-based model achieves a similar accuracy of 91.13%.

	Ambiguous Tokens	All Tokens
No Context	72.22	78.06
Local Context	80.10	84.29
Full Context	86.45	88.95
Left-to-Right	**89.30**	**91.27**

Table 6: Disambiguation results for Arabic

We see a different pattern in Table 6 for Arabic. Like in Turkish and Russian, there is a large gap between the no context baseline and the local context model. The left-to-right model performs the best on Arabic. Habash et al. (2005) report an accuracy of 96.2% on all parses, while Smith et al. (2005) achieves an accuracy of 95.4% on different subsets of the ATB.

We can also note that surface-context models performed relatively poorly in Arabic. This is likely because of the greater ambiguity of Arabic (9.11 parses per word), which stems in part from the absence of vowels in Arabic writing. Manual inspection of the Arabic output suggested that the surface-context models were frequently making the same mistakes as the no-context model (Table 7), which did not tend to occur in the Turkish output. So, in contrast to the Turkish systems, in which having only surface context was as good as having disambiguated context, in the Arabic systems having only surface context was more similar to having no context at all, emphasizing the need for disambiguated context in more highly ambiguous languages.[1]

Table 7: Example outputs for Arabic for targets "`SEbp`" and "`AlAntfADp`"

Within our experiments, context clearly does play a role in learning to disambiguate possible morphological analyses. The type and extent of the context needed, however, appears to vary based on features of the language, such as the word order or the degree of morphological ambiguity. This raises the possibility of a future system that can choose the best disambiguation context based on a language's typological properties.

[1]Following this hypothesis, we would expect the CRF architecture to perform well on Arabic. However, the much higher ratio of parses-per-word in Arabic made our neural CRF model computationally impractical.

4.2 Future Work

As mentioned in Section 2.4, a disadvantage of using greedy decoding with our left-to-right analysis model is the label-bias problem. Because decisions depend on the previously selected parses, an incorrect decision made early on can propagate through the sentence. Thus, a natural extension to the left-to-right model is to use beam search for decoding instead of our greedy approach. The advantage of using beam search is that it allows the model to explore multiple previous parse paths. This partially gives the model the ability to recover from making a decision that appears locally optimal in the short-term but leads to greater losses in the long-term.

Another model of context inspired by recent advances in machine translation (Bahdanau et al., 2015) and caption generation (Xu et al., 2015) is using an attentional mechanism to define the important context for a target word. For the full surface context model, rather than using separate LSTMs over the left and right contexts of the word, an attentional context model can learn to attend to different parts of the surrounding context of a target word based on its sentence position and candidate parse representations. This model will potentially allow us to capture longer-range surface dependencies without decay.

5 Related Work

A common early approach to morphological disambiguation is to rely purely on hand-crafted rules to select the correct parse out of a set of candidate analyses (Daybelge and Cicekli, 2007; Daoud, 2009). These rule-based methods primarily try to capture the relationship between a target word and its candidate analyses. Other approaches used a blend of rules and statistical methods. For example, Oflazer and Tür (1996) used a set of linguistically motivated rules and corpus-dependent statistics to either choose or delete possible parses in Turkish. The model also learned rules based on unambiguous words that appear in unambiguous contexts within the corpus. Similarly, Hajič et al. (2007) built upon the same type of deletion disambiguation, using the output from a choose-delete rule-based system to first reduce the number of possible parses before running a statistical part of speech tagger in Czech.

Yuret and Türe (2006) used the Greedy Prepend Algorithm to learn rules for Turkish disambiguation. For every tag in their dataset, a decision list of patterns was created to determine whether the tag is contained in the best analysis. A heuristic search that added new attributes to patterns already in the decision list was used to generate more candidate patterns for a tag.

Other statistical approaches to morphological disambiguation tried to directly model the context of a target word. Hakkani-Tür et al. (2002) proposed a statistical approach for Turkish disambiguation using a language model trained on disambiguated data. They trained trigram language models under different root and inflectional group independence assumptions and used the resulting language models to select the best candidate parses. Smith et al. (2005) used a conditional random field to learn to disambiguate over sentence by modeling local contexts. Sak et al. (2007) and (2008) used the perceptron algorithm on a set of 23 handcrafted features, including bigrams and trigrams at the word and inflectional group level.

There is relatively little work on designing neural models specifically for morphological disambiguation. Yildiz et al. (2016) proposed a convolutional architecture that creates a representation for the surface form of a word from a root and a set of morpheme features. They then trained their model to predict the correct analysis of a word given the ground truth annotations for the previous words within a window of the target. Their model was able to achieve an accuracy of 84% over ambiguous tokens in Turkish. In contrast, our proposed model uses long short-term memory (LSTM)-based architectures to capture longer range dependencies between a target word and its surrounding context. Additionally, we consider the context of a target word at both the surface-form and analysis level, providing additional information to our models.

6 Conclusion

In this paper, we present several LSTM-based neural network architecture for disambiguating morphological parses using varying amounts of surrounding context. We demonstrate using these architectures that the type and amount of context needed for disambiguation varies between languages based on the

linguistic features of a particular language. For a language like Turkish, where most of the morphological information is apparent based on the surrounding context, a model that uses the surface context can capture long-range information to make disambiguation decisions. Other languages, where the surface representation is less informative, such as Arabic, greatly benefit from using representations of the surrounding parse candidates in addition to the surface forms of the surrounding words. We also show that, while this system is language agnostic and can be applied to typologically different languages, the best architecture for a language depends on its morphological and syntactic properties.

Asynchronous Parallel Learning for Neural Networks and Structured Models with Dense Features

Xu Sun

†School of Electronics Engineering and Computer Science, Peking University
xusun@pku.edu.cn

Abstract

Existing asynchronous parallel learning methods are only for the sparse feature models, and they face new challenges for the dense feature models like neural networks (e.g., LSTM, RNN). The problem for dense features is that asynchronous parallel learning brings gradient errors derived from overwrite actions. We show that gradient errors are very common and inevitable. Nevertheless, our theoretical analysis shows that the learning process with gradient errors can still be convergent towards the optimum of objective functions for many practical applications. Thus, we propose a simple method *AsynGrad* for asynchronous parallel learning with gradient error. Base on various dense feature models (LSTM, dense-CRF) and various NLP tasks, experiments show that *AsynGrad* achieves substantial improvement on training speed, and without any loss on accuracy.

1 Introduction

Stochastic learning methods can accelerate the training speed compared with traditional batch training methods. A widely used stochastic learning method is the stochastic gradient descent method (SGD) (Bertsekas, 1999; Bottou and Bousquet, 2008; Shalev-Shwartz and Srebro, 2008; Sun et al., 2012; Sun et al., 2014). For large-scale datasets, the SGD training methods can be much faster than batch training methods. For further improve the training speed over multi-core machines and clusters, a variety of asynchronous (lock-free) parallel learning methods has been developed based on stochastic learning (Niu et al., 2011; Mcmahan and Streeter, 2014). Those asynchronous methods have shown to be more efficient than the synchronous (locked) parallel learning versions (Langford et al., 2009; Gimpel et al., 2010). Other related work on parallel stochastic learning also includes (Zinkevich et al., 2010; Dekel et al., 2012; Recht and Re, 2013; Dean et al., 2012).

Existing asynchronous parallel learning methods are mainly for the sparse feature models, and feature sparseness is a major assumption for those parallel learning methods (Niu et al., 2011; Mcmahan and Streeter, 2014). For example, Niu et al. (2011) proposed an interesting asynchronous parallel learning method *HogWild* for strict sparse machine learning problems with sparse separable cost functions (e.g., sparse SVM, low-rank matrix completion). Niu et al. (2011) stated that the key idea that underlies their lock-free approach is that the targeted machine learning problems are sparse. More recently, Mcmahan and Streeter (2014) proposed a delay-tolerant asynchronous parallel learning method, which is an extension of the method of Niu et al. (2011). This asynchronous parallel learning method proposed by Mcmahan and Streeter (2014) also strictly requires the sparseness of the features.

The situation is different for the dense feature models like neural networks (e.g., LSTM, RNN). Since the existing asynchronous parallel learning methods are strictly for sparse feature models, it is no longer reasonable to apply those methods for the dense feature models like neural networks. To our knowledge, there is very limited study on developing asynchronous parallel learning methods for neural networks. In most cases only synchronous versions of parallel learning are applied to neural networks, such as

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 192–202, Osaka, Japan, December 11-17 2016.

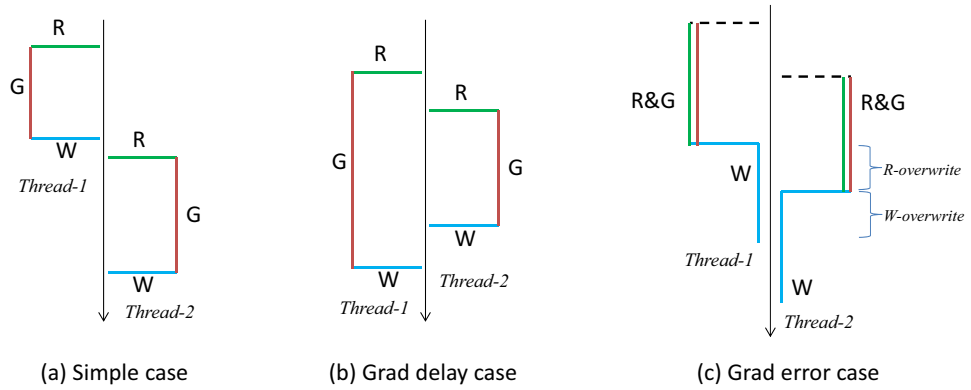

Figure 1: Illustrations of the *simple case* (left), the *gradient delay case* (middle), and the *gradient error case* (right) based on stochastic parallel learning. G means the gradient-computing action. R means the read action of shared memory. W means the write action.

GPU-based and mini-batch-based parallel learning methods. For GPU-based parallel learning, a matrix is computed in a synchronously parallelized way by using GPU units. For mini-batch-based parallel learning, the gradient of a mini-batch of samples are calculated in a synchronously parallelized way as well.

The major problem for applying asynchronous parallel learning to dense feature models is from the gradient errors. We show that gradient errors are very common and inevitable in applying asynchronous parallel learning to dense feature models. Suppose a dense feature model with 10 features/parameters, and we apply asynchronous (lock-free) parallel learning. When one thread is computing gradient, it needs to read the parameters from the shared memory. It is possible that 5 parameters are overwritten by another thread, which makes the computed gradient wrong. Not only there can be read-overwrite errors, but also there can be write-overwrite errors, as shown in Figure 1 (right).

Figure 1 illustrates the *simple case* (left), the *gradient delay case* (middle), and the *gradient error case* (right) for stochastic parallel learning. The simple case is normally from the synchronous parallel learning setting. The gradient delay case is considered for asynchronous parallel learning over sparse feature models (Niu et al., 2011; Mcmahan and Streeter, 2014). Essentially, the gradient delay problem is a simplification of the asynchronous parallel learning problem, and the simplification is from the feature sparseness. For the dense feature models like neural networks, it is unreasonable to use this simplification, and it goes to the gradient error case. As we can see from Figure 1 (right), there are both read-overwrite and write-overwrite problems between the two threads, and this created the gradient error. The gradient error problem is more complex than the gradient delay problem, and it requires new analysis and solutions. We will give more detailed analysis in Section 2.

Although the gradient error problem is more complex, it does not mean that the asynchronous parallel learning is doomed for the dense feature models. We give theoretical analysis to show that the learning process with the gradient error problem can still achieve the optimum given certain conditions, and those conditions are usually valid for the final convergence region of real-world applications.

Based on the analysis, we propose a simple asynchronous parallel learning method for dense feature models including neural networks and other structured models, and it works well in real-world NLP tasks in spite of gradient errors. Base on various dense feature models (LSTM, dense-CRF) and various NLP tasks, experiments show that our method achieves substantial improvement on training speed, and without any loss on accuracy.

2 *AsynGrad*: Asynchronous Parallel Learning with Gradient Error

As we can see from Figure 1, the gradient delay case is mostly considered for sparse feature models (Niu et al., 2011; Mcmahan and Streeter, 2014). Here the read and write of parameters for each sample is fast because the only a very small portion of the features are used for each sample. In this case, the read and write actions are considered being almost atomic actions, and the major concern goes to the "delay" of

Algorithm 1 *AsynGrad*: Asynchronous Parallel Learning with Gradient Error

Input: model weights $\boldsymbol{w}$, training set S of m samples
Run k threads in parallel with share memory, and procedure of each thread is as follows:
repeat
  Get a sample $\boldsymbol{z}$ uniformly at random from S
  Get the update term $\boldsymbol{s_z}(\boldsymbol{w})$, which is computed as $\nabla f_{\boldsymbol{z}}(\boldsymbol{w})$ but usually contains error
  Update $\boldsymbol{w}$ such that $\boldsymbol{w} \leftarrow \boldsymbol{w} - \gamma \boldsymbol{s_z}(\boldsymbol{w})$
until Convergence
return $\boldsymbol{w}$

the gradients (Niu et al., 2011; Mcmahan and Streeter, 2014). In Figure 1 (middle), thread-1's gradient is delayed by thread-2, because the former is expected to write to the memory before thread-2's write action. The *HogWild* method (Niu et al., 2011) and the delay-tolerant method (Mcmahan and Streeter, 2014) mainly cast/simplify the asynchronous parallel learning problem as the gradient delay problem, and they give solutions accordingly — they show that asynchronous parallel learning can achieve the optimum when dealing with the gradient delay problem.

The gradient delay problem is a simplification of the asynchronous parallel learning problem, and the simplification is from the feature sparseness. For the dense feature models like neural networks, it is no longer reasonable to use the simplification. The major problem for applying asynchronous parallel learning to dense feature models is the gradient errors.

As shown in Figure 1 (right), for dense feature models the read action is together with the gradient-computing action. When the feature is dense, it is not efficient to read all the parameters into a thread before computing the gradient. Also, when the feature is dense, the write action is no longer a fast action. As we can see from Figure 1 (right), there are both read-overwrite and write-overwrite problems, which create gradient errors. The gradient error problem is more complex than the gradient delay problem, and it requires new analysis and solutions.

2.1 *AsynGrad* Algorithm

Let $f(\boldsymbol{w})$ be the objective function of dense feature model and $\boldsymbol{w} \in \mathcal{W}$ is the weight vector. Recall that the SGD update with learning rate γ has a form like this:

$$\boldsymbol{w}_{t+1} \leftarrow \boldsymbol{w}_t - \gamma \nabla f_{\boldsymbol{z}_t}(\boldsymbol{w}_t) \tag{1}$$

where t represents a time stamp, and $\nabla f_{\boldsymbol{z}}(\boldsymbol{w}_t)$ is the stochastic estimation of the gradient based on $\boldsymbol{z}$, which is randomly drawn from the training set S.

Then, we assume a shared memory machine with multiple processors, and a vector of variables $\boldsymbol{w}$ in the shared memory is accessible to all processors. Each processor can read and update $\boldsymbol{w}$.

Based on the multicore computing machine, the proposed method creates k parallel threads, and $\boldsymbol{w}$ is shared among the k threads. For each thread, it gets a sample $\boldsymbol{z}$ uniformly at random from the training set S. Then, it tries to compute the update term $\boldsymbol{s_z}(\boldsymbol{w})$ as follows:

$$\boldsymbol{s_z}(\boldsymbol{w}) \leftarrow^{\approx} \nabla f_{\boldsymbol{z}}(\boldsymbol{w}) \tag{2}$$

where $\leftarrow^{\approx}$ means the $\boldsymbol{s_z}(\boldsymbol{w})$ is computed as the gradient $\nabla f_{\boldsymbol{z}}(\boldsymbol{w})$ in a single thread, but the shared weights $\boldsymbol{w}$ may be partially or completely overwritten by other threads when computing the gradient, which leads to gradient errors of $\nabla f_{\boldsymbol{z}}(\boldsymbol{w})$. Hence, $\boldsymbol{s_z}(\boldsymbol{w})$ is an approximation of the gradient $\nabla f_{\boldsymbol{z}}(\boldsymbol{w})$ with potential errors.

Then, the thread updates the shared weights $\boldsymbol{w}$ based on the update term $\boldsymbol{s_z}(\boldsymbol{w})$, such that

$$\boldsymbol{w} \leftarrow \boldsymbol{w} - \gamma \boldsymbol{s_z}(\boldsymbol{w}) \tag{3}$$

For each thread, it repeats this process until it reaches convergence — later we will show that this process can reach convergence by given certain conditions.

To summarize, the proposed parallel learning algorithm called *AsynGrad* is shown in Algorithm 1.

Although the implementation of *AsynGrad* is simple, the method *AsynGrad* itself is not that straightforward, because people may think it is wrong to use a method like *AsynGrad*. There is not much existing theoretical analysis and empirical evidence supporting the design of *AsynGrad*. In this paper, we show that it is actually reasonable and promising to use a method like *AsynGrad*. We give theoretical justification of the convergence of *AsynGrad* based on certain conditions, and we show experimental results that *AsynGrad* indeed works well in practice.

2.2 Theoretical Analysis of *AsynGrad*

Although *AsynGrad* does the weight update in parallel from different threads, from the viewpoint of $\boldsymbol{w}$ it simply receives a sequence of gradient updates (but with potential errors, which is the major difference from non-parallel SGD learning). In other words, the *AsynGrad* learning problem can be casted as a traditional SGD learning problem, and the only difference compared with traditional SGD is that the gradients are with errors. To state our convergence analysis results, we need several assumptions.

We assume f is strongly convex with modulus c, that is, $\forall \boldsymbol{w}, \boldsymbol{w}' \in \mathcal{W}$,

$$f(\boldsymbol{w}') \geq f(\boldsymbol{w}) + (\boldsymbol{w}' - \boldsymbol{w})^T \nabla f(\boldsymbol{w}) + \frac{c}{2}||\boldsymbol{w}' - \boldsymbol{w}||^2 \tag{4}$$

where $||\cdot||$ means 2-norm $||\cdot||_2$ by default in this work. For some dense feature models like dense-CRF, this assumption is suitable for the objective function. For some other dense feature models like neural networks, this assumption is a bit too strong because we know that the objective function of neural networks is non-convex. Nevertheless, even when the objective function is non-convex, the assumption usually holds within the final convergence region because the cost function is locally convex in many practical applications.

We also assume Lipschitz continuous differentiability of ∇f with the constant q, that is, $\forall \boldsymbol{w}, \boldsymbol{w}' \in \mathcal{W}$,

$$||\nabla f(\boldsymbol{w}') - \nabla f(\boldsymbol{w})|| \leq q||\boldsymbol{w}' - \boldsymbol{w}|| \tag{5}$$

Also, let the norm of $\boldsymbol{s_z}(\boldsymbol{w})$ is bounded by $\kappa \in \mathbb{R}^+$:

$$||\boldsymbol{s_z}(\boldsymbol{w})|| \leq \kappa \tag{6}$$

Moreover, it is reasonable to assume

$$\gamma c < 1 \tag{7}$$

because even the ordinary gradient descent methods will diverge if $\gamma c > 1$ (Niu et al., 2011).

Based on the conditions, we show that *AsynGrad* converges closely towards the minimum (optimum) $\boldsymbol{w}^*$ of $f(\boldsymbol{w})$ with a small distance expressed by ϵ, and the convergence rate is given as follows.

Theorem 1 (*AsynGrad* convergence and convergence rate)**.** *With the conditions (4), (5), (6), (7), let $\epsilon > 0$ be a target distance of convergence (i.e., the closeness of the convergence point to the real optimum). Let τ denote the bound to describe the severeness of gradient errors, such that*

$$[\nabla f(\boldsymbol{w}) - \boldsymbol{s}(\boldsymbol{w})]^T (\boldsymbol{w} - \boldsymbol{w}^*) \leq \tau \tag{8}$$

where $\boldsymbol{w}$ is the weight vector during AsynGrad *training, and $\boldsymbol{s}(\boldsymbol{w})$ is expected $\boldsymbol{s_z}(\boldsymbol{w})$ over $\boldsymbol{z}$ such that $\boldsymbol{s}(\boldsymbol{w}) = \mathbb{E}_{\boldsymbol{z}}[\boldsymbol{s_z}(\boldsymbol{w})]$. Let γ be a learning rate as*

$$\gamma = \frac{c\epsilon - 2\tau q}{\beta q \kappa^2} \tag{9}$$

where we can set β as any value as far as $\beta \geq 1$. Let t be the number of updates as follows

$$t \doteq \frac{\beta q \kappa^2 \log(q a_0/\epsilon)}{c(c\epsilon - 2\tau q)} \tag{10}$$

Table 1: Some major experimental results on dense-CRF. Time means time cost per iteration.

Method	POS-Tag		Chunking		MSR-WordSeg	
	Acc (%)	Time (s)	F-score (%)	Time (s)	F-score (%)	Time (s)
SGD	97.18	466.08	94.55	1.92	97.13	64.94
AsynGrad(10-thread)	97.18	108.38	94.59	0.25	97.15	8.11
AsynGrad(10-thread)+SR	97.35	25.99	94.60	0.21	97.22	6.59

where $\doteq$ means ceil-rounding of a real value to an integer, and a_0 is the initial distance such that $a_0 = ||\boldsymbol{w}_0 - \boldsymbol{w}^*||^2$. Then, after t updates of $\boldsymbol{w}$, AsynGrad *converges towards the optimum such that $\mathbb{E}[f(\boldsymbol{w}_t) - f(\boldsymbol{w}^*)] \leq \epsilon$, as far as the gradient errors are bounded such that*

$$\tau \leq \frac{c\epsilon}{2q} \tag{11}$$

The proof is in Section 4.

This theorem shows that *AsynGrad* is also convergent towards the optimum of the objective function, as far as the gradient errors are bounded such that Eq.(11) holds. For real-world applications, those assumptions and conditions usually hold at the final convergence region. In the final convergence region, $\boldsymbol{w}$ is not far away from the optimum $\boldsymbol{w}^*$, and both $||\nabla f(\boldsymbol{w})||$ and $||\boldsymbol{s}(\boldsymbol{w})||$ are supposed to be small. Thus, $[\nabla f(\boldsymbol{w}) - \boldsymbol{s}(\boldsymbol{w})]^T(\boldsymbol{w} - \boldsymbol{w}^*)$ is supposed to be small. This makes the bound τ to be small, which makes Eq.(11) valid in the final convergence region.

Moreover, the convergence rate is given in the theorem — *AsynGrad* is guaranteed to converge with t updates, and the value of t is given by Eq.(10).

The theoretical analysis can be concluded as follows. First, it shows that *AsynGrad* is convergent with gradient errors by given certain assumptions and conditions. Second, those assumptions and conditions are usually valid in the final convergence region of practical applications. Third, the convergence speed is given.

3 Experiments

We conduct experiments on natural language processing tasks as follows. Experiments are performed on a computer based on Intel(R) Xeon(R) 3.0GHz CPU of 12 cores, and with 128G memory.

Part-of-Speech Tagging (POS-Tag): We use the standard benchmark dataset in prior work (Collins, 2002), which is derived from PennTreeBank corpus and uses sections 0 to 18 of the Wall Street Journal (WSJ) for training (38,219 samples), and sections 22-24 for testing (5,462 samples). The evaluation metric is per-word accuracy.

Text Chunking (Chunking): The phrase chunking data is extracted from the data of the *CoNLL-2000 shallow-parsing shared task* (Sang and Buchholz, 2000; Sun et al., 2008). The training set consists of 8,936 sentences, and the test set consists of 2,012 sentences. The evaluation metric for this task is balanced F-score.

Word Segmentation (WordSeg). For the LSTM model, we use the social media word segmentation data (Weibo-WordSeg) provided by the NLPCC 2016 Shared Task.The training set contains around 60% of the data set, with 12,081 sentences. The test set contains around 40% of the data set, with 8,055 sentences. However, this data set is relatively new and we do not have good feature templates to implement the dense-CRF model. To deal with this problem, we use the MSR word segmentation data set (MSR-WordSeg) for the experiments on dense-CRF. The MSR-WordSeg data set is provided by *SIGHAN-2004 contest* (Gao et al., 2007). There are 86,918 training samples and 3,985 test samples. For this data set, we have standard feature templates, which are similar to (Sun et al., 2014). The evaluation metric is balanced F-score.

3.1 Experiments on Dense-CRF (Moderately Dense Case)

The dense-CRF is a moderately dense version of CRF by adding rich edge features, which usually has much better accuracy than traditional CRF for NLP tasks (Sun et al., 2012; Sun et al., 2014). For

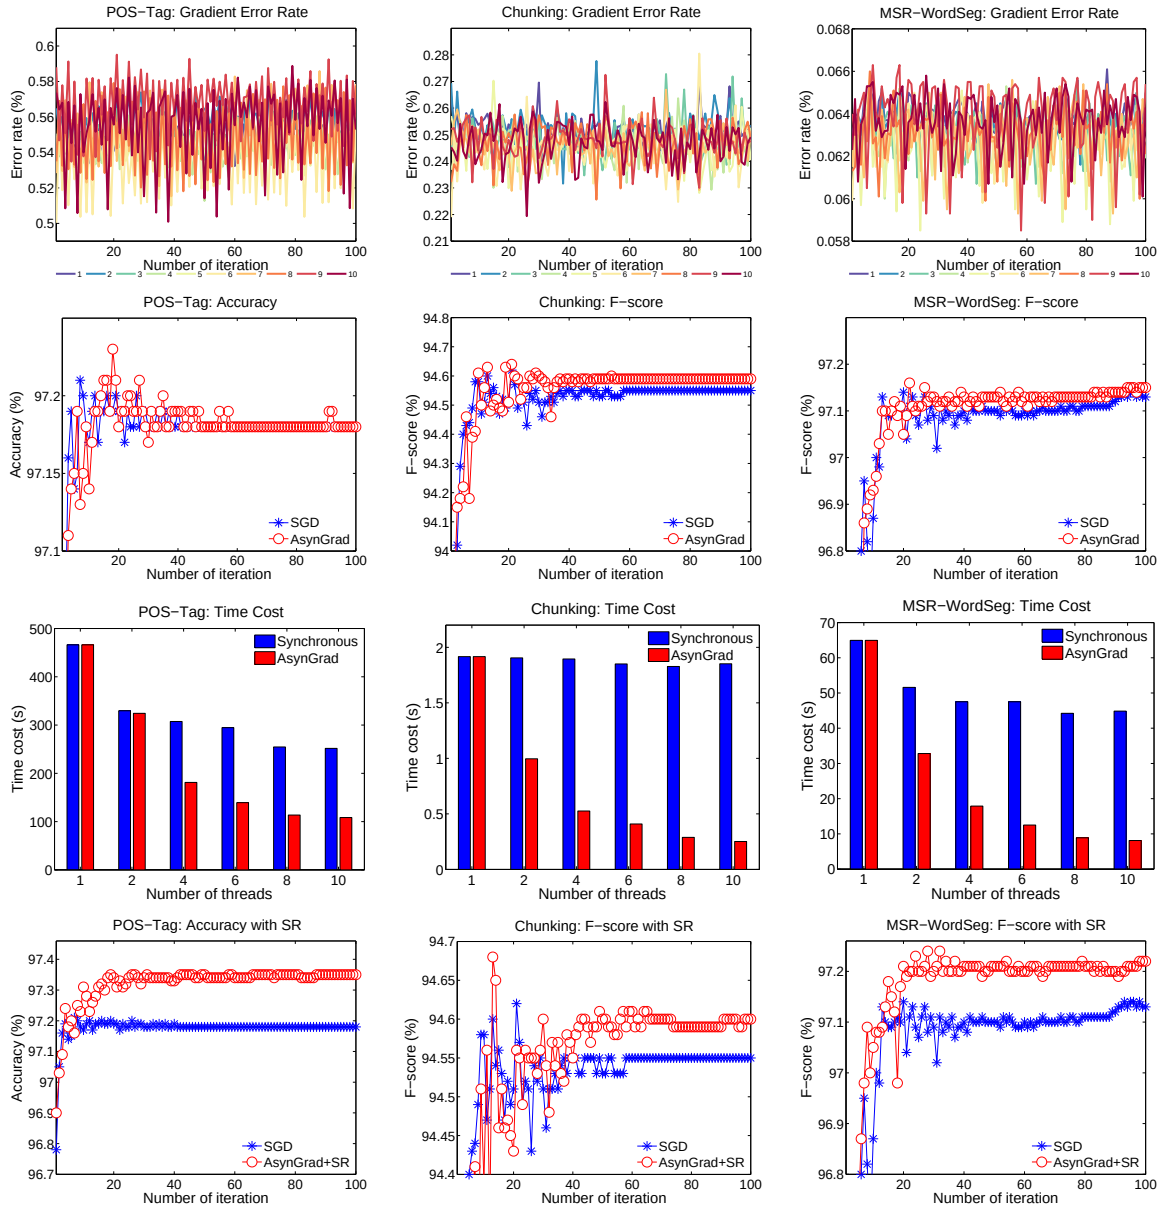

Figure 2: Experimental results on dense-CRF. For the 1st row, 1 to 10 denote the 10 threads of *AsynGrad*. For the 2nd row, *AsynGrad* denotes *AsynGrad* with 10 threads.

traditional implementation of CRF, usually the edges features contain only tag transitions with the form (y_{i-1}, y_i). In dense-CRF, we incorporate local tokens of $\boldsymbol{x}$ into the edge features, which is called rich edge features (Sun et al., 2012; Sun et al., 2014). For example, a rich edge feature can be (x_i, y_{i-1}, y_i) or even $(x_{i-1}, x_i, y_{i-1}, y_i)$. A simple way to automatically create massive rich edge features is to extend each node feature (x, y_i) to the rich edge feature (x, y_{i-1}, y_i), where x means the tokens of a local window. Usually a naive way to do this will cause feature explosion. However, it is easy to solve this problem — only extend high frequency node features (e.g., frequency larger than 10) to rich edge features. In many real-world tasks we find this type of dense-CRF works much better than traditional CRF, and without feature explosion problem even for tasks with many tags (e.g., the POS tagging task).

The standard SGD learning method (Bertsekas, 1999; Bottou and Bousquet, 2008; Shalev-Shwartz and Srebro, 2008) is chosen as the baseline. Based on tuning, the initial learning rate of SGD is set as 0.02, 0.05, 0.1 for the POS-Tag, Chunking, and MSR-WordSeg tasks, respectively. To control overfitting, we use the L_2 regularizer, i.e., a Gaussian prior. The L_2 regularization strength (i.e., the term λ) is set as 1, 0.5, 1 for the three tasks, respectively.

The experimental results are shown in Figure 2. The 1st row shows the percentage of gradient errors

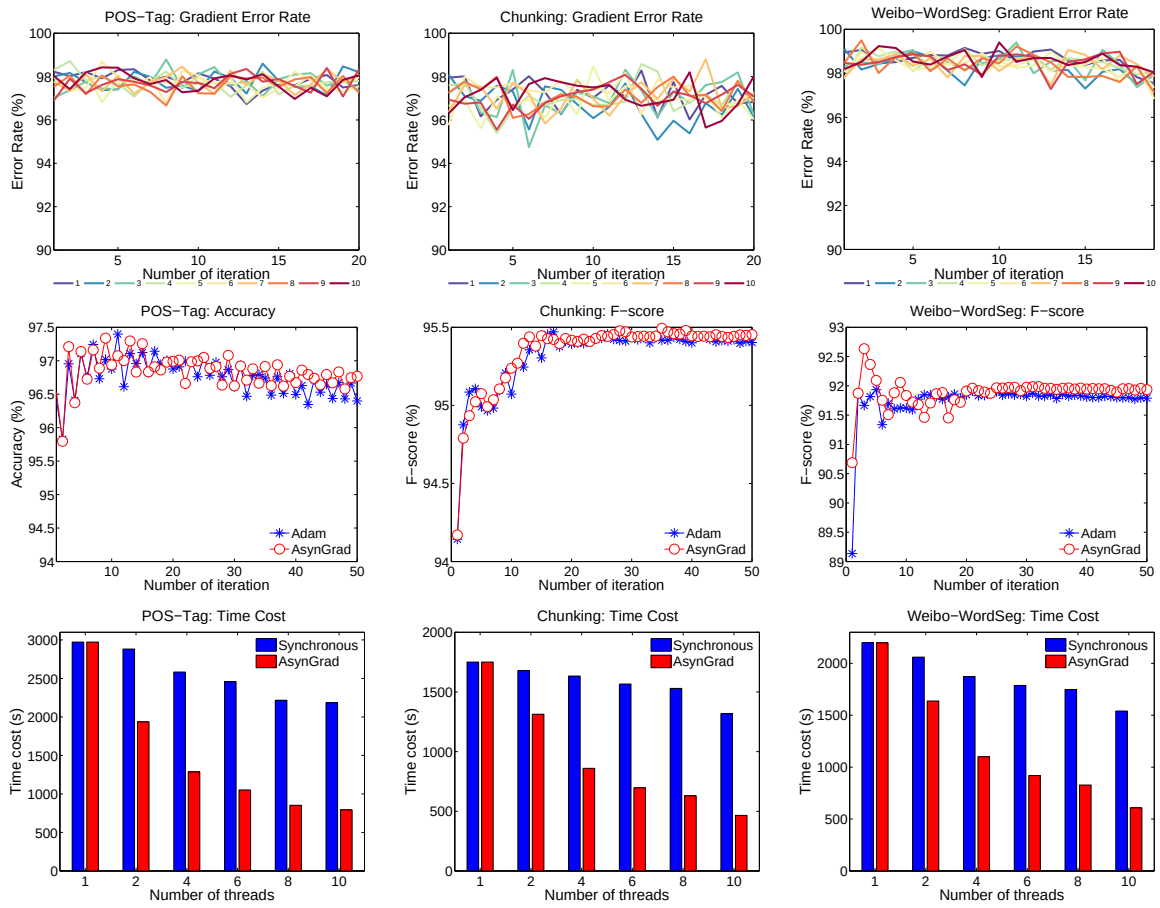

Figure 3: Experimental results on LSTM. For the 1st row, 1 to 10 denote the 10 threads of *AsynGrad*. For the 2nd row, *AsynGrad* denotes *AsynGrad* with 10 threads.

Table 2: Some major experimental results on LSTM. Time means time cost per iteration.

Method	POS-Tag		Chunking		Weibo-WordSeg	
	Acc (%)	Time (s)	F-score (%)	Time (s)	F-score (%)	Time (s)
Adam	96.40	2972.13	95.40	1750.68	91.79	2198.45
AsynGrad(10-thread)	96.77	793.40	95.45	465.95	91.93	607.22

among total gradients. For example, if a thread used 100 gradients and 5 gradients are with errors in this iteration, its gradient error rate is 5%. As we can see, the gradient errors are not rare in asynchronous parallel learning.

The 2nd row shows the accuracy/F-score curves. As we can see, when facing the gradient errors, the proposed asynchronous parallel learning method *AsynGrad* has no loss at all on the accuracy/F-score, compared with traditional SGD (single thread).

The 3rd row shows the speed acceleration of *AsynGrad*, compared with synchronous parallel learning method (Langford et al., 2009). As we can see, when adding more threads for parallel learning, *AsynGrad* achieves substantially better acceleration on the training speed than the synchronous parallel learning method.

The 4th row shows the accuracy/F-score curves by combining *AsynGrad* with structure regularization (SR) (Sun, 2014). SR is a simple method to prevent overfitting by splitting samples into mini-samples, thus it reduces the complexity and sparsity of structures (Sun, 2014). As we can see, *AsynGrad* can easily combine with SR to improve the accuracy/F-score on those tasks.

Some major experimental results are summarized in Table 1.

3.2 Experiments on LSTM (Completely Dense Case)

Recently, long short term memory networks (LSTM) has widely applied to many tasks (Chen et al., 2015; Hammerton, 2003; Cho et al., 2014). In this work, we use the bi-directional long short term memory network (Bi-LSTM) as the implementation of LSTM, which has better accuracy than single-directional LSTM in many practical tasks. The LSTM recurrent cell is controlled by three "gates", namely input gate, forget gate and output gate.

Adaptive learning versions of SGD are popular to train large neural networks, including the Adam learning method (Kingma and Ba, 2014), the RMSProp learning method (Tieleman and Hinton, 2012), and so on. The experiments on LSTM are based on the Adam learning method, with the hyper parameters as follows: $\beta_1 = \beta_2 = 0.95$, $\epsilon = 1 \times 10^{-4}$ (Kingma and Ba, 2014). The input/hidden dimension is 170, 280, and 220 for the POS-Tag, Chunking, and Weibo-WordSeg tasks, respectively. For the tasks with LSTM, we find there is almost no difference on the results by adding L_2 regularization or not. Hence, we do not add L_2 regularization for LSTM. All weight matrices, except for bias vectors and word embeddings, are diagonal matrices and randomly initialized by normal distribution.

The experimental results are shown in Figure 3. The 1st row shows the percentage of gradient errors among total gradients. As we can see, for neural networks like LSTM, the gradient errors are very common (the rate is over 90%) in asynchronous parallel learning. The gradient error rate is much higher than the dense-CRF case, this is because the LSTM is a much more dense model compared with dense-CRF. In fact, LSTM can be seen as a completely dense model because there is totally no sparse feature existing.

The 2nd row shows the accuracy/F-score curves. As we can see, when facing the intensive gradient errors which are over 90% on very dense models like LSTM, *AsynGrad* has no loss at all on accuracy/F-score.

The 3rd row shows the speed acceleration of *AsynGrad*, compared with synchronous parallel learning method (Langford et al., 2009). As we can see, when adding more threads for parallel learning, *AsynGrad* achieves substantially better acceleration on the training speed than the synchronous version.

The experiments shows that *AsynGrad* can substantially accelerate the training speed of LSTM, and without any loss on accuracy. Some major experimental results are summarized in Table 2.

4 Proof

Here we give the proof of Theorem 1. First, the recursion formula is derived. Then, the bounds are derived.

4.1 Recursion Formula

By subtracting $\boldsymbol{w}^*$ from both sides and taking norms for (1), we have

$$\begin{aligned} ||\boldsymbol{w}_{t+1} - \boldsymbol{w}^*||^2 &= ||\boldsymbol{w}_t - \gamma \boldsymbol{s}_{\boldsymbol{z}_t}(\boldsymbol{w}_t) - \boldsymbol{w}^*||^2 \\ &= ||\boldsymbol{w}_t - \boldsymbol{w}^*||^2 - 2\gamma(\boldsymbol{w}_t - \boldsymbol{w}^*)^T \boldsymbol{s}_{\boldsymbol{z}_t}(\boldsymbol{w}_t) + \gamma^2 ||\boldsymbol{s}_{\boldsymbol{z}_t}(\boldsymbol{w}_t)||^2 \end{aligned} \tag{12}$$

Taking expectations and let $a_t = \mathbb{E}||\boldsymbol{w}_t - \boldsymbol{w}^*||^2$, we have

$$\begin{aligned} a_{t+1} &= a_t - 2\gamma \mathbb{E}[(\boldsymbol{w}_t - \boldsymbol{w}^*)^T \boldsymbol{s}_{\boldsymbol{z}_t}(\boldsymbol{w}_t)] + \gamma^2 \mathbb{E}[||\boldsymbol{s}_{\boldsymbol{z}_t}(\boldsymbol{w}_t)||^2] \\ &\quad \text{(based on (6))} \\ &\leq a_t - 2\gamma \mathbb{E}[(\boldsymbol{w}_t - \boldsymbol{w}^*)^T \boldsymbol{s}_{\boldsymbol{z}_t}(\boldsymbol{w}_t)] + \gamma^2 \kappa^2 \\ &\quad \text{(since the random draw of } \boldsymbol{z}_t \text{ is independent of } \boldsymbol{w}_t) \\ &= a_t - 2\gamma \mathbb{E}[(\boldsymbol{w}_t - \boldsymbol{w}^*)^T \mathbb{E}_{\boldsymbol{z}_t}(\boldsymbol{s}_{\boldsymbol{z}_t}(\boldsymbol{w}_t))] + \gamma^2 \kappa^2 \\ &= a_t - 2\gamma \mathbb{E}[(\boldsymbol{w}_t - \boldsymbol{w}^*)^T \boldsymbol{s}(\boldsymbol{w}_t)] + \gamma^2 \kappa^2 \end{aligned} \tag{13}$$

We define

$$\delta(\boldsymbol{w}) = \nabla f(\boldsymbol{w}) - \boldsymbol{s}(\boldsymbol{w}) \tag{14}$$

and insert it into (4), it goes to

$$\begin{aligned} f(\boldsymbol{w}') &\geq f(\boldsymbol{w}) + (\boldsymbol{w}' - \boldsymbol{w})^T[\boldsymbol{s}(\boldsymbol{w}) + \delta(\boldsymbol{w})] + \frac{c}{2}||\boldsymbol{w}' - \boldsymbol{w}||^2 \\ &= f(\boldsymbol{w}) + (\boldsymbol{w}' - \boldsymbol{w})^T\boldsymbol{s}(\boldsymbol{w}) + \frac{c}{2}||\boldsymbol{w}' - \boldsymbol{w}||^2 + (\boldsymbol{w}' - \boldsymbol{w})^T\delta(\boldsymbol{w}) \end{aligned} \tag{15}$$

By setting $\boldsymbol{w}' = \boldsymbol{w}^*$, we further have

$$\begin{aligned} (\boldsymbol{w} - \boldsymbol{w}^*)^T\boldsymbol{s}(\boldsymbol{w}) &\geq f(\boldsymbol{w}) - f(\boldsymbol{w}^*) + \frac{c}{2}||\boldsymbol{w} - \boldsymbol{w}^*||^2 - (\boldsymbol{w} - \boldsymbol{w}^*)^T\delta(\boldsymbol{w}) \\ &\geq \frac{c}{2}||\boldsymbol{w} - \boldsymbol{w}^*||^2 - (\boldsymbol{w} - \boldsymbol{w}^*)^T\delta(\boldsymbol{w}) \end{aligned} \tag{16}$$

Combining (13) and (16), we have

$$\begin{aligned} a_{t+1} &\leq a_t - 2\gamma\mathbb{E}\Big[\frac{c}{2}||\boldsymbol{w}_t - \boldsymbol{w}^*||^2 - (\boldsymbol{w}_t - \boldsymbol{w}^*)^T\delta(\boldsymbol{w}_t)\Big] + \gamma^2\kappa^2 \\ &= (1 - c\gamma)a_t + 2\gamma\mathbb{E}[(\boldsymbol{w}_t - \boldsymbol{w}^*)^T\delta(\boldsymbol{w}_t)] + \gamma^2\kappa^2 \end{aligned} \tag{17}$$

Considering (8) and (14), it goes to

$$a_{t+1} \leq (1 - c\gamma)a_t + 2\gamma\tau + \gamma^2\kappa^2 \tag{18}$$

We can find a steady state a_∞ by the formula $a_\infty = (1 - c\gamma)a_\infty + 2\gamma\tau + \gamma^2\kappa^2$, which gives

$$a_\infty = \frac{2\tau + \gamma\kappa^2}{c} \tag{19}$$

Defining the function $A(x) = (1 - c\gamma)x + 2\gamma\tau + \gamma^2\kappa^2$, based on (18) we have

$$\begin{aligned} &a_{t+1} \leq A(a_t) \\ &\quad \text{(Taylor expansion of } A(\cdot) \text{ based on } a_\infty\text{, with } \nabla^2 A(\cdot) \text{ being 0)} \\ &\quad = A(a_\infty) + \nabla A(a_\infty)(a_t - a_\infty) \\ &\quad = A(a_\infty) + (1 - c\gamma)(a_t - a_\infty) \\ &\quad = a_\infty + (1 - c\gamma)(a_t - a_\infty) \end{aligned} \tag{20}$$

Thus, we have $a_{t+1} - a_\infty \leq (1 - c\gamma)(a_t - a_\infty)$, and unwrapping it goes to

$$a_t \leq (1 - c\gamma)^t(a_0 - a_\infty) + a_\infty \tag{21}$$

4.2 Bounds

Since $\nabla f(\boldsymbol{w})$ is Lipschitz according to (5), we have

$$f(\boldsymbol{w}) \leq f(\boldsymbol{w}') + \nabla f(\boldsymbol{w}')^T(\boldsymbol{w} - \boldsymbol{w}') + \frac{q}{2}||\boldsymbol{w} - \boldsymbol{w}'||^2$$

Setting $\boldsymbol{w}' = \boldsymbol{w}^*$, it goes to $f(\boldsymbol{w}) - f(\boldsymbol{w}^*) \leq \frac{q}{2}||\boldsymbol{w} - \boldsymbol{w}^*||^2$, such that

$$\mathbb{E}[f(\boldsymbol{w}_t) - f(\boldsymbol{w}^*)] \leq \frac{q}{2}\mathbb{E}||\boldsymbol{w}_t - \boldsymbol{w}^*||^2 = \frac{q}{2}a_t$$

In order to have $E[f(\boldsymbol{w}_t) - f(\boldsymbol{w}^*)] \leq \epsilon$, it is required that $\frac{q}{2}a_t \leq \epsilon$, that is

$$a_t \leq \frac{2\epsilon}{q} \tag{22}$$

Combining (21) and (22), it is required that

$$(1 - c\gamma)^t(a_0 - a_\infty) + a_\infty \leq \frac{2\epsilon}{q} \tag{23}$$

To meet this requirement, it is sufficient to set the learning rate γ such that both terms on the left side are less than $\frac{\epsilon}{q}$. For the requirement of the second term $a_\infty \leq \frac{\epsilon}{q}$, recalling (19), it goes to $\gamma \leq \frac{c\epsilon - 2\tau q}{q\kappa^2}$. Thus, introducing a real value $\beta \geq 1$, we can set γ as

$$\gamma = \frac{c\epsilon - 2\tau q}{\beta q \kappa^2} \tag{24}$$

Note that, to make this formula meaningful, it is required that $c\epsilon - 2\tau q \geq 0$. Thus, it is required that

$$\tau \leq \frac{c\epsilon}{2q}$$

which is solved by the condition of (11).

On the other hand, we analyze the requirement of the first term that $(1 - c\gamma)^t (a_0 - a_\infty) \leq \frac{\epsilon}{q}$. Since $a_0 - a_\infty \leq a_0$, it holds by requiring $(1 - c\gamma)^t a_0 \leq \frac{\epsilon}{q}$, which goes to

$$t \geq \frac{\log \frac{\epsilon}{q a_0}}{\log (1 - c\gamma)} \tag{25}$$

Since $\log (1 - c\gamma) \leq -c\gamma$ given (7), and that $\log \frac{\epsilon}{q a_0}$ is a negative term, we have

$$\frac{\log \frac{\epsilon}{q a_0}}{\log (1 - c\gamma)} \leq \frac{\log \frac{\epsilon}{q a_0}}{-c\gamma}$$

Thus, (25) holds by requiring

$$t \geq \frac{\log \frac{\epsilon}{q a_0}}{-c\gamma} = \frac{\log (q a_0 / \epsilon)}{c\gamma} \tag{26}$$

Combining (24) and (26), the problem can be addressed as far as

$$t \geq \frac{\beta q \kappa^2 \log (q a_0 / \epsilon)}{c(c\epsilon - 2\tau q)}$$

Thus, setting $t \doteq \frac{\beta q \kappa^2 \log (q a_0 / \epsilon)}{c(c\epsilon - 2\tau q)}$ can solve the problem. This completes the proof. □

5 Conclusions

In this paper we show that gradient errors are very common and inevitable in dense feature models. Nevertheless, we show that the learning process with the gradient error problem can still approach the optimum in many practical applications. We propose a simple method *AsynGrad* for asynchronous stochastic parallel learning with gradient error. We show that *AsynGrad* works well for dense feature models like neural networks and dense-CRF, in spite of gradient errors. Base on various NLP tasks, our experiments show that *AsynGrad* can substantially accelerate the training speed of LSTM and dense-CRF, and without any loss on accuracy.

Abstract

In this paper, we empirically explore the effects of various kinds of skip connections in stacked bidirectional LSTMs for sequential tagging. We investigate three kinds of skip connections connecting to LSTM cells: (a) skip connections to the gates, (b) skip connections to the internal states and (c) skip connections to the cell outputs. We present comprehensive experiments showing that skip connections to cell outputs outperform the remaining two. Furthermore, we observe that using gated identity functions as skip mappings works pretty well. Based on this novel skip connections, we successfully train deep stacked bidirectional LSTM models and obtain state-of-the-art results on CCG supertagging and comparable results on POS tagging.

1 Introduction

In natural language processing, sequential tagging mainly refers to the tasks of assigning discrete labels to each token in a sequence. Typical examples include part-of-speech (POS) tagging and combinatory category grammar (CCG) supertagging. A regular feature of sequential tagging is that the input tokens in a sequence cannot be assumed to be independent since the same token in different contexts can be assigned to different tags. Therefore, the classifier should have memories to remember the contexts to make a correct prediction.

Bidirectional LSTMs (Graves and Schmidhuber, 2005) become dominant in sequential tagging problems due to the superior performance (Wang et al., 2015; Vaswani et al., 2016; Lample et al., 2016). The horizontal hierarchy of LSTMs with bidirectional processing can remember the long-range dependencies without affecting the short-term storage. Although the models have a deep horizontal hierarchy (the depth is the same as the sequence length), the vertical hierarchy is often shallow, which may not be efficient at representing each token. Stacked LSTMs are deep in both directions, but become harder to train due to the feed-forward structure of stacked layers.

Skip connections (or shortcut connections) enable unimpeded information flow by adding direct connections across different layers (Raiko et al., 2012; Graves, 2013; Hermans and Schrauwen, 2013). However, there is a lack of exploration and analyzing various kinds of skip connections in stacked LSTMs. There are two issues to handle skip connections in stacked LSTMs: One is where to add the skip connections, the other is what kind of skip connections should be used to pass the information. To answer the first question, we empirically analyze three positions of LSTM blocks to receive the previous layer's output. For the second one, we present an identity mapping to receive the previous layer's outputs. Furthermore, following the gate design of LSTM (Hochreiter and Schmidhuber, 1997; Gers et al., 2000) and highway networks (Srivastava et al., 2015a; Srivastava et al., 2015b), we observe that adding a multiplicative gate to the identity function will help to improve performance.

In this paper, we present a neural architecture for sequential tagging. The input of the network are token representations. We concatenate word embeddings to character embeddings to represent the word and morphemes. A deep stacked bidirectional LSTM with well-designed skip connections is then used

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 203–212, Osaka, Japan, December 11-17 2016.

to extract the features needed for classification from the inputs. The output layer uses *softmax* function to output the tag distribution for each token.

Our main contribution is that we empirically evaluated the effects of various kinds of skip connections within stacked LSTMs. We present comprehensive experiments on the supertagging task showing that skip connections to the cell outputs using identity function multiplied with an exclusive gate can help to improve the network performance. Our model is evaluated on two sequential tagging tasks, obtaining state-of-the-art results on CCG supertagging and comparable results on POS tagging.

2 Related Work

Skip connections have been widely used for training deep neural networks. For recurrent neural networks, Schmidhuber (1992); El Hihi and Bengio (1995) introduced deep RNNs by stacking hidden layers on top of each other. Raiko et al. (2012); Graves (2013); Hermans and Schrauwen (2013) proposed the use of skip connections in stacked RNNs. However, the researchers have paid less attention to the analyzing of various kinds of skip connections, which is our focus in this paper.

The works closely related to ours are Srivastava et al. (2015b), He et al. (2015), Kalchbrenner et al. (2015), Yao et al. (2015), Zhang et al. (2016), and Zilly et al. (2016). These works are all based on the design of extra connections between different layers. Srivastava et al. (2015b) and He et al. (2015) mainly focus on feed-forward neural network, using well-designed skip connections across different layers to make the information pass more easily. The Grid LSTM proposed by Kalchbrenner et al. (2015) extends the one dimensional LSTMs to many dimensional LSTMs, which provides a more general framework to construct deep LSTMs.

Yao et al. (2015) and Zhang et al. (2016) propose highway LSTMs by introducing gated direct connections between internal states in adjacent layers and do not use skip connections, while we propose gated skip connections across cell outputs. Zilly et al. (2016) introduce recurrent highway networks (RHN) which use a single recurrent layer to make RNN deep in a vertical direction, in contrast to our stacked models.

3 Recurrent Neural Networks for Sequential Tagging

Consider a recurrent neural network applied to sequential tagging: Given a sequence $x = (x_1, \ldots, x_T)$, the RNN computes the hidden state $h = (h_1, \ldots, h_T)$ and the output $y = (y_1, \ldots, y_T)$ by iterating the following equations:

$$h_t = f(x_t, h_{t-1}; \theta_h) \tag{1}$$

$$y_t = g(h_t; \theta_o) \tag{2}$$

where $t \in \{1, \ldots, T\}$ represents the time. x_t represents the input at time t, h_{t-1} and h_t are the previous and the current hidden state, respectively. f and g are the transition function and the output function, respectively. θ_h and θ_o are network parameters.

We use a negative log-likelihood cost to evaluate the performance, which can be written as:

$$\mathcal{C} = -\frac{1}{N} \sum_{n=1}^{N} \log y_{t^n} \tag{3}$$

where $t^n \in \mathbb{N}$ is the true target for sample n, and y_{t^n} is the t-th output in the *softmax* layer given the inputs x^n.

The core idea of Long Short-Term Memory networks is to replace (1) with the following equation:

$$c_t = f(x_t, h_{t-1}) + c_{t-1} \tag{4}$$

where c_t is the internal state of the memory cell, which is designed to store the information for much longer time. Besides this, LSTM uses gates to avoid weight update conflicts.

Standard LSTMs process sequences in temporal order, which will ignore future context. Bidirectional LSTMs solve this problem by combining both the forward and the backward processing of the input sequences using two separate recurrent hidden layers:

$$\overrightarrow{h_t} = \text{LSTM}(\overrightarrow{x_t}, \overrightarrow{h_{t-1}}, \overrightarrow{c_{t-1}}) \tag{5}$$

$$\overleftarrow{h_t} = \text{LSTM}(\overleftarrow{x_t}, \overleftarrow{h_{t-1}}, \overleftarrow{c_{t-1}}) \tag{6}$$

$$y_t = g(\overrightarrow{h_t}, \overleftarrow{h_t}) \tag{7}$$

where LSTM$(\cdot)$ is the LSTM computation. $\overrightarrow{x_t}$ and $\overleftarrow{x_t}$ are the forward and the backward input sequence, respectively. The output of the two hidden layers $\overrightarrow{h_t}$ and $\overleftarrow{h_t}$ in a birectional LSTM are connected to the output layer.

Stacked RNN is one type of deep RNNs, which refers to the hidden layers are stacked on top of each other, each feeding up to the layer above:

$$h_t^l = f^l(h_t^{l-1}, h_{t-1}^l) \tag{8}$$

where h_t^l is the t-th hidden state of the l-th layer.

4 Various kinds of Skip Connections

Skip connections in simple RNNs are trivial since there is only one position to connect to the hidden units. But for stacked LSTMs, the skip connections need to be carefully treated to train the network successfully. In this section, we analyze and compare various types of skip connections. At first, we give a detailed definition of stacked LSTMs, which can help us to describe skip connections. Then we start our construction of skip connections in stacked LSTMs. At last, we formulate various kinds of skip connections.

Stacked LSTMs without skip connections can be defined as:

$$\begin{pmatrix} i_t^l \\ f_t^l \\ o_t^l \\ s_t^l \end{pmatrix} = \begin{pmatrix} \text{sigm} \\ \text{sigm} \\ \text{sigm} \\ \text{tanh} \end{pmatrix} W^l \begin{pmatrix} h_t^{l-1} \\ h_{t-1}^l \end{pmatrix} \qquad \begin{aligned} c_t^l &= f_t^l \odot c_{t-1}^l + i_t^l \odot s_t^l \\ h_t^l &= o_t^l \odot \tanh(c_t^l) \end{aligned} \tag{9}$$

During forward pass, LSTM needs to calculate c_t^l and h_t^l, which is the cell's internal state and the cell outputs state, respectively. To get c_t^l, s_t^l needs to be computed to store the current input. Then this result is multiplied by the input gate i_t^l, which decides when to keep or override information in memory cell c_t^l. The cell is designed to store the previous information c_{t-1}^l, which can be reset by a forget gate f_t^l. The new cell state is then obtained by adding the result to the current input. The cell outputs h_t^l are computed by multiplying the activated cell state by the output gate o_t^l, which learns when to access memory cell and when to block it. "sigm" and "tanh" are the sigmoid and tanh activation function, respectively. $W^l \in \mathbb{R}^{4n \times 2n}$ is the weight matrix needs to be learned.

The hidden units in stacked LSTMs have two forms. One is the hidden units in the same layer $\{h_t^l, t \in 1, \ldots, T\}$, which are connected through an LSTM. The other is the hidden units at the same time step $\{h_t^l, l \in 1, \ldots, L\}$, which are connected through a feed-forward network. LSTM can keep the short-term memory for a long time, thus the error signals can be easily passed through $\{1, \ldots, T\}$. However, when the number of stacked layers is large, the feed-forward network will suffer the gradient vanishing/exploding problems, which make the gradients hard to pass through $\{1, \ldots, L\}$.

The core idea of LSTM is to use an identity function to make the constant error carrosel. He et al. (2015) also use an identity mapping to train a very deep convolution neural network with improved performance. All these inspired us to use an identity function for the skip connections. Rather, the gates of LSTM are essential parts to avoid weight update conflicts, which are also invoked by skip connections. Following highway gating, we use a gate multiplied with identity mapping to avoid the conflicts.

Skip connections are cross-layer connections, which means that the output of layer $l-2$ is not only connected to the layer $l-1$, but also connected to layer l. For stacked LSTMs, h_t^{l-2} can be connected to the gates, the internal states, and the cell outputs in layer l's LSTM blocks. We formalize these below:

Skip connections to the gates. We can connect h_t^{l-2} to the gates through an identity mapping:

$$\begin{pmatrix} i_t^l \\ f_t^l \\ o_t^l \\ s_t^l \end{pmatrix} = \begin{pmatrix} \text{sigm} \\ \text{sigm} \\ \text{sigm} \\ \tanh \end{pmatrix} \left(W^l \; I^l \right) \begin{pmatrix} h_t^{l-1} \\ h_{t-1}^l \\ h_t^{l-2} \end{pmatrix} \tag{10}$$

where $I^l \in \mathbb{R}^{4n \times n}$ is the identity mapping.

Skip connections to the internal states. Another kind of skip connections is to connect h_t^{l-2} to the cell's internal state c_t^l:

$$c_t^l = f_t^l \odot c_{t-1}^l + i_t^l \odot s_t^l + h_t^{l-2} \tag{11}$$
$$h_t^l = o_t^l \odot \tanh(c_t^l) \tag{12}$$

Skip connections to the cell outputs. We can also connect h_t^{l-2} to cell outputs:

$$c_t^l = f_t^l \odot c_{t-1}^l + i_t^l \odot s_t^l \tag{13}$$
$$h_t^l = o_t^l \odot \tanh(c_t^l) + h_t^{l-2} \tag{14}$$

Skip connections using gates. Consider the case of skip connections to the cell outputs. The cell outputs grow linearly during the presentation of network depth, which makes the h_t^l's derivative vanish and hard to convergence. Inspired by the introduction of LSTM gates, we add a gate to control the skip connections through retrieving or blocking them:

$$\begin{pmatrix} i_t^l \\ f_t^l \\ o_t^l \\ g_t^l \\ s_t^l \end{pmatrix} = \begin{pmatrix} \text{sigm} \\ \text{sigm} \\ \text{sigm} \\ \text{sigm} \\ \tanh \end{pmatrix} W^l \begin{pmatrix} h_t^{l-1} \\ h_{t-1}^l \end{pmatrix} \qquad \begin{aligned} c_t^l &= f_t^l \odot c_{t-1}^l + i_t^l \odot s_t^l \\ h_t^l &= o_t^l \odot \tanh(c_t^l) + g_t^l \odot h_t^{l-2} \end{aligned} \tag{15}$$

where g_t^l is the gate which can be used to access the skipped output h_t^{l-2} or block it. When g_t^l equals 0, no skipped output can be passed through skip connections, which is equivalent to traditional stacked LSTMs. Otherwise, it behaves like a feed-forward LSTM using gated identity connections. Here we omit the case of adding gates to skip connections to the internal state, which is similar to the above case.

Skip connections in bidirectional LSTM. Using skip connections in bidirectional LSTM is similar to the one used in LSTM, with a bidirectional processing:

$$\begin{aligned} \overrightarrow{c_t^l} &= \overrightarrow{f} \odot \overrightarrow{c_{t-1}^l} + \overrightarrow{i} \odot \overrightarrow{s_t^l} \\ \overrightarrow{h_t^l} &= \overrightarrow{o} \odot \tanh(\overrightarrow{c_t^l}) + \overrightarrow{g} \odot \overrightarrow{h_t^{l-2}} \end{aligned} \qquad \begin{aligned} \overleftarrow{c_t^l} &= \overleftarrow{f} \odot \overleftarrow{c_{t-1}^l} + \overleftarrow{i} \odot \overleftarrow{s_t^l} \\ \overleftarrow{h_t^l} &= \overleftarrow{o} \odot \tanh(\overleftarrow{c_t^l}) + \overleftarrow{g} \odot \overleftarrow{h_t^{l-2}} \end{aligned} \tag{16}$$

5 Neural Architecture for Sequential Tagging

Sequential tagging can be formulated as $P(t|w;\theta)$, where $w = [w_1, \ldots, w_T]$ indicates the T words in a sentence, and $t = [t_1, \ldots, t_T]$ indicates the corresponding T tags. In this section we introduce an neural architecture for $P(\cdot)$, which includes an input layer, a stacked hidden layers and an output layer. Since the stacked hidden layers have already been introduced, we only introduce the input and the output layer here.

5.1 Network Inputs

Network inputs are the representation of each token in a sequence. There are many kinds of token representations, such as using a single word embedding, using a local window approach, or a combination of word and character-level representation. Here our inputs contain the concatenation of word representations, character representations, and capitalization representations.

Word representations. All words in the vocabulary share a common look-up table, which is initialized with random initializations or pre-trained embeddings. Each word in a sentence can be mapped to an embedding vector w_t. The whole sentence is then represented by a matrix with columns vector $[w_1, w_2, \ldots, w_T]$. We use a context window of size d surrounding with a word w_t to get its context information. Following Wu et al. (2016), we add logistic gates to each token in the context window. The word representation is computed as $w_t = [r_{t-\lfloor d/2 \rfloor} w_{t-\lfloor d/2 \rfloor}; \ldots; r_{t+\lfloor d/2 \rfloor} w_{t+\lfloor d/2 \rfloor}]$, where $r_t := [r_{t-\lfloor d/2 \rfloor}, \ldots, r_{t+\lfloor d/2 \rfloor}] \in \mathbb{R}^d$ is a logistic gate to filter the unnecessary contexts, $w_{t-\lfloor d/2 \rfloor}, \ldots, w_{t+\lfloor d/2 \rfloor}$ is the word embeddings in the local window.

Character representations. Prefix and suffix information about words are important features in sequential tagging. Inspired by Fonseca et al. (2015) et al, which uses a character prefix and suffix with length from 1 to 5 for part-of-speech tagging, we concatenate character embeddings in a word to get the character-level representation. Concretely, given a word w consisting of a sequence of characters $[c_1, c_2, \ldots, c_{l_w}]$, where l_w is the length of the word and $L(\cdot)$ is the look-up table for characters. We concatenate the leftmost most 5 character embeddings $L(c_1), \ldots, L(c_5)$ with its rightmost 5 character embeddings $L(c_{l_w-4}), \ldots, L(c_{l_w})$. When a word is less than five characters, we pad the remaining characters with the same special symbol.

Capitalization representations. We lowercase the words to decrease the size of word vocabulary to reduce sparsity, but we need an extra capitalization embeddings to store the capitalization features, which represent whether or not a word is capitalized.

5.2 Network Outputs

For sequential tagging, we use a *softmax* activation function $g(\cdot)$ in the output layer:

$$y_t = g(W^{hy}[\overrightarrow{h_t}; \overleftarrow{h_t}]) \tag{17}$$

where y_t is a probability distribution over all possible tags. $y_k(t) = \frac{\exp(h_k)}{\sum_{k'} \exp(h_{k'})}$ is the k-th dimension of y_t, which corresponds to the k-th tags in the tag set. W^{hy} is the hidden-to-output weight.

6 Experiments

6.1 Combinatory Category Grammar Supertagging

Combinatory Category Grammar (CCG) supertagging is a sequential tagging problem in natural language processing. The task is to assign supertags to each word in a sentence. In CCG the supertags stand for the lexical categories, which are composed of the basic categories such as N, NP and PP, and complex categories, which are the combination of the basic categories based on a set of rules. Detailed explanations of CCG refers to (Steedman, 2000; Steedman and Baldridge, 2011).

The training set of this task only contains 39604 sentences, which is too small to train a deep model, and may cause over-parametrization. But we choose it since it has been already proved that a bidirectional recurrent net fits the task by many authors (Lewis et al., 2016; Vaswani et al., 2016).

6.1.1 Dataset and Pre-processing

Our experiments are performed on CCGBank (Hockenmaier and Steedman, 2007), which is a translation from Penn Treebank (Marcus et al., 1993) to CCG with a coverage 99.4%. We follow the standard splits, using sections 02-21 for training, section 00 for development and section 23 for the test. We use a full category set containing 1285 tags. All digits are mapped into the same digit '9', and all words are lowercased.

6.1.2 Network Configuration

Initialization. There are two types of weights in our experiments: recurrent and non-recurrent weights. For non-recurrent weights, we initialize word embeddings with the pre-trained 200-dimensional GolVe vectors (Pennington et al., 2014). Other weights are initialized with the Gaussian distribution

Model	Dev	Test
Clark and Curran (2007)	91.5	92.0
Lewis et al. (2014)	91.3	91.6
Lewis et al. (2016)	94.1	94.3
Xu et al. (2015)	93.1	93.0
Xu et al. (2016)	93.49	93.52
Vaswani et al. (2016)	94.24	94.5
7-layers + skip output + gating	94.51	94.67
7-layers + skip output + gating (no char)	94.33	94.45
7-layers + skip output + gating (no dropout)	94.06	94.0
9-layers + skip output + gating	**94.55**	**94.69**

Table 1: 1-best supertagging accuracy on CCGbank. "skip output" refers to the skip connections to the cell output, "gating" refers to adding a gate to the identity function, "no char" refers to the models that do not use the character-level information, "no dropout" refers to models that do not use dropout.

$\mathcal{N}(0, \frac{1}{\sqrt{\text{fan-in}}})$ scaled by a factor of 0.1, where *fan-in* is the number of units in the input layer. For recurrent weight matrices, following Saxe et al. (2013) we initialize with random orthogonal matrices through SVD to avoid unstable gradients. Orthogonal initialization for recurrent weights is important in our experiments, which takes about 2% relative performance enhancement than other methods such as Xavier initialization (Glorot and Bengio, 2010).

Hyperparameters. For the word representations, we use a small window size of 3 for the convolutional layer. The dimension of the word representation after the convolutional operation is 600. The size of character embedding and capitalization embeddings are set to 5. The number of cells of the stacked bidirectional LSTM is set to 512. We also tried 400 cells or 600 cells and found this number did not impact performance so much. All stacked hidden layers have the same number of cells. The output layer has 1286 neurons, which equals to the number of tags in the training set with a RARE symbol.

Training. We train the networks using the back-propagation algorithm, using stochastic gradient descent (SGD) algorithm with an equal learning rate 0.02 for all layers. We also tried other optimization methods, such as momentum (Plaut and others, 1986), Adadelta (Zeiler, 2012), or Adam (Kingma and Ba, 2014), but none of them perform as well as SGD. Gradient clipping is not used. We use on-line learning in our experiments, which means the parameters will be updated on every training sequences, one at a time. We trained the 7-layer network for roughly 2 to 3 days on one NVIDIA TITAN X GPU using Theano [1] (Team et al., 2016).

Regularization. Dropout (Srivastava et al., 2014) is the only regularizer in our model to avoid overfitting. Other regularization methods such as weight decay and batch normalization do not work in our experiments. We add a binary dropout mask to the local context windows on the embedding layer, with a drop rate p of 0.25. We also apply dropout to the output of the first hidden layer and the last hidden layer, with a 0.5 drop rate. At test time, weights are scaled with a factor $1 - p$.

6.1.3 Results

Table 1 shows the comparisons with other models for supertagging. The comparisons do not include any externally labeled data and POS labels. We use stacked bidirectional LSTMs with gated skip connections for the comparisons, and report the highest 1-best supertagging accuracy on the development set for final testing. Our model presents state-of-the-art results compared to the existing systems. The character-level information (+ 3% relative accuracy) and dropout (+ 8% relative accuracy) are necessary to improve the performance.

[1] `http://deeplearning.net/software/theano/`

6.1.4 Experiments on Skip Connections

We experiment with a 7-layer model on CCGbank to compare different kinds of skip connections introduced in Section 4. Our analysis mainly focuses on the identity function and the gating mechanism. The comparisons (Table 2) are summarized as follows:

No skip connections. When the number of stacked layers is large, the performance will degrade without skip connections. The accuracy in a 7-layer stacked model without skip connections is 93.94% (Table 2), which is lower than the one using skip connections.

Various kinds of skip connections. We experiment with the gated identity connections between internal states introduced in Zhang et al.(2016), but the network performs not good (Table 2, 93.14%). We also implement the method proposed in Zilly et al. (2016), which we use a single bidirectional RNH layer with a recurrent depth of 3 with a slightly modification[2]. Skip connections to the cell outputs with identity function and multiplicative gating achieves the highest accuracy (Table 2, 94.51%) on the development set. We also observe that skip to the internal states without gate get a slightly better performance (Table 2, 94.33%) than the one with gate (94.24%) on the development set. Here we recommend to set the forget bias to 0 to get a better development accuracy.

Identity mapping. We use the sigmoid function to the previous outputs to break the identity link, in which we replace $g_t \odot h_t^{l-1}$ in Eq. (15) with $g_t \odot \sigma(h_t^{l-1})$, where $\sigma(x) = \frac{1}{1+e^{-x}}$. The result of the sigmoid function is 94.02% (Table 2), which is poor than the identity function. We can infer that the identity function is more suitable than other scaled functions such as sigmoid or tanh to transmit information.

Exclusive gating. Following the gating mechanism adopted in highway networks, we consider adding a gate g_t to make a flexible control to the skip connections. Our gating function is $g_t^l = \sigma(W_g^l h_{t-1}^l + U_g^l h_t^{l-2})$. Gated identity connections are essential to achieving state-of-the-art result on CCGbank.

Case	Variant	Dev	Test
H-LSTM, Zhang et al.(2016)	-	93.14	93.52
RHN, Zilly et al. (2016)	$L = 3$, with output gates	94.28	94.24
no skip connections	-	93.94	94.26
to the gates, Eq. (10)	-	93.9	94.22
to the internals	no gate, Eq. (11)	94.33	94.63
	with gate	94.24	94.52
to the outputs	no gate, Eq. (14)	93.89	93.98
	with gate, $b_f = 5$, Eq. (15)	94.23	94.81
	with gate, $b_f = 0$, Eq. (15)	94.51	94.67
	sigmoid mapping: $g_t \odot \sigma(h_t^{l-1})$	94.02	94.18

Table 2: Accuracy on CCGbank using 7-layer stacked bidirectional LSTMs, with different types of skip connections. b_f is the bias of the forget gate.

6.1.5 Experiments on Number of Layers

Table 3 compares the effect of the depth in the stacked models. We can observe that the performance is getting better with the increased number of layers. But when the number of layers exceeds 9, the performance will be hurt. In the experiments, we found that the number of stacked layers between 7 and 9 are the best choice using skip connections. Notice that we do not use layer-wise pretraining (Bengio et al., 2007; Simonyan and Zisserman, 2014), which is an important technique in training deep networks.

[2]Our original implementation of Zilly et a. (2016) with a recurrent depth of 3 fails to converge. The reason might be due to the explosion of s_L^t under addition. To avoid this, we replace s_L^t with $o_t * \tanh(s_L^t)$ in the last recurrent step.

Further improvements might be obtained with this method to build a deeper network with improved performance.

#Layers	Dev	Test
3	94.21	94.35
5	94.51	94.57
7	94.51	94.67
9	94.55	94.7
11	94.43	94.65

Table 3: Accuracy on CCGbank using gated identity connections to cell outputs, with different number of stacked layers.

6.2 Part-of-speech Tagging

Part-of-speech tagging is another sequential tagging task, which is to assign POS tags to each word in a sentence. It is very similar to the supertagging task. Therefore, these two tasks can be solved in a unified architecture. For POS tagging, we use the same network configurations as supertagging, except the word vocabulary size and the tag set size. We conduct experiments on the Wall Street Journal of the Penn Treebank dataset, adopting the standard splits (sections 0-18 for the train, sections 19-21 for validation and sections 22-24 for testing).

Model	Test
Søgaard (2011)	97.5
Ling et al. (2015)	97.36
Wang et al. (2015)	**97.78**
Vaswani et al. (2016)	97.4
7-layers + skip output + gating	97.45
9-layers + skip output + gating	97.45

Table 4: Accuracy for POS tagging on WSJ.

Although the POS tagging result presented in Table 4 is slightly below the state-of-the-art, we neither do any parameter tunings nor change the network architectures, just use the one getting the best development accuracy on the supertagging task. This proves the generalization of the model and avoids heavy work of model re-designing.

7 Conclusions

This paper investigates various kinds of skip connections in stacked bidirectional LSTM models. We present a deep stacked network (7 or 9 layers) that can be easily trained and get improved accuracy on CCG supertagging and POS tagging. Our experiments show that skip connections to the cell outputs with the gated identity function performs the best. Our explorations could easily be applied to other sequential processing problems, which can be modelled with RNN architectures.

Abstract

Summarization aims to represent source documents by a shortened passage. Existing methods focus on the extraction of key information, but often neglect coherence. Hence the generated summaries suffer from a lack of readability. To address this problem, we have developed a graph-based method by exploring the links between text to produce coherent summaries. Our approach involves finding a sequence of sentences that best represent the key information in a coherent way. In contrast to the previous methods that focus only on salience, the proposed method addresses both coherence and informativeness based on textual linkages. We conduct experiments on the DUC2004 summarization task data set. A performance comparison reveals that the summaries generated by the proposed system achieve comparable results in terms of the ROUGE metric, and show improvements in readability by human evaluation.

1 Introduction

Automatic summarization is extremely useful in this age of information overload. It provides readers with easier access to information without the labour of reading the source text. According to the number of documents dealt with, summarization falls into two categories: single document summarization and multi-document summarization. While they both aim to represent the source text using a shorten passage, the latter deals with a set of documents sharing the same topic. Based on the method adopted, existing approaches to summarization can be divided into two kinds: abstraction based or extraction based. The difference lies in the sentences they use to generate summaries: the former selects sentences (clauses, or other text units, hereafter we refer to all of them as sentences.) from source documents and the latter generates new sentences. Most existing summarization systems are extraction-based because abstraction-based methods require the use of natural language generation technology, which is still a growing field. This paper, without exception, also employs extraction-based methods and we focus on multi-documents summarization.

Currently the extraction-based methods face some major challenges. One is informativeness, which means we need to maintain the important information of source documents in summaries. This is the focus of almost all research on summarization. Another challenge is presentation, namely that the extracted text should be well presented, i.e., it should contain little redundancy and be coherent so as to be readily understandable. Previous work has addressed the problem of redundancy, and some successful solutions like Maximum Marginal Relevance (MMR) (Carbonell and Goldstein, 1998) have been proposed and widely adopted (e.g., (Li and Li, 2013)), but very few try to deal with coherence. Therefore the generated summaries generally suffer as regards readability and are very difficult to use for practical applications. In the report of the TAC 2011 summarization task (Owczarzak and Dang, 2011), it is stated that "in general, automatic summaries are better than baselines[1], except *Readability*." Such a statement suggests, as for summarization, coherence should be treated with the same as salience and redundancy.

[1]The baseline they used is the lead paragraph method and summaries are evaluated by human and ROUGE (Recall-Oriented Understudy for Gisting Evaluation (Lin, 2004)).

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 213–223, Osaka, Japan, December 11-17 2016.

Existing work addresses coherence in summarization from different aspects. One kind of method employs reordering after selecting sentences, and the drawback is evident: coherence is considered after sentence selection. Another kind of widely adopted method takes discourse relations into consideration when selecting sentences, as discourse relations are believed to be essential for maintaining textual coherence. Hirao et al. (2013) formulated single document summarization as to extract a sub tree from the complete discourse tree and thus preserve the relations between extracted document units to form a readable text. Wang et al. (2015) extended it to multi-document summarization by regarding a document set as one document and developed a model which combined discourse parsing and summarization together. Christensen et al. (2013) proposed a graph-based model to bypass the tree constraints. They employed rich textual features to build a discourse relation graph for source documents with the aim of representing the relations between sentences (both inter and intra-document relations). Christensen et al. (2013) reported ROUGE scores lower than some baselines. This is because that, they claim, ROUGE is salience-focused and fails to notice the improvement in coherence. In a further human evaluation, they reported improvements in readability.

These discourse-based methods without exception have discourse analysis as a prerequisite. As we all know, discourse analysis is still under development thus preventing the expected improvement. Furthermore, languages other than English do not enjoy plenty of ready-to-use discourse analysis tools. This also limits the usage of these discourse-based methods.

Is it possible to consider coherence in summarization without discourse analysis? Before answering this question, we need to find out what is the key to coherence in text. According to the centering theory (Grosz et al., 1995; Walker et al., 1998), the coherence of text is to a large extent maintained by entities and the relations between them. This indicates that discourse analysis is not a must to preserve coherence; we can directly take advantages of entities and their relations to generate coherence text.

Based on this point, we design a novel graph-based model for multi-document summarization that eliminates the effort of conducting discourse relation analysis (inter or intra document) and generates informative and readable summaries. We formulate the document set as a graph whose nodes corresponds to sentences. These nodes are connected with each other according to the entities they contains and the relations between their containing entities. Each path in the graph represents a piece of text and is evaluated using a novel scoring function that considers informativeness and coherence. To extract a summary is to find a path in the graph with the highest score. This is a weighted longest path problem. We further present a variant of the proposed model based on local coherence and explore decoding algorithms for both of them.

Experiments are conducted on the Document Understanding Conference (DUC) 2004 multi-document summarization task data set. As ROUGE cannot fully capture our improvement in coherence which is one of the key contributions of this work, we also conduct a human evaluation. Results show that we obtain summaries comparative with state-of-the-art systems in terms of ROUGE metrics and get improvements in readability in human evaluations.

This work provides a method of generating high quality summaries without the effort of discourse analysis. The proposed method can be easily extended to other languages without much efforts. It also provides inspiration as regards other tasks that require computers to generate coherent text. The rest of the papers is organized as follows: Section 2 presents the centering theory and a coherence model based on entities. Section 3 presents our model. Section 4 describes the experiments and results. Section 5 presents some previous work and Section 6 concludes this paper.

2 Centering Theory and Coherence Modelling

The centering theory (Grosz et al., 1995) as a popular theory on discourse analysis, serves as the basis of some coherence evaluation methods (Barzilay and Lapata, 2008; Burstein et al., 2010; Li and Hovy, 2014; Li and Jurafsky, 2016) and enables us to measure the coherence score of any given text without discourse parsing solely based on the reappearance of entities. Entities here refer to noun/pronoun

word/phrases [2].

According to the centering theory, we have the following assumptions:

1. Text that contains successive mentions of the same entities would be more coherent.

2. The main entities that are focused on tend to play an important grammatical role, such as the subject or object of the sentences.

Therefore the key to the coherence of a text lies in what entities it contains and how their roles change. The coherence of a generated text can be evaluated accordingly.

Barzilay and Lapata (2008) presented such a model. The key is to represent text as an *entity grid*. Assume text T contains n sentences $\{S_1, S_2..., S_n\}$ and m entities. r_i^k represents the grammatical role of Entity e_k in Sentence S_i. Four kinds of roles are used, i.e., "subj", "obj", "others" and "absent". "Others" indicates that the entity is present, but is neither the subject nor the object. Then the grammatical roles of e_k in text T can be expressed as a sequence: $\{r_1^k, r_2^k, ..., r_n^k\}$. For each entity in T, such a chain showing how the entity's grammatical roles change in T is extracted. Thus text T can be represented as an $n * m$ matrix $M(T)$ where n is the number of sentences and m is the number of entities in T, and $M(T)_{ij}$ corresponds to the grammatical roles of Entity j in Sentence i. $M(T)$ is referred to as the *Entity Grid* of T (Barzilay and Lapata, 2008).

To calculate the coherence score of T, Barzilay and Lapata (2008) used $M(T)$ as a feature vector. They calculated the transition probability for $|\{s(subj), o(bj), x(others), -(absent)\}^2| = 16$ transition patterns from $M(T)$ without distinguishing between entities, to form a vector $f(T)$ for T, and a weight vector w was then learnt from training data so that $w * f(T)$ can be used as the coherence score for T.

This kind of method has been adopted in many studies (Filippova and Strube, 2007; Barzilay and Lapata, 2008; Burstein et al., 2010). In particular, Filatova and Hatzivassiloglou (2004) extends entity grids to model semantical relations between entities, which provides a possible further improvement for our models.

3 Modeling Summarization

The above model can only be used to measure coherence but summarization is much complex as it involves not only coherence bust also informativeness and redundancy. We design a much more sophisticated models leveraging entities.

Two models are presented below. Both of them are based on entities and consider coherence as well as informativeness. The first one is based on global coherence and the second one local coherence. The global coherence consider the full sequence when evaluating coherence and the local coherence is calculated based on relations between adjacent sentences. Intuitively, global coherence is better than local coherence, but considering the full sequence increases the time complexity. The model based on local coherence, on the other hand, reduces the time complexity and enables us to obtain an exact solution efficiently.

3.1 Problem Set-up

Assume we have K documents with n sentences in total. Note that we are dealing with multi-document summarization, and we do not distinguish between inter-document and intra-document relations. We construct a graph with n nodes, each of which corresponds to one sentence. Weighted directed edges are used to connect these nodes together. To each node, we assign a cost score, which is the number of words the corresponding sentence contains. To each path in the directed graph, we assign a gain score. The gain score is a comprehensive evaluation of the informativeness and coherence of the sequence of sentences represented by the path. The problem of extracting a good summary becomes the problem of extracting the best path. Note that it is an asymmetric graph. Gain scores for $A \rightarrow B \rightarrow C$ and $C \rightarrow B \rightarrow A$ are different. The direction determines the positions of corresponding sentences in the generated text.

[2] In some previous work on summarization (Takamura and Okumura, 2009; Hirao et al., 2013), concepts are used to measure informativeness. Concepts can be used to refer any non functional words, including adjectives, adverbs. All the entities can be regarded as concepts, but some concept words (non-nominal words) are not entities. Entity is a subset of Concept.

One more thing to consider is the redundancy. Instead of formulating redundancy explicitly, we remove edges connecting similar sentences to turn the complete graph into an incomplete graph. This ensures that similar sentences do not occupy adjacent positions in the generated summaries and thus reduce redundancy. The similarities of sentence pairs are based on word overlaps and we keep $d\%$ of all the edges.

Note that for temporal text removing edges can also help us maintain the temporal relations between sentences, though we do not explore this point here.

3.2 Summarization Considering Global [3] Coherence

To extract a summary is to find such a sequence of sentences Seq that maximizes $Score(Seq)$.

$$\begin{aligned} Score(Seq) &= \sum_{k=1}^{m} a_k F_k \\ F_k &= \prod_i p_{e_k}(r_i^k r_{i+1}^k), S_i, S_{i+1} \in Seq \\ s.t. &\sum_{S_i \in Seq} length(S_i) \leq threshold \end{aligned} \tag{1}$$

a_k is the weight of Entity e_k. r_i^k is the state of Entity e_k in Sentence S_i. Here we use four states: "s", "o", "x", "-", which represent "subj", "obj", "present" and "absent" respectively. It is also possible to use more or fewer states.

$p_{e_k}(**)$ is the transition probability between two states for e_k. For each document set, the transition probabilities for each entity is estimated using $p_{e_k}(ab) = \frac{\#e_k(a)e_k(b)}{n-K}$. $\#e_k(a)e_k(b)$ marks the times that Entity e_k presents as grammatical role a in the preceding sentence and as grammatical role b in the following one. $n-K$ denotes the total number of adjacent sentence pairs in a document set with K documents and n sentences. F_k is the coherence score contributed by e_k in the extracted sequence Seq. F_k is based on the transitions of e_k between adjacent sentences in Seq. We use $Score(Seq)$ which considers salience, coherence and redundancy as an index as to how suitable the extracted sentence sequence Seq is as a summary. This model is a weighted longest path problem with a fixed length.

This is an NP-hard problem. Due to the time cost, we adopt the simple randomized algorithm as shown in Algorithm 1 to obtain an approximated solution. Other decoding algorithms like greedy algorithms

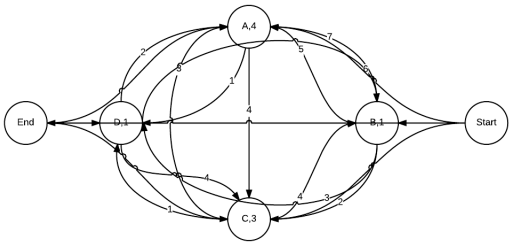
Algorithm 1 A randomized algorithm for the weighted longest path problem

```
Initialization:
Set U ⟵ all the sentences in the current doc set
Set S ⟵ EmptySet
Queue Q ⟵ EmptySet
repeat
  randomly select sentence s ∈ U & s ∉ Q;
  if length(s) + Σ_i length(s_i) <= threshold, s_i ∈ Q then
    push s to the rear of Q
  else
    push Q into S, Queue Q ⟵ EmptySet
  end if
until 10K times
return argmax_Q F(T), Q ∈ S
```

can also be employed. But none of them are capable of obtaining an exact solution. Below we present another model considering *local* coherence.

[3] "Global" means the model considers coherence according to the *whole* text.

Figure 1: A Complete Graph with Dummy Start and End Nodes



3.3 Summarization Considering Local Coherence

The above model considers global coherence which is calculated according to the whole text. The model presented below is directly based on local coherence and enables us to obtain an exact solution. We want to maximize $Score(Seq)$:

$$\begin{aligned} Score(Seq) &= \sum_{S_i \in Seq} (\alpha \sum_{e_k \in S_i} a_k + (1-\alpha) gain_{i,(i+1)}) \\ s.t. \quad & \sum_{S_i \in Seq} length(S_i) \leq threshold \end{aligned} \tag{2}$$

This formulation contains two parts. $\sum_{e_k \in S_i} a_k$ implies the weight of Sentence S_i, which is the sum of its containing entities' weights. $gain_{i,(i+1)}$ is the gain score for $Edge(S_i, S_{i+1})$. α manipulates the impacts of the two parts.

$$gain(S_i, S_{i+1}) = \sum_{e_k \in S_i \bigcup S_{i+1}} p_{e_k}(r_i^k r_{i+1}^k) \tag{3}$$

As is stated, r_i^k is the state of Entity e_k in Sentence S_i.

For the convenience of decoding, we turn the above model to an integer linear programming (ILP) problem. We add two dummy nodes, called $Start$ and End Node. All paths start from $Start$ and end with End. The costs of both $Start$ and End are 0. The gains of edges connected with $Start$ or End are 0. Note that although here we present a full connected graph for simplicity, in reality we deleted several edges to reduce redundancy. Following such a setting, an arbitrary path in the old graph (the one without dummy Start and End nodes) can be represented as a path from $Start$ to End. We write the $Start$ node as Node 0 and the End node as Node t. Then we formulate the problem of the weighted longest path as follows:

$$maximize \alpha \sum_i (\sum_{e_k \in S_i} a_k) x_i + (1-\alpha) \sum_{i,j} gain_{i,j} y_{ij}$$

subject to

$$\begin{cases} 1) \sum_i cost_i x_i \leq threshold \\ 2) \sum_i y_{0i} = 1 \\ 3) \sum_i y_{it} = 1 \\ 4) \sum_i y_{ij} + y_{0j} - (\sum_i y_{ji} + y_{jt}) = 0, \forall j \\ 5) \sum_i y_{ij} + y_{0j} - x_j = 0, \forall j \\ 6) x_i \in \{0,1\}, \forall i \\ 7) y_{ij} \in \{0,1\}, \forall i,j \end{cases} \tag{4}$$

Equations 2 and 3 are used to ensure we have only one start and one end node. Equation 4 ensures that the in degree equals the out degree for all nodes. Equation 5 ensures that the in degree is either 0 or 1 and equals x_a for all nodes. $x_i = 1$ indicates that S_i is selected for the summary. $x_i = 0$ means S_i is

not contained in the summary. $y_{ij} = 1$ means S_i and S_j are selected and placed as adjacent sentences in the summary. $cost_i$ is the number of words in S_i (length of S_i).

We resolve this ILP problem using the dual simplex method provided by IBM CPLEX optimizer [4] which is a powerful optimization software package. CPLEX provides both a primal simplex method and a dual simplex method for ILP problems. Here we adopt the latter.

4 Experiments & Analysis

4.1 Experiment

Experiments are conducted on the data set of the DUC2004 Summarization Task, which is a multi-document summarization task. 50 document clusters, each of which consists of 10 documents, are given. One summary is to be generated for each cluster. The target length is up to 100 words. Weights of entities are learnt by logistic regression as is adopted by Takamura and Okumura (2009) [5]. For entities that are not contained in DUC2003, we assign tf-based weights to them as Barzilay and Lapata (2008) did.

For the evaluation we firstly use the generally acknowledged metric for summarization: ROUGE metric. It essentially calculates n-gram overlaps between automatically generated summaries and human written (the gold standard) summaries. A high level of overlap indicates a high level of shared information between the two summaries. Among others, we focus on ROUGE-1 in the discussion of the result, because ROUGE-1 has proved to have a strong correlation with human annotation (Lin, 2004).

Some necessary preprocessing includes stemming, removing stop-words and simple simplification. In previous work, there is usually no co-reference resolution and different words are regarded as different entities. Here we use Stanford CoreNLP toolkit (Manning et al., 2014) to deal with the co-reference problem. The Stanford CoreNLP toolkit contains a ready-to-use entity identification tool and a co-reference resolution tool. The co-reference resolution is not a must, though preferred if reliable tools are available.

After the co-reference resolution, different forms of the same entities are replaced by their unified forms. For each document set, we need to estimate the transition probabilities for each entity according to the documents contained in the cluster as stated above.

Parameters are tuned using the DUC2003 dataset. d is the threshold of redundancy. We keep d percent of all edges and d varies from 10 to 100 with an interval of 10. We tune the parameter using the randomized algorithm and evaluate the results using ROUGE-1 Recall. In the following experiments, we set $d = 80$, which means we keep 80% of the sentences.

As for the model presented in Section 3.3, we need to tune α. Using the same data, we try α from 0 to 1 with an interval of 0.1 and eventually choose $\alpha = 0.4$.

4.2 Evaluation & Discussion

We compare our models with state-of-the-art multi-document summarization systems using ROUGE and human evaluation. The former aims to evaluate informativeness and the latter targets readability.

ROUGE Evaluation MCKP is the maximum coverage methods proposed by Takamura and Okumura (2009). Lin is a model that uses a class of submodular functions (Lin and Bilmes, 2011). Christ is a graph based model proposed by Christensen et al. (2013). DPP is the determinantal point processes model Borodin (2009) and ICSI is another model based on maximum coverage Gillick et al. (2008). The results of DPP and ICSI comes from the repository presented in Hong et al. (2014). M1 is our model described in Section 3.1. M2 is the model described in Section 3.3, which is resolved using an ILP method. MEAD Radev et al. (2004a) is a baseline that employs ranking algorithms to generate multi-document summaries.

The results are shown in Table 1. As we can see, our system (M1 and M2) produces comparable results to the state-of-the-art systems. With the MCKP method, all content words are used as concepts. But in

[4] http://www-03.ibm.com/software/products/en/ibmilogcpleoptistud/

[5] This method was first proposed by Yih et al. (2007) and then improved by Takamura and Okumura (2009). Here we follow the same steps with Takamura and Okumura (2009).

our systems, only nouns and pronouns are regarded as entities. There are fewer nouns and pronouns than content words. This has a negative impact on the evaluation of information coverage. But according to the experiment results, our approach still obtain satisfying results based on these entities. It proves that even with much simpler feature settings of just nouns and pronouns, the proposed model generates summaries with good coverage of the important information in source documents. We have addressed that ROUGE is merely an index of informativeness and cannot evaluate our improvements in readability as has been proved by *Christ*, another coherence-focused model (Christensen et al., 2013). So we also conduct a human evaluation.

Human Evaluation As some of the systems mentioned in Table 1 are not accessible, in this work we compare summaries produced by some typical systems: M2 (the best proposed system evaluated by ROUGE), MCKP (one of the state-of-the-art salience-focused methods) and humans (the gold standard).

We asked four professional annotators (who are not the authors of this paper and have rich experience in annotating various NLP tasks and are fluent in English) to assign a score to each summary regarding its readability. We randomly selected 48 summaries (16+16+16) from the three systems, and asked them to assign a readability score to each document without reading the source documents (summarization is useful because we do not need to read source documents). The score is an integer between 1 (very poor) and 5 (very good).

The average scores for the 3 systems are $Human = 4.3; M2 = 3.5; MCKP = 3.1$. Significance testing (significance level $\alpha = 0.05$) shows that the summaries generated by the proposed method show improvements in readability compared with previous salience-focused work.

Type	SysName	ROUGE-1(R)
Simple Ranking	MEAD	.339
Maximum Coverage	MCKP	.385
	ICSI	.384
Point Process	DPP	.398
Sub Modular	Lin	.394
Discourse-based	Christ	.373
	M1	.383
	M2	.390

Table 1: ROUGE Results on DUC2004

In our model, we assume the states of entities can be formulated as Markov chains. Although sophisticated models can be employed, such assumptions help simplify the model and they are proved to be of use. Also we can use more or fewer grammatical roles for entities. We tried using just two kinds of roles: presence and absence, and the performance we obtained was unsatisfying.

5 Related Work

A summary is much shorter than the original documents but still needs to provide readers with sufficient information. Hence the summarization systems need to identify important information and keep as much of it as possible. Most existing research follows such a guideline and takes salience as its sole focus.

Salience-focused systems cannot guarantee the readability of the generated text as they fail to take coherence into consideration. Sentence reordering, as a post processing task has began to develop. Apparently, it cannot make up for the flaws of salience-focused systems because it is simply a reorganization of sentences. Besides, it also faces problems when dealing with temporal text (Yan et al., 2011; Ge et al., 2015). A better solution is to consider coherence when selecting sentences. Such comprehensive models have been proposed. Most of them are discourse driven and sacrifice informativeness for coherence. In this sense, our model is novel in dealing with coherence without discourse analysis.

5.1 Salience-Focused Method

As stated, the summarization systems need to identify the important information and keep as much of it in the generated summaries as possible. One straightforward method is Maximum Marginal Relevance (Carbonell and Goldstein, 1998) (MMR). It is a greedy method, and is proposed to select sentences that are most relevant but not too similar to the already selected ones. It tries to keep a balance between relevance and redundancy. MMR is also widely employed to avoid redundancy in summarization systems. Among existing research, one popular kind is the ranking method (e.g., Textrank (Mihalcea and Tarau, 2004), Lexrank (Erkan and Radev, 2004) and its variants (Wan et al., 2007; Wang et al., 2012)), which construct a graph between text units and use ranking algorithms to select top sentences to build summaries. Another kind is the optimization method. Our work is one of this kind. It formulates summarization as finding a subset that optimizes certain objective functions without violating certain constraints. To find such an optimal subset is a combinatorial optimization problem, which is an NP hard problem and hence cannot be solved in linear time (McDonald, 2007).

Recently, maximum coverage methods have been proposed and yield good results (Gillick et al., 2009; Gillick and Favre, 2009; Takamura and Okumura, 2009). Maximum coverage methods formulate summarization as a maximum knapsack problem (MKMC). In MKMC methods, the meanings of sentences are believed to be made up by concepts, which usually refer to content words. And summarization involves extracting a subset of sentences that covers as many important concepts as possible without violating the length constraint. It is usually formulated as an integer linear problem. And some algorithms are proposed for obtaining approximated solutions (Takamura and Okumura, 2009; Gillick et al., 2009). Lin and Bilmes (2011) design a class of submodular functions for document summarization. The functions they use combine two parts, encouraging the summary to be representative of the corpus, and rewarding diversity separately. Other methods that have been applied to summarization include centroid-based methods (Radev et al., 2004b; Saggion and Gaizauskas, 2004), and minimum dominating set methods (Shen and Li, 2010). All these methods suffer in coherence.

5.2 Coherence-Focused Method

Sentence reordering methods are developed to correct the salience-focused models. Sentence reordering tries to generate a more coherent text by reordering its contents. Rich semantic and syntactic features are used to find a better permutation for input sentences (Barzilay et al., 2001; Bollegala et al., 2010; Okazaki et al., 2004).

The drawback to sentence reordering is obvious. The preceding sentence selection focuses solely on informativeness and totally neglects coherence. Thus it prevents the improvements expected from permutation. This is confirmed by the fact that the above methods all reports limited improvement. A consideration of coherence during sentence selection leads to new methods, and these are mainly discourse driven models. Some of the summarization methods encode discourse analysis results in feature presentations together with other frequency based features for sentence selection/compression. The problem is that these discourse based features usually play secondary roles, because the models all try to improve information coverage, which are evaluated by ROUGE. And ROUGE, as is commonly known, is not sensitive to coherence.

Some others work directly on discourse analysis results, and they usually try to derive a passage from a given parse tree. The problem of summarization is regarded as finding a text T so that $T = \arg\max F(T|Tr)$ for a given tree Tr. Here F is the objective function. Early representative work of this kind includes that of Marcu (1998) and that of Daumé III and Marcu (2002). Recently, Hirao et al. (2013) has viewed summarization as a knapsack problem on trees, and uses an integer linear problem (ILP) to formulate it. A sub tree that maximizes some objective function and obeys some given constraints is extracted from the original parse tree as the summary.

Discourse tree based methods cannot be extended to multi-document summarization. Christensen et al. (2013) propose a graph model that bypasses the tree constraints. They build a graph to represent discourse relations between sentences and then extract summaries accordingly.

Recently the neural network based discourse analysis (Li et al., 2014; Ji and Eisenstein, 2014) provides

us with an alternative way of conducting discourse analysis without traditional feature engineering. It can be used in our future work of modelling coherence using semantic relations.

6 Conclusion

Previous summarization methods have usually focused on salience and neglected coherence. This work proposed a novel summarization system that combines coherence with salience. By taking entities and links between them into consideration, our weighted longest path model successfully improves the quality of summaries. The proposed model does not require discourse analysis and hence can be applied to languages which do not enjoy plenty of ready-to-use discourse analysis tools.

In this paper only syntactic linkages are used for modelling coherence. In the future, we can take advantage of the semantic relations between entities to evaluate coherence and to further improve our system.

Syntactic realization with data-driven neural tree grammars

Brian McMahan and **Matthew Stone**
Computer Science, Rutgers University
brian.mcmahan, matthew.stone@rutgers.edu

Abstract

A key component in surface realization in natural language generation is to choose concrete syntactic relationships to express a target meaning. We develop a new method for syntactic choice based on learning a stochastic tree grammar in a neural architecture. This framework can exploit state-of-the-art methods for modeling word sequences and generalizing across vocabulary. We also induce embeddings to generalize over elementary tree structures and exploit a tree recurrence over the input structure to model long-distance influences between NLG choices. We evaluate the models on the task of linearizing unannotated dependency trees, documenting the contribution of our modeling techniques to improvements in both accuracy and run time.

1 Introduction

Where natural language understanding systems face problems of ambiguity, natural language generation (NLG) systems face problems of choice. A wide coverage NLG system must be able to formulate messages using specialized linguistic elements in the exceptional circumstances where they are appropriate; however, it can only achieve fluency by expressing frequent meanings in routine ways. Empirical methods have thus long been recognized as crucial to NLG; see e.g. Langkilde and Knight (1998).

With traditional stochastic modeling techniques, NLG researchers have had to predict choices using factored models with handcrafted representations and strong independence assumptions, in order to avoid combinatorial explosions and address the sparsity of training data. By contrast, in this paper, we leverage recent advances in deep learning to develop new models for syntactic choice that free engineers from many of these decisions, but still generalize more effectively, match human choices more closely, and enable more efficient computations than traditional techniques.

We adopt the characterization of syntactic choice from Bangalore and Rambow (2000): the problem is to use a stochastic tree model and a language model to produce a linearized string from an unordered, unlabeled dependency graph. The first step to producing a linearized string is to assign each item an appropriate *supertag*—a fragment of a parse tree with a leaf left open for the lexical item. This process involves applying a learned model to make predictions for the syntax of each item and then searching over the predictions to find a consistent assignment for the entire sentence. The resulting assignments allow for many possible surface realization outputs because they can underdetermine the order and attachment of adjuncts. To finish the linearization, a language model is used to select the most likely surface form from among the alternatives. While improving the language model would improve the linearized string, we focus here on more accurately predicting the correct supertags from unlabeled dependency trees.

Our work exploits deep learning to improve the model of supertag assignment in two ways. First, we analyze the use of embedding techniques to generalize across supertags. Neural networks offer a number of architectures that can cluster tree fragments during training; such models learn to treat related structures similarly, and we show that they improve supertag assignments. Second, we analyze the use of tree recurrences to track hierarchical relationships within the generation process. Such networks can track more of the generation context than a simple feed-forward model; as a side effect, they can

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 224–235, Osaka, Japan, December 11-17 2016.

simplify the problem of computing consistent supertag assignments for an entire sentence. We evaluate our contributions in two ways: first, by varying the technique used to embed supertags, and then by comparing a feed-forward model against our recurrent tree model.

Our presentation begins in § 2 with an introduction to tree grammars and a deterministic methodology for inducing the elementary trees of the grammar. Next, § 3 presents the techniques we have developed to represent a tree grammar using a neural architecture. Then, in § 4, we describe the specific models we have implemented and the algorithms used to exploit the models in NLG. The experiments in § 5 demonstrate the improvement of the model over baseline results based on previous work on stochastic surface realization. We conclude with a brief discussion of the future potential for neural architectures to predict NLG choices.

2 Tree Grammars

Broadly, tree grammars are a family of tree rewriting formalisms that produce strings as a side effect of composing primitive hierarchical structures. The basic syntactic units are called elementary trees; elementary trees combine using tree-rewrite rules to form derived phrase structure trees describing complex sentences. Inducing a tree grammar involves fixing a formal inventory of structures and operations for elementary trees and then inferring instances of those structures to match corpus data.

2.1 Grammar Formalism

The canonical tree grammar is perhaps lexicalized tree-adjoining grammar (LTAG) (Joshi and Schabes, 1991). The elementary trees of LTAG consist of two disjoint sets with distinct operations: initial trees can perform substitution operations and auxiliary trees can perform adjunction operations. The substitution operation replaces a non-terminal leaf of a target tree with an identically-labeled root node of an initial tree. The adjunction operation modifies the internal structure of a target tree by expanding a node identically-labeled with the root and a distinguished foot note in the auxiliary tree. The lexicalization of the the grammar requires each elementary tree to have at least one lexical item as a leaf.

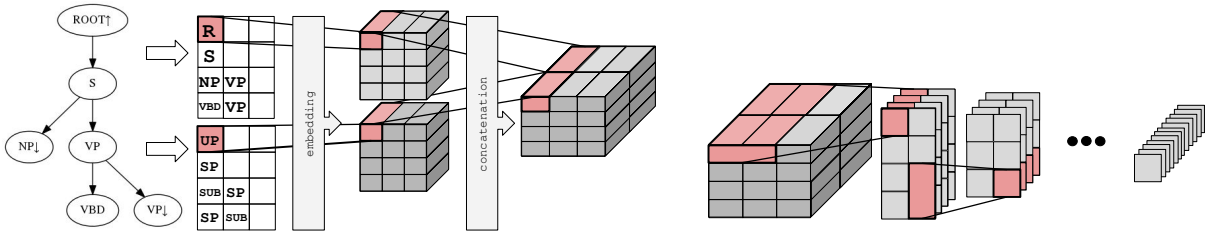
LTAG incurs computational costs because it is mildly context-sensitive in generative power. Several variants reduce the complexity of the formalism by limiting the range of adjunction operations. For example, the Tree Insertion Grammar allows for adjunction as long as it is either a left or right auxiliary tree (Schabes and Waters, 1995). Tree Substitution Grammars, meanwhile, allow for no adjunction and only substitutions (Cohn et al., 2009). We adopt one particular restriction on adjunction, called sister-adjunction or *insertion*, which allows trees to attach to an interior node and add itself as a first or last child (Chiang, 2000). Chiang's sister-adjunction allows for the flat structures in the Penn Treebank while limiting the formalism to context-free power.

2.2 Grammar Induction

In lexicalized tree grammars, the lexicon and the grammatical rules are one and the same. The set of possible grammatical moves which can be made are simultaneously the set of possible words which can be used next. This means that inducing a tree grammar from a data set is a matter of inferring the set of constructions in the data.

We follow previous work in using bracketed phrase structure corpora and deterministic rules to induce the grammar (Bangalore et al., 2001; Chiang, 2000). Broadly, the methodology is to split the observed trees into the constituents which make it up, according to the grammar formalism. We use head rules (Chiang, 2000; Collins, 1997; Magerman, 1995) to associate internal nodes in a bracketed tree with the lexical item that owns it. We use additional rules to classify some children as complements, corresponding to substitution sites and root notes of complement trees; and other children as adjuncts, corresponding to insertion trees that combine with the parent node, either to the right or to the left of the head. This allows us to segment the tree into units of substitution and insertion.[1]

[1] One particular downside of deterministically constructing the grammar this way is that it can produce an excess of superfluous elementary trees. We minimize this by collapsing repeated projections in the treebank. Other work has provided Bayesian models for reducing grammar complexity by forcing it to follow Dirichlet or Pitman-Yor processes (Cohn et al., 2010)—an interesting direction for future work.



(A) Tree Node Embedding (B) Convolutional Filter Encoding

Figure 1: Embedding supertags using convolutional neural networks. In (A), a tree is encoded by its features and then embedded. In (B), convolutional layers are used to encode the supertag into a vector.

3 Neural Representations

The grammar induction of § 2 allows us to construct an inventory of supertags to match a corpus. For NLG, we also need to predict the most likely supertag for any lexical item given the generation context. We approach this problem using neural networks. In particular, this work makes two contributions to improve stochastic tree modeling with neural networks. First, we represent supertags as vectors through embedding techniques that enable to model to generalize over complex, but related structures. Second, we address the hierarchical dependence between choices using a recurrent tree network that can capture long-distance influences as well as local ones. We now describe these representations in more detail.

3.1 Embedding Supertags

Different supertags for the same word can encode differences in the item's own combinatorial syntax, differences in argument structure, and differences in word order. Accordingly, words have many related supertags, with substantial overlaps in structure, and, presumably, corresponding similarities in their patterns of occurrence. A traditional machine learning approach to supertag prediction would treat individual supertags as atoms for classification; generalizing across supertags would require linking model parameters to handcrafted features or back-off categories.

By contrast, neural techniques work by embedding such tokens into a vector space. This process learns an abstract representation of tokens that clusters similar items together and makes further predictions as a function of those items' learned features. The resulting ability to generalize across sparse data seems to be one of the most important reasons for the success of deep learning in NLP.

The simplest way to embed supertags is to treat each structure as a distinct token that indexes a corresponding learned vector. This places no constraints on the learned similarity function, but it also ignores the hierarchical structure of the elementary trees themselves. Previous work on deep learning with graph structures suggests convolutional neural networks can exploit similarities in structure (Kalchbrenner et al., 2014; Niepert et al., 2016). Thus, we developed analogous techniques to encode supertags based on their underlying tree structure. In particular, to embed a supertag, we embed each node, group the resulting vectors to form a tensor, and then summarize the tensor into a single vector using a series of convolutional neural networks.

Note that each elementary tree is a complex structure with nodes labeled by category and assigned a role that enables further tree operations. The root node's role represents the overall action associated with that elementary tree—either substitution or insertion. The remaining nodes either have the substitution point role or the spine role—they are along the spine from root to the lexical attachment point, and thus provide targets for further insertion.

We first embed each node independently, then combined the vectors to form a tensor of embeddings. Specifically, symbols representing the syntactic category and node roles are treated as distinct vocabulary tokens, mapped to integers, and used to retrieve a vector representation that is learned during training. The vectors are grouped into a tensor by placing the root node into the first cell of the first row and left-aligning the descendants in the subsequent rows. The two tensors are concatenated along the embedding dimension. This embed-and-group method is shown in on the left in Figure 1.

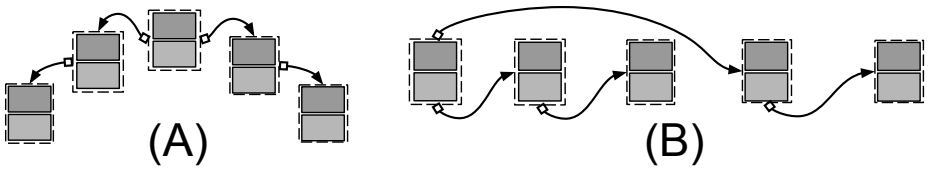


Figure 2: A recurrent tree network. (A) The dependency structure as a tree. (B) The dependency structure as a sequence.

Using a series of convolutional neural networks which learn their weights during training, the tensor of embeddings can be reduced to a single vector. To reduce the tensor to a vector, the convolutions are designed with increasingly larger filter sizes. Additionally, the dimensions are reduced alternatingly to also facilitate the capture of features. The entire process is summarized in Eq. 1 with Λ representing the supertags, G representing embedding matrices, and C representing the convolutional neural network layers. Specifically, G_s is the syntactic category embedding matrix and G_r is the node role embedding matrix. Each convolutional layer C is shown with its corresponding height and width as $C^{i,j}$. The encoding first constructs the tensor, T_Λ, through the embed-and-group method. Then, the embedding matrix G_Λ is summarized from T_Λ using the series of convolutional layers.

$$\begin{aligned} T_\Lambda &= [G_s(\Lambda_{syntactic\ category});\ G_r(\Lambda_{role})] \\ G_\Lambda &= C^{4,5}(C^{3,1}(C^{1,3}(C^{2,1}(C^{1,2}(T_\Lambda))))) \end{aligned} \tag{1}$$

The final product, a vector per supertag, is aggregated with the other vectors and turned into an embedding matrix. This is visualized in on the right in Figure 1. During training and test time, supertags are simply input as indices and their feature representations retrieved as an embedding.

3.2 Recurrent Tree Networks

Our models predict supertags as a function of the target word and its context. Neural networks make it possible to generalize over such contexts by learning to represent them with a hidden state vector that aggregates and clusters information from the relevant history. Our approach is to do this using a recurrent tree network. While recurrent neural networks normally use the previous hidden state in the sequential order of the inputs, recurrent tree networks use the hidden state from the parent. Utilizing the parent's hidden state rather than the sequentially previous hidden state, the recurrent connection can travel down the branches of a tree. An example of a recurrent tree network is shown in Figure 2.

In our recurrent tree network, child nodes gain access to a parent's hidden state through an internal *tree state*. During a tree recurrence, the nodes in the dependency graph are enumerated in a top-down traversal. At each step in the recurrence, the resulting recurrent state is stored in the tree state at the step index. Descendents access the recurrent state using a topological index that is passed in as data.

The formulation is summarized in Equation 2. The input to each time step in the current tree is the data, x_t, and a topological index, p_t. The recurrent tree uses p_t to retrieve the parent's hidden state, s_p, from the tree state, S_{tree}, and applies the recurrence function, $g(\dot{)}$. The resulting recurrent state is the hidden state for child node, s_c. The recurrent state s_c is stored in the tree state, S_{tree}, at index t.

$$\begin{aligned} s_c &= RTN(x_t, p_t) \\ &= g(x_t, S_{tree}[p_t]) \\ &= g(x_t, s_p) \\ S_{tree}[t] &= s_c \end{aligned} \tag{2}$$

The use of topological indices allows for many recurrent tree networks to be run in parallel on a GPU for efficiency. GPU implementations must be formulated homogeneously so that the same operations are applied across the entire data structure. Normally, tree operations involve conditional access to parent nodes, but using topological indices and a tree state accesses the parent in a homogeneous way.

4 Models

To analyze the representations we describe in § 2 and § 3, we developed two alternative architectures for predicting supertags in context. The first is a feed-forward neural network designed to solve a closely analogous task to the supertagging step of Bangalore and Rambow (2000)'s original FERGUS model. We call it Fergus-N (for Neuralized). The second uses a recurrent tree network to model the generation context. Because it has this richer context representation, it takes advantage of a slightly different characterization of the supertag prediction problem to streamline the problem solving involved in using the model. We call this Fergus-R (for Recurrent).

For both stochastic tree models, a recurrent neural network language model is used to complete the linearization task. The same language model is used to eliminate the confound of language model performance and measure performance differences in the stochastic tree modeling.

4.1 Model 1: Fergus-N

Fergus-N is a stochastic tree model which uses local parent-child information as inputs to a feed-forward network. Each parent-child pair is treated as independent of all others. The probability of the parent's supertag is predicted using an embedding of the pair's lexical material and an embedding of the child's supertag. (Our experiments compare the different embedding options surveyed in § 3.) Training maximizes the likelihood of the training data according to the model. Formally, our objective is to minimize the negative log probability of the observed parent supertags for each parent-child pair, as formally defined in Eq. 3.

$$min_\theta - [\sum_p \sum_{p \rightarrow c} log[P_\theta(tag_p | lex_p, lex_c, tag_c)] + \sum_c log[P_\theta(tag_c | lex_p, lex_c)]] \tag{3}$$

Here tag_p is the parent supertag, tag_c is the child supertag, lex_p is the parent's lexical material, and lex_c is the child's lexical material. Note that the probability of supertags for the leaves of the tree are computed with respect to their parent's lexical material.

The model is implemented as a feed-forward neural network. Equation 4 details the model formulation. The lexical material, lex_p and lex_c, are embedded using the word embedding matrix, G_w, concatenated, and mapped to a new vector, ω_{lex}, with a fully connected layer, FC_1. The child supertag, tag_c, is embedded using the target supertag embedding G_s and concatenated with the lexical vector, ω_{lex}, forming an intermediate vector representation of the node, ω_{node}. The node vector is repeated for each of the parent's possible supertags, $tagset_p$, and then concatenated with their embeddings to construct the set of treelet vectors, $\Omega_{treelet}$. The vector states for the leaf nodes are similarly constructed, but instead combine the lexical vector, ω_{lex} with the embeddings of the child's possible supertags, $tagset_c$. The final operation induces a probability distribution over the treelet and leaf vectors using a score computed by the vectorized function, $\Psi_{predict}$, as the scalar in a softmax distribution.

$$\begin{aligned}
&\omega_{lex} = FC_1([G_w(lex_p); G_w(lex_c)]) \\
&\omega_{node} = concat([G_s(tag_c);\ \omega_{lex}]) \\
&\Omega_{treelet} = concat([repeat(\omega_{node}),\ G_s(tagset_p)]) \\
&\Omega_{leaf} = concat([repeat(\omega_{lex}),\ G_s(tagset_c)]) \\
&P_\theta(tag_{p,i} | lex_p, lex_c, tag_c) = \frac{exp(\Psi_{predict}(\omega_{treelet_i}))}{\sum_{j \in |tagset_p|} exp(\Psi_{predict}(\omega_{treelet_j}))} \\
&P_\theta(tag_{c,i} | lex_p, lex_c) = \frac{exp(\Psi_{predict}(\omega_{leaf_i}))}{\sum_{j \in |tagset_c|} exp(\Psi_{predict}(\omega_{leaf_j}))}
\end{aligned} \tag{4}$$

At generation time, we are given a full dependency tree. A decoding step is necessary to compute a high probability assignment for all supertags simultaneously. In this process, tags for children must be chosen consistently with one another, and the resulting probabilistic information must be propagated upward to rerank tags elsewhere in the tree. We solve this problem with an A* algorithm. At each step,

the algorithm uses a priority queue to select subtrees based on their inside-outside scores. The inside score is computed as the sum of the log probabilities of the supertags in the subtree. The outside score is the sum of the best supertag for nodes outside the subtree, similar to Lewis and Steedman (2014). Once selected, the subtree is attached to the possible supertags of its parent that are both locally consistent and consistent among its already attached children. These resulting subtrees are placed into the priority queue and the algorithm iterates to progress the search. The search succeeds when the first complete tree has been found.[2]

4.2 Model 2: Fergus-R

Fergus-R is a stochastic tree model implemented in a top-down recurrent tree network and augmented with soft attention. For each node in the input dependency tree, soft attention—a method which learns a vectorized function to weight a group of vectors and sum into a single vector—is used to summarize its children. The soft attention vector and the node's embedded lexical material serve as the input to the recurrent tree. The output of the recurrent tree represents the vectorized state of each node and is combined with each node's possible supertags to form prediction states. Importantly, removing the conditional dependence on descendents' supertags results in the simplified objective function in Eq. 5 where lex_C is the children's lexical information, lex_p is the parent's lexical information, tag_p is the supertag for the parent node, and RTN is the recurrent tree network.

$$min_\theta - [\sum_{(p,C)} P_\theta(tag_p | RTN,\ lex_p,\ lex_C)] \tag{5}$$

The Fergus-R model uses only lexical information as input to calculate the probability distribution over each node's supertags. The specific formulation is detailed in Eq. 6. First, a parent node's children, lex_C, are embedded using the word embedding matrix, G_w, and then summarized with an attention function, Ψ_{attn}, to form the child context vector, ω_C. The child context is concatenated with the embedded lexical information of the parent node, lex_p, and mapped to a new vector space with a fully connected layer, FC_1, to form the lexical context vector, ω_{lex}. The context vector and a topological vector for indexing the internal tree state (see § 3.2) are passed to the recurrent tree network, RTN, to compute the full state vector for the parent node, ω_{node}. Similar to Fergus-N, the state vector is repeated and concatenated with the vectors of the parent node's possible supertags, $tagset_p$, and mapped to a new vector space with a fully connected layer, FC_2. A vector in this vector space is labeled $\omega_{elementary}$ because the combination of supertag and lexical item constitutes an elementary tree. The last step is to compute the probability of each supertag using the vectorized function, $\Psi_{predict}$.

$$\begin{aligned}
&\omega_C = \Psi_{attn}(G_w(lex_C)) \\
&\omega_{lex} = FC_1(concat(\omega_C,\ G_w(lex_p))) \\
&\omega_{node} = RTN(\omega_{lex},\ topology) \\
&\Omega_{elementary} = FC_2(concat(repeat(\omega_{node}),\ G_s(tagset_p))) \\
&P_\theta(tag_{p,i} \mid RTN,\ lex_p,\ lex_C) = \frac{exp(\Psi_{predict}(\omega_{elementary_i})))}{\sum_{j \in |\Omega|} exp(\Psi_{predict}(\omega_{elementary_j}))}
\end{aligned} \tag{6}$$

Although the same A* algorithm from Fergus-N is used, the decoding for Fergus-R is far simpler. As supertags are incrementally selected in the algorithm, the inside score of the subsequent subtree is computed. Where Fergus-N had to compute a incremental dynamic program to evaluate the inside score, Fergus-R decomposes into a sum of conditionally independent distributions. The resulting setup is a chart parsing problem where the inside score of combining two consistent (non-conflicting) edges is just the sum of their inside scores.

[2] Although, the data has some noise so that sometimes there is no complete tree that can possibly be formed.

4.3 Linearization

The final step to linearizing the output of Fergus-N and Fergus-R—a dependency tree annotated with supertags and partial attachment information—is a search over possible orderings with a language model. There are many possibilities, primarily due to ambiguities in insertion order. Following Bangalore and Rambow (2000), a language model is used to select between the alternate orderings. The language model used is a two-layer LSTM trained using the Keras library on the surface form of the Penn Treebank. The surface form was minimally cleaned[3] to simulate realistic scenarios.

The difficulty of selecting orderings with a language model is that the possible linearizations can grow exponentially. In particular, our implementations result in a large amount of insertion trees.[4] We approach this problem using a prefix tree which stores the possible linearizations as back-pointers to their last step and the word for the current step. The prefix tree is greedily searched with 32 beams.

5 Experiments

Using the representations of § 3, the models of § 4 can be instantiated in six different ways. We can use a feed-forward Fergus-N architecture or a recurrent Fergus-R architecture. Each architecture can embed supertags *minimally*, by learning a scalar corresponding to each supertag; *atomically*, by learning an embedding vector corresponding to each supertag; or *structurally*, by using convolutional coding over each supertag's tree structure to form a vector. In each case, the vector (a size-one vector in the minimal condition) is concatenated as described in § 4.

5.1 Training

We trained six such models using a common experimental platform. We started from the Wall Street Journal sections of the Penn Treebank, which have been previously used for evaluating statistical tree grammars (Chiang, 2000).[5] Our data pipeline breaks each sentence in the treebank into component elementary trees and then represents the sentence in terms of a derivation tree, specifying the tree-rewriting operations required to construct the actual treebank surface tree from the basic supertags. Removing supertags from the derivation tree leads to the unlabeled dependency trees our models assume as input.

From this input, we extracted the atomic supertag prediction instances and trained a network defined by each of the architectures of § 4 and each of the supertag representations of § 3. As always, we used Sections 02-21 for training, Section 22 for development, and Section 23 for testing. A complete description of network organization and training parameters is given in the appendix. The code and complete experimental setup are publicly available.[6]

5.2 Performance Metrics

We evaluate the performance of the models in several ways. First, we look at the accuracy of the supertag predictions directly output by each model. Second, we look at the accuracy of the final supertags obtained by decoding the model predictions to the best-ranked consistent global assignment. These metrics directly assess the ability of the models to successfully learn the target distributions.

Next, we evaluate the models on the full NLG task, including linearization. The linearization task allows more freedom in supertag classifications because supertags may differ in minor ways, such as the projections present along the spine, which will not affect generation output for a particular target input. The freedom means models may not be penalized based on decisions that don't matter—thus, at the same time, it also mutes the distinctions between classification decisions. We report a modified edit distance measure, Generation String Accuracy, following (Bangalore et al., 2000). Since linearization uses a beam search, we report statistics both for the top-ranked beam and for the empirically based beam among the candidates computed during search. The difference gives an indication of the effect of the language model in guiding the decisions that remain after supertagging.

[3] With respect to the surface form, the only cleaning operations were to merge proper noun phrases into single tokens. Punctuation and other common cleaning operations were not performed.

[4] Many of the validation examples had more than 2^{40} possible linearizations.

[5] A possible additional data source, the data from the 2011 Shared Task on Surface Realization, was not available.

[6] `https://github.com/braingineer/neural_tree_grammar`

		Accuracy		
Model	**Embedding**	**Raw Model**	**After Decoding**	**Running Time**
Fergus-N	Structural	58.17%	57.40%	1.97s
	Atomic	60.69%	55.56%	1.81s
	Minimal	52.09%	54.18%	2.02s
Fergus-R	Structural	67.62%	57.04%	0.30s
	Atomic	82.65%	62.73%	0.36s
	Minimal	10.13%	19.66%	0.54s

Table 1: For each supertag and embedding pair, the mean accuracy of supertag classification directly output by the model and in the consistent global assignment output by A* decoding. Also shown is the median running time—which includes model computation and A* search. The structural embeddings are computed with convolutional coding, the atomic embeddings as rows in a matrix, and the minimal embeddings as scalars in a vector.

Finally, we report statistics about the run time of different generation steps. This allows us to assess the complexity of the different decoding steps involved in generation, to reveal any tradeoffs among the models between speed and accuracy.

5.3 Results

Table 1 shows the results of supertag prediction. All differences between model are significant using a Paired-Sample t-test ($p < 10^{-5}$) The structural and atomic embedding methods consistently perform better, suggesting that the clustering capabilities of neural methods is a crucial part of their effectiveness. For post-decoding performance, Fergus-N utilizes the structural embeddings more than the atomic embeddings. This merits further investigation: it might be because Fergus-N predicts one supertag as a function of another, and so the compositional relationships among the two trees are more important—or because Fergus-R's contextualized decisions depend on similarities among supertags (involving argument structure or information structure) that are difficult for the convolutional coding to represent or learn. Additionally, the minimal embeddings suggests that Fergus-N's architecture might provide enough structure to reduce the difficulty of a large number of cases.

The overall best results come from Fergus-R, suggesting that it is worthwhile to take additional context into account in this task. At the same time, the median time taken to classify and decode a sentence with Fergus-R is just one sixth that of Fergus-N. We suspect that there is a general lesson in this speedup: because neural models can be more flexible about the information they take into account in decisions, it's especially advantageous in designing neural architectures to break a problem down into decisions that can be combined easily.

Finally, decoding the network generally leads to lower accuracy. It seems that our models are not doing a good job of using the predictions they make to triangulate to accurate and consistent supertags. This suggests that the models could be improved by taking more or better information into account in decoding. This is more pronounced in the atomic embeddings than the structural embeddings, which suggests that the lack of structure in the vector representation allows for the model to learn clustering relationships that don't correlate with the structural requirements.

Figure 2 shows the NLG evaluation results for the different models. All differences in model are significant using an Independent t-test ($p < 10^{-5}$). [7] For both models, the differences between structural embeddings (using convolutional coding) and atomic embeddings (using standard vector embedding techniques) were not significant, while the differences between the two embeddings and minimal embeddings were significant ($p < 10^{-5}$). The performance confirms our expectation that differences in supertag accuracy after decoding correlate with NLG accuracy overall, but that differences in NLG performance are attenuated. We note by comparison that Bangalore and Rambow report an accuracy of

[7] An Indepedent t-test was used instead of a Paired-Sample t-test because of intermittent failures during linearization that resulted in slightly different numbers of observations.

		Accuracy	
Model	**Embedding**	**Top Scoring**	**Best Performance**
Fergus-N	Structural	65.80%	72.58%
	Atomic	65.52%	71.82%
	Minimal	63.79%	71.09%
Fergus-R	Structural	68.22%	74.70%
	Atomic	69.29%	75.56%
	Minimal	58.23%	65.04%

Table 2: Shown above as accuracy is the percentage of tokens in the linearized strings that are in correct positions according to an edit distance measure.

74.9% in their best evaluation of FERGUS—on a data set of just 100 sentences with an average length of 16.7. Our evaluation, on 2400 sentences with an average length of 22.1, is more strenuous.

6 Related Work

There are several lines of related work which explore stochastic tree models from the standpoint of parsing and understanding. While using the same methods, NLG has different goals and we think the perspective is instructive. Where parsing infers the most probable underlying structure, generation infers the most likely way of expressing a semantic structure. This divergence of goals leads to different concerns, alternatives, and emphasis.

The works most similar to ours explicitly model tree structures, but focus on resolving the uncertainty involved with the latent structure of an observed sentence. For example, the top down tree structure of Zhang et al. (2016) expresses the generation of a dependency structure as the decisions of a set of long short-term memory networks. For each decision, the possible options are different tree structures which can produce the target linear form. In contrast, the generation problem is concerned with different linear forms that can result from the same tree structure. In more extensive tasks, the generation problem can include simulated interpretation to inform decisions; using the ease of structural inference from linear form quantifies the understandability of a sentence.

Although the methodology presented in this work is closely related to several recent neural networks models for long-distance relationships, it differs distinctly in its treatment of state and search. Specifically, forward-planning in a generation task produces a growing horizon of syntactic choices while shrinking the horizon of semantic goals. At each step, syntactic operations grow the number of available syntactic choices while limiting the number of semantic goals left to express. In contrast, parsing and understanding begin with the surface form and construct the organized semantic content, either for a downstream decision or just for the structure itself. The most notable works in this line of research are the recurrent neural network grammars (Dyer et al., 2016), a shift-reduce parser and interpreter (Bowman et al., 2016), and a dynamic network for composing other neural network modules (Andreas et al., 2016). Interestingly, there is a common theme of using indexable and dynamic data structures in neural architecture to make long-distance decisions.

7 Conclusion

This paper has explored issues in deep learning of probabilistic tree grammars from the standpoint of natural language generation. For NLG, we need models that predict high-probability structures to encode deep linguistic relationships—rather than to infer deep relationships from surface cues. This problem brings new challenges for learning, as it requires us to represent new kinds of linguistic elements and new kinds of structural context in order to capture the regularities involved. Despite these challenges, however, the problem continues to have the mix of data sparsity, rich primitives and combinatorial interactions that has made deep learning attractive for use in natural language parsing and understanding.

Of the range of models we surveyed here, the best combines a top down tree recurrence to cluster contexts with appropriate embedding methods to cluster syntactic and lexical elements. Our evaluations

suggest that the model is more accurate and faster than alternative techniques. However, it would still be good to analyze the performance of the model more deeply. Can we get better results in the key decoding step? How do human readers find the output of the system?

Looking forward, we see this research a step towards learned models that capture more of the NLG task. We plan to explore similar techniques in planning surface text from more properly semantic inputs or even from abstract communicative goals. Further, we plan to integrate learned methods with knowledge-based techniques to offer designers more control over system output in specific applications. Developing methods appropriate to such settings will require researchers to revisit the core problems of generalizing across linguistic structures and contexts—and, we hope, to build on and extend the provisional solutions we have explored here.

Acknowledgments

This research was supported in part by NSF IIS-1526723 and by a sabbatical leave from Rutgers to Stone.

A Appendix

All of our models were implemented in the Keras (Chollet, 2015) and Theano (Theano Development Team, 2016) libraries. The specific parameters that were used are shown in Table 3. The parameters were selected by measured performance on the development portion of the data set. In the accompanying code repository, the full experiment parameters—including programmatic parameters controlling the experimental design—are specified in configuration files.

In our experiments, the corpus was preprocessed using Stanford NLP tools (De Marneffe et al., 2006) to fix common issues and remove extraneous information. The resulting parse trees were then analyzed to mark the head words, the dependents, and the adjuncts. The marked-up trees were split at adjunction and substitution positions to form the grammar. Our models use an output distribution that's restricted to the set of supertags that have occurred with the lexical item, which requires indices to the supertag embedding matrix to be passed into the computation with the rest of the data. We implement the affinity matrix between the supertag embeddings and lexical state vectors, by concatenating the vectors, mapping them to a new space using a fully connected layer, and computing a score with a vectorized function. (The vectorized function operation is the same mechanism which calculates the probability distribution used in soft attention.)

Model Parameter	Value
Fergus-N Parameters	
Fully connected layer size	256
Batch size	128
Fergus-R Parameters	
Fully connected layer size	256
Hidden state size	128
Batch size	16
Embedding Parameters	
Convolution filter size	48
Syntactic category embedding size	32
Node role embedding size	32
Word embedding size (Pennington et al., 2014)	300

Model Parameter	Value
Language Model Parameters	
Hidden state size	368
Batch size	32
Optimization Parameters

Abstract

This paper studies the abstractive multi-document summarization for event-oriented news texts through event information extraction and abstract representation. Fine-grained event mentions and semantic relations between them are extracted to build a unified and connected event semantic link network, an abstract representation of source texts. A network reduction algorithm is proposed to summarize the most salient and coherent event information. New sentences with good linguistic quality are automatically generated and selected through sentences over-generation and greedy-selection processes. Experimental results on DUC 2006 and DUC 2007 datasets show that our system significantly outperforms the state-of-the-art extractive and abstractive baselines under both pyramid and ROUGE evaluation metrics.

1 Introduction

Automatic summarization on news documents enables readers more easily to get general information of interesting news. Most of existing summarization methods have neglected the important event-oriented characteristics of news texts although some popular tasks such as DUC (Document Understanding Conference) and TAC (Text Analysis Conference) target at summarizing news documents. The examples below show that the core information of news texts is the atomic event mentions as shown in bolded words and their related concepts as shown in italic phrases.

- Lawyer *Morris Dees*, who is **representing** *Victoria Keenan* after she was **attacked** by *two guards* in *July 1998*, **introduced** *depositions* to **contradict** *the men's testimony*.
- *Morris S. Dees Jr.*, who was the co-founder of the Southern Poverty Law Center, **defended** for *Keenan* after she was **assaulted** by *two security guards* near *the headquarters of the Aryan Nations*.

An event usually tells us "**who** did **what** to **whom when** and **where** ..." The most important components of an event include its **actor** (who, the agent of the event), **action** (what, the core meaning of the event) and **receiver** (whom, the target of the event action). Other arguments indicate other attributes of the event, such as **time** (when) and **location** (where). The event arguments are concepts related with the event action. For event-based news summarization, extracting the most salient events and related concepts are the core tasks.

One of the most similar related work (Glavaš and Šnajder, 2014) investigated constructing event graph for multi-document summarization. The nodes in event graph denote event mentions while edges denote temporal relations between event mentions. It ranks event mentions based on the temporal relations and then generates summary by extracting sentences that contain salient event mentions. However, the problems of information overlapping and lacking of coherence cannot be overcomed by extractive methods. This paper explores the issue of abstractive summarization for event-oriented news texts. The semantic relations between events like cause-effect relation are also extracted to help generate more coherent and informative summary in our system.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 236–246, Osaka, Japan, December 11-17 2016.

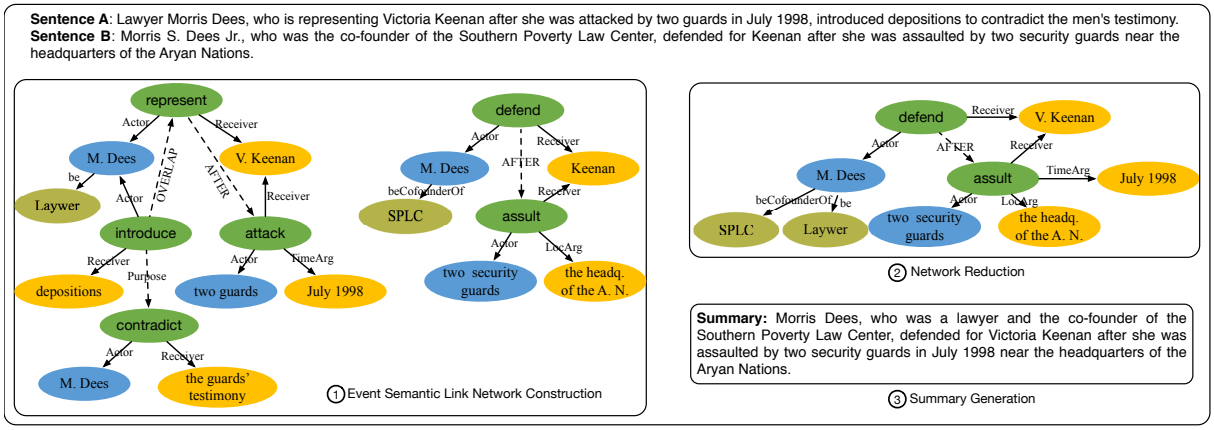

Figure 1: An example illustrating the framework of our summarization system.

Figure 1 illustrates the procedure of our system. Firstly, the semantic information of texts is represented by constructing event semantic link network (Zhuge, 2012). The semantic nodes of the network are events extracted from the source texts while semantic links are relations between events. Concept co-reference resolution and event co-reference resolution are both conducted within and cross documents to aggregate information from different places. Secondly, the event semantic link network is reduced to obtain connected and condensed summary network. A network reduction algorithm that makes use of the semantic links between event nodes is proposed to trade off among selecting salient information, maintaining coherence, and conveying correct and complete information. Finally, coherent and concise summary is automatically generated based on the summary network through sentences over-generation and greedy selection processes. The contributions of this work include:

- The abstractive summarization for event-oriented news texts is made by extracting fine-grained events and constructing event semantic link network as the abstract representation of source texts.
- An ILP-based network reduction algorithm using semantic links between events is proposed to obtain the most condensed, salient and coherent semantic information of source texts.
- Informative and concise summary is automatically generated based on the event semantic link network after reduction.

2 Event Semantic Link Network Construction

As shown in Figure 1, the first procedure of our system is to extract events and construct event semantic link network (ESLN). Within ESLN, semantic nodes are event mentions consisting of event actions and arguments. The action indicates the central meaning of an event, while the arguments render the attributes of an event (Ahn, 2006). In this work, each event is represented as a tree with the event action as its root node. The children of the root node are event arguments, including actor, receiver, time and location. The collapsed form of an event tree can be denoted as *e=Action (Actor, Receiver, TimeArg, LocArg)*. We use semantic relations between events as semantic links (subsection 2.3). ESLN provides an event-based abstract representation for news documents, which is a directed and connected graph.

The ESLN is constructed by: (1) extracting concepts from documents; (2) identifying event actions and extracting event arguments; (3) predicting the semantic links between event mentions.

2.1 Concept Extraction

All noun phrases extracted from documents are defined as concepts. To enrich the semantics of a concept, we model it as an object which consists of its core noun phrase and attributes. The attributes of a concept reflect the relationships between this concept and other concepts. A concept a implied by its core noun phrase is denoted by $a(\xrightarrow{r_1} c_1, \xrightarrow{r_2} c_2, \cdots, \xrightarrow{r_n} c_n)$ where c_i indicates another concept and r_i indicates a specific relation between concept a and concept c_i. Concept c_i is defined as an attribute of concept a.

Lexical features	word, lemma of the token and its surrounding tokens (five tokens to the left and right)
POS-tag features	part-of-speech tags of the token and its surrounding tokens (five to the left and right)
Syntactic features	the set of dependency relations of the token
Modifier features	modal modifiers, auxiliary verbs and negations.
Word vectors	100-dimensional GloVe word vector (Pennington et al., 2014)

Table 1: The features for the event identification model

Position features	the set of features that measure the distance between event actions (number of tokens) and their relative position (same sentence, adjacent sentences, adjacent event mentions)
Lexical features	word, lemma, stem, and pos-tag of both event actions as well as features indicating whether the word forms are the same, the semantic similarity between actions words, the word and lemma of each token between the action words
Syntactic features	syntactic path between the actions (dependency labels on the syntactic path between the actions), features indicating whether one action syntactically dominates the other, features indicating whether one is a predicate of an adverbial clause governed by the other event, and the set of dependency relations of both actions
Modifier features	the set of features that describe the modal, auxiliary, negation, and determination modifiers of both event actions
Word vectors	100-dimensional GloVe word vector of both event action words
Discourse features	the discourse relations between event mentions. We use the document-level discourse analysis method (Joty et al., 2013) to extract the discourse relations between event mentions.

Table 2: The features for the event relation prediction model

We extract concepts and their attributes based on dependency trees. Texts are preprocessed by Stanford CoreNLP pipeline (Manning et al., 2014). The dependency trees are transformed into semantic graph by pronoun resolution (Schuster et al., 2015). All named entities are identified as concepts. For other nouns, we expand on "`compound`", "`name`", "`amod`", "`neg`", "`nummod`" and "`dep`" dependency edges to build the basic noun-phrase concept. We also expand on "`appos`", "`acl`", "`acl:relcl`", "`nmod:of`" and "`nmod:poss`" edges for non-proper nouns, since these are relative clauses that convey important information.

To extract the attributes of a concept, we extract the relations between the concept and other related concepts. In order to differentiate with event actions, the valid syntactic patterns of relations between the head concept and its attributes is restricted as "`be`", "`be-NP-prep`" and "`be-AP-prep`" where NP indicates noun phrase and AP indicates adjective phrase, such as *"Morris Dees* **is** *a lawyer"* and *"Morris Dees* **is the co-founder of** *Southern Poverty Law Center"*. Several syntactic rules, which use the dependency labels (including "`nsubj`", "`appos`", "`nmod:of`" and "`nmod:poss`") between head tokens of concepts, are designed to detect those specific relations between concepts.

To aggregate information across documents, we need to recognize all concept co-references across documents. The co-reference resolution within single document has been conducted during the preprocessing stage by Stanford CoreNLP pipeline, so those resolution rules can be adopted. We formulate the co-references detection in a hierarchical agglomerative clustering framework similar to (Shen et al., 2013). A set of clusters are obtained and each cluster contains mentions refer to the same concept in the documents. For each cluster of co-referential concepts, we only reserve the most representative one and merge the attributes of all other mentions. For example, the concept *"Morris Dees"* in Figure 1.

2.2 Event Identification

The procedure of event identification consists of two steps: event action identification and event arguments extraction. The first step is formulated as a supervised classification task with features as shown in Table 1.

The arguments of an event are concepts related to the event action. Since we have extracted all concepts from documents, the argument extraction is to judge the argument type of each concept. We define in total fifteen dependency patterns using Semgrex expressions (Chambers et al., 2007). These patterns mainly capture the subject-predicate-object constructions, subject-predicate constructions, passive constructions, prepositional constructions and clausal constructions.

Since important events are usually mentioned many times in the documents. For example, in Figure 1 "*Victoria Keenan* was **attacked** by *two guards* in *July 1998*" and "*Keenan* was **assaulted** by *two security guards*" refer to the same event. To determine whether two event mentions are co-referential, both the event actions and event arguments are compared. We use WordNet-based similarity method (Pedersen et

al., 2004) to judge the semantic similarity between event actions. Two event mentions are identical only when the similarity between event actions is above a threshold (set as 0.8 after tuning) and corresponding event arguments are identical or co-referential. For all identical event mentions, we just reserve the most representative one and merge the relations and arguments of other mentions.

2.3 Event Relation Prediction

We leverage the sentence structures and discourse features in documents to infer the relations between events in order to construct an informative event semantic link network. Through analyzing large numbers of news texts, we find following types of semantic relations between events are very common:

- *Temporal link*. It indicates the temporal relations between two events, which consists of directed asymmetric links (BEFORE and AFTER) and symmetric links (OVERLAP). For symmetric links, we add two directed links in opposite directions between two event nodes;
- *Cause-effect link*, denoted by ce as in $e \xrightarrow{ce} e^{'}$, for which the predecessor event e is a cause of its successor event $e^{'}$ and the successor event $e^{'}$ is an effect of its predecessor event e.
- *Purpose link*, denoted by pur as in $e \xrightarrow{pur} e^{'}$, for which the successor event $e^{'}$ is the purpose of its predecessor event e. Event $e^{'}$ is to be realized through event e.
- *Means link*, denoted by mea as in $e \xrightarrow{mea} e^{'}$, for which the event $e^{'}$ is a method or instrument which tends to make realization of event e more likely.
- *Condition link*, denoted by con as in $e \xrightarrow{con} e^{'}$, for which the predecessor event e is a condition of its successor event $e^{'}$. Realization of $e^{'}$ depends on realization of event e.
- *Sequential link*, denoted by seq as in $e \xrightarrow{seq} e^{'}$, for which the event $e^{'}$ is a successor of event e. It usually describes a number of event actions with succession relationships.
- *Attribution link*, denoted by $attri$ as in $e \xrightarrow{attri} e^{'}$, for which event $e^{'}$ is an attribution of event e, indicating its specific contents.

For predicting the semantic links between each pair of event nodes, we use an L2-regularized maximum entropy classifier with features as shown in Table 2.

In order to make the event semantic link network denser and more informative, we add "*Common Argument*" links between event nodes that share the same concept as argument. For example, "*Morris Dees defended for Keenan*" and "*Morris Dees contradicted the men's testimony*" both use concept "*Morris Dees*" as actor argument. After expanding the semantic links between events, we get a unified, connected and informative ESLN to represent the abstract information of source texts.

3 Summarization

The constructed ESLN is an abstract representation of source documents. We summarize the documents by summarizing the network and generate summary based on the reduced network. For event-based summarization, the summary network must contain the most salient events and concepts information. We model the summarization of ESLN as a structured prediction problem (Collins, 2002) that trades off among selecting salient information, maintaining coherence, and conveying correct and complete information.

Let E and C denote all the event nodes and concepts in ESLN, where each node $e \in E$ represents a unique event and each concept $c \in C$ is an argument of an event. To obtain the most salient and condensed summary network, we seek to maximize the summation of saliency scores of the selected events and concepts. For summary network which contains event set $E^{'}$ and concept set $C^{'}$, its saliency score is:

$$\sum_{e \in E^{'}} \theta^T f(e) + \sum_{c \in C^{'}} \psi^T g(c) \quad (1)$$

where $f(e)$ and $g(c)$ represent the features of event e and concept c respectively (described in Table 3). θ and ψ are vectors of feature weights for events and concepts respectively.

The network reduction problem is decoded as an integer linear programming (ILP) by incorporating some priori knowledge as constraints (§3.1). Features weights are estimated by using structured pre-

Concept Features	Concept Type	binary feature indicates whether it's named entity and whether it appears in the topic description
	Concept Freq.	one binary feature for each frequency threshold t=0/1/2/5/10
	Concept Pos.	average and foremost position of sentences containing the concept (binarized by 5 thresholds)
	Concept Head	word, lemma, pos, depth in the dependency tree (binarized by 5 thresholds) and whether it appears in the topic description
	Concept Span	average and longest word span of concept (binarized by 5 thresholds)
Event Features	Action Word	word, lemma, pos, depth in the dependency tree (binarized by 5 thresholds) and whether it appears in the topic description
	Action Freq.	binary feature for each frequency threshold t=0/1/2/5/10, average and foremost position of sentences containing the concept
	Actor Arg.	all concept features of actor argument
	Receiver Arg.	all concept features of receiver argument. If don't contain receiver argument, all set as 0
	Time Argument	one binary feature indicates whether it contains time argument
	Location Arg.	one binary feature indicates whether it contains location argument
	Semantic Links	total number of links from and to the event node in event graph (binarized by 5 thresholds))

Table 3: Event and concept features (all binaries)

diction algorithm (§3.2). After obtaining the summary network, concise and coherent summary can be generated through sentences over-generation and greedy selection (§3.3).

3.1 Network Reduction

Let M and N be the total number of event nodes and concepts in source ESLN. We use e_i and c_j to represent the i-th event and j-th concept respectively. Let u_i and v_j be binary variables. u_i is set to 1 iff event e_i is selected and v_j is set to 1 iff concept c_j is selected.

The ILP maximization objective can be transformed into Equation 2, which contains two parts: the first part tends to select more important events; and the second part tends to select more concepts to increase information diversity and reduce redundancy in the summary.

$$\sum_{i=1}^{M} u_i \theta^T f(e_i) + \sum_{j=1}^{N} v_j \psi^T g(c_j) \tag{2}$$

To ensure the summary network could generate coherent summary and convey complete and correct information, the following groups of constraints are required:

Complete facts. To guarantee the selected event node convey complete fact, the following constraints are introduced:

$$\forall i, if c_j \in Arguments(e_i), v_j \geq u_i \tag{3}$$

$$\forall j, \sum_{i \in c_j.relatedEvents} u_i + \sum_{k \in c_j.attributes} v_k \geq v_j \tag{4}$$

$$\forall i, k, \text{if } e_i \xrightarrow{Attribution} e_k, u_i \leq u_k \tag{5}$$

Equation 3 ensures that if an event was selected, the arguments of the event should all be selected. Equation 4 guarantees that if a concept was selected, at least one event that it related to or an attribute that it has should be selected. These two constraints ensure the selected event or concept convey complete information. If event e_k is an attribution of event e_i, then e_k describes specific contents of event e_i. Equation 5 guarantees that if event e_i is selected, its attribution e_k must be selected.

Coherence. In order to generate coherent summary, the reduced summary network should be connected. Flow-based constraints have previously been used (Thadani and McKeown, 2013; Liu et al., 2015) to ensure the connectivity of subgraph. For each pair of event nodes e_i and e_k, the binary variable $l_{i,k}$ indicates the semantic link between them. Only if both e_i and e_k are selected and there is a link between them, $l_{i,k}$ can be set to 1, otherwise 0, which can be formulated as following:

$$\begin{aligned} &\forall i, k, l_{i,k} \leq e_i, l_{i,k} \leq e_k \\ &\text{if there is no link from } e_i \text{ to } e_k, l_{i,k} = 0 \end{aligned} \tag{6}$$

A set of single-commodity flow variables $f_{i,k}$ that each takes a non-negative integral value and represents the flow from event node e_i to e_k, were used to enforce the connectivity of summary network. We set a dummy "ROOT" node which is connected with only one selected event node in the ESLN (Equation 7), denoted as e_0 . The root node sends up to M units of flows to the selected event nodes (Equation 8). Each selected node consumes one unit of flow (Equation 9). Flow can only be sent over a link if and only if the link variable l is 1 (Equation 10).

CONCEPT DESCRIPTION RULES
For concept $a(\xrightarrow{r_1} c_1, \xrightarrow{r_2} c_2, \cdots, \xrightarrow{r_n} c_n)$, the description of concept a can be:
1.**Appositive modifier** "a, $c_1, c_2 \ldots$", e.g. *"Morris Dees, civil rights lawyer, co-founder of Souther Poverty Low Center, ..."*
2.**Attributive clause** *"a who/which/that $r_1 c_1 \ldots$"*, e.g. *"Morris Dees who was the co-founder of Southern Poverty Law Center and a civil rights lawyer ..."*
3.**Appositive modifier mixed with attributive clause**, e.g. *"Civil rights lawyer Morris Dees who was the co-founder of Southern Poverty Law Center ..."*
SENTENCE STRUCTURING RULES
if $e_1 \xrightarrow{after/before/overlap} e_2$, then generate "$e_1$ after/before/when e_2"; if $e_1 \xrightarrow{ce} e_2$,then generate "Because $e_1, e_2,$ " and "e_2 because e_1";
if $e_1 \xrightarrow{pur} e_2$,then generate "$e_1$ in order to e_2" and "e_1 so that e_2"; if $e_1 \xrightarrow{mea} e_2$, then generate "$e_1$ by e_2" and "e_1 by the way that e_2"
if $e_1 \xrightarrow{attri} e_2$, then generate "$e_1$ e_2", "e_1 about/on/in/with/at e_2" and "e_1 that e_2"; if $e_1 \xrightarrow{seq} e_2$, then generate "$e_1, e_2$", "$e_1$ and e_2";

Table 4: The set of concept description and sentence structure rules.

$$\forall i \geq 1, l_{0,i} \leq u_{i;}, \sum_{i=1}^{M} l_{0,i} = 1 \tag{7}$$

$$\sum_{i=1}^{M} f_{0,i} - \sum_{i=1}^{M} u_i = 0 \tag{8}$$

$$\forall k \geq 1, \sum_{i} f_{i,k} - \sum_{p} f_{k,p} - u_k = 0 \tag{9}$$

$$\forall i \geq 0, k \geq 1, M \cdot l_{i,k} - f_{i,k} \geq 0 \tag{10}$$

Length Constraint. To control the summary compression rate, the total number of selected events is limited less than L:

$$\sum_{i=1}^{M} u_i \leq L \tag{11}$$

where parameter L is set to control the graph size after reduction.

3.2 Feature Weights Estimation

We learn feature weights θ and ψ by training on a set of source ESLN paired with gold summary network. The source ESLN is constructed from source texts whereas the gold summary network is constructed from reference summaries and then mapped to the source ESLN by texts similarity method (Pilehvar et al., 2013). We formulate our estimation problem as follows:

$$-score(G^*) + max_G(score(G) + cost(G; G^*)) \tag{12}$$

where G^* denotes the gold summary network. $score()$ is defined in Equation 1. $cost(G; G^*)$ penalizes each event or concept in G but not in G^*, which can be easily incorporated into the linear objective in Equation 2. We optimize our objective using AdaGrad (Duchi et al., 2011) with l_2 regularization ($\lambda = 0.01$), with an initial step size 0.1. The ILP model is solved using Gurobi 6.5.2.

3.3 Summary Generation

Since each event node is structured as *e=Action (Actor, Receiver, TimeArg, LocArg)*, we can generate complete sentence efficiently for it using SimpleNLG (Gatt and Reiter, 2009). However, through experiments we find that low linguistic quality is the biggest problem with the generated sentences, which include syntax error, monotone sentence structure and repetition of the same noun phrases. To improve the linguistic quality of summary, we first over-generate large numbers of summary sentences and then use a greedy algorithm to select sentences with the best linguistic quality and no information overlapping.

Sentence over-generation. To generate a complete and informative sentence, both the description of concepts and the organization of sentence structures need to be settled in following ways:

- Each concept with several attributes can be described in different ways using concept description rules in Table 4.
- For each event node, we use SimpleNLG (Gatt and Reiter, 2009) tool to generate several different sentences, among which the description of concepts or the orders of arguments are different.

	Concepts	Events	Event Relations	After Expanding
avg#/topic	5206	1538	1089	10383

Table 5: The average number of concepts, events, event relations and relations after expanding of each topic in annotated DUC2007 (including 45 topics, each topic has 25 documents).

	precision	recall	F1-score
Concept Extraction	N/A	0.7928	N/A
Event Action identification	0.8532	0.8468	0.8499
Event Mention extraction	0.7272	0.7067	0.7168
Event Relations prediction	0.5894	0.6222	0.6054

Table 6: The performance of concepts extraction, events identification and event relations prediction.

- If two events share semantic links with each other, we merge them to generate one unified sentence by using corresponding sentence structuring rules in Table 4. Note that, when two events share the same actor concept, only one is reserved.
- For any two events that share the same actor, we merge them to generate one sentence using conjunction word "and" to connect event actions and arguments. Only one actor is kept as the subject.

Greedy selection. After the above step, we get large numbers of candidate summary sentences. Some of them would have information overlapping with each other if generated from the same event node. To improve the linguistic quality of summary, we iteratively select a sentence with the highest linguistic quality and delete sentences that have information overlapping with it from the candidate sentences set. The linguistic quality of sentence $s = \{w_1, w_2, \ldots, w_L\}$ is defined similarly as (Banerjee et al., 2015):

$$LQ(s) = 1 \Big/ \left(1 - \left(log_2 \prod_{t=1}^{L} P(w_t|w_{t-1}w_{t-2})\right) \Big/ L\right) \quad (13)$$

where L is the total number of words in sentence s; w_0 and w_{-1} both represent the beginning of sentence s. The 3-gram model $P(w_t|w_{t-1}, w_{t-2})$ is trained on the English Gigaword corpus (`http://www.keithv.com/software/giga/`).

The coherence constraints guarantee the selected summary network to be connected and have a flow from the ROOT node to selected nodes. The selected sentences are ordered based on the direction of flows to obtain a coherent summary.

4 Evaluation Results

4.1 Dataset and Experimental Settings

To evaluate the performance of our system, we use two datasets that have been widely used in multi-document summarization shared tasks: DUC 2006 and DUC 2007. Each task has a gold standard dataset consisting of document clusters and reference summaries. DUC 2007 was manually annotated by using annotation tool brat (`http://brat.nlplab.org`) to extract gold events and gold relations between events, which are used for training the event identification model and event relations prediction model. Table 5 shows the details of the annotated dataset.

The annotated dataset was split into training set (25 topics), development set (5 topics) and test set (15 topics). After training and tuning, the performance of our system is evaluated on the test set as shown in Table 6. An event mention is correctly extracted only if both the event action and event arguments are correct. Table 6 only shows the recall of concept extraction, because we extract all kinds of concepts, whereas only event arguments are annotated in the annotated dataset. The feature weights θ and ψ of event nodes and concepts are also estimated on the training set.

To evaluate the performance of our summarization model, we use both ROUGE (Lin and Hovy, 2003) and Pyramid (Nenkova and Passonneau, 2004) evaluation metrics.

4.2 Results with ROUGE Evaluation

ROUGE-1.5.5 toolkit was used to evaluate the quality of summary on DUC 2006 and DUC 2007 (test set) dataset. We differentiate the different components of our system by including and not including the coherence constraints in ILP-based network reduction algorithm and using the manually annotated gold ESLN in our system. Our systems are compared with several baselines: Centroid (Radev et al., 2000) and

Gold-ESLN with Coherence	0.44532	0.12229	0.17267	N/A	0.41162	0.09642	0.15348	N/A

Table 7: Comparison of ROUGE scores (F-score) and Pyramid scores on DUC 2006 and 2007(test set).

LexRank (Erkan and Radev, 2004). The performance of NIST baseline and the average ROUGE scores of all the participating systems (i.e. *AveDUC*) both for DUC 2006 and DUC 2007 main tasks are also listed. According to the results in Table 7, our systems significantly outperform (paired t-test with $p<0.05$) all the baselines, which demonstrates that extracting event information from texts and summarizing based on structured information is much more effective than summarizing on sentence level.

In addition, we also compare our system (ESLN with coherence) with several state-of-the-art summarization methods: graph-based extractive method MultiMR (Wan and Xiao, 2009), sparse-coding-based compressive method RA-MDS (Li et al., 2015), and two most recently developed abstractive methods ILPSumm (Banerjee et al., 2015) and PSM (Bing et al., 2015). The results show that our system significantly (paired t-test with $p<0.05$) outperforms all the other four systems.

The results also show that our system with coherence constraints achieves better performance than the counterpart without coherence constraints. So the coherence constraints are very helpful to select more salient and coherent information. Just as expected, the system using gold ESLN achieves the best performance. Incorrect dependency parsing and co-reference resolution will reduce the accuracy of extracting event information. On the other hand, it also verifies that the method that summarize texts based on accurate event information is effective.

4.3 Results with Pyramid Evaluation

Since ROUGE metric evaluates summaries by strict string matching, we also use the pyramid evaluation metric which can measure the summary quality beyond simply string matching. It involves semantic matching of summary content units (SCUs) so as to recognize alternate realizations of the same meaning, which provides a better metric for abstractive summary evaluation. We employ the automated version of pyramid scoring (set threshold value to 0.6) in (Passonneau et al., 2013). Table 7 shows the evaluation results of our system and two abstractive baselines on both DUC 2006 and DUC 2007(test set). The results show that our system significantly ($p<0.05$) outperform the two baselines on both datasets, which demonstrates that our system can generate more informative summary.

4.4 Discussion

Table 8 shows a comparison of summaries generated by our system and human on DUC 2007 dataset (D0701A). The results show that our summary behaves similarly to human summary in following aspects: (1) Aggregating information from different places. For example, the description of *"Morris Dees"* includes information from several different documents, which are extracted as attributes of concept *"Morris Dees"* in our system; (2) Organizing sentences coherently. The coherence constraints in ILP-based network reduction component ensure the selected event information to be coherent. (3) Clearly pronoun reference. The adjacent sentences with the same subject in the summary are post-edited by replacing subjects of successor sentences with appropriate pronouns. Even though we incorporate the sentences over-generation and greedy-selection components in our system, some sentences in the generated summaries also have few syntax errors. Most cases are because of non-accurate event extraction caused by incorrect dependency parsing or coreference resolution.

Summary by Our System: Morris Dees who was a crusader against intolerance, Keenans' attorney, the chief trial counsel, executive director and co-founder of the Southern Poverty Law Center used lawsuit to fight hate groups. He kept track of hate crime. He put East Peoria leader and won significant civil judgment against White Aryan Resistance and Ku Klux Klan in touch in Chicago with David Ostendorf. He formed a broad-based coalition and won a series of civil rights suit against other racist group in a campaign on race issue. He got an unwarranted slap in the Media Watch column and introduced photograph in the same issue. Southern Poverty Law Center, montgomery-based used civil suit and previously recorded a 20-percent increase in hate group. It battled racial bias and used civil law. It tracked hate group and won major legal fight against other white supremacist group and Ku Klux Klan. The 1973 federal lawsuit had the practical effect. The practical effect provided equal service to black...	**Human-written Summary:** The Southern Poverty Law Center is a nonprofit research group based in Montgomery, Alabama that battles racial bias. It tracks US hate crimes and the spread of racist organizations. It covers right-wing extremists in its magazine Intelligence Report. Through its Teaching Tolerance program, it provides materials to teachers to promote interracial and intercultural understanding. It freely distributes booklets on combating hate to schools, mayors, police chiefs, and other interested groups and citizens. It advises city leaders faced with hate crimes. Morris Dees co-founded the SPLC in 1971 and is its chief trial counsel and executive director, following Julian Bond. Dees and the SPLC seek to destroy hate groups through multi-million dollar civil suits that go after assets of groups and their leaders. In six lawsuits based on hate crimes or civil rights abuses, they have never lost. They successfully sued the Ku Klux Klan and the related Invisible Empire Klan, United Klan of America and ...

5 Related Work

Abstractive Multi-document summarization. Previous researches have shown that human write summaries through sentence aggregation and fusion (Cheung and Penn, 2013). Abstraction-based approaches that gather information across sentences boundaries have become more and more popular in recent years. Different abstractive summarization methods can be summarized into four technique routes: (1) sentence fusion based methods (Barzilay and McKeown, 2005; Filippova and Strube, 2008; Banerjee et al., 2015) first cluster sentences into several themes and then generate a new sentence for each cluster by fusing the common information of all sentences in the cluster; (2) information extraction based methods (Genest and Lapalme, 2011; Li, 2015) extract information units, such as Information Items or Basic Semantic Unit, as components for generating sentences; (3) summary revision based methods (Nenkova, 2008; Siddharthan et al., 2011) try to improve quality of summary by noun phrases rewriting and co-reference resolution; (4) pattern-based sentence generation methods (Wang and Cardie, 2013; Pighin et al., 2014; Bing et al., 2015) generate new sentences based on a set of sentence generation patterns learned from corpus or designed templates.

Recently, some works studied the use of deep learning techniques for abstractive summarization tasks, which use sequence-to-sequence generation techniques on single document or sentence summarization (Rush et al., 2015; Chopra et al., 2016). A multi-dimensional summarization methodology was proposed to transform the paradigm of traditional summarization research through multi-disciplinary fundamental exploration on semantics, dimension, knowledge, computing and cyber-physical society (Zhuge, 2016).

Event extraction. Event extraction is a traditional task in Information Extraction, which aims to recognize event mentions and arguments of predefined types (such as the ACE tasks). The works on event extraction either divide the task into separate subtasks, such as event-trigger extraction and argument extraction (Liao and Grishman, 2010; Hong et al., 2011) or model it jointly (Li et al., 2013; Li and Ji, 2014). These works mainly focus on predefined event and argument types. However, we focus on open-domain and more fine-grained event information extraction for multi-document summarization.

Abstract representations. With the development of Abstract Meaning Representation (AMR) (Banarescu et al., 2012), representing semantic information with graphs has been studied in such tasks as summarization (Liu et al., 2015) and event detection (Kai and Grishman, 2015). Although several techniques on parsing sentences to AMR (Flanigan et al., 2014; Wang et al., 2015) have been developed, the performance of AMR parsing is very limited at the present.

6 Conclusions

The approach proposed in this paper generates summary based on event information extraction and abstract representation, which achieves good performance on both DUC 2006 and DUC 2007 datasets. It generates new sentences based on structured event information and organizes sentences coherently based on semantic links. The experiment results show that the summaries generated by our system are relatively informative, coherent and compact, which demonstrates that the semantic link network based abstract representation of source texts is effective in making abstractive summarization.

Abstract

Extracting summaries via integer linear programming and submodularity are popular and successful techniques in extractive multi-document summarization. However, many interesting optimization objectives are neither submodular nor factorizable into an integer linear program. We address this issue and present a general optimization framework where any function of input documents and a system summary can be plugged in. Our framework includes two kinds of summarizers – one based on genetic algorithms, the other using a swarm intelligence approach. In our experimental evaluation, we investigate the optimization of two information-theoretic summary evaluation metrics and find that our framework yields competitive results compared to several strong summarization baselines. Our comparative analysis of the genetic and swarm summarizers reveals interesting complementary properties.

1 Introduction

Extractive multi-document summarization (MDS) is often cast as a discrete optimization problem where the document collection is considered as a set of sentences and the task is to select an optimal subset of the sentences under a length constraint. Many successful approaches solve this problem using integer linear programming (ILP) or submodular function maximization. Both ILP and submodular function maximization require that the objective function to maximize has certain properties: it needs to be submodular or linearly factorizable (for ILP). The commonly used optimization objective that combines maximizing the coverage of relevant units while minimizing their redundancy has been shown to be submodular by Lin and Bilmes (2011). Lin and Bilmes (2011) also proved that the summary evaluation metric ROUGE itself is submodular, which has been leveraged by Sipos et al. (2012) to optimize ROUGE directly via submodular function maximization. Peyrard and Eckle-Kohler (2016) optimize an approximation of ROUGE via ILP. Using ROUGE as an optimization objective in MDS is reasonable, because ROUGE-1 and ROUGE-2 have been shown to correlate well with the results of human evaluation (e.g., Owczarzak et al. (2012)), and are therefore good proxies for system summary quality.

The results we present in this paper start from the observation that ROUGE is just one possible proxy for summary quality – there are other automatic metrics to evaluate system summaries, which also correlate well with human judgments (Louis and Nenkova, 2013). For example, the Jensen Shannon divergence (JS divergence), an information-theoretic measure not relying on human-written summaries, compares system summaries with source documents regarding their underlying probability distribution of n-grams (Lin et al., 2006). However, unlike ROUGE, JS divergence is neither submodular nor factorizable (see, e.g., Louis and Nenkova (2013)), and consequently can not be optimized via ILP or submodular function optimization. Similarly, we can imagine other interesting, arbitrarily complex summary evaluation metrics, which are neither submodular nor factorizable, but which we might want to optimize. For example, we might be interested in combining several metrics such that the combination correlates well with human evaluation scores.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 247–257, Osaka, Japan, December 11-17 2016.

In order to solve a discrete optimization problem (which is NP-hard) in the general case, where the optimization objective does not have specific properties, we have to rely on search algorithms. A particular promising class of search algorithms to tackle this problem are metaheuristics (Bianchi et al., 2009). In this paper, we consider two kinds of metaheuristics – genetic algorithms and a swarm intelligence approach called Artificial Bee Colony – and propose a general optimization framework for MDS where the function to be optimized is a parameter and can be exchanged.

Our contributions can be summarized as follows: we present an optimization framework for extractive MDS that is able to optimize an arbitrarily complex objective function of input documents and a summary, without making any assumptions on its properties. For our framework, we developed two summarizers, one based on genetic algorithms, the other based on swarm intelligence. In our experimental evaluation, we investigate the optimization of information-theoretic summary evaluation metrics and find that our framework yields competitive results compared to several strong baselines. We also comparatively analyze the behavior of our two summarizers, and observe that there are several system summaries with very high ROUGE score, which have almost no sentences in common.

2 Background

Some branches of research on optimization study the landscape of functions to maximize (also called fitness landscape). When the landscape has particular properties, methods can be derived to find optima efficiently. For example, ILP leverages the linear properties (Schrijver, 1986) of an objective function. Recently, submodular functions have been extensively studied and simple algorithms have been proved to yield nice solutions (Krause and Golovin, 2014; Schrijver, 2003).

However, we might not want to restrict ourselves to particular kinds of functions, because often, the landscape of the objective function does not have easy to exploit properties (Bianchi et al., 2009). To maximize such functions, the optimization field developed techniques that do not make any assumption about their landscape (Blum and Roli, 2003; Wright, 1932; Fogel et al., 1966).

To solve such complex optimization problems, search-based techniques are used (i.e., they do not find the exact solution like ILP), which employ various strategies to efficiently explore the search space. The majority of the successful search-based techniques are biologically inspired and take efficient and adaptive optimization strategies used in nature as a role model.

These algorithms can roughly be divided into two main categories according to their biological inspiration: **Genetic algorithms** which simulate the evolution process, and **swarm intelligence** algorithms which simulate the behavior of swarms and colonies of animals such as bees, ants or fireflies.

Genetic Algorithms In artificial intelligence, genetic algorithms (GA) use mechanisms inspired by biological evolution, such as reproduction, mutation and selection (Wright, 1932; Goldberg, 1989).

The candidate solutions of the optimization problem are represented as individuals in a population. The fitness function is the function to optimize and determines the quality of an individual. To apply a GA to an optimization problem, the parameters that define a candidate solution are considered as the genotype of the individual. The genotype is the footprint that uniquely identifies every possible solution.

Evolution of the population takes place after multiple iterations where biological operators are applied: Reproduction and mutation search the space of solutions by creating new candidate solutions, while the selection operator ensures that better candidate solutions survive to the next generation more often than worse ones.

Swarm Intelligence Swarm Intelligence (SI) refers to the collective behavior of decentralized, self-organized artificial systems. The agents in such systems follow very simple rules, and although there is no centralized control structure, local and random interactions between agents lead to the emergence of intelligent global behavior, unknown to the individual agents themselves (Beni and Wang, 1993; Bonabeau et al., 1999; Parsopoulos and Vrahatis, 2002).

While the population of the GAs consists of candidate solutions, the swarm population is made up of agents which search the solution space and interact locally with the environment. The candidate solutions are points in the space investigated by the agents. The agent interactions with the candidate space usually

consist of the evaluation of a given area. To apply a SI algorithm to an optimization problem, one must define a space where candidate solutions live. A point in the space of candidate solutions is analogous to the vectors of genes (parameters, i.e., genotype) of the GA. Simple communication channels allow agents to exchange information about promising areas. Examples of such natural systems are ant colonies, fireflies glowing, fish schooling or bird flocking.

One successful model we decided to follow in this work is the model of honey bees searching for nectar in a field, also known as Artificial Bee Colony (ABC) (Karaboga and Basturk, 2007; Karaboga et al., 2014). In ABC, there are three groups of bees: employed bees, onlookers and scouts.

There is only one employed bee per food source (the number of employed bees in the colony is equal to the number of food sources investigated in parallel). Employed bees collect food from their food source and dance in this area after evaluating the quantity of food in the direct neighborhood. The dance indicates the amount of food in the area identified by the employed bee. When the food source is abandoned, the employed bee becomes a scout and starts to search for a new food source elsewhere. Onlookers watch the dances of employed bees and choose food sources which are especially promising. The overall behavior allows the swarm to find areas which contain a lot of nectar (or food). The employed bees and onlookers use the nectar function to evaluate the quantity of nectar at a given location (i.e., candidate solution) which is the equivalent to the fitness function in the GA.

We will study the differences and similarities of these algorithms when we adapt them to extractive summarization in the following section.

3 Optimization Framework

We propose a general framework that extracts a summary with high score for any metric that is a function of the source documents and the summary only. The metric to maximize is a parameter of our framework that can easily be changed. First, we present the metrics we considered in our framework, and then the optimization techniques we used.

3.1 Metrics

In our framework, we consider classical similarity metrics for comparing the source documents and the summary content.

As it was shown in previous work, good summaries are often characterized by a low divergence between the probability distributions of n-grams in the source documents and the summary (Haghighi and Vanderwende, 2009; Louis and Nenkova, 2013). One common metric for determining this divergence is the Kullback Leibler (KL) divergence. The KL divergence between two probability distributions P and Q is given by:

$$KL(P\|Q) = \sum_g p_P(w) log_2 \frac{p_P(w)}{p_Q(w)} \tag{1}$$

In the case of MDS, the two probability distributions P and Q are computed from the source documents and the summary.

Jensen Shannon (JS) divergence is a symmetric version of the KL divergence, incorporating the idea that the distance between two distributions cannot be very different from the average of distances from their mean distribution. It is given by:

$$JS(P\|Q) = \frac{1}{2}(KL(P\|A) + KL(Q\|A)) \tag{2}$$

where $A = \frac{P+Q}{2}$ is the mean distribution of P and Q.

The metrics are defined on the basis of n-grams, and are not restricted to words only. In practice, we use both the unigram and bigram version of these metrics. It is important to point out that these metrics only serve as example metrics – any other metric function of the input documents and the summary can be plugged into the framework.

3.2 Biologically-Inspired Optimization Techniques

In this section, we will describe how to adapt GA and SI to the problem of extractive summarization.

Genetic Summarizer In order to produce a Genetic Summarizer, we use a simple analogy to the problem of extractive summarization.

- **Population** The individuals of the population are the candidate solutions which are valid extractive summaries. Valid means that the summary meets the length constraint. The size of the population is a hyper-parameter of the algorithm.

- **Genome and Genotype** The genome is the set of sentences in the source documents of the topic. It corresponds to the building blocks of each possible individual. Then, the genotype of a summary is simply a binary vector indicating which sentences it contains.

- **Fitness Function** The fitness function which evaluates the individuals (i.e., summaries) is the function we wish to maximize (or minimize). For example, it might be one of the metrics we described above. The population is scored and sorted according to the fitness function, a threshold indicates which summaries will survive to the next generation. The survival rate is another hyper-parameter.

- **Mutation** The mutation of a summary is done by randomly removing one of its sentences and adding a new one that does not violate the length constraint. Mutation affects individuals of a population randomly, and the mutation rate is a hyper-parameter.

- **Reproduction** The reproduction is done by randomly selecting parents among the survivors of the previous generation. Then, the union set of the sentences of the parents is considered. The child is a random valid summary extracted from these sentences. Similar as for the mutation, we define a reproduction rate which controls the number of children in each generation.

- **Initial Population** The initial population is simply created by randomly building valid summaries. We observe a convergence speed-up if we help the algorithm by including good summaries in the initial population (e.g., summaries produced by baseline algorithms).

We note that in nature, the fertilized egg cell undergoes a process known as embryogenesis before becoming a mature embryo. This is believed to make the genetic search more robust by reducing the probability of fatal mutation. At each step, we only consider valid summaries, which is the direct analogy to embryogenesis.

Swarm Summarizer

- **Food Location** The locations in the field are the candidate solutions which are the valid extractive summaries. The number of food locations is a hyper-parameter equivalent to the size of the population in the Genetic Summarizer.

- **Location Coordinates** The summaries are points in the space searched by the bees. The coordinates are given by the binary vector indicating which sentences the summary contains. The coordinates of a food location is the equivalent to the genotype of an individual.

- **Nectar Function** The nectar function which evaluates the food locations (i.e., summaries) is the function to maximize. It corresponds to the fitness function.

- **Employed Bees Local Search** At each iteration, employed bees evaluate the direct neighborhood of their assigned food location. To move to a neighbor, a sentence is randomly removed from the current summary (i.e., food location) and a new sentence that does not violate the length constraint is added. This is the analogy to a mutation.

- **Employed Bees Dance and Onlooker Bees** When employed bees have evaluated the summaries, all the summaries are scored and sorted. Onlooker bees observe this distribution of scores and randomly choose one location to join and help with the neighbor search. This random choice is based on the following probability:

$$P_i = \frac{score_i}{\sum_k score_k} \tag{3}$$

  As a result, onlookers choose high scoring locations (i.e., summaries) more often.

- **Scouting Bees** An employed bee stays in place if the neighbor it evaluates is not better than its current location. After several iterations at the same place, it abandons it and becomes a scouting bee. To move to another place, the scouting bee selects a random valid summary. This is equivalent to generating an individual from the initial population in the Genetic Summarizer. The number of iterations before becoming a scouting bee is the second hyper-parameter of the Swarm Summarizer.

Genetic vs. Swarm In the Genetic Summarizer, the reproduction produces significant changes in the summaries studied, because, on average, half of the genotype of the child is different from its parents. But at the same time, it stays in a reasonable distance range from its parents because it keeps half of the genotype from each parent (on average). In this sense, we say that the Genetic Summarizer has efficient mid-range search capabilities. The local search is much reduced because it is done via mutations happening randomly and rarely in the population. The long-range search is done via insertion of random individuals into the population whenever the population becomes too small. A new completely random individual is quite likely to have a low fitness score and to die in the next generation with few opportunities to reproduce or mutate.

The Swarm Summarizer has complementary strengths and weaknesses. The employed bees perform intensive local search around a specific location and the onlooker bees help them around the locations of interest. For long-range search, the scout bees regularly look for new locations and investigate each new area for at least t rounds (where t is the hyper-parameter controlling the number of retry before becoming a scout bee). However, in the Swarm Summarizer, the mid-range search is limited compared to the reproduction mechanism, because it is achieved only by either successfully applying several local movements, or by randomly scouting the mid-range areas, both of which are unlikely.

Even if we did not conduct an extensive hyper-parameters optimization, we observe that the Swarm Summarizer has much less hyper-parameters, which would make it simpler to optimize.

4 Experiments

4.1 Summarizer Performance

Baselines: We compare our algorithms to several classical baselines:

TF*IDF weighting This simple heuristic was introduced by Luhn (1958). Each sentence receives a score from the TF*IDF of its terms and the best sentences are greedily extracted until the length constraint is met.

LexRank (Erkan and Radev, 2004) is a popular graph-based approach. A similarity graph $G(V, E)$ is constructed where V is the set of sentences and an edge e_{ij} is drawn between sentences v_i and v_j if and only if the cosine similarity between them is above a given threshold. Sentences are scored according to their PageRank score in G. We use the implementation available in the sumy package.[1]

ICSI (Gillick and Favre, 2009) is a recent system that has been identified as one of the state-of-the-art systems by Hong et al. (2014). It is a global linear optimization framework that extracts a summary by solving a maximum coverage problem considering the most frequent bigrams in the source documents. Boudin et al. (2015) released a Python implementation (ICSI sume) that we use in our experiments.

KL-div Greedy Haghighi and Vanderwende (2009) presented a greedy algorithm to minimize the KL-divergence of extracted summaries. The approach iteratively selects a sentence s_i to be included in the summary S, which is done by picking the sentence that minimizes the KL divergence between the

Table 1: Performance of biologically inspired algorithms to minimize JS and KL divergence.

word distributions of the original input documents and $S \cup s_i$. We also implement **JS-div Greedy** which is the same greedy algorithm, but minimizes JS divergence instead.

Experimental Setup: In our experiments, we use two datasets from the Document Understanding Conference (DUC) (Over et al., 2007), namely the datasets from 2002 and 2003 (DUC-02 and DUC-03). We compare algorithms with the JS divergence metric for both the unigrams (JS-1) and the bigrams (JS-2) variants. The results are shown in Table 1. For completeness, we also report the ROUGE scores identified by Owczarzak et al. (2012) as strongly correlating with human evaluation methods: ROUGE-1 (R-1) and ROUGE-2 (R-2) recall with stemming and stopwords not removed. Our algorithms are denoted by F-A-(2), where F is the function minimized, A is the algorithm used (Genetic or Swarm), and 2 is present if the bigram version of the function is minimized.

We use a standard implementation of JS divergence with stemming to get the JS divergence scores. ROUGE scores are obtained with the ROUGE-1.5.5 toolkit.[2]

Results Analysis: We observe that Genetic and Swarm summarizers have similar performances, there is no statistically significant difference when evaluated with JS and ROUGE evaluation metrics.

Both summarizers outperform the greedy versions by a large margin in all experiments. This shows that the Genetic and Swarms summarizers are strong search algorithms for extractive summarization.

We compare the behavior of Swarm and Genetic in more detail in section 4.2.

Our summarizers perform on par with the state-of-the-art algorithm ICSI in terms of ROUGE (no statistically significant difference). However, the Genetic and Swarm summarizers perform significantly better for the JS divergence evaluation metric. This suggests that there are several different high scoring summaries in terms of ROUGE, and our algorithms find summaries different from ICSI. We investigate this observation in more detail in section 4.3. ROUGE is known to have issues with distinguishing good summaries, and here we observe that JS is a complementary metric allowing us to distinguish high-scoring summaries.

The biologically inspired algorithms can even outperform ICSI and the other baselines for the ROUGE metric, thus confirming the correlation between JS divergence and ROUGE.

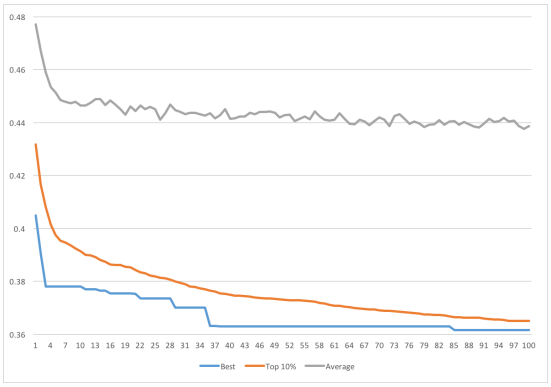
4.2 Convergence behavior

In this section, we study the behavior of our algorithms by investigating the convergence process of both the Genetic Summarizer and the Swarm Summarizer. For this experiment, we focus on the JS divergence minimization with the topic d30003t of DUC-2003.

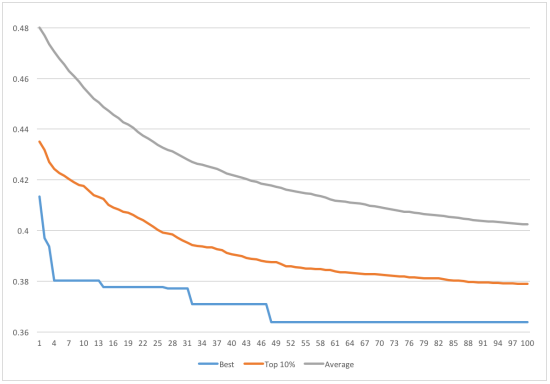
We plot in Figure 1a a graph displaying the evolution of three measures of the Genetic Summarizer across generations: the JS divergence of the best individual found, the average JS divergence of the top

[2]ROUGE-1.5.5 with the parameters: -n 2 -m -a -l 100 -x -c 95 -r 1000 -f A -p 0.5 -t 0. The length parameter becomes -l 200 for DUC-02.

10% of the population, and the average JS divergence of the population. The same analysis is reported for the Swarm Summarizer in Figure 1b.



(a) Genetic Summarizer convergence behavior (d30003t from DUC-2003).



(b) Swarm Summarizer convergence behavior (d30003t from DUC-2003).

Similarities: For both summarizers, the score of the best solution is quickly decreasing until some plateau is reached. Then, only punctual breakthroughs lead to significant improvements of the best solution. The top 10% of the population is regularly improving, following an exponentially decreasing curve, which makes it a good indicator that the algorithm has converged. Indeed, the best individual curve can plateau for several iterations and experience a large jump in one iteration. In Figure 1a, we observe a big breakthrough at generation 35 after a long period without improvement.

Differences: In the Genetic Summarizer, the average of the whole population quickly drops in the first few iterations and then stabilizes. In contrast, in the Swarm Summarizer, the curve of the overall average follows the curve of the top 10%.

The Genetic algorithm includes a lot of randomness at each generation. The majority of the population is randomly generated at each iteration (random restart and reproduction), and therefore the average of the population stays constant (there is a drop in the first iterations because the best members of the population are not random).

In the Swarm Summarizer, the randomness is controlled and the focus is put on local search. Employed bees and onlooker bees work on promising areas, and new random restarts (scouting bees) are introduced only when an area is not promising enough. By driving its workforce towards local search around promising areas, the Swarm Summarizer keeps working around better solutions.

For the Genetic summarizer, we also observe that the best elements of the population are closing the gap with the best individual, and the newly accumulated potential in the population allows for a new breakthrough via reproduction. The top 10% of the population are closer to the best solution than the top 10% of the Swarm summarizer.

With a good initialization (by introducing good summaries in the initial candidate solutions), the Swarm Summarizer converges much faster than the Genetic Summarizer. While the Genetic Summarizer keeps finding breakthroughs after 85 iterations, the Swarm Summarizer has converged already after 50 iterations.

In terms of runtime, both algorithms can find summaries close to the best ones after only several seconds. The Swarm Summarizer converges within about a minute for a given topic, while the Genetic Summarizer converges within 2-3 minutes on average [3].

4.3 Summaries Found

Our experiments in section 4.1 suggested that there are several different high scoring summaries. In this section, we study how different the summaries are from each other, and measure the diversity of the summaries discovered by our techniques.

[3] On a standard MacBook Pro with 16GB of RAM and i5 2.9GHz.

	JS-Gen	JS-Swarm
Jaccard to ICSI	0.0556	0.0610
Jaccard among top 10% (avg.)	0.4350	0.1786

Table 2: Diversity of summaries found by JS-Gen and JS-Swarm.

We know from section 4.1 that summaries produced by our algorithms and ICSI have many words and bigrams in common. However, since extractive MDS is a combinatorial problem, we can compare two summaries by comparing which sentences have been selected.

For this, we use the Jaccard distance between two summaries (each represented as set of sentences). It indicates the percentage of sentences two summaries have in common. We measure the Jaccard distance between the summaries of ICSI and the ones created by JS-Gen and JS-Swarm. To measure the diversity among the summaries found by our summarizers, we also measure the average Jaccard distance between two summaries belonging to the top 10% of solutions. The results are reported in Table 2. Surprisingly, we see that the summaries found by JS-Gen or JS-Swarm and those found by ICSI do use different sentences, as they have less than 10% of sentences in common – even though the JS-Gen and JS-Swarm summaries tend to use the same words and bigrams as ICSI. As they are not significantly different in terms of ROUGE scores, this indicates that there exist several extractive summaries with high ROUGE scores. In contrast, the JS divergence metric is able to distinguish between these summaries with high ROUGE scores.

We also observe that JS-Swarm works on more diverse summaries than JS-Gen, because the average Jaccard distance between summaries in the top 10% is much smaller compared to JS-Gen. JS-Swarm is capable of finding high scoring summaries in different areas and is therefore more likely to identify many of the different good summaries.

5 Related Work and Discussion

Previous applications of metaheuristics in the context of MDS used several different approaches to solve the MDS task. There are clustering-based approaches where metaheuristics are used to obtain a good sentence clustering (Aliguliyev, 2009; Song et al., 2011), and also ranking-based approaches where metaheuristics perform an optimization of an importance metric for sentence scoring (Litvak et al., 2010).

Most related to our framework is previous work where extractive MDS is also cast as a discrete optimization problem that is solved using metaheuristics. Several approaches applied genetic algorithms or variants to perform extractive MDS, but used different optimization objectives than us. Alguliev et al. (2013) employ differential evolution, an algorithm similar to GA where mutation is the main operation, and optimize a combination of content coverage and diversity. However, the runtime complexity of differential evolution is high and also depends on the runtime complexity of the fitness function used, which is high as well because their function includes a similarity comparison between sentences.

Nandhini and Balasundaram (2013) also use GA for extractive MDS, but consider the creation of assistive summaries rather than generic ones, and thus optimize a combination of readability, cohesion and topic-relatedness. He et al. (2006) use GA with an objective that combines the maximization of informativeness, the reduction of redundancy and also includes the length constraint. In contrast, our use of GA performs embryogenesis, i.e., non-valid individuals (summaries that do not have the required length) are not born.

While we considered KL and JS divergence as exemplary optimization objectives in our framework, any metric that is a function of the input documents and the summary can be used instead (e.g., other metrics from previous works), and also any combination of such metrics. Provided that human evaluation scores are available, we could even learn such a combination metric with the training objective that it correlates well with the human scores. This makes our optimization framework highly customizable to more specific summarization tasks, or genres other than newswire, where JS divergence might not be the best optimization objective (such as opinion and biographical texts as studied by Saggion et al. (2010)). To encourage the community to experiment with different metrics and summarization tasks, we provide the implementation of both the genetic and swarm summarizer at `https://github.com/UKPLab/`

coling2016-genetic-swarm-MDS.

6 Conclusion

We presented a general optimization framework for extractive MDS where any function of input documents and summary can be plugged in and used as an optimization objective. The algorithms we consider belong to the class of metaheuristics, and we developed an adaptation of genetic algorithms and of a swarm intelligence approach called Artificial Bee Colony to the task of extractive MDS. The Python implementation of the genetic and swarm summarizers is freely available[4] and can be extended with any other scoring function. As exemplary optimization objectives, we studied the summary evaluation metrics KL divergence and JS divergence. Our evaluation on the DUC-02 and DUC-03 datasets shows a competitive performance of our framework. In our detailed analysis we found interesting complementary properties of the genetic and swarm summarizers and of a strong baseline.

Abstract

This paper presents a deep learning architecture for the semantic decoder component of a Statistical Spoken Dialogue System. In a slot-filling dialogue, the semantic decoder predicts the dialogue act and a set of slot-value pairs from a set of n-best hypotheses returned by the Automatic Speech Recognition. Most current models for spoken language understanding assume (i) word-aligned semantic annotations as in sequence taggers and (ii) delexicalisation, or a mapping of input words to domain-specific concepts using heuristics that try to capture morphological variation but that do not scale to other domains nor to language variation (e.g., morphology, synonyms, paraphrasing). In this work the semantic decoder is trained using unaligned semantic annotations and it uses distributed semantic representation learning to overcome the limitations of explicit delexicalisation. The proposed architecture uses a convolutional neural network for the *sentence representation* and a long-short term memory network for the *context representation*. Results are presented for the publicly available DSTC2 corpus and an In-car corpus which is similar to DSTC2 but has a significantly higher word error rate (WER).

1 Introduction

In most existing work on Spoken Language Understanding (SLU), semantic decoding is usually seen as a sequence tagging problem with models trained and tested on datasets with word-level annotations (Tür et al., 2013; Mesnil et al., 2015; Yao et al., 2013; Sarikaya et al., 2011; Deoras and Sarikaya, 2013; Sarikaya et al., 2014). Spoken language understanding from *unaligned data*, in which utterances are annotated with an abstract semantics, faces the additional challenge of not knowing which specific words are relevant for extracting the semantics. This problem was tackled in (Zhou and He, 2011), by using conditional random fields (CRFs) driven by finely-tuned hand-crafted features. Other discriminative approaches that deal with unaligned data use some form of *delexicalisation* or mapping of the input to known ontological concepts (Henderson et al., 2012; Henderson et al., 2014a). The main disadvantage of delexicalisation is the difficulty in scaling it, not only to larger and more complex dialogue domains but also to handle the many forms of language variation.

We propose in this paper a semantic decoder that learns from unaligned data (Figure 1) and that exploits rich semantic distributed word representations instead of delexicalisation. The semantic decoder predicts the dialogue act and the set of slot-value pairs from a set of n-best hypotheses returned by an automatic speech recognition (ASR). The prediction is made in two steps. First, a deep learning architecture is used for the joint prediction of dialogue acts and the presence or absence of slots. Second, the same architecture is reused for predicting the values of the slots that were detected by the first joint-classifier. The deep architecture combines sentence and context representations. A convolutional neural network (CNN) (Collobert et al., 2011) is used to generate the sentence representation, while a long-short term memory (LSTM) network (Hochreiter and Schmidhuber, 1997) is used to generate the context representation. A non-linear function then combines the top layers of these neural networks and distinct softmax layers are used to predict the dialogue act and slots in the first joint model. In the second model, a single softmax predicts the possible values for each slot.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 258–267, Osaka, Japan, December 11-17 2016.

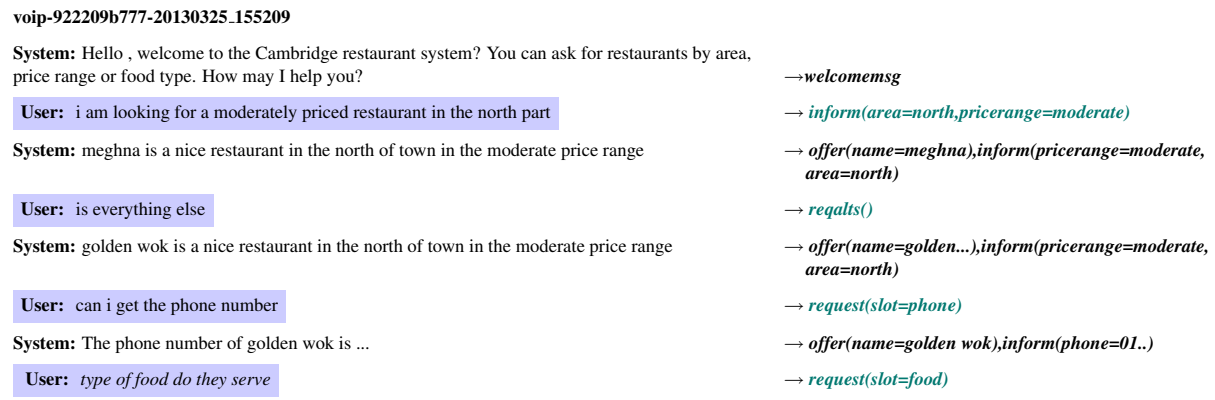

Figure 1: Excerpt from a dialogue in the DSTC2 corpus. The top-best ASR hypothesis is shown highlighted on the left, and the corresponding user semantics is shown highlighted on the right.

Our models are evaluated on two datasets DSTC2 (Henderson et al., 2014b) and In-car (Tsiakoulis et al., 2012) using accuracy, f-measure and the Item Cross Entropy (ICE) score (Thomson et al., 2008). We show that these models outperform previous proposed models, without using manually designed features and without any preprocessing of the input (e.g., stop words filtering, delexicalisation). They do this by exploiting distributed word representations and we claim that this allows semantic decoders to be built that can easily scale to larger and more complex dialogue domains.

The remainder of this paper is structured as follows. We first present related work in Section 2 and then we describe our architecture in Section 3. We describe the experimental setup in 4 and the evaluation results are introduced in Section 5. Finally, we present conclusions and future work in Section 6.

2 Related Work

Sequence tagging discriminative models such as CRFs and sequence neural networks have been widely explored for spoken language understanding. For instance, Recurrent Neural Networks have been proposed in (Yao et al., 2013; Mesnil et al., 2015) and generative Deep Neural Networks consisting of a composition of Restricted Boltzmann Machines (RBM) have been studied by (Sarikaya et al., 2011; Deoras and Sarikaya, 2013; Sarikaya et al., 2014). A combination of neural networks and triangular CRFs is presented in (Celikyilmaz and Hakkani-Tur, 2010), in which a convolutional neural network is used for extracting the input features of a triangular CRF in order to perform joint intent detection and slot filling. All these models use word-level semantic annotations. However, providing these word-level semantic annotations is costly since it requires specialised annotators. (Zhou and He, 2011) has proposed learning CRFs from unaligned data, however they use manually tuned lexical or syntactic features. In this work we avoid the need for word-level annotation by exploiting distributed word embeddings and using deep learning for feature representation.

Convolutional Neural Networks (CNNs) have been used previously for sentiment analysis (Kim, 2014; Kalchbrenner et al., 2014) and in this work we explore a similar CNN to the one presented by Kim (2014) for generating a sentence representation. However unlike Kim (2014), the input in not a single well formed sentence but a set of ill-formed ASR hypotheses. Additionally, the softmax layer used for binary classification (i.e., positive or negative sentiment) is replaced by a softmax layer for multiclass dialogue act prediction and a further softmax layer is added for each distinct slot in the domain. (Chen and He, 2015) proposed a CNN for generating intent embeddings in SLU, which uses tri-letter input vectors. Instead, in this paper the models are initialised with GloVe word embeddings (Pennington et al., 2014). These GloVe embeddings were trained in an unsupervised fashion on a large amount of data to model the contextual similarity and correlation between words. Chen and He's model aims to learn the embeddings for utterances and intents such that utterances with similar intents are close to each other in the continuous space. Although we share the same spirit, we use sentence embeddings not only for intent

(or dialogue act) recognition but also for slot-filling within a dialogue system and we combine them with embeddings for dialogue context.

Approaches for adaptive SLU have been proposed in (Ferreira et al., 2015; Zhu et al., 2014), however they focused more on domain adaptation on top of an existing SLU component. Moreover, they use classical discriminative models for SLU such as CRFs and SVMs that require manually designed features. In contrast, the focus of this paper is to exploit deep learning models for SLU, which learn feature representations automatically.

Recently, some researchers have focused on mapping word level hypotheses directly to beliefs without using an explicit semantic decoder step (Henderson et al., 2014a; Mrkšić et al., 2015). These systems track the user's goal through the course of the dialogue by maintaining a distribution over slot-value pairs. Such systems are interesting, but it is not clear that they can be scaled to very large domains due to the constraint of delexicalisation. Furthermore, they still require an explicit semantic decoding layer for domain identification and general *Topic Management*.

3 Deep Learning Semantic Decoder

We split the task of semantic decoding into two steps: (i) training a joint model for predicting the dialogue act and presence or absence of slots and (ii) predicting the values for the most probable slots detected in (i). As shown in Figure 2, we use the same deep learning architecture in both steps for combining sentence and context representations to generate the final hidden unit that feeds one or many softmax layers. In the first step, as shown in the Figure, there are distinct softmax layers for the joint optimisation of the dialogue act and each possible slot. In the second step there is a single softmax layer that predicts the value of each specific slot. In the following we explain this architecture in more detail.

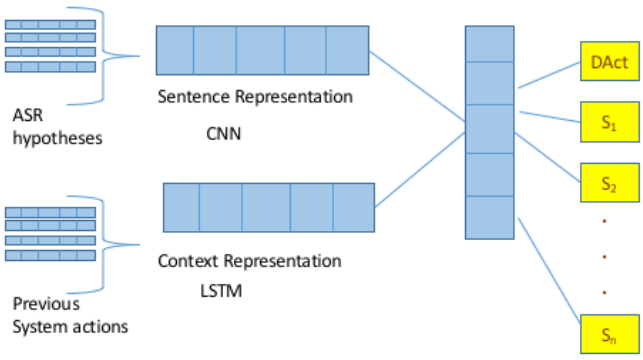

Figure 2: Combination of sentence and context representations for the joint prediction of dialogue acts and slots.

3.1 Sentence Representation

A CNN is used for generating the hypothesis representation, then these representations are weighted by their confidence scores and then summed up to obtain the sentence representation (Figure 3).

The CNN is a variant of (Kim, 2014), in which the inputs are the word vectors in each *ASR hypothesis*. Let x_i be a $k-$dimensional word embedding for the i-th word in a hypothesis. A hypothesis of length m is represented as: $x_{1:m} = \mathbf{x}_1 \bigoplus \mathbf{x}_2 \bigoplus ... \bigoplus \mathbf{x}_m$ where $\bigoplus$ is the concatenation operator. A convolutional operation is applied to a window of l words to produce a new feature.

$$c_i = f(\mathbf{w} \cdot \mathbf{x}_{i:i+l-1} + b) \tag{1}$$

where f is the hyperbolic tangent function; $w \in \mathbb{R}^{lk}$ is a filter applied to a window of l words and $b \in \mathbb{R}$ is a bias term. The filter is applied to every window of words in the sentence to produce a feature map.

$$\mathbf{c} = [c_1, c_2, ..., c_{n-l+1}] \tag{2}$$

with $\mathbf{c} \in \mathbb{R}^{n-l+1}$. A max pooling operation is then applied to give the maximum value $c = max\{\mathbf{c}\}$ as the representative feature for that filter. Multiple filters can be applied by varying the window size to obtain several adjacent features for a given hypothesis. These features $\hat{f}_j$ for the hypothesis $j \in H$ are then multiplied by the ASR confidence score p_j[1] and summed over all ASR hypotheses to generate a representation for the sentence s_t (Equation 3), as shown in Figure 3.

$$s_t = \sum_{j \in H} \hat{f}_j * p_j \tag{3}$$

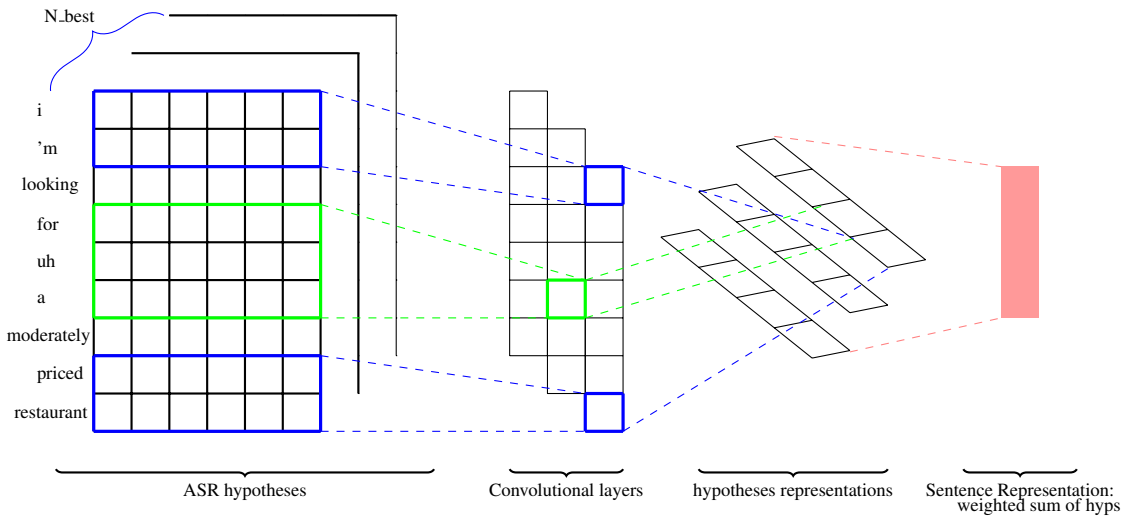

Figure 3: Sentence Representation: after applying convolution operations on the N-best list of ASR hypotheses, the resulting hidden layers are weighted by the ASR confidence scores and summed.

3.2 Context Representation

An LSTM (Hochreiter and Schmidhuber, 1997) is used for tracking the context implied by previous dialogue system actions. The top layer of this LSTM network then provides the context representation for decoding the current input utterance.

An LSTM is a sequence model that utilises a memory cell capable of preserving states over long periods of time. This cell is recurrently connected to itself and it has three multiplication units, an input gate, a forget gate and an output gate. These gating vectors are in [0,1]. The cell makes selective decisions about what information is preserved, and when to allow access to units, via gates that open and close. The LSTM transition equations are as follows:

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}^{(i)} \cdot x_t + \mathbf{U}^{(i)} \cdot h_{t-1} + b^{(i)}), \\
\mathbf{f}_t &= \sigma(\mathbf{W}^{(f)} \cdot x_t + \mathbf{U}^{(f)} \cdot h_{t-1} + b^{(f)}), \\
\mathbf{o}_t &= \sigma(\mathbf{W}^{(o)} \cdot x_t + \mathbf{U}^{(o)} \cdot h_{t-1} + b^{(o)}), \\
\mathbf{u}_t &= tanh(\mathbf{W}^{(u)} \cdot x_t + \mathbf{U}^{(u)} \cdot h_{t-1} + b^{(u)}), \\
\mathbf{c}_t &= \mathbf{i}_t \bigodot \mathbf{u}_t + \mathbf{f}_t \bigodot \mathbf{c}_{t-1}, \\
\mathbf{h}_t &= \mathbf{o}_t \bigodot tanh(\mathbf{c}_t)
\end{aligned} \tag{4}$$

where h_t is the hidden unit at time step t, x_t is the input at the current time step, b is a bias, σ is the logistic sigmoid function and $\bigodot$ denotes elementwise multiplication.

As shown in Figure 1, system actions are encoded in the form of a system dialogue act plus one or more slot-value pairs. To track the history of system actions, slots and values are treated as words and the input x_t is formed from its corresponding word vectors. The length of the context can vary. We consider

[1]The posterior probability of hypothesis j in the N-best list.

all the system actions previous to the current user utterance, or a window l of the previous system actions. For instance, if we are currently processing the last user input in Figure 1, in which L is the total number of system actions, we can consider all previous system actions (L=4), or the last l system actions, where $l < L$.

3.3 Combining Sentence and Context

We study in this paper two ways of combining the sentence $\mathbf{s}_t$ and the context $\mathbf{h}_t$ representations. The first straightforward way is to apply a non linear function to their weighted sum:

$$\hat{\mathbf{h}}_\mathbf{t} = tanh(\mathbf{Ws} \cdot \mathbf{s}_t + \mathbf{Wc} \cdot \mathbf{h}_t) \tag{5}$$

The second way is to let the sentence representation be the last input to the LSTM network, then $\hat{\mathbf{h}}_\mathbf{t} = \mathbf{h}_t$.

For classification a softmax layer is used for each prediction:

$$P(Y = k|\hat{h}, W, b) = \frac{e^{(W_k \hat{h} + b_k)}}{\sum_{k\prime} e^{(W_{k\prime} \hat{h} + b_{k\prime})}} \tag{6}$$

where k is the index of the output neuron representing one class. For dialogue act classification k is one of the possible values: inform, request, offer, ... etc. For the slot prediction k is either 0 for absent or 1 for present. For slot-value prediction k will correspond to one of the possible values for each slot. For instance, for the slot price-range the possible values are cheap, moderate, expensive and dontcare. The result of the prediction is the most probable class:

$$\hat{y} = \text{argmax}_k(P(Y = k|\hat{h}, W, b)) \tag{7}$$

The back-propagation optimisation is done by minimising the negative log-likelihood loss function through stochastic gradient descent.

4 Experimental Evaluation

In this section we introduce the corpora, and describe the experiments performed and the evaluation metrics used.

4.1 Corpora

Experimental evaluation used two similar datasets: DSTC2 (Henderson et al., 2014b) and In-car (Tsiakoulis et al., 2012). Both corpora were collected using a spoken dialogue system which provides restaurant information system for the city of Cambridge. Users can specify restaurant suggestions by area, price-range and food type and can then query the system for additional restaurant specific information such as phone number, post code and address. The first dialogue corpus was released for the dialogue state tracking challenge and we use here the semantic annotations that were also provided [2]. The trainset has 2118 dialogues and 15611 turns in total while the testset has 1117 dialogues and 9890 turns in total.

The second corpus contains dialogues collected under various noisy in-car conditions. In a stationary car with the air conditioning fan on and off, in a moving car and in a car simulator (Tsiakoulis et al., 2012) [3]. The trainset has 1508 dialogues and 10532 turns in total and the testset has 641 dialogues and 4861 turns in total. Because of the noise, the average word error rate (WER = 37%) is significantly higher than for DSTC2 (around 29%).

4.2 Hyperparameters and Training

Dropout was used on the penultimate layers of both the CNN and the LSTM networks to prevent co-adaptation of hidden units by randomly dropping out a proportion of the hidden units during forward propagation (Hinton et al., 2012). The models were implemented in Theano (Bastien et al., 2012). We

[2]The DSTC2 corpus is publicly available in: `http://camdial.org/~mh521/dstc/`

[3]This corpus has been obtained in an industry funded project and therefore it is not available for public use.

used filter windows of 3, 4, and 5 with 100 feature maps each for the CNN. A dropout rate of 0.5 and a batch size of 50 was employed, 10% of the trainset was used as validation set and early stopping was adopted. Training is done through stochastic gradient descent over shuffled mini-batches with Adadelta update rule (we used an adadelta decay parameter of 0.95). To initialise the models, GloVE word vectors were used (Pennington et al., 2014) with a dimension $d = 100$. System-action word-embeddings are tuned during training, instead hypothesis word-embeddings are not because of the heavy computations.

4.3 Experiments

Step I: Joint classification of dialogue-acts and slots: We evaluated five different model configurations for the joint classification of dialogue-acts and presence or absence of slots.

- **CNN**: the softmax layers for the joint classification of dialogue acts and slots are connected directly to the CNN sentence representation with no context.
- **CNN+LSTM**: we study the influence of context by considering the previous system actions (Section 3.2, Eq. 5), here we study the different context length, by using a context window of 1, 4, and all the previous system actions, namely **CNN+LSTM_w1**, **CNN+LSTM_w4** and **CNN+LSTM_w** respectively.
- **LSTM_all**: Finally, we study the impact of long distance dependencies, by using mainly the LSTM model, with the previous system actions as input, but we inject the sentence representation as the last LSTM input.

Step II: Classification of slot value pairs: We select the best model in step I for predicting the presence of slots, then for each slot present we predict the value, by using again the best architecture from the previous step.

4.4 Evaluation Metrics

We evaluate the performance of our models by using the conventional metrics for classification, namely accuracy, precision, recall and F-measure (F1-score).

In addition, we used the ICE score (Eq. 8) between the hypotheses and the reference semantics (ie. ground-truth) to measure the overall quality of the distribution returned by the models(Thomson et al., 2008). Let U be the number of utterances and W be the number of available semantic items. Given $u = 1..U$ and $w = 1...W$, let:

$$c_{uw} = \begin{cases} p, \text{ the confidence assigned to the hypothesis that the } w^{th} \text{ semantic item is part of utterance } u, \\ 0, \text{ if none was assigned.} \end{cases}$$

$$\delta_{uw} = \begin{cases} 1, \text{ if the } w^{th} \text{ item is in the reference semantics for } u, \\ 0, \text{ otherwise} \end{cases}$$

and $N = \sum_{uw} \delta_{uw}$, be the total number of semantic items in the reference semantics.

$$\text{ICE} = \frac{1}{N_w} \sum - \log(\delta_{uw} c_{uw} + (1 - \delta_{uw})(1 - c_{uw}) \tag{8}$$

5 Results and Discussion

In this section we report the results on DSTC2 and In-car dialogue corpora.

Step I: Joint classification of dialogue-acts and slots: For this step, the classifiers must predict jointly 14 dialogue acts and 5 slots for the DSTC2 dataset as well as 14 dialogue acts and 7 slots for the In-car dataset. We evaluate both (i) using 10 fold cross-validation on the trainsets and (ii) on the corpora' testsets.

Table 1 shows the 10 fold cross-validation results on both corpora. These results suggest that for DTSC2, the context representation is not significantly impacting the prediction. Although, the model with a window of 4 ,**CNN+LSTM_w4**, improves slightly the accuracy and f1-score. On the In-car dataset, however, including the context does help to disambiguate the semantic predictions from ill-formed hypotheses. This is expected, since this data set has a much higher error rate and hence higher levels of confusion in the ASR output. Although there is no significant difference on the f1-score when using the immediate previous system act ($w1$) or a longer context, **CNN+LSTM_w** gives a better accuracy and a lower ICE score on this dataset.

Corpus	Metric	CNN	CNN+LSTM		
-	-	-	w1.	w4	w
DSTC2	acc.	$96.1\% \pm 0.002$	$95.97\% \pm 0.003$	$\mathbf{96.11}\% \pm 0.002$	$95.9\% \pm 0.003$
	P.	$90.17\% \pm 0.007$	$89.33\% \pm 0.007$	$89.77\% \pm 0.004$	$89.21\% \pm 0.008$
	R.	$85.61\% \pm 0.009$	$85.66\% \pm 0.007$	$86.40\% \pm 0.006$	$85.96\% \pm 0.006$
	F1	$87.8\% \pm 0.007$	$87.43\% \pm 0.006$	$\mathbf{88.03}\% \pm 0.004$	$87.53\%0.005$
	ICE	$\mathbf{0.245 \pm 0.013}$	0.275 ± 0.02	0.271 ± 0.02	0.277 ± 0.02
In-car	acc.	$90.45\% \pm 0.005$	$91.66\% \pm 0.003$	$91.49\% \pm 0.007$	$\mathbf{91.77}\% \pm 0.04$
	P.	$83.87\% \pm 0.01$	$84.31\% \pm 0.01$	$84.16\% \pm 0.01$	$83.89\% \pm 0.01$
	R.	$71.57\% \pm 0.007$	$74.91\% \pm 0.005$	$74.6\% \pm 0.02$	$74.76\% \pm 0.01$
	F1	$76.96\% \pm 0.008$	$\mathbf{79,16}\% \pm \mathbf{0.003}$	$78.85\% \pm 0.01$	$78.83\% \pm 0.007$
	ICE	0.498 ± 0.0013	0.457 ± 0.02	0.459 ± 0.03	$\mathbf{0.448 \pm 0.02}$

Table 1: 10 fold cross-validation evaluation of step I, the joint classification of dialogue acts and slots. Here we study the impact of the context by comparing **CNN** and **CNN+LSTM**.

Table 2 shows the results on the test sets. Consequently, when evaluating on the DSTC2 test set, a window of 4 ($w4$), performs slightly better than other window sizes and better than the simple **CNN** model. On the In-car testset, a context window of 4 outperforms all the other settings: **CNN+LSTM**. However, on this test set using the sentence representation as the last input to the LSTM context neural network (section 3.3) improves the f1-score and reduces the ICE error.

Corpus	Metric	CNN	CNN+LSTM			LSTM_all
-	-	-	w1.	w4	w	-
DSTC2	acc.	96.03%	95.79%	95.79%	95.69%	95.59%
	P.	89.73%	88.69%	88.95%	88.38%	88.15%
	R.	84.74%	85.09%	86.02%	85.96%	84.76%
	F1	87.14%	86.83%	**87.43%**	87.12%	86.42%
	ICE	**0.268**	0.278	0.292	0.297	0.308
In-car	acc.	**87.60%**	82.19%	82.25%	82.14%	82.3%
	P.	69.96%	79.52%	79.29%	80.25%	78.12%
	R.	62.14%	71.09%	71.59%	70.9%	74.04%
	F1	65.53%	74.89%	75.15%	75.02%	**75.9%**
	ICE	1.332	1.344	1.333	1.421	**1.106**

Table 2: Evaluation of the Step I on DSTC2 and In-car testsets. We also compare two ways of combining sentence and context representation: **CNN+LSTM** models (combining sentence and context representation through a non linear function) and **LSTM_all** model (embedding the sentence representation into the context model).

Step II: Prediction of slot value pairs For evaluating Step II, we selected the best model obtained during the 10-fold cross-validation experiments in terms of F1 score. For both corpora, this was the **CNN+LSTM_w4** configuration. For DSTC2, it was the 4^{th}-fold crossvalidation with $Acc = 90.42\%$,

$F1 = 88.69\%$ and ICE $= 0.251$. For In-car, it was the 5^{th}-fold crossvalidation with $Acc = 93.13\%$, $F1 = 81.49\%$ and ICE $= 0.393$. We used these models to classify whether a given slot appears in a given hypothesis or not. Then for that slot, we train another **CNN+LSTM_w4** classifier for predicting its values. In the In-car corpus the slot "type" has only one possible value "restaurant". Similarly, the slot "task" can only be the value "find". For these slots with only one value, we report values using the model of Step I, since it is enough to detect the slot in the utterance.

	DSTC2					In-car				
Slot	Acc.	P.	R.	F1	ICE	Acc.	P.	R.	F1	ICE
Slot[4]	95.29%	90.89%	95.72%	93.24%	0.478	89.92%	74.73%	61.56%	67.51%	0.743
Area	91.77%	92.66%	92.83%	92.74%	0.563	72.03%	72.56%	74.28%	73.41%	1.676
Food	71.37%	73.19%	76.02%	74.58%	1.989	66.46%	64.27%	68.70%	66.41%	2.309
Price	94.62%	91.33%	94.49%	92.89%	0.729	93.96%	88.77%	92.03%	90.37%	0.632
This[5]	98.70%	96.79%	93.92%	95.33%	0.113	97.16%	96.14%	84.72%	90.07%	0.214
Type	-	-	-	-	-	95.56%	95.09%	86.69%	90.69%	0.290
Task	-	-	-	-	-	97.12%	83.24%	64.93%	72.95%	0.175
Mean	90.35%	88.97%	90.60%	89.76%	0.774	87.47%	82.11%	76.13%	78.77%	0.863
St.Dev.	0.109	0.091	0.082	0.085	0.715	0.128	0.121	0.118	0.112	0.821

Table 3: Evaluation of the step II: the slot-value pairs classification on DSTC2 and In-car.

Given that there is no domain specific delexicalisation, the models achieve a good level of performance overall (Table 3). Note that the slot "food" has 74 possible values in DSTC2 and 25 in In-car. Hence, this slot has much higher cardinality than all the other slots.

Overall performance A baseline for assessing overall performance is provided by the model presented in (Henderson et al., 2012), in which the vector representation is obtained by summing up the frequency of n-grams extracted from the 10-best hypotheses, weighted by their confidence scores. Here we compare our performance against Henderson's model with and without context features, namely WNGRAMS+Ctxt and WNGRAMS repectively. Henderson reported his results on the In-car dataset. A similar model, namely SLU1, was evaluated on DSTC2 in (Williams, 2014). Both implementations consist of many binary classifiers for dialogue act and slot-value pairs.

Corpus	Model	F1	ICE
DSTC2	SLU1 (Williams, 2014)	80.2%	1.943
	CNN+LSTM_w4	**83.59%**	**0.758**
In-car	WNGRAMS (Henderson et al., 2012)	70.8%	1.76
	WNGRAMS+Ctxt (Henderson et al., 2012)	**74.2%**	1.497
	CNN+LSTM_w4	73.06%	**1.106**

Table 4: Overall performance of the setting CNN+LST_w4 semantic decoder.

In terms of the ICE score, the model CNN+LSTM W4 outperforms all the baselines (Table 4). In terms of the F1 score, the model significantly outperforms the SLU1 and WNGRAMS baselines. However it is slightly worse than WNGRAMS+Ctxt, which has been enhanced with context features on In-car. Remember however, that our model uses only word-embeddings for automatically generating sentence and context representations without having any manually designed features or using explicit application specific semantic dictionaries.

[4]"Slot" is used when no value is given for the slot (e.g., "What kind of food do they serve?"/request(slot=food)).
[5]"This" is used for annotating elliptical utterances (e.g., "I dont care"/inform(this='dontcare')).

6 Conclusion and Future Work

This paper has presented a deep learning architecture for semantic decoding in spoken dialogue systems that exploits semantically rich distributed word vectors. We compared different models for combining sentence and context representations. We found that context representations significantly impact slot F-measure on ASR hypotheses generated under very noisy conditions. The combination of sentence and context representations, with a context window of 4 words, outperforms all the baselines in terms of the ICE score. In terms of the F1 scores, our model outperforms the baseline on the DSTC2 corpus and the baseline without manually designed features on the In-car corpus. Although the F-score of our model does not outperforms the baseline enriched with context features on the In-car corpus, the proposed model remains competitive, especially considering that our model requires no manually designed features or application specific semantic dictionaries.

7 Future Work

Semantic distributed vector representations can be used for detecting similarity between domains. As future work, we want to study the adoption of the sentence and the contex representations generated in the Step I (i.e., the joint prediction of dialogue act and slots) within a *Topic Management* in multi-domain dialogue systems. The Topic Manager is in charge of detecting the domain and the intention behind users' utterances. Furthermore, it would be interesting to study these embeddings for domain adaptation on potentially open-domains.

Acknowledgments

This research was partly funded by the EP-SRC grant EP/M018946/1 Open Domain Statistical Spoken Dialogue Systems. The data used in this paper was produced in an industry funded project and it is not available for public use.

Predictive Incremental Parsing Helps Language Modeling

Arne Köhn and **Timo Baumann**
Department of Informatics
Universität Hamburg
{koehn,baumann}@informatik.uni-hamburg.de

Abstract

Predictive incremental parsing produces syntactic representations of sentences as they are produced, e. g. by typing or speaking. In order to generate connected parses for such unfinished sentences, upcoming word types can be hypothesized and structurally integrated with already realized words. For example, the presence of a determiner as the last word of a sentence prefix may indicate that a noun will appear somewhere in the completion of that sentence, and the determiner can be attached to the predicted noun. We combine the forward-looking parser predictions with backward-looking N-gram histories and analyze in a set of experiments the impact on language models, i. e. stronger discriminative power but also higher data sparsity. Conditioning N-gram models, MaxEnt models or RNN-LMs on parser predictions yields perplexity reductions of about 6 %. Our method (a) retains online decoding capabilities and (b) incurs relatively little computational overhead which sets it apart from previous approaches that use syntax for language modeling. Our method is particularly attractive for modular systems that make use of a syntax parser anyway, e. g. as part of an understanding pipeline where predictive parsing improves language modeling at no additional cost.

1 Introduction

N-gram models are the best performing language models capable of online decoding. Interestingly, they perform well despite discarding all information contained in a sentence except the last N-1 words to predict the next one. At least intuitively, it seems implausible that N-grams are a natural model for sentences. In particular, humans seem to use strong predictive skills that rely on non-local aspects of pragmatics (i.e., the conversational context), semantics (i.e., meaningful continuations), or syntax (i.e., syntactically correct continuations). Sturt and Lombardo (2005) show that humans have strong expectations about upcoming words based on the predicted syntactic structure of the sentence. This includes effects spanning long distances in the sentence. For example, reading a word that does not match expectations slows down the reading process.

Syntactic dependency trees provide long-spanning context information not contained in N-grams. They have, however, not widely been used for language modeling. Previous work (see Sec. 2) has integrated parsing into the language modeling process either by post-hoc (re-)scoring of full sentences or by parsing the partial sentence including the word to be predicted. The first approach is not suitable for online decoding at all and the second is computationally expensive as outlined below.

We propose to use a predictive dependency parser that produces syntactic structure for yet-unfinished sentences. The parser is able to include upcoming ('virtual') nodes in the predicted structure (see Sec. 3). We use this forward-looking information to condition our models. In a range of experiments, we confirm the value of parser predictions using a very simple setup in Sec. 4. In Sec. 5, we integrate the predictions with several types of language modeling approaches, and obtain perplexity reductions in all of them.

Author ordering based on a fair coin toss.

2 Related Work

Existing approaches that have exploited syntax for language modeling fall into 3 clusters: post-hoc reranking, the application of tree probabilities, and the use of predictions (as in our work).

Recent research focused on the reranking of n-best hypotheses or lattices either based on the probability of the syntax tree for the full sentence (Filimonov and Harper, 2009; Charniak, 2001; Tan et al., 2012) or by training a discriminative model (Collins et al., 2005). A special case of reranking is the task of sentence completion, where one word of a sentence is missing and the correct word out of five possibilities needs to be selected to fill the gap (Zweig and Burges, 2011). For evaluation purposes, the possible words are selected specifically to have a similar probability under a plain N-gram model. Zhang et al. (2016) propose a model based on LSTMs that predicts dependency trees instead of word sequences. They obtain state of the art results for the sentence completion challenge by computing the probabilities of the alternatives and choosing the best one. However, these models do not cope with sentence prefixes, and hence they can only be applied non-incrementally in a rescoring fashion, e.g. to improve ASR results after a first pass over the input data; thus, they are not applicable to interactive use-cases which require incremental processing.

Parsers that assign probabilities to the derived parse tree can be used for language modeling by comparing parse tree probabilities for all possible continuations of the sentence prefix, e. g using a limited-domain hand-written PCFG with learned rule-weights (Jurafsky et al., 1995), or by learning structure using a hierarchical HMM (Schwartz et al., 2011). As an alternative, Roark (2001) estimates the probability of a sentence prefix by measuring the probability of all parse trees (within a beam) that are derivable for the prefix ending in the queried N-gram divided by the probability of all parse trees for the prefix ending at the N-1'th word. For these approaches, sentence prefixes including the N'th word must be computed, which is computationally expensive. When obtaining a probability distribution for the next word, the cost grows with the vocabulary size. In contrast, our approach parses only once, up to the N-1'th word (i. e. the context portion of the prefix when determining the N'th word).

Chelba and Jelinek (1998) use a tree adjoining grammar to parse the sentence prefix up to (but not including) the word being queried, and the parser state (the top two elements of the stack) is used to condition the language model upon. The probability is summed over all possible trees for the prefix. Thus, again many parses are required for a single query, resulting in a high complexity. Nevertheless, this approach shows many similarities to ours as parsing is done incrementally and the parser state implicitly encodes information about upcoming structure. In our model, we make the predictions explicit which may also be useful to other modules in a system.

The main contributions of our work are as follows: first, our method only needs raw text (not treebanks) for estimating syntactic LMs (as our parser is trained independently) while retaining high run-time performance on single machines. Tan et al. (2012) use a similar amount of data but need 400 servers to apply their admittedly more sophisticated models which also include semantics and topic for full-document modelling. Second, our approach is applicable to online decoding for incremental systems such as highly interactive spoken dialogue systems, whereas other methods are often limited to post-hoc lattice rescoring.

3 Predictive Parsing

Dependency parsers generate the syntax tree for a sentence by attaching every token (the dependent of the relation) to another token (the head) or a root node. For sentence prefixes, the head of a dependent may not yet be available resulting in an incomplete tree (as in Figure 1 (a)).

Trees can be completed by using what Beuck et al. (2013) call virtual nodes which serve as stand-ins for upcoming words. Words without a matching head in the prefix can be attached to a virtual node (see Figure 1 (b)) which is fully integrated into the syntactic structure. Such nodes can also be introduced when no word needs to be attached to them, e.g. because otherwise a valency can not be satisfied (see Figure 1 (c)).

Each virtual node has a type corresponding to the PoS of the words it can stand for. We use the prediction about the upcoming word types for language modeling, following the intuition that e. g. a verb might be more likely when the parser predicts that a verb is missing to complete the sentence.

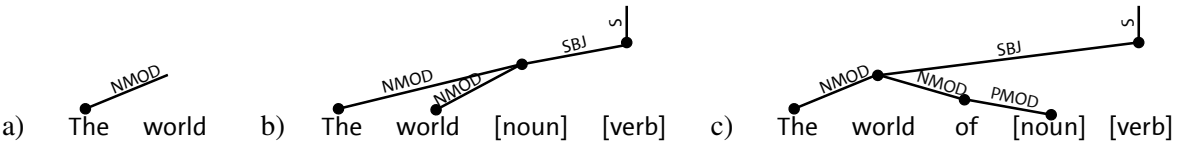

Figure 1: Dependency trees for prefixes of the sentence *The world of politics has no rules.* showing: (a) an incomplete tree (no head exists for *world*), (b) a predicted noun and verb head (lexicalization leads the parser to assume that *world* is part of a more complex noun phrase), and (c) an additional predicted noun dependent when *of* is added. (b) and (c) are actual outputs of the predictive parser.

We use a parser based on TurboParser (Martins et al., 2013) which was extended by Köhn and Menzel (2014) to produce predictive analyses of sentence prefixes. The parser predicts up to one upcoming verb and one upcoming noun, which results in a good coverage/precision trade-off for English. The parser is trained on the Penn-Treebank (Marcus et al., 1994) and not specifically tuned for language modeling nor for the corpus used for estimating the LM. Predictions of vn nodes reach an F-score of .68 (precision: .79; recall: .60). The parser output for full sentences is as accurate as the original TurboParser.

Throughout this paper, we abbreviate the prediction of the virtual verb and noun as vn where v stands for the verb and n for the noun. For specific predictions, $\overset{+}{v}$ and $\overset{+}{n}$ denotes that the corresponding virtual node was predicted, $\overset{-}{v}$ and $\overset{-}{n}$ that it was not. The distribution of predictions for sentence prefixes is shown in Table 1; as can be seen, both v and n split the prefixes roughly equally into four parts, yielding an information of 1.90 bit. Other forward-looking syntactic features (e.g. dependency direction of an expected virtual node or the dependency type) would likely be less informative, hence we focus on only these two features in our work. We experiment with models that use both or just one of the predictions.

sentence prefixes		verb predicted		
		$\overset{-}{v}$	$\overset{+}{v}$	Sum
noun predicted	$\overset{-}{n}$	41.6	22.7	**64.3**
	$\overset{+}{n}$	18.7	17.0	**35.7**
	Sum	**60.3**	**39.7**	

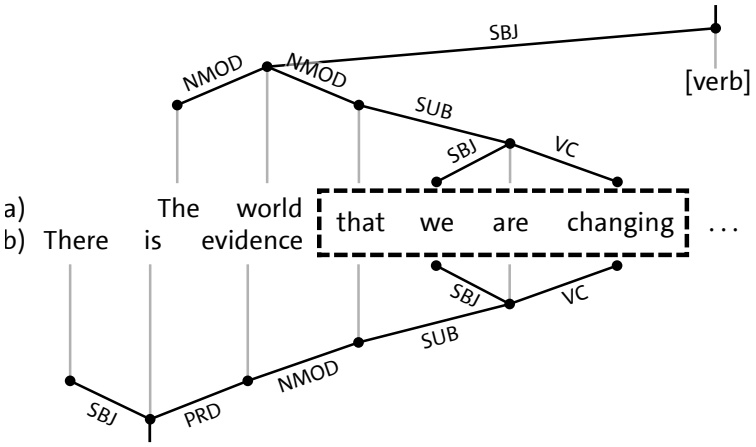
Table 1: Distribution (in percent) of virtual node predictions for sentence prefixes in the Billion Word Corpus.

4 Basic Idea and Proof-of-Concept

Our experiments are based on the assumption that probabilities for a word (such as "likes") depend on whether a verb (or noun) is structurally required to complete the sentence. In addition, we believe that this *forward-looking* structural information is not well-captured by the *backward-looking* local context of an N-gram. Notice that we do not make any assumption on the kinds of probability shifts but only the assumption that *some* shift occurs, i.e. "likes" might as well be preferred when a (plural) noun is predicted.

A language model computes the probability of a sentence: $P(w_1 \dots w_n)$. Applications such as speech recognition perform online decoding and use the decomposition according to the chain rule $P(w_1 \dots w_n) = \prod_{i=1}^{n} P(w_i|w_1 \dots w_{i-1})$, as well as the (N-gram) approximation based on the Markov assumption ($P(w_i|w_1 \dots w_{i-1}) \approx P(w_i|w_{i-N} \dots w_{i-1})$). This approximation limits language models to local contexts but makes the probability estimation problem tractable by reducing data sparsity. We enhance the model by including parser predictions $p_{i-1} \in \{\overset{+}{v}\overset{+}{n}, \overset{+}{v}\overset{-}{n}, \overset{-}{v}\overset{+}{n}, \overset{-}{v}\overset{-}{n}\}$ extracted from the predictive parse for the *full* history of the sentence $w_1 \dots w_{i-1}$. Thus, the parser predictions encode additional information about the continuation that enhance the local history in a very dense form – using only two bits.

The non-locality of parsing predictions is exemplified in Figure 2 (the example is restricted to just the verb prediction v). In the two sentences given in the figure, the local N-gram context is identical for either sentence prefix. In fact, the cause for different parser predictions can be arbitrarily far into the past (for example by exchanging *we* for a complex noun phrase in the example). For the given N-gram context, we queried language models that make use of the (non-)prediction of verbs ($\overset{+}{v}$ vs. $\overset{-}{v}$, as described below) and differences in $\log_{10}$ probabilities for some continuations of either sentence are shown in tabular form. As expected, we find that plausible continuations of Sentence 2 (a) are much more probable in the $\overset{+}{v}$ case, and plausible continuations of 2 (b) are more probable in the $\overset{-}{v}$ case.



continuation	$\log_{10}$prob difference between $\overset{+}{v}/\bar{v}$ model
has/hasn	+1.18 / +1.12
will	+1.10

and	+0.05
in	−0.06
worlds	−0.34
it	−1.28
a/an	−1.41 / −1.35
our	−1.69
lives	−2.52

Figure 2: Predictive parses for two sentence beginnings (left). While the parser predicts a verb to be neccessary to complete (a), it does not predict a verb for (b). The differences in the sentences (that cause the different parses) lie outside of the local N-gram context (dashed box). Possible continuations and the relative differences in assigned probabilities depending on $\overset{+}{v}/\bar{v}$ context are shown in tabular form (right).

To make use of the predictions in an N-gram model, we split the N-gram counts by the parser predictions of the corresponding prefix histories: an N-gram $(w_{i-N} \dots w_{i-1} w_i)$ is sorted according to p_{i-1}.[1] With the prefixes split into four bins ($\overset{+}{v}\overset{+}{n}$, $\overset{+}{v}\bar{n}$, $\bar{v}\overset{+}{n}$, and $\bar{v}\bar{n}$), we train four separate N-gram models. During decoding, we switch between these four models: given a sentence prefix $(w_1 \dots w_{i-1})$, we extract p_{i-1} and query the corresponding model for the probability of w_i. Note that the output of the parser does not depend on w_i and we therefore only need to parse once for every sentence prefix even if we query the full probability distribution (as in speech recognition). We also perform experiments with only two bins by splitting either by v or by n, obtaining two N-gram models.

All experiments in this paper are carried out on the Billion Word Corpus (BWC; Chelba et al. (2013)), for which we parsed every sentence prefix.[2] N-gram models are generated with SRILM (Stolcke et al., 2011) using standard settings (modified Kneser-Ney smoothing (Chen and Goodman, 1996) and interpolation, a limited vocabulary of 100,000 words, and dropping singleton N-grams for N>2).[3]

4.1 Exemplary Effects of Parsing Splits on Trigrams

We first illustrate the effects of parser predictions on probability distributions for prefixes ending in *the world*. The probabilities of the most frequent continuations for *the world* (i.e., standard N-gram probabilities) as well as probabilities under the four different split models are shown in Table 2 (middle part). We discuss the highlighted numbers: *the world 's* has a high probability when a noun is predicted (particularly $\bar{v}\overset{+}{n}$). This subsumes cases where a verb has a valency to which *world* is a bad fit.[4] Hence, *the world* is regarded as a possessive adjective to the predicted argument and *'s* makes the connection between the two. The continuation "." has a high probability when neither a verb nor a noun is predicted to continue the sentence. A comma is more likely under the $\overset{+}{v}\overset{+}{n}$ model, presumably because this constellation dominates at the end of introductory prepositional phrases. Lastly, *and* is most likely under $\bar{v}\bar{n}$, similarly to the full stop, as it connects material to an already complete structure.

While these observations may or may not be interesting linguistically, our main point is that probabilities shift (sometimes radically, as highlighted in the right part of the table) when dissecting the N-gram history by our longer-range vn information. This increased discriminatory power is what our method is about.

[1] Simply including parser prediction in an N-gram model like a context word (using the N-grams $(w_{i-N} \dots w_{i-1} p_{i-1} w_i)$) would break the count-of-count assumptions for Kneser-Ney smoothing.

[2] This takes 30 ms per prefix, totalling about one CPU year; parsing results as well as code to replicate our experiments are available at `https://nats-www.informatik.uni-hamburg.de/PIPLM` to encourage further research.

[3] SRILM allows to manipulate N-gram counts and is still able to compute correct backoff values unlike e.g. KenLM which, however, would allow to include singleton N-grams. Data sparsity (see below) would be less grave if singletons were included.

[4] Note that since our parser is lexicalized, it automatically learns valency relations.

		probabilities				relative change			
tri-gram	avg	$\overset{+}{v}\overset{+}{n}$	$\overset{+}{v}\overset{-}{n}$	$\overset{-}{v}\overset{-}{n}$	$\overset{-}{v}\overset{+}{n}$	$\overset{+}{v}\overset{+}{n}$	$\overset{+}{v}\overset{-}{n}$	$\overset{-}{v}\overset{-}{n}$	$\overset{-}{v}\overset{+}{n}$
the world 's	.33	.41	.37	.28	**.81**	×1.2	×1.1	÷1.2	×2.5
the world .	.14	.02	.03	**.19**	.01	**÷7.0**	**÷4.9**	×1.4	**÷13**
the world ,	.10	**.17**	.07	.11	.02	×1.6	÷1.5	×1.1	**÷4.9**
the world and	.02	.01	.01	**.03**	.004	÷2.2	÷2.2	×1.3	**÷5.3**
the world *everything else*	.41	.39	.52	.39	.16	÷1.1	×1.3	÷1.1	÷2.6

Table 2: Some tri-grams and their probabilities in the full corpus (avg) vs. split by parser prediction.

4.2 The Detrimental Effect of Data Sparsity

The splitting method outlined above increases data sparsity in the sub-models for each of the four vn bins. We here differentiate between gains from parsing prediction-induced discriminatory power and losses from splitting-induced data sparsity. For this purpose, we devise a baseline model which replaces the parser predictions with random bins, using the same distribution as in Table 1. If the parser's predictions were to provide no additional information, both models should obtain the same perplexity, as they are comparably impacted by data sparsity.

Table 3 shows the cross-entropies obtained by our syntax splitting model, the baseline model, and standard N-gram models trained on the full material.[5] We find that data sparsity inhibits the results for N>2-grams. While our method achieves a gain from syntax predictions (e. g. ~.3 bit for 4/5-grams), additional data sparsity deteriorates results slightly more (~.4 bit for 4/5-grams). Nevertheless, we find that syntax gain even increases with N-gram order, that is higher-order N-grams do not implicitly encode longer-range information in the same way that syntax predictions do. We also find that both v and n help similarly and that their gains roughly add up (i. e. they are orthogonal). In total, each of v/n in isolation shows slightly better performance than combined vn splitting given their lower data sparsity.

4.3 Exemplary Comparison of Split and Standard Model

To further analyze the strengths and weaknesses of the split model, we look word-by-word at the probability assignments of standard 5-gram models and vn state-specific 5-gram models. We restrict this analysis to 500 test sentences with 6-14 tokens and focus attention on sentences with large differences.

In the qualitative analysis, we find some patterns that are illustrated by the sentence plots in Figure 3. Each plot shows for every word the probability assigned by either model, the parser's prediction for the prefix leading up to this word, and the backoff order necessary if the queried 5-gram is not contained in the model. The backoff order is a strong indicator for data sparsity pressure.

[5]Entropies reported in Table 3 are higher than for the final N-gram results in Section 5.1, as the preliminary models employed here are not order-interpolated and sentence-ends are excluded from perplexity computation.

		syntax pred. A:	random splits B:	standard C:	syntax gain B-A:	splitting loss B-C:
2-grams	vn	7.819	7.968	7.881	0.149	0.087
	v	7.837	7.918		0.081	0.037
	n	7.861	7.917		0.057	0.036
3-grams	vn	6.988	7.209	6.938	0.221	0.271
	v	6.969	7.071		0.102	0.133
	n	6.959	7.067		0.108	0.129
4-grams	vn	6.735	7.025	6.633	0.290	0.392
	v	6.703	6.839		0.136	0.206
	n	6.671	6.830		0.159	0.197
5-grams	vn	6.685	6.994	6.566	0.309	0.428

Table 3: Cross-entropies (in bit; lower is better) obtained by splitting the training data according to the parser's prediction (verb, noun, or both), vs. random splitting and comparison to standard models.

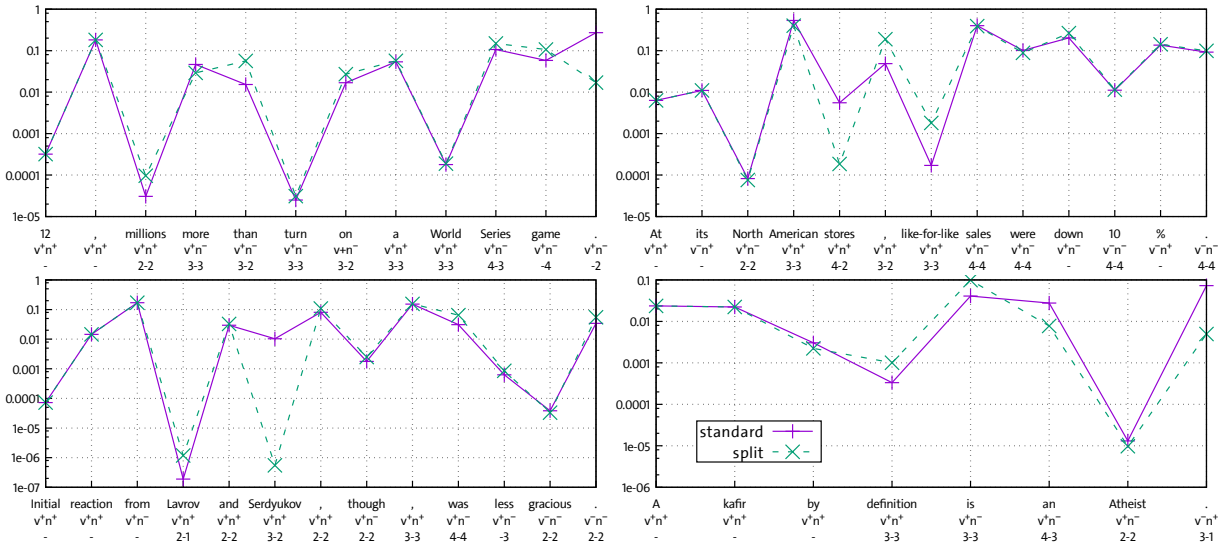

Figure 3: Sentences with their per-word probabilities in standard and split models. For each word, we show syntax prediction and the N-gram order backed off by the standard and split model respectively, if backoff is needed (e.g., "Lavrov $\overset{+}{v}\overset{+}{n}$ 2-1" indicates the parser predicting both $\overset{+}{v}$ and $\overset{+}{n}$ for the prefix up to "from" and both models backing off: the standard model to bigrams, the split model even to unigrams).

Probability estimates are **identical for the N-1 sentence-initial words** as syntax predictions are implicitly contained in the N-gram history and both models provide the same information (lower N if a model is forced into backoff). Models perform similarly under no or little data sparsity, i. e. no backoff (or just to 4-grams). **Moderate improvements** often occur **under data sparsity** when both models back off to the same order. The first sentence shows some improvements for the syntax predictions even when using lower N-gram orders (syntax being more useful than one more word of history) but fails at predicting the sentence final full stop (the parser still expects a verb and this could be classified as a parsing error), in this case due to the incompleteness of the sentence (it is both authors' feeling that this sentence *should* go on).

Inherently, the standard model is never impacted more strongly by data sparsity than the split model. Thus, **critical cases occur when the split model needs to back off more** than the standard model. While positive effects are also noticeable to some extent for the second and third sentence, these sentences are hurt badly by not 'knowing' infrequent co-occurrences, i. e. N-grams in which the last word has a high conditional probability given the full history of the N-gram: "North American stores" (where "stores" is a likely continuation for "North American" but not for "American" *per se*), and "Lavrov and Serdyukov" (where "Lavrov" must be in the history to assign a relevant probability, yet the split model backs off to "and Serdyukov"). Further analysis of this last example shows that there are two occurrences of the trigram in the training data, which fall into two different prediction states ($\overset{+}{v}\overset{+}{n}$ and $\overset{-}{v}\overset{+}{n}$). As singleton N-grams are ignored, both occurrences of the trigram are lost and not used in the split model.

A histogram of $\log_{10}$prob differences is shown in Figure 4 (left side; notice the logarithmic y-axis). The majority of the differences are positive (55 %), indicating that our method is helpful more often than not. However, the very long tail of rare gross mistakes results in a overall slightly negative $\log_{10}$prob loss of -0.025, in line with our analysis of the examples in Figure 3 and the overall loss in Table 3.

In summary, we find that most often, probability estimates are similar or slightly improve with syntax predictions as used by the split model due to the better discrimination from non-local context. On the other hand, splitting increases the random variation of N-gram counts in particular for rarely seen N-grams; more often than not, the positive effect appears to outweigh the negative effect. Unfortunately, few but large errors are introduced systematically by the fact that each of the split model's sub-models is trained on less data. We deal with data sparsity in the following section, where we build prediction-enhanced models that outperform their baselines.

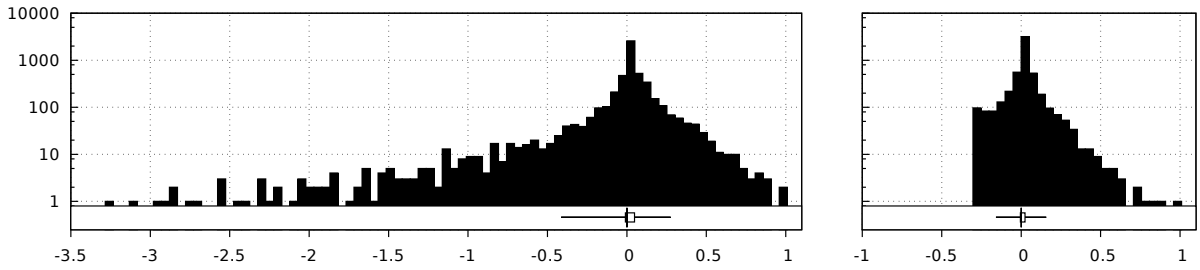

Figure 4: Left: Histogram over $\log_{10}$prob differences between the split and the standard model. Right: Differences between the interpolated and standard model (see Section 5.1). Notice the logarithmic y-axis. The boxplots below show 25/75% (box) and 5/95% (whiskers) intervals and median.

5 Experiments

To assess the merit of predictive parsing, we perform a wide range of experiments. We use SRILM (Stolcke et al., 2011) for N-grams on the BWC, for which Chelba et al. (2013) quote a cross-entropy of 6.08 bit for unpruned interpolated Kneser-Ney smoothed 5-grams. We build MaxEnt N-gram models (Rosenfeld, 1994) as well as RNN-LMs (Mikolov et al., 2011) using faster-rnnlm.[6] For the BWC, faster-rnnlm in its best setting (after extensive hyper-parameter search) results in a cross-entropy of 6.8 bit and combined with its MaxEnt model of 6.4 bit (the MaxEnt model alone has not previously been benchmarked).[6]

The numbers reported below are not necessarily directly comparable to reference numbers for several reasons: we use limited-vocabulary N-grams and separate OOV handling as we plan to apply our models to speech recognition. In contrast, faster-rnnlm by default discards all sentences containing OOV tokens which results in lower perplexity. We use SRILM defaults (pruned N-grams) to create models that easily fit in memory, and do not search for optimal RNN hyper-parameters. Nonetheless, given the breadth of our experiments, the general findings of our work are likely independent of these particularities.

5.1 Interpolated N-gram models

We first present interpolated N-gram models that reduce the impact of additional data sparsity in the plain syntax splitting models presented in Section 4.2. Interpolation exploits the averaging effect when combining models with different characteristics. As noted above, the syntax-enhanced model is slightly better *often* but much worse sometimes (see Figure 4, left side). Using interpolation, the outliers can be greatly reduced in magnitude by averaging the models; in particular, a probability from the interpolated model is at worst half as probable as the probability from the better model. Therefore, no $\log_{10}$prob difference is smaller than $log_{10}(0.5) \approx -0.3$ (cmp. Figure 4, right side). Although the magnitude of improvements is also reduced, that effect is much smaller and the overall average advantage over the standard model turns from negative to positive. In effect, interpolation allows to optimize the tradeoff between discrimination and accumulation of evidence under data sparsity, and we try several strategies:

1. The split model uses two binary predictions, thus each of the sub-models is trained on (roughly) one quarter of the training data, only. One possible route to improvements is to build separate sub-models for the v and the n variable (**1a**), each of which can be trained with roughly half of the training data, i.e. with less data sparsity. We can then select the two models that match the vn state and interpolate between them. An alternative approach for reducing data sparsity (**1b**) is to join the N-gram counts of the corresponding v and n state and to build pre-aggregated models. (E. g. the model for $\bar{v}\overset{+}{n}$ would accumulate counts from the $\bar{v}$ and the $\overset{+}{n}$ bins.) Either way, we account for the fact that an N-gram may be seen during testing in a different vn state than in training (that is nevertheless related by one of the variables).

2. We interpolate between the standard model which is trained on all data and the split models which are more discriminative (**2a**). We also combine this method with **1b** as **2b**.

The cross-entropies of the plain syntax-splitting method (**0**) and the standard 5-gram model as well as the experimental conditions described above are given in Table 4. We find that interpolating the vn

[6] github.com/yandex/faster-rnnlm

model type	setting	standard	syntax	gain
5-grams	**0.** plain splitting	6.253	6.374	−0.12
	1a. interp. from $v \times n$		6.254	−0.001
	1b. joint counts		6.187	0.07
	2a. vn interp. w/ std		6.234	0.02
	2b. joint counts interp. w/ std		6.170	**0.08**
MaxEnt	2-grams	8.41	8.31	0.10

	4-grams	7.88	7.87	0.01
	4-grams (large GPGPU)	7.55	7.49	**0.06**
RNN-LM	syntax in input	7.94	7.90	0.04
	syntax in NCE		7.89	**0.05**

Table 4: Cross-entropies (in bit; lower is better) of the experiments presented in Section 5, for 5-grams, MaxEnt models, and RNN-LMs, as discussed in the respective sub-sections, with the standard model, syntax-enhanced model, and gain (or loss) between the two. As can be seen, the baseline standard models are outperformed for all model types.

models from v and n leads to a large improvement, in particular when using more training data for each individual model (**1b**) rather than interpolating from v and n models (**1a**). Interpolating between the standard and plain syntax-splitting models (**2a**) leads to good results (which peaked at an interpolation weight of .367 for the splitting model). Finally, interpolation of **1b** with the standard model (weight .675) outperforms the standard model by 0.083 bit (a perplexity improvement of 6 % from 76.3 down to 72.0).

5.2 Maximum Entropy Models

We extend the faster-rnnlm MaxEnt model with parser predictions. In the model, the score for a word w_i is computed by summing over all N-gram scores: $s(w_i) = \sum_{j=0}^{n} f(w_i \dots w_{i-j})$. During decoding, the softmax over all possible words w_i yields a probability distribution. f hashes the N-gram (as well as lower order N-grams) and then looks up their scores in a fixed-size table. We extend s by adding vn-annotated (N…1)-grams to the summation: $s(w_i) = \sum_{j=0}^{n} f(w_i \dots w_{i-j}) + f(p_{i-1} w_i \dots w_{i-j})$ We use a hash table with 400M elements, the maximum for our GPGPU card.

Results are presented in Table 4, showing averages of several runs (to account for random initialization). We find that the vn-enhanced models perform significantly better than the standard ones.[7] Performance did not improve with N>3 with our setup, likely due to an increase in hash collisions, as our method puts almost five times as many items into the table. We tested 4-grams on a larger GPGPU card allowing a hash table with 1,600M elements and see that both overall performance and syntax gain improve as expected.

5.3 RNN-based Models

We explore how to integrate parser predictions into a RNN-LM in two different ways as depicted in Figure 5. Either, we add vn as two additional dimensions to the input layer, with positive weight if the corresponding virtual node was predicted and with negative weight otherwise. For example, $\bar{v}\bar{n}$ translates to $(-0.5, 0.5)$. Alternatively, we add vn to the output layer, which is used for noise contrastive estimation (NCE) because intuitively, parser predictions do not need to be fed forward to the next prediction.

For all experiments, we use faster-rnnlm with noise contrastive estimation and a sigmoid layer of size 100 (we ignore MaxEnt here and test RNN in isolation). To account for random initialization (and to allow the estimation of significance), each experiment condition is run 6 times. For both versions, we compared results with a corresponding standard RNN model as reported in Table 4. Both methods significantly[7] outperform the baseline model, and the addition of vn to the NCE layer is slightly better. We conclude that explicitly encoded syntactic long-range information even helps for RNN-LMs which in principle are able to capture longer-range dependencies, at least implicitly.

[7] Wilcoxon rank sum test based on the multiple runs of each experiment condition, $p < .01$.

6 Summary and Discussion

We have explored the integration of syntactic structure for online decodable language models, which we base on predictive parsing. This approach incurs a far lower computational cost than previous work on integrating parsing into language models as we parse just once for the history and use the prediction to generate the full probability distribution over possible next words. Our model is built with loose coupling in mind: the parser model is tuned for high syntax parsing accuracy and in no way for language modeling. It can hence be used for other purposes (such as incremental understanding) in an integrated system as well. If a predictive parser is already used in such a system, our proposed approach yields a perplexity improvement for free by feeding back parser predictions to the language model.

Predictions encode information about the next words that are not present in N-grams, i. e. they are able to transport information over long distances in a dense form. Explicit syntax predictions also help RNN-LMs which at least implicitly already model longer-range dependencies. We find that both verb and noun predictions are valuable for language modeling. Combined, they provide a gain of ~0.3 bit for 4- and 5-grams over the split baseline (cmp. Section 4.2). Despite the additional data sparsity introduced by the vn predictions, using count-merging and interpolation yields a perplexity improvement of 6 % over standard N-grams. We also integrated predictions into MaxEnt and RNN-LMs and find consistent and modest improvements for both.

We have used a limited vocabulary and discarded singleton N-grams for computational efficiency. We do not believe that our results will be fundamentally different at larger vocabularies or with unpruned models, but we plan to improve our setup to assess the effect nonetheless in the future. We also plan to integrate our models with online speech recognition to asses whether the observed perplexity reduction carries over to WER. Additional information extracted from the dependency tree may yield further improvements, especially with RNN models, which are robust against data sparsity. Finally, improvements to the parser that result in better predictions should transfer to language modeling as well.

We plan to extend our work beyond English data, as predictive parsing is language independent. However, Beuck and Menzel (2013) find a larger set of virtual nodes to be optimal for German for which we want to assess the merit to our method.

Acknowledgements We would like to thank Wolfgang Menzel for helpful discussion and comments, and the anonymous reviewers for valuable suggestions and remarks. This work is supported by a Daimler and Benz Foundation PostDoc Grant to the second author.

A Neural Attention Model for Disfluency Detection

Shaolei Wang, Wanxiang Che, and **Ting Liu**

{slwang, car, tliu}@ir.hit.edu.cn

Abstract

In this paper, we study the problem of disfluency detection using the encoder-decoder framework. We treat disfluency detection as a sequence-to-sequence problem and propose a neural attention-based model which can efficiently model the long-range dependencies between words and make the resulting sentence more likely to be grammatically correct. Our model firstly encodes the source sentence with a bidirectional Long Short-Term Memory (BI-LSTM) and then uses the neural attention as a pointer to select an ordered subsequence of the input as the output. Experiments show that our model achieves the state-of-the-art f-score of 86.7% on the commonly used English Switchboard test set. We also evaluate the performance of our model on the in-house annotated Chinese data and achieve a significantly higher f-score compared to the baseline of CRF-based approach.

1 Introduction

Disfluency detection is the task of detecting the infelicities in spoken language transcripts. The task is important for natural language understanding, since most downstream NLU systems are built on the fluent utterances. Disfluency of a sentence can be categorized into five classes (Wu et al., 2015): uncompleted words, filled pauses (e.g. "uh", "um"), editing terms (e.g. "you know"), discourse markers (e.g. "i mean") and repairs that are discarded, or corrected by its following words. Typically, as shown in Figure 1, a repair type disfluency consists of a filled pause ("um"), a reparandum ("Boston") and an Interregnum("I mean") followed by its repair ("Denver"). The goal of the repair type disfluency detection is to detect the reparandum. The former four classes of disfluencies are easy to detect as they often consist of fixed phrases (e.g. "uh", "you know"). However, the repair type disfluency (see Table 1 for more examples) is more difficult to detect, because reparandums are in arbitrary form. Most of the previous disfluency detection works focus on detecting the repair type disfluencies.

A flight to $\underbrace{\text{um}}_{\text{FP}}$ $\underbrace{\text{Boston}}_{\text{RM}}$ $\underbrace{\text{I mean}}_{\text{IM}}$ $\underbrace{\text{Denver}}_{\text{RP}}$ Tuesday

Figure 1: A sentence with disfluencies annotated in the style of (Shriberg, 1994) and the Switchboard corpus. FP=Filled Pause, RM=Reparandum, IM=Interregnum, RP=Repair. We follow previous works in evaluating the system on the accuracy with which it identifies speech-repairs, marked *reparandum* above.

Modeling long-range dependencies between repair phrases is one of the core problems for disfluency detection. Previous sequence tagging methods (Ferguson et al., 2015; Georgila, 2009; Qian and Liu, 2013) require carefully designed features to capture the information of long distance, but usually suffer from the sparsity problem. Another line of syntax-based disfluency detection works (Honnibal and Johnson, 2014; Wu et al., 2015) try to model the repair phrases on a syntax tree by compressing the unrelated

Table 1: Sentences in which the former four classes of disfluencies have been removed. "/E" means that the word belong to a reparandum and should be deleted.

phrases and allowing the repair phrases to interact with each other. However, data that both have syntax trees and disfluency annotations are scarce. The performance of syntax parsing models (about 92% on English) also hinders disfluency detection's performance. There are also works that try to use recurrent neural network (RNN), which can capture dependencies at any length in theory, on disfluency detection problem (Hough and Schlangen, 2015). The RNN method treats sequence tagging as classification on each input token and doesn't model the transition between tags which is important in recognizing the repair phrases of multi-words. Another core problem for disfluency detection is to keep the generated sentences grammatical. However, the sequence tagging methods and RNN method have no power of modeling the linguistic structural integrity. The output of syntax-based methods is a syntax tree and can keep the output sentence grammatical in theory, but limited by the performance of syntax parsing models.

In this paper, we address the above challenges by seeing disfluency detection as a sequence-to-sequence problem and presenting a neural attention-based model to learn the conditional probability of the output which is an ordered subsequence of the input, inspired by the work of (Rush et al., 2015; Vinyals et al., 2015). Our model repurposes the attention mechanism (Bahdanau et al., 2014) to create pointers to the input elements. More specifically, we first encode the input sentence with a bidirectional Long Short-Term Memory (BI-LSTM) and then use the neural attention as a pointer to select a member of the input sequence as the output. In the decoding process, we use the attention mechanism only over the candidate words within a window and select the word with the maximum attention weight in each step. Once a word is selected, all the candidate words before it will be labeled as reparandum and be deleted.

While our neural attention-based model is structurally simple, it is very suitable for disfluency detection for that (1) taking into account the language model and a constrained vocabulary (words appear in the input sentence) during generation, which makes the resulting sentence more likely to be grammatically correct, and (2) utilizing the global representation of the input for generating, and selecting the word by joint decision with our neural attention mechanism, which can effectively model the long-range dependencies.

Experiments show that our model achieves the state-of-the-art f-score of 86.7% on the commonly used English Switchboard test set. We also evaluate the performance of our model on Chinese annotated data. As there is no public disfluency data in Chinese, we annotate 200k Chinese sentences manually for training and testing. We achieve a 61.4% f-score with more than 7 points gained compared to the CRF-based baseline, showing that our models are robust.

Our original major contributions in this paper include:

- We firstly study the problem of disfluency detection using the encoder-decoder framework.
- We propose a novel neural attention-based model for disfluency detection, and demonstrate its effectiveness on both English Switchboard corpus and in-house annotated Chinese corpus.

2 Background: Neural Models for Sequence-to-sequence Learning

Sequence-to-sequence learning can be expressed in a probabilistic view as maximizing the likelihood of observing the output (target) sequence given an input (source) sequence.

2.1 RNN Encoder-Decoder

RNN-based Encoder-Decoder is successfully applied to real world sequence to sequence tasks, first by (Sutskever et al., 2014; Cho et al., 2014). In the Encoder-Decoder framework, the source sequence $X = [x_1, ..., x_T]$ is converted into a fixed length vector c by the encoder RNN, i.e.

$$h_t = f(x_t, h_{t-1}); \quad c = q(\{h_1, ..., h_T\}) \tag{1}$$

where $h_t \in R^n$ is a hidden state at time t, and c is a vector generated from the sequence of the hidden states. f and q are some nonlinear functions. (Sutskever et al., 2014) used an LSTM as f and $q(\{h_1, ..., h_T\}) = h_T$, for instance.

The decoder is often trained to predict the next word y_t given the context vector c and all the previously predicted words $\{y_1, ..., y_{t-1}\}$. In other words, the decoder defines a probability over the translation y by decomposing the joint probability into the ordered conditionals:

$$p(y) = \prod_{t=1}^{T} p(y_t \mid \{y_1, ..., y_{t-1}\}, c), \tag{2}$$

where $y = \{y_1, ..., y_{t-1}\}$. With an RNN, each conditional probability is modeled as

$$p(y_t \mid \{y_1, ..., y_{t-1}\}, c) = g(y_{t-1}, s_t, c), \tag{3}$$

where g is a nonlinear, potentially multi-layered, function that outputs the probability of y_t, and s_t is the hidden state of the RNN. Note that y_t belongs to a fixed output vocabulary dictionary.

2.2 The Attention Mechanism

The attention mechanism was first introduced to sequence to sequence (Bahdanau et al., 2014) to release the burden of summarizing the entire source into a fixed-length vector as context. Instead, the attention uses a dynamically changing context c_t in the decoding process. c_t at each output time t is computed as follows:

$$\begin{aligned} u_{tj} &= v^T tanh(W_1 h_j + W_2 s_{t-1}) \quad j \in (1, ..., n) \\ a_{tj} &= \frac{exp(u_{tj})}{\sum_{k=1}^{T} exp(u_{tk})} \quad j \in (1, ..., n) \\ c_t &= \sum_{j=1}^{n} a_{tj} h_j \end{aligned} \tag{4}$$

where s_{t-1} is the decoder hidden states for time $t-1$. v, W_1, and W_2 are learnable parameters of the model. Lastly, c_t and s_{t-1} are concatenated as the hidden states which will be used for making predictions and fed to the next time step in the decoder RNN. We call u_{tj} a relevance score, or an alignment weight of the j-th input. Note that the vanilla attention mechanism compute the relevance among all the input each step.

3 Model Description

Disfluency detection requires that the output should be an ordered subsequence of the input. The vanilla sequence-to-sequence approach(Sutskever et al., 2014) requires the size of the output dictionary to be fixed a priori, which means that it can only generate one word of the output dictionary at any step. Because of this constraint, we cannot directly apply the vanilla sequence-to-sequence framework to disfluency detection, since it (1) may generate a word out of the input, (2) can't generate the word out of the fixed output dictionary but in the input when applying the model on the test set, and (3) has no power of modeling the order of the generated words. To address the constraint, we propose a new attention-based model as illustrated in Figure 2. Our model is still an encoder-decoder framework in a slightly generalized sense.

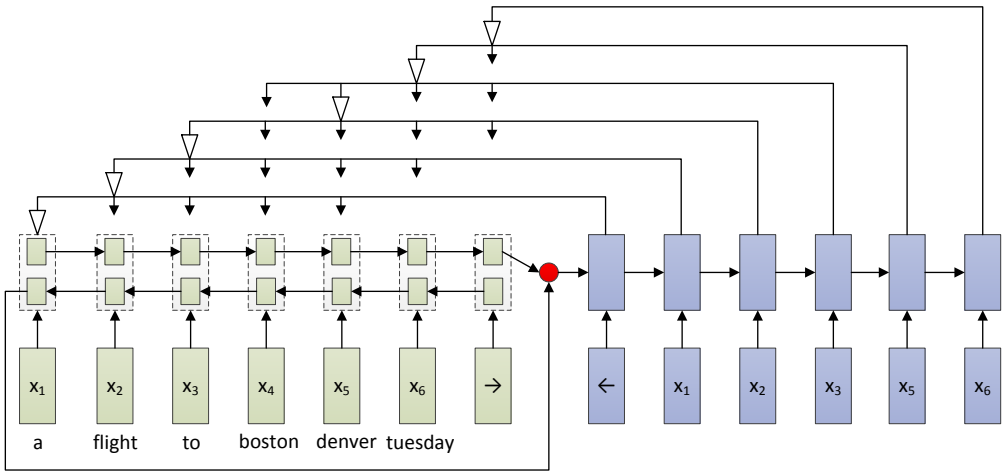

Figure 2: our attention-based network: An encoding RNN converts the input sequence to a vecter that is fed to the generating network. At each step, the generating network produces a vector that modulates a content-based attention mechanism over the words in a window. The word with maximum attention value is selected.

3.1 Input representation

To represent each input token, we use four vectors: a learned word embedding w; a fixed word embedding $\widetilde{w}$; a learned POS-tag embedding p; a hand-crafted feature representation d. The four vectors are concatenated together, transformed by a matrix V and fed to a rectified layer to learn feature combination, as

$$x = max\{0, V[\widetilde{w}; w; p; d] + b\} \tag{5}$$

where $[\widetilde{w}; w; p; d]$ means the concatenation.

We extract two kinds of hand-crafted discrete features (as shown in Table 2) for each token in a sentence and incorporate them into our neural networks by translating them into the 0-1 vector d. The dimension of d is 78, which equals to the number of discrete features. For a token x_t, d_i fires if x_t matches the i-th pattern of the feature templates. The duplicate features care whether x_t has a duplicated word/POS-tag in certain distance. The similarity features care whether the surface string of x_t resembles its surrounding words.

duplicate features
$Duplicate(i, w_{i+k}), -15 \leq k \leq +15$ and $k \neq 0$: if w_i equals w_{i+k}, the value is 1, others 0
$Duplicate(p_i, p_{i+k}), -15 \leq k \leq +15$ and $k \neq 0$: if p_i equals p_{i+k}, the value is 1, others 0
$Duplicate(w_i w_{i+1}, w_{i+k} w_{i+k+1}), -4 \leq k \leq +4$ and $k \neq 0$: if $w_i w_{i+1}$ equals $w_{i+k} w_{i+k+1}$, the value is 1, others 0
$Duplicate(p_i p_{i+1}, p_{i+k} p_{i+k+1}), -4 \leq k \leq +4$ and $k \neq 0$: if $p_i p_{i+1}$ equals $p_{i+k} p_{i+k+1}$, the value is 1, others 0
similarity features
$fuzzyMatch(w_i, w_{i+k}), k \in \{-1, +1\}$: $similarity = num\_same\_letters/(len(w_i) + len(w_{i+k}))$. if $similarity > 0.8$, the value is 1, others 0

Table 2: Discrete features used in our neural attention-based networks. p is the POS tag. w is the word. Duplicate indicates if the two units are same. fuzzyMatch indicates the similarity of two words.

3.2 Encoder

We use bidirectional LSTM-based RNN which consists of forward and backward RNNs to transform the source sequence into a series of hidden states, with each hidden state h_t corresponding to word x_t. The

  end for
end for

forward RNN reads the input sequence $x = (x_1, ..., x_T)$ in a forward direction, resulting in a sequence of hidden states $(\overrightarrow{h_1}, ..., \overrightarrow{h_T})$. The backward RNN reads x in an opposite direction and outputs $(\overleftarrow{h_1}, ..., \overleftarrow{h_T})$. We concatenate a pair of the hidden states at each time step to build a sequence of annotation vectors $(h_1, ..., h_T)$ where $h_j = [\overrightarrow{h_j}; \overleftarrow{h_j}]$. Each annotation vector h_j encodes the information about the j-th word with respect to all the other surrounding words in the sentence.

3.3 Attention-based Decoder

We address the constraint of the fixed output dictionary in vanilla sequence-to-sequence approaches by modifying the decoder framework. The mainly changes are (as shown in Algorithm 1) as bellows:

- We select a word from the candidate words $(x_i, ...x_j)$ rather than on a fixed output dictionary in each step. This mechanism keeps all the generated words come from the input sentence and has the ability to generate a word that occurs in the test sentence but not in the train sentence.
- Once a word x_k is selected, all the words $(x_i, ..., x_{k-1})$ will be deleted and the candidate words in the next step will be $(x_{k+1}, ...x_l)$. This mechanism keeps the selected words in the order that they appear in the input sentence.

Now the key question is how to choose the correct word from the candidate words $(x_i, ...x_j)$ in each step t. We achieve it by selecting the word x_k with the highest relevance weight u_{tk}, which is computed by repurposing the attention mechanism of Section 2.2. The attention mechanism of Section 2.2 computes the relevance weight vector u_t on all the input sentence $(x_1, ..., x_T)$ in each step t. This mechanism is unsuited to our task since we only need to consider the relevance weights of the subsequence $(x_i, ...x_j)$ in each step t. Hence, we make a modification of the attention mechanism in Equation 4 and model $p(y_t \mid \{y_1, ..., y_{t-1}\}, c)$ in Equation 3 as follows:

$$\begin{aligned} u_{tk} &= v^T tanh(W_1 h_k + W_2 s_{t-1} + W_3 d_{k-i}) \quad k \in (i, ..., j) \\ p(y_t \mid \{y_1, ..., y_{t-1}\}, c) &= softmax(u_t) \end{aligned} \tag{6}$$

where d_{k-i} is the embedding of the distance between previous selected word x_{i-1} and the word x_k. The distance information is very important for our model, since the latter word is more likely to be selected when two words have similar context embeddings in disfluency detection. Once x_k is selected, we will use it to update the state of the decoder RNN and select another word from the words ranging from

$(x_{k+1}, ..., x_l)$ (as shown in Figure 2). To learn the parameters of our neural attention-based model, we minimize the negative log-probability of the output sequence over the input data $\{(x_i, y_i)\}_{n=1}^{N}$ during training:

$$-\sum_{i=1}^{N} log(p(y_i|x_i)) = -\sum_{i=1}^{N} log(\prod_{t=1}^{T} softmax(u_t)) \quad (7)$$

The detailed learning algorithm is shown in Algorithm 1.

4 Network training

4.1 Parameters

Pretrained word embedding. There are lots of methods for creating word embeddings. As (Dyer et al., 2015) does, we use a variant of the skip n-gram model introduced by (Ling et al., 2015), named "structured skip n-gram", where a different set of parameters are used to predict each context word depending on its position relative to the target word. The hyperparameters of the model are the same as in the skip n-gram model defined in word2vec (Mikolov et al., 2013). We set the window size to 5, and use a negative sampling rate to 10. The AFP portion of English Gigaword corpus (version 5) is used as the training corpus.

Hyper-Parameters. The LSTMs of both encoder and decoder has two hidden layers and their dimensions are set to 100. Pretrained word embeddings have 100 dimensions and the learned word embeddings have also 100 dimensions. Pos-tag embeddings have 12 dimensions. The dimension of distance d in Equation 6 is set to 8.

Parameter initialization. The learned parameters in the neural networks are randomly initialized with uniform samples from $[-\sqrt{\frac{6}{r+c}}, +\sqrt{\frac{6}{r+c}}]$, where r and c are the number of rows and columns in the parameter structure.

4.2 Optimization Algorithm

Parameter optimization. Parameter optimization is performed with stochastic gradient descent (SGD) with an initial learning rate of $\eta_0 = 0.1$ and a gradient clipping of 5.0. The learning rate is updated on each epoch of training as $\eta_t = \eta_0/(1 + \rho t)$, in which t is the number of epoch completed and the decay rate $\rho = 0.05$.

Early Stopping. We use early stopping (Giles, 2001) based on performance on dev sets. The best parameters appear at around 12 epochs, according to our experiments.

Dropout Training. To reduce overfitting, we apply the dropout method (Srivastava et al., 2014) to regularize our model. We apply dropout not only on input and output vectors of LSTM, but also between different hidden layers of LSTM. We observe a significant improvement on model performances after using dropout.

Unknown Word Handling. As described in section 3, the input layer contains a learned vector representation for the word w and a corresponding fixed pretrained vector representation $\widetilde{w}$. We randomly replace the singleton word in the training data with the UNK token during training, but keep corresponding $\widetilde{w}$ unchanged. This technique can deal with out-of-vocabulary words.

5 Experiments

5.1 Settings

Dataset. Firstly, we conduct our experiments on the English Switchboard corpus. Following the experiment settings in (Charniak and Johnson, 2001; Honnibal and Johnson, 2014; Wu et al., 2015), we use directory 2 and 3 in PARSED/MRG/SWBD as our training set and split directory 4 into test set, development set and others. We extract the repair disfluencies according to the EDITED label in the Switchboard corpus. Following (Honnibal and Johnson, 2014), we lower-case the text and remove all punctuations and partial words[1]. We also discard all the 'um' and 'uh' tokens and merge 'you know'

[1]words are recognized as partial words if they are tagged as 'XX' or end with '-'

semi-CRF (Ferguson et al., 2015)	90.1%	80.0%	84.8%
UBT (Wu et al., 2015)	90.3%	80.5%	85.1%

Table 4: Comparison of our neural attention-based model with the previous state-of-the-art methods on the test set of English Switchboard data.

and 'i mean' into single token. Automatic POS-tags generated from pocket_crf (Qian and Liu, 2013) are used as POS-tag in our experiments.

No public Chinese corpus is available now. For our Chinese experiments, we collect about 200k spoken sentences from minutes of meetings and annotate them with only disfluency annotations according to the guideline proposed by (Meteer et al., 1995). We respectively select about 20k sentences for development and testing. The rest are used for training. We use the word segmentation and POS-tag tools provided by the Language Technology Platform (Che et al., 2010) for preprocessing the original data in our experiments.

Metric. Following previous works (Ferguson et al., 2015; Wu et al., 2015), token-based precision (P), recall (R), and f-score (F1) are used as the evaluation metrics.

5.2 Performance of disfluency detection on English Swtichboard corpus

We build a baseline system using the Conditional Random Field (CRF) model. The hand-crafted discrete features of our CRF refer to those in (Ferguson et al., 2015). Table 3 shows the result of our model on both the development and test set.

We compare our neural attention-based model to four previous top performance systems. Our model outperforms state-of-the-art work and achieves a 86.7% f-score as shown in Table 4. Our model achieves 1.6 point improvements over UBT (Wu et al., 2015), which is the best syntax-based method for disfluency detection. The best performance by linear statistical sequence labeling methods is the semi-CRF method (Ferguson et al., 2015), achieving a 84.8% F1 score without leveraging prosodic features. Our model beats the semi-CRF model, obtaining 1.9 point improvements. Note that our method performs better than previous methods not only on precision , but also on recall. The comparison shows that our model is a good solution to disfluency detection.

5.3 Ablation Test

As described in section 3.1, we extract two kinds of hand-crafted discrete features for each token in a sentence. The duplicate features are extracted, because the reparandum(RM) and the following repair(RP) often share some identical words/POS-tags. In some cases, the word in a reparandum is the singular or plural of the word in the following repair, hence we extract the similarity features.

To test the individual effectiveness of duplicate features and similarity features, we conduct feature ablation experiments for our neural attention-based model. Table 5 shows the result. We can see that both the two kinds of features contribute to the performance improvements of disfluency detection and we can achieve a higher performance by integrating all of them into our model. This indicates that duplicate features and similarity features are both important to the neural model and they provide different kinds of information for disfluency detection.

Method	Dev			Test		
	P	R	F1	P	R	F1
Attention-based	93.0%	81.6%	86.9%	91.6%	82.3%	**86.7**%
- Duplicate	93.6%	78.0%	85.1%	90.8%	76.3%	82.9%
- Similarity	93.3%	82.0 %	87.3%	92.3%	80.9%	86.2%
- Duplicate - Similarity	93.2%	76.8%	84.2%	89.4%	76.2%	82.3%

Table 5: Results of feature ablation experiments on English Switchboard data.

Method	Dev			Test		
	P	R	F1	P	R	F1
CRF	76.5%	42.0%	54.2%	75.9%	41.6%	53.8%
Attention-based method	83.7%	50.6%	63.1%	82.4%	48.9%	61.4%

Table 6: Disfluency detection performance on Chinese annotated data.

5.4 Performance of disfluency detection on Chinese annotated corpus

In addition to English experiments, we also apply our method on Chinese annotated data. As there is no standard Chinese corpus, no Chinese experimental results are reported in (Honnibal and Johnson, 2014) and (Qian and Liu, 2013). We only use the CRF-based labeling model as our baselines. Table 6 shows the results of Chinese disfluency detection. Our models outperform the CRF model by more than 7 points on f-score which shows that our method is more effective.

6 Related Work

Most related works on disfluency detection are aimed at detecting repair type of disfluencies. (Johnson and Charniak, 2004) proposed a TAG-based noisy channel model for disfluency detection. The TAG model was used to find rough copies. Following the work of (Johnson and Charniak, 2004), (Zwarts and Johnson, 2011) extended the TAG model using minimal expected f-loss oriented n-best reranking with additional corpus for language model training. (Qian and Liu, 2013) proposed a muiti-step learning method using weighted max-margin markov network (M^3N). They showed that M^3N model outperformed many other labeling models such as CRF model. (Ferguson et al., 2015) used the Semi-Markov CRF model for disfluency detection and achieved high f-score by integrating prosodic features.

Many syntax-based approaches have been proposed which jointly perform dependency parsing and disfluency detection. (Lease and Johnson, 2006) involved disfluency detection in a PCFG parser to parse the input along with detecting disfluencies. (Rasooli and Tetreault, 2013) designed a joint model for both disfluency detection and dependency parsing. (Honnibal and Johnson, 2014) presented a new joint model by extending the original transition actions with a new "Edit" transition. This model achieved good performance on both disfluency detection and parsing. (Wu et al., 2015) proposed a right-to-left transition-based joint method and achieved the state-of-the-art performance compared with previous syntax-based approaches.

RNN had been used to disfluency detection. (Hough and Schlangen, 2015) explored incremental detection, with an objective that combines detection performance with minimal latency. This approach achieved worse performance compared with other works for the latency constraints. (Cho et al., 2013) used word embeddings learned by an RNN as features in a CRF classifiers.

7 Conclusion and Future Work

In this paper, we firstly regard the disfluency detection as a sequence-to-sequence problem and propose a neural attention-based model. Our model break the constraint of vanilla sequence-to-sequence method that the size of the output dictionary should be fixed a priori by modifying the structure of decoder. Experimential results show that our method achieves the best reported performance on the commonly used English Switchboard corpus and a better performance than CRF model on in-house Chinese annotated data.

In the future, we will try to incorporate character-based representations into the encoder model. We would also like to jointly model disfluency detection and automatic punctuation using some neural network.

Detecting Sentence Boundaries in Sanskrit Texts

Oliver Hellwig
Düsseldorf University, SFB 991
ohellwig@phil-fak.uni-duesseldorf.de

Abstract

The paper applies a deep recurrent neural network to the task of sentence boundary detection in Sanskrit, an important, yet underresourced ancient Indian language. The deep learning approach improves the F scores set by a metrical baseline and by a Conditional Random Field classifier by more than 10%.

1 Introduction

Most NLP tasks that deal with written texts take it for granted that sentences are separated reliably by punctuation marks, although punctuation has been added quite late to many writing systems. The large corpora in Old- and Middle-Indian languages, which belong to the central sources for understanding the history of South Asia, generally lack dedicated punctuation marks. This paper applies deep recurrent neural networks (RNN) to a combination of morphological and lexical features for detecting sentence boundaries (SB) in Sanskrit, the oldest and most important of these Indian languages.

Traditional editions of Sanskrit texts use a *scriptio continua*, which lacks several orthographic elements that structure texts in modern Western languages. Single words are frequently not separated by blank spaces due to missing orthographic regulation, or because the words are merged through the euphonic rules called *sandhi* ("connection").[1] Moreover, Sanskrit texts don't have a consistent and unambiguous system for marking SBs. Editors and scribes insert so called (double) *daṇḍa*s ("sticks", indicated by | and || in this paper) to mark the end of metrical structures. The position of these *daṇḍa*s can be derived directly from the prosodic structure of a text, and *daṇḍa*s always occur at the end of text lines, which coincide with half-verses in most printed editions. While single *daṇḍa*s mark the end of a half-verse, double *daṇḍa*s should, at least theoretically, indicate, where a stanza in the given metre is completed. Double *daṇḍa*s typically occur after every second line or half-verse of a metrical text, because the stanzas are finished at these points. In this function, they are meant to improve the readability of a text. As many sentences terminate at the end of a half-verse or of a stanza, *daṇḍa*s provide a good baseline for punctuation prediction (refer to Table 3). Many editors, however, also insert double *daṇḍa*s after a single or after three metrical lines, when they feel that a sentence is completed at these positions.[2] In this way, the purely metrical motivation of double *daṇḍa*s is mingled with the new function of a punctuation mark – leaving aside the fact that the philologically interesting inner-line SBs cannot be marked in the *daṇḍa* system.

Linguistic peculiarities of Sanskrit complicate the task. English, for example, encodes a large amount of its syntax through a strongly regulated word order, and structures its sentences by subordinating conjuctions. While these data provide a lot of the information necessary for restoring punctuation, Sanskrit has a rather loose word order with a tendency to subject-object-verb constructions, it uses conjunctions quite sparingly, and their position provides only weak indications for the presence of SBs. As the Indian

[1] The two words *parvatasya agre*, for example, are merged into one string *parvatasyāgre* by the rule *a+a=ā*; refer to Kielhorn (1888, 6ff.) for an overview. *Sandhi* is one of the main problems for Sanskrit NLP.

[2] Refer to Hopkins (1901, 194): "The number of verses in a (...) stanza may be decreased or increased by one or two (...). Sometimes, however, where one or three hemistichs make a stanza, it is merely a matter of editing."

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 288–297, Osaka, Japan, December 11-17 2016.

grammatical tradition has emphasized (Section 2), determining the boundaries of a sentence is equivalent to grasping its full semantic meaning.

The need for reliable punctuation on sentence level is beyond question. Access to full sentences is central for NLP tasks such as dependency parsing or role labeling. In addition, detecting SBs is also important from a philological perspective. The metrical texts considered in this paper belong to a tradition of (pseudo-)oral poetry that still survives in parts of India (Smith, 1987). The constituent structure of sentences (e.g., extensive right branchings) or the presence of enjambements, which are easily detected when SBs are known, provide important evidence for understanding the transition of these epics from an oral to a written state (Sellmer, 2015; Parry, 1930). More generally, Sanskrit provides a challenging application scenario for NLP due to the richness of its phonetics (*sandhi*), morphology, lexicon, and semantics. In spite of its historical importance, it is heavily underressourced from the perspective of NLP, and the size of its corpus prevents a purely manual annotation of linguistic phenomena.[3]

The remainder of the paper is structured as follows. Section 2 sketches how a sentence was defined in the tradition of classical Indian grammar, and summarizes related research from NLP and automatic speech recognition. Section 3 reports results of a test annotation, details the annotation guideline, and describes the data prepared for this study. Section 4 introduces the features and the deep learning model. Section 5 describes the evaluation baselines given by prosodical markers and a CRF model, discusses the performance of the model, and identifies critical areas. Section 6 summarizes the paper.

2 Related Work

Classical Sanskrit was systematically de- and prescribed in the famous grammar Aṣṭādhyāyī of Pāṇini (around 350 BCE, Scharfe (1977)), who used Sanskrit as a metalanguage, and applied methods such as rewrite rules and rule inheritance for minimizing the text length (Kiparsky, 2009). While the Aṣṭādhyāyī deals exhaustively with phonetics and morphology, syntax only plays a subordinate role. Its main syntactic contribution is the *kāraka* theory, which describes the interaction between nominal case suffixes and verbs (Cardona, 1976, 215ff.). The grammatical tradition following Pāṇini provided empirical, verb-centered definitions of sentences (Matilal, 1966, 377ff.). Because many Sanskrit sentences don't overtly express the copula "to be", these definitions gave rise to extended discussions about the underlying grammatical and cognitive structures of sentences such as *puṣpaṃ raktam* (flower:NSG red:NSG), which may mean "a red flower" or the complete sentence "the flower is red" (Deshpande, 1991). Missing copulae introduce a high degree of ambiguity in the SB detection task, as will be seen in Section 5.3. The later philosophical school of Nyāya concentrated on the conditions that make a sentence meaningful and complete for a competent speaker of Sanskrit (Matilal, 1966, 385ff.), and that include the semantic compatibility of the words (*yogyatā*) and their correct grouping (*saṃnidhi*; see Kulkarni et al. (2015)). If an utterance fulfills these conditions, it creates the intended cognition (*śābdabodha*) in the listener. So, the Indian tradition claims that only a competent speaker can determine the boundary of a sentence, but does not provide formal criteria for deciding if a sentence is complete or not.

Related research in NLP mainly deals with punctuation restoration in speech transcripts, and in languages such as Chinese that traditionally don't use punctuation marks for structuring syntactic sequences. Liu et al. (2005) contrast Hidden Markov Models (HMM), Maximum Entropy classifiers and Conditional Random Fields (CRF). They obtain a significant decrease of the SB detection error when processing lexical and automatically induced POS features using a CRF. Baldwin and Joseph (2009) perform simultaneous case and punctuation restoration in English texts. They process automatically annotated lexical, POS, and chunk features with a linear kernel Support Vector Machine. The authors report the highest F score for punctuation restoration, when they iteratively label the training and test sets with the output of the classifier, and retrain with the augmented feature space ("iterative retagging"). Zhao et al. (2012) train CRFs on the task of inserting punctuation in Chinese text, using features from different annotation levels of a Chinese treebank, and observe an increase in the F score, when higher level features such as

[3]There exist no reliable estimations of the real size of Sanskrit literature. The GRETIL website (`http://gretil.sub.uni-goettingen.de/`), which provides digital transcripts of a few percent of all printed Sanskrit texts, may contain around 15 million lexical tokens (estimation of the author; numbers may be significantly higher due to Sandhi). Large parts of the Sanskrit literature are still only transmitted as manuscripts.

POS tags or chunks are combined with lexical information. Tilk and Alumäe (2015) model the restoration of commas and periods in Estonian speech transcripts with a two-stage Long Short-term Memory (LSTM) approach. The first LSTM is trained on a large written corpus with lexical information in 1-hot-encoding as predictors and the associated punctuation as predicted classes. Following Seide et al. (2011, 26), the authors combine the output of the last hidden layer of this text LSTM with duration features from a smaller corpus of punctuated speech transcripts. This combined feature set is fed into a second LSTM that performs the final classification.

Algorithms based on short range models (n-grams, HMMs) or those requiring strict positional information may not be applicable to Sanskrit for several reasons. Sanskrit has a relatively free word order (Gillon and Shaer, 2005; Hock, 2013), and encodes many syntactical relations through its morphology, so that the positional information inherent in an n-gram model may not contribute as strongly as in English or Chinese. In addition, Sanskrit NLP suffers from data sparsity in the lexical domain. The corpus on which the models are trained contains 3,950,000 disambiguated lexical tokens. New data for pretraining a lexical model cannot be generated on the fly, because the phonetic phenomenon of Sandhi introduces a high degree of ambiguity (Hellwig, 2015b), and sufficiently large digitized Sanskrit corpora are missing.

CRFs as used by Liu et al. (2005) and Zhao et al. (2012) are more flexible than HMMs in modeling the feature space involved in SB detection, because their input features can, in principle, come from arbitrarily long ranges around a focus word, and because they are trained to maximize the classification accuracy. RNNs as used by Tilk and Alumäe (2015) are equally able to capture the long-range interactions between morphology, lexicon, and output symbols that can be hypothesized to play an important role in SB detection. Section 5 will compare their efficiency in the present task. The problems of exploding and vanishing gradients (Pascanu et al., 2013) can be handled with Long Short-Term Memory units (LSTM, for the vanishing ones (Hochreiter and Schmidhuber, 1997), combined with a gradient cutoff) or with Hessian free training of the network (Martens and Sutskever, 2011). Stacked LSTMs as used by Sutskever et al. (2014) with bidirectional units (Schuster and Paliwal, 1997) seem to provide a promising approach for labeling SBs in Sanskrit.

3 Data

3.1 Test annotation

The discussion in Section 2 has shown, that the Sanskrit grammatical tradition does not provide a solid basis for developing a practical annotation guideline for SBs. As a consequence, ten sequences of at least two metrical lines that contain complex syntactic phenomena were annotated independently by three external annotators and the author of the paper. Given the small size of the data set, this annotation was not primarily meant to determine the true inter-annotator agreement (IAA), but rather to obtain quantitative support for ambiguous cases in the annotation guideline. The lines were tokenized according to Western editorial standards without resolving Sandhis and compounds.

Assuming that a period can be inserted after each of the 360 tokens, the annotation yielded an IAA of 0.805, using Fleiss' κ (Fleiss, 1971). When only those tokens are considered after which at least one annotator inserted a period, the IAA drops to $\kappa = 0.312$. A detailed analysis shows that almost all unanimous annotations concern periods that coincide with (double) *daṇḍa*s, while there is substantial disagreement about inner-line periods.

3.2 Guideline

Drawing from the results of the initial annotation and from ideas proposed in Matilal (1966), this paper defines a Sanskrit sentence as a sequence of words that contains at least an overtly expressed finite verb (type s_1; minimal sentence length: one word[4]), or two non-verbal elements with an unexpressed copula denoting equivalence or existence[5] (type s_2). s_1 and s_2 can be expanded by (recursive and/or compound) subordinate clauses and matrix sentences. As a direct consequence, sentences on the s_1 or s_2 levels that

[4]Sentences such as *gacchāni* 'I shall go' don't need to overtly express the personal pronoun *aham*.

[5]Existence: *hastināpure vaṇik* "[there is/was a] merchant in [the city of] Hastināpura"; equivalence: *puṣpaṃ raktam*, see page 2.

are connected by a (coordinating) conjunction such as *ca* 'and' are interpreted as separate sentences in this paper. The following three cases need special consideration:

Overtly Expressed Subjects No period is inserted between main clauses separated by a coordinating conjunction such as *ca* 'and', if the first sentence overtly expresses the subject, and the following sentences use the same subject without overtly expressing it.

The particle *iti* The particle *iti* 'thus' marks the end of a direct speech, or of a personal opinion presented as a direct speech. The direct speech terminated by *iti* is interpreted as a matrix sentence and, therefore, not separated by an SB.

Formulae and interjections Interjections and formulaic phrases are marked as separate clauses, if they are not embedded as matrix sentences.[6]

3.3 Data

One annotator used the guideline (Section 3.2) to mark sentence ends in 226 chapters with 96,292 lexical tokens, which were drawn from the metrical texts in the Digital Corpus of Sanskrit (DCS, Hellwig (2015a)[7]). Although each chapter constitutes a single long sequence with unknown punctuation, most metrical texts simulate an oral presentation by inserting the stock line "[some person] said[8]" between closed narrative blocks. Therefore, the chapters have been split up into a total of 609 of such blocks ("sequences"), which represent the individual statements of the persons participating in a conversation. The epic Mahābhārata (MBH) contributes most of the data. Because the text has probably grown over centuries and incorporated diverse written and oral sources (Brockington, 1998), the predominance of the MBH does not bias the data unduly towards the style of one author.

A total of 9,562 SBs has been annotated. 85.6% of the SBs coincide with (double) *daṇḍa*s, which provide a strong baseline for SB detection (Table 3). The annotated chapters contain a total of 9,027 word types, 3,838 of which are hapax legomena. The sentences have a mean length of 10 tokens (median: 8), and 90% of all sentence lengths are found in the interval [3,20].

4 Experimental Settings

4.1 Features

This section describes which features were considered for SB detection, and motivates their use. Their influence on the prediction accuracy is reported in Section 5.1.

***Daṇḍa* information** Because *daṇḍa*s provide a strong baseline for SB detection (see Table 3), and omitting them drastically reduces the F score in all configurations, they are used as features in all settings. (Double) *daṇḍa*s are encoded as dummy variables.

Morphological Information Sanskrit has a rich, though partly ambiguous Indo-Aryan morphology. Nouns, adjectives, pronouns, and declinable verbal participles are inflected in eight cases, three numbers (including dual), and three genders, while finite verbal forms occur in three numbers, three persons, and over tenses and modes (aspects). Although Sanskrit also uses conjunctions to join subordinate and main clauses, verbal subordination is typically expressed by the indeclinable absolutive (gerund; *tvānta* and *lyabanta*).[9]

As morphology provides strong indications for the inner structure of a sentence, it is included in the feature set either in 1-hot- (**1h**, each observed combination of morphological subfeatures is mapped to

[6] Refer to Wackernagel (1978 (reprint from 1896, II, 5) on short sentences with a particle-like function.

[7] This corpus collects 279 texts from different domains with 3,950,000 tokens with gold-annotations on the morphological, lexical, and word semantic level.

[8] *vyāsa uvāca* "[The sage] Vyāsa said" is a typical example of these stock lines, which are always terminated by a single *daṇḍa*, and not written in śloka metre.

[9] A typical toy example for this construction runs like: *rāmo* ('Rāma' NSG) *vanaṃ* ('forest' ASG) *gatvā* ('go' ABS) *sītāṃ* ('Sītā' ASG) *paśyati* ('see' PR3.SG), "Rāma, having gone to the forest, sees Sītā." = "After Rāma has gone to the forest, he sees Sītā."

a distinct position in a 1-hot vector v_M) or in a decomposed encoding, in which each position of v_M encodes the presense or absence of a subfeature such as 'nominative' or 'perfect tense' (**dec**, refer to the featurization in Cotterell and Schütze (2015, 1289)). Both encoding modes (**1h**, **dec**) don't distinguish between different morphological derivations of tenses and modes.

Because the DCS does not contain syntactic annotations, morphological information is also used to generate possible syntactic links. Given a context size of $s = 5$, a word w_p at position p in a sequence, and the set of words $W_q = \{w_q | \, |q - p| \leq s, q \neq p\}$, a link between w_p and w_q is generated, if (1) $p < q$ and w_p belongs to the same compound (*samāsa*) as w_q, (2) w_p and w_q are nominal forms with the same case, number, and gender, (3) if one of w_p and w_q is a verb and the other one a congruent nominative, (4) if one of w_p and w_q is an absolutive and the other one a finite verb, or (5) if w_p and w_q belong to a set of correlative conjunctions and pronouns such as *yadā* 'when'-*tadā* 'then' or *yad* 'which'-*tad* 'that'. These links are encoded as two sums weighted with $\frac{1}{|p-q|}$ for the left and right contexts. Although the existence of a link does not guarantee that w_p and w_q belong to the same sentence, t-tests of the weighted values with the SB labels as binary factor yield highly significant test statistics of $t = -31.99$ (left) and $t = 45.70$ (right), such that testing the predictive power of these features appears justified.

Lexical Information Sanskrit has a rich vocabulary, and Sanskrit authors put importance on the use of synonyms. An unsophisticated text such as the MBH, for example, uses 35 synonyms to denote the warrior Arjuna, or 14 for the concept "mountain". As a consequence, one faces considerable data sparsity, when lexical information is used in 1-hot encoding. Low dimensional embeddings built from reduced vector space models (VSM, Turney and Pantel (2010)) or from neural networks (Bengio et al., 2003; Mikolov et al., 2011) have been shown to offer a workaround for this problem. Therefore, word embeddings generated with the `word2vec` tool (Mikolov et al., 2011)[10] are used as lexical features in all configurations marked with **w2v**.

As an alternative to a fully lexicalized model, the setting **indecl** uses the set of the most frequent 100 conjunctions and indeclinables in 1-hot encoding as the sole lexical information. This setting is motivated by the idea that these words indicate the basic structure of a sentence.

Yuret (1998) has shown that pointwise mutual information (PMI) between words can be used for building dependency structures. Therefore, normalized PMI for a window of size $s = 5$ around each w_p is added to the feature space in analogy to the syntactic links described above. PMI is either calculated from lexical information (**lpmi**), or from a mixture of lexical and word semantic data (**lspmi**).

4.2 Network Architecture and Settings

The RNN consists of a linear input layer with a dropout rate of 0.1 (Hinton et al., 2012), one or more bidirectional LSTM layers without peephole units, and a softmax output layer. All network weights are randomly initialized with a uniform distribution in $[-0.01, +0.01]$. The initial learning rate is set to 0.0008, and linearly decreased to the value of 0.0001. Training is performed with stochastic gradient descent, gradient clipping at the LSTM units, and a constant momentum of 0.95. Because the output of the network is a single binary variable, it is decoded using a threshold of 0.5. The model is implemented in C++.

The experiments reported in Section 5 are performed with a ten-fold cross-validation (CV). In order to make the results comparable to each other, the same random split of the data was used in all experiments.

5 Evaluation

5.1 Feature Selection

In order to assess how the features (Section 4.1) influence the classification results, flat networks with dropout and one bidirectional LSTM are trained on subsets of morphological and lexical features. Table 1 shows that the decomposed morphological encoding creates better results than the 1-hot encoding. It may be conjectured that the decomposed version can estimate the relevance of rare morphological features (e.g., genitive dual) from their more frequent subfeatures (e.g., genitive in all numbers). The

[10] Settings: Trained with full chapters, i.e. *daṇḍa*s were ignored; embedding size: 200, bow, window size: 10, 5 iterations.

w2v	**lspmi**	85.50	**79.31**	**82.28**

Table 2: Influence of lexical features; settings as in Table 1; decomposed morphological features (**dec**), no morphological links

hard-coded morphological links don't improve the performance, and are therefore discarded from the feature set.

Table 2 shows that lexical features have a noticeable, though not too large effect on the classification results. While the fully unlexicalized setting produces the worst results, the combination of word embeddings (**w2v**) with semantically enriched lexical links (**lspmi**) produces the best F scores (Table 2). This result demonstrates that neural language models create meaningful embeddings even from small training corpora, although the full lexical disambiguation of the training data is certainly helpful in learning proper representations.

The LSTM models for the final evaluation are trained on decomposed morphological features, neural embeddings of size 200, and semantically enriched lexical links. The basic architecture follows the description in Section 4.2, and the number of inner bidirectional LSTM layers is set to 2 or 3.

5.2 Comparing baseline models and LSTMs

Table 3 presents the baselines and the results for different LSTM architectures. The prosodical baselines are calculated by inserting an SB either at each *daṇḍa* or double *daṇḍa* ("baseline *daṇḍa*"), or at each double *daṇḍa* only ("baseline double *daṇḍa*"). As remarked in Section 1, editors tend to move double *daṇḍa*s by one line, if they are able to indicate an SB in this way. Therefore, double *daṇḍa*s present a rather precise baseline for SB detection in metrical Sanskrit texts, although their recall is low.

As many previous papers apply CRFs to SB detection (Section 2), CRFs trained with morphological features and different levels of lexical features are used as a second set of baselines. The central rows in Table 3 show that the F scores of CRFs are only slightly higher than those of the prosodical baselines. Error analysis reveals that CRFs base their predictions mainly on *daṇḍa* information, which explains the comparatively small differences between the F scores of the two baselines (75.55 vs. 73.80).

Bidirectional LSTMs significantly outperform both baselines. Comparing Tables 1, 2 and 3 shows that their F scores increase with their depth, i.e. the number of stacked LSTM layers. When using a deeper architecture, the strongest improvements are observed in the model recall. The best single model in Table 3 almost reaches precision and recall of the two metrical baselines, and improves the F score of the double *daṇḍa* baseline by almost 13%.

Classifier	Architecture	P	R	F
Prosodical baseline	*daṇḍa*	59.34	**85.54**	70.07
	double *daṇḍa*	**89.34**	62.86	73.80
CRF	no lex.	83.85	68.75	75.55
	freqindecl	83.82	68.74	75.54

0-1-0	1.07	14 (0.80)	36 (1.05)	22 (0.75)	26 (1.98)	4 (2.92)

Table 4: Sentence based evaluation of the output of the best RNN from Table 3, stratified by sentence length classes (columns 3ff.). Column 1: $b_i = 1$: b(eginning) of sentence s_i is detected; $e_i = 1$: e(nd) detected; $i_i = 1$: the i(nner) part of s_i does not contain superfluous SBs.

5.3 Discussion

Table 3 demonstrates that RNNs clearly outperform both baselines, and that stacking the bidirectional LSTM layers further improves the performance. However, the results don't tell much about the actual usability of the SB labeler, especially about how many full sentences were labeled correctly, and which sentence structures or types are prone for errors. To assess these questions, a metric similar to the "strict" evaluation in Liu and Shriberg (2007) is used. Instead of measuring the annotation precision for single instances of SBs, this metric considers if full sentences have been annotated correctly, and where errors occur in their annotation. For every sentence s_i in the gold annotation it is tested, if the RNN has marked the beginning b_i of s_i (= the end of s_{i-1}) and the end e_i of s_i correctly, and if it has inserted additional SBs in between b_i and e_i (variable i_i). A sentence is accepted as correct in this evaluation, if b_i and e_i are correct ($b_i = 1$, $e_i = 1$), and if there exist no superfluous SBs between them ($i_i = 1$).

Table 4 shows the proportions of the $2^3 = 8$ combinations of these three binary labels for the output of the best RNN from Table 3 (3 hidden layers, dropout). The model achieves an overall "strict" accuracy of 65.08% (configuration 1-1-1, column 2). If the configurations in which only one SB has been missed (0-1-1, 1-0-1) or in which wrong SBs have been inserted between two correctly labeled SBs (1-1-0) are accepted as partial matches, this "lenient" accuracy goes up to 95.54%.

It has been noted in Section 1 that sentences starting or ending in the middle of a text line convey important text historical information. In addition, the CRF failed almost completely to detect these more unusual SBs. In order to examine how these cases are handled by the LSTM, the output of the best LSTM from Table 3 has been stratified according to the start and end positions of the sentences. It may be expected that sentences starting at the beginning of a text line (b) and ending at a *daṇḍa* (d) or double *daṇḍa* (d2) may have lower error rates than those starting and/or ending in the middle of a line (m). The results displayed in Table 5 support this hypothesis. The highest accuracy rates are observed for the

Start-end	Corr.	1 err.	>1 err.	Acc.
b-m	463	673	149	36.03
b-d	1185	495	72	67.64
b-d2	4034	1044	65	78.44
m-m	27	37	34	27.55
m-d	146	202	68	35.10
m-d2	368	461	39	42.40

Table 5: Sentence based evaluation of the output of the best RNN from Table 3, stratified by start and end positions of sentences. b: Sentence starts at the b(eginning) of a text line, m: in the m(iddle); d/d2: sentence ends at a *daṇḍa*/double *daṇḍa*

configurations b-d and b-d2, while accuracy rates for *-m-* configurations are clearly lower. Although these cases constitute only a minority of the training data, and their accuracy rates may rise when more labeled data are available, the presence of the (double) *daṇḍa* feature (page 4) is certainly most relevant for the observed differences in the accuracy levels.

Columns 3ff. of Table 4 provides another view of the same data, which have been stratified with regard to length classes of sentences. As could be hypothesized from Table 5, the highest accuracy is observed for length class 3, which contains, among others, all sentences that extend over two lines between two double *daṇḍa*s (subset of configuration b-d2). A closer inspection of class 5 (sentences containing at least 30 words) shows, that most of the correct instances of this class have between 30 and 50 words, although the model also marks two very long sentences correctly. MBH 1.19.3-15, a description of the ocean, is a right-branching construction typical for poetic style (*kāvya*). The initial phrase *dadṛśāte tadā tatra samudram* ("Then, both of them saw the ocean there") is expanded by several lines of accusative constructions that depend on the head word *samudram*. Apart from congruent adjectives and appositions, the expansions also contain subordinate participle clauses. This means that the whole sentence can not be reduced to an easily memorizable pattern in the form verb-adverb*-acc*, and demonstrates that stacked LSTM units are in principle able to capture such long-range syntactic dependencies.

A considerable number of errors is produced by short sentences that start or end in the middle of a text line (*-m-* configurations), and for which only one boundary is detected correctly (configurations 0-1-1 and 1-0-1 with length class 1 in Table 4). One of the syntactical patterns that produce most of the errors in this class consists of sequences of words in nom. sg. lacking a copula as observed in MBH 1.147.11:

ātmā	*putraḥ•*	*sakhā*	*bhāryā•*
self:NSGM	son:NSGM	friend:NSGM	wife:NSGF

"[The] son [is the] self. [The] wife [is a] friend."

Another problematic pattern is formed by sequences of the form verb-sg acc-sg* (MBH 6.41.64):

anumānaye	*tvāṃ•*	*yotsyāmi* ...
ask:PR1.SG	you:ASG	fight:FUT1.SG

"I ask you [for permission]. I will fight ..."

As soon as more training data are available, a Viterbi search over decoded sentence patterns or an additional CRF layer (Huang et al., 2015) may help to reduce the number of such errors.

6 Conclusion

Although the proposed deep bidirectional LSTM model clearly outperforms the metrical and CRF baselines, its accuracy is currently not high enough for performing a reliable unsupervised annotation of SBs. As the evaluation of short sentences has shown, many of the problematic cases cannot be solved on the morpho-syntactic level, but require comprehensive lexical and word semantic information. This finding suggests that a larger amount of training data, including more tokenized texts and more annotated SBs, may improve the performance. In this context, the LSTM model will be used for pre-annotating SBs. Another line of future research will concentrate on the representation of input features. Recent studies

such as Labeau et al. (2015), but also Hellwig (2015b) for Sanskrit have demonstrated that the processing of morphologically rich languages may benefit from using sub-word units, skipping lexicalization altogether, or integrating it into a "deeper level" of the network architecture. Given the complexity of Sanskrit phonetics and the richness of its vocabulary, such an approach may prove useful, as soon as more SB annotations are available.

Abstract

In this paper, we propose a new annotation approach to Chinese word segmentation, part-of-speech (POS) tagging and dependency labelling that aims to overcome the two major issues in traditional morphology-based annotation: Inconsistency and data sparsity. We re-annotate the Penn Chinese Treebank 5.0 (CTB5) and demonstrate the advantages of this approach compared to the original CTB5 annotation through word segmentation, POS tagging and machine translation experiments.

1 Introduction

The definition of "word" is an open problem in Chinese linguistics. In previous studies of Chinese corpus annotation (Duan et al., 2003; Huang et al., 1997; Xia, 2000), the judgement of word-hood of a meaningful string is based on the analysis of morphology: A morpheme in Chinese is defined as the smallest combination of meaning and phonetic sound in Chinese language, which can be classified into two major types:
1). **Free morphemes**, which can either be words by themselves or form words with other morphemes; and
2). **Bound morphemes**, which can only form words by attaching to other morphemes.

An issue with word definition using morpheme classification is that, it potentially undermines the consistency of the representation of words. For example, "论" (theory) is a bound morpheme, therefore the string "进化论" (theory of evolution) is treated as a word; on the other hand the string "进化 | 理论" (theory of evolution) are treated as two words, despite the fact that the two strings have the same meaning and structure. In another example, "者" (person) is considered as a bound morpheme, therefore "反对自由贸易者" (people who are against free trade) is treated as one word, while the string without the bound morpheme, i.e. "反对 | 自由 | 贸易" (be against free trade), can only be treated as a phrase of three words.

The morphology-based word definition can also make the data sparsity problem worse in corpus annotation. As an evidence, in the Penn Chinese Treebank 5.0 (CTB5) which is an annotated corpus widely used to train Chinese morphological analysis systems, we found that one of the major sources of the out-of-vocabulary (OOV) words is the compounds that end with a monosyllabic bound morpheme. For example, compounds 利用率 (utility rate) and 次品率 (rate of defective product) end with the bound morpheme 率 (rate); 完成度 (degree of completion) and 活跃度 (degree of activity) end with the bound morpheme 度 (degree); 持续性 (sustainability) and 挥发性 (property of volatile) end with the bound morpheme 性 (property). While these compounds are sparse in the corpus, the morphemes which they

POS Pattern	Example
pronoun + noun	我校 (this university)
locative + noun	后门 (back door)
locative + verb	前述 (described above)
noun + locative	室内 (indoor)
pronoun + locative	此外 (besides)
adverb + verb	猝死 (sudden death)
noun + noun	厂房 (factory plant)
noun + measure	车辆 (vehicles)
adjective + noun	佳酿 (wines)
adjective + measure	高层 (high level)
verb + verb	抽取 (extract)
verb + particle	写完 (finish writing)
verb + adjective	打碎 (break)
verb + locative	综上 (accordingly)
verb + noun	辞职 (resign)
adjective + adjective	优雅 (elegant)
adverb + adjective	最新 (latest)
determiner + noun	各界 (all walks of life)
determiner + temporal	翌日 (the next day)

Table 1. Disyllabic character-level POS patterns.

CTB5 Example	Re-annotation
副主席/NN (vice president)	副/JJ (vice) 主席/NN (president)
透明度/NN (transparency)	透明/JJ (transparent) 度/SFN (degree)
非生产性/NN (unproductiveness)	非/JJ (none) 生产/VV (produce) 性/SFN (property)
中央集权式/JJ (politically centralized)	中央/NN (center) 集权/NN (centralization) 式/SFA (type)

Table 2. Some examples of the word and POS annotation in the original CTB5 and our re-annotation.

consist of can be frequently observed; this means these OOV words can be observed and learnt by a word segmenter if we split the morphemes as individual words in the annotation.

In this paper, we propose a simple annotation approach for Chinese word segmentation that overcomes the two issues: inconsistency and data sparsity, which are found in the traditional morphology-based annotation approach. We further propose a tagset for part-of-speech tagging and a label set for dependency labelling, which are consistent with our word segmentation strategy and capture more Chinese-specific syntactic structures. We re-annotate the entire CTB5 using this approach, and through word segmentation, POS tagging and machine translation experiments we demonstrate the advantages of our annotation approach compared to the original approach adopted in CTB5.

The remainder of this paper is organized as follows: in section 2 we will describe our proposed annotation approach to word segmentation; in section 3 we will present a POS tagset which is consistent with our word segmentation strategy and a new dependency label set; in section 4 we will demonstrate the effectiveness of our approach compared to the original CTB5 through experiments; we will conclude our work in the last section.

2 Word Segmentation Annotation

We categorize the words in CTB5 into three categories: Common words, names, and idioms. For names and idioms, we keep them as individual words since their word boundaries are relatively easy to recognize and the consistency in manual annotation can be achieved with less efforts. We will mainly focus on describing the treatments of common words in this section.

Tag	Description	Count in CTB5	Proposed annotation
NN	Noun	134,321	137,816
PU	Punctuation	75,794	75,935
VV	Verb	68,789	75,033
AD	Adverb	36,122	35,922
NR	Proper Noun	29,804	30,985
P	Preposition	17,280	17,721
CD	Cardinal Number	16,030	21,493
M	Measure Word	13,668	18,091
JJ	Adjective	12,979	13,898
DEC	Complementizer	12,310	12,346
DEG	Genitive Marker	12,145	12,145
NT	Temporal Noun	9,467	4,524
LC	Locative	7,676	0
VA	Predicative Adjective	7,630	7,518
CC	Coordinating Conjunction	7,137	7,134
PN	Pronoun	6,536	6,646
DT	Determiner	5,901	5,970
VC	Copula	5,338	5,521
AS	Aspect Particle	4,027	4,033
VE	“you3” (“have”)	2,980	2,980
OD	Ordinal Number	1,661	1,661
MSP	Other Particles	1,316	1,316
ETC	“deng3” (“etc.”)	1,287	0
CS	Subordinating Conjunction	888	888
BA	Causative Auxiliary	751	756
DEV	Manner Marker	621	627
SP	Sentence-final Particle	466	466
SB	Short Passive Auxiliary	451	451
DER	Resultative Marker	258	258
LB	Long Passive Auxiliary	245	245
FW	Foreign Word	33	391
IJ	Interjection	12	17
X	Unknown	6	6
SFN*	Nominal Suffix	0	13,212
SFA*	Adjectival Suffix	0	438
SFV*	Verbal Suffix	0	129

Table 3. Proposed tagset for part-of-speech tagging. The underlined characters in the examples correspond to the tags on the left-most column. The CTB POS are also shown.

The key in our method to define the boundaries of common words is the character-level POS pattern. Character-level POS has been introduced in previous studies (Zhang et al., 2013; Shen et al., 2014) which captures the grammatical roles of Chinese characters inside words; we further develop this idea and use it as a criterion in word definition.

We treat a meaningful disyllabic strings as a word if it falls into one of the character-level POS patterns listed in Table 1. The reason we focus on disyllabic patterns instead of other polysyllabic ones is that, based on our observation, meaningful strings with 3 or more syllables (other than names and idioms) are always compounds in Chinese, and therefore can be segmented into a sequence of monosyllabic and disyllabic tokens based on their internal structures. On the other hand, the internal structure in a disyllabic token, though still exists, is more implicit and harder to describe with syntactical relations; we believe that it would increase the difficulties for subsequent tasks, such as dependency parsing, if we further segment these disyllabic strings.

Following this strategy, a polysyllabic word can be then segmented based on its structure. This is illustrated with examples in Table 2.

3 Part-of-Speech and Dependency Label Set

To perform POS tagging re-annotation on CTB5 together with our proposed word segmentation approach, we use a POS tagset which is derived from the one used in the original CTB5 annotation. We show the tagset in Table 3 with comparison of number of occurrences of each tag in the original CTB5 and the re-annotated version, respectively. The tagset introduces several changes: First, we eliminate the use of the "LC" tag for locative words. This tag is assigned to all words that indicate locations and directions, such as 上 (up), 下(down), 左 (left), 右 (right), 内 (inside), 外 (outside) etc.. We instead tag these words based on their real syntactic roles in sentences, such as "NN" (noun), "AD" (adverb) or "VV" (verb). Second, we add three new tags into the tagset for suffixes: "SFN" (nominal suffix), "SFA" (adjectival suffix), and "SFV" (verbal suffix). These tags are given to monosyllabic tokens appearing at the end of compounds, which are the bound morphemes in the traditional view. Based on our observation, these tokens have the ability to determine the syntactic role of the entire compound. For example, any compound that end with a nominal suffix "度" (degree) always act as nouns in a sentence. It should be noted that because of this characteristic of suffixes, we can tag the children of suffixes in compounds based on their meaning but not their syntactic roles. We show some examples in Table 2 to illustrate our POS tagging strategy for compounds.

In Table 4 we present a dependency label set developed based on the Stanford Dependencies (De Marneffe et al., 2006) and its Chinese version (Chang et al., 2009), which defines 45 dependency relations for Chinese sentences. This label set is also closely related to the Universal Dependency[1] with many of their labels compatible with each other. We explain the major characteristics of our label set in the following subsection.

3.1 Chinese Specific Labels

dislocated The label "dislocated" is originally defined in the *universal dependencies* for languages such as Japanese to describe the syntactic relation of words in a topic–comment structure, but is not defined for Chinese. However, in Chinese it is frequent to see the topic–comment structure in a sentence, for example:

1. 這/this 本/-measure- 書/book 他/he 買/buy 的/-particle- (This book, he bought it)

In this sentence, 这本书 (this book) is the topic and 他买的 (he bought) is the comment. One common view of the syntactic structure of this sentence is that, 他 (he) is the subject of the predicate 他 (buy), and 书 (book) is the direct object. This treatment sees a topic–comment structure as having an OSV (object-subject-verb) word order, which is acceptable; it however has some problems in certain cases, for example:

2. 這/this 本/-measure- 書/book 他/he 買/buy 的/-particle- 昨天/yesterday 不見/disappear 了/-particle- (This book that he bought disappeared yesterday)

In this sentence, 书 (book) is still the direct object of 买 (buy), while it is also the subject of 不见 (disappear). Because of the nature of the dependency grammar we adopted, for such a structure we would have to choose one relation for 书 (book), either "nsubj" or "dobj", and discard the other relation which would cause a loss of the syntactic information encoded in the parse tree.

Moreover, the OSV word order cannot explain all topic-comment structure such as the following example:

3. 這/this 場/-measure- 火/fire 幸虧/fortunately 消防/firefighting 隊/team 來/come 得/-particle- 早/early (This fire, fortunately the firefighters came in time)

[1] http://universaldependencies.org/

Label	Description	Example Phrase	Example Dependency
acomp	adjectival complement	鞋是全新的 (the shoes are brand new)	**acomp**(是 are, 全新 brand new)
advmod	adverbial modifier	他看上去很疲倦 (he looks very tired)	**advmod**(疲倦 tired, 很 very)
amod	adjectival modifier	漂亮的首飾 (cute accessory)	**amod**(首飾 accessory, 漂亮 cute)
appos	appositional modifier	總統奧巴馬 (president Obama)	**appos**(奧巴馬 Obama, 總統 president)
asp	aspect marker	他給了我一本書 (he gave me a book)	**asp**(給 gave, 了 -aspect-)
attr	attributive modifier	他是個醫生 (he is a doctor)	**attr**(是 is, 醫生 doctor)
aux	auxiliary verb	必須解決 (must solve)	**aux**(解決 solve, 必須 must)
auxpass	passive auxiliary	他被刺殺了 (he was assassinated)	**auxpass**(刺殺 assassinated, 被 -auxiliary-)
auxcaus	causative auxiliary	把問題解決(solve the problem)	**auxcaus**(解決 solve, 把 -auxiliary-)
cc	coordinating conjunction	聰明又可愛 (smart and cute)	**cc**(聰明 smart, 又 and)
ccomp	closed clausal complement	他說他喜歡游泳 (He said that he likes swimming)	**ccomp**(說 said, 喜歡 likes)
conj	conjunct	聰明又可愛 (smart and cute)	**conj**(聰明 smart, 可愛 cute)
csubj	clausal subject	能夠代表祖國參賽是他的夢想 (being able to play in the game for his country is his dream)	**csubj**(是 is, 參賽 play)
csubjpass	clausal passive subject	他在考試中作弊被老師發現了 (that he cheated during the exam is found out by the teacher)	**csubjpass**(發現 find out, 作弊 cheet)
dep	undefined dependency	添加一個日程安排時間星期二地點 3 樓 (add an event, time Tuesday, location 3rd floor)	**dep**(時間, 添加)
det	determiner	那本書 (that book)	**det**(本 -measure-, 那 that)
discourse	discoursal modifier	唉，終於到星期五了 (oh, thank God it's Friday)	**discourse**(到 is, 唉 oh) **discourse**(到 is, 了-sentence-final particle-)
dislocated	dislocated modifier	書是他買的 (book he bought) 這場火幸虧消防隊來得早. (this fire, fortunately the firefighters came in time)	**dislocated**(書 book, 買 buy) **dislocated**(火 fire, 來 come)
dobj	direct object	買了一本書(bought a book)	**dobj**(買 bought, 書 book)
foreign	foreign compound	職棒大聯盟（Major League Baseball）	**foreign**(Major, League) **foreign**(Major, Baseball)
iobj	indirect object	他給了我一本書 (he gave me a book)	**iobj**(給 gave, 我 me)
list	list relation	添加一個日程安排時間星期二地點 3 樓 (add an event, time Tuesday, location 3rd floor)	**list**(時間 time, 地點 location)
mark	clause marker	他把信件給我之後就走了 (he left after he gave me the letter)	**mark**(給 give, 之後 after) **mark**(走 leave, 就 then)
mes	measure relation	一本書(a book)	**mes**(書 book, 本 -measure-)

ncomp	nominal complement	坐在椅子上 (sit on a chair)	**ncomp**(椅子 chair, 上 -complementizer-)
neg	negation modifier	不擅長 (be not good at)	**neg**(擅長 be good at, 不 not)
nn	noun compound modifier	原油期貨價格 (oil futures price)	**nn**(價格 price, 原油 oil) **nn**(價格 price, 期貨 futures)
npadvmod	noun phrase adverbial modifier	大約十米左右寬 (about 10 m wide)	**npadvmod**(寬 wide, 米 m)
nsubj	nominal subject	他給了我一本書 (he gave me a book)	**nsubj**(給 gave, 他 he)
nsubjpass	passive nominal subject	他被刺殺了 (he was assassinated)	**nsubjpass**(刺殺 assassinated, 他 he)
num	numeric modifier	一本書 (a book)	**num**(本 -measure-, 一 a)
p	punctuation	梨、橘子和香蕉 (pears, oranges, bananas)	**p**(梨 pears, 、)
pcomp	prepositional complement	由於路上人太多，我遲到了 (because it was so crowded, I was late)	**pcomp**(由於 because, 太多 so crowded)
pobj	prepositional object	他坐在椅子上 (he sits on a chair)	**pobj**(在 on, 椅子 chair)
ps	associative marker	這是我的家 (this is my home)	**ps**(我 me, 的 ‘s)
poss	possessive modifier	這是我的家 (this is my home)	**poss**(家 home, 我 me)
prep	prepositional modifier	他坐在椅子上 (he sits on a chair)	**prep**(坐 sits, 在 on)
prt	phrasal verb particle relation	他們打起來了 (they started a fight) 把數據整理成報告 (summarize the data into a report)	**prt**(打 fight, 起來 -auxiliary-) **prt**(整理 summarize, 成 become)
rcmodrel	relative clause complementizer	他回來的時候 (by the time he came back)	**rcmodrel**(回來 come back, 的 -complementizer-)
		這本是他買的書 (this is the book he bought)	**rcmodrel**(買 buy, 的 -complementizer-)
rcmod	relative clause modifier	他回來的時候 (by the time he came back)	**rcmod**(時候 time, 回來 come back)
		這本是他買的書 (this is the book he bought)	**rcmod(**書 book, 買 buy)
suff	suffix relation	科技界 (sci-tech industry)	**suff**(界 industry, 科技 sci-tech)
tmod	temporal modifier	他回來的時候天已經亮了 (it was bright outside by the time he came back)	**tmod**(亮 bright, 時候 time)
topic	topic marker	這本書是他買的 (this is the book he bought)	**topic**(書 book, 是 is)
		這是他們所不能想像的 (this is what they can’t imagine)	**topic**(這 this, 是 is)
vmod	verb modifier	他打開門發現屋裏有人 (he opened the door and found out there is somebody inside)	**vmod**(發現 found out, 打開 open)
xcomp	open clausal complement	他不喜歡打網球 (he doesn’t like to play tennis)	**xcomp**(喜歡 like, 打 play)

Table 4. Proposed dependency label set.

Unlike in the other two examples, the topic here, 這場火 (this fire), is not the direct object of the verb in the comment, 幸虧消防隊來得早 (fortunately the firefighters came in time).

To overcome these difficulties, we employ a different view which treats the topic–comment structure as having double subjects in a SSV word order. We define the first subject, 这本书 (this book) in example 2, as the head in a "dislocated" relation, and the subject-verb phrase, 他买的 (he bought) in example 2, as the modifier. The head in this dislocated relation can then form a "nsubj" (nominal subject) relation with the main predicate of the sentence, 不见 (disappear). Similarly, in example 3, the topic and the comment still form a dislocated relation even though the topic is not a direct object of the verb in the comment.

prt and ***prep*** We define the "prt" relation in two ways:

i. A relation between a verb and a particle. For example, 想像 (imagine) is the head in a "prt" relation of 所 (particle) in the sentence 這是他們所不能想像的 (this is what they can't imagine).
ii. A relation between a verb and its succeeding complement. For example, 打掃 (clean) is the head in a "prt" relation of 完 (finish) in the sentence 房間打掃完了 (the room has been cleaned).

We use the "prt" relation in the second case to capture the predicate-complement structure in Chinese. The verb 完 (finish) in the second example above functions to complement the meaning of the main verb, 打掃 (clean), and the sentence is still grammatical when the complement verb is removed: 房間打掃了 (the room is cleaned).

The complement verb sometimes also functions as a coverb in a serial verb construction, which takes its own direct object. For example:

4. 把/-auxiliary- 數據/data 整理/summarize 成/become 報告/report (summarize the data into a report)

Here the two verbs 整理 (summarize) and 成(become) form a "prt" relation, while they are the heads of 數據 (data) and 報告 (report) in the "dobj" relation.

A difficulty with labeling "prt" is that, it can be easily confused with the "prep" (prepositional modifier) relation. For example, one can argue that 成 (become) is a preposition instead of a verb and should be tagged as IN, so that the relation between 整理 (summarize) and 成 (become) would be "prep". To overcome this ambiguity, we apply a simple test: If the phrase headed by the word with a VV vs. IN ambiguity can be moved to a position before the main verb, then this word is a preposition and a prepositional modifier of the main verb; otherwise it is a verb. Here since the phrase "成 報告" (into report) cannot be moved to the position before 整理 (summarize), it should in fact be a verb phrase, not a prepositional phrase.

suff We define the suffix relation in a compound which has a "stem-suffix" structure. The suffix word with a POS tag SFN, SFA, or SFV is the root of the subtree formed by the words in the compound. It has one and only one child in this subtree, which is the head of the "stem", and the dependency relation between them is labelled as "suff".

The motivation of employing the "suff" label is to relieve the data sparseness problem of word forms in annotated corpora. Compounds, especially those with a "stem-suffix" structure, is a major source of new words in Chinese language. These compounds, however, often share a set of suffix words which has a limited amount of instances. We think it is more effective for a parser to learn from features with word forms by treating the suffix words as the heads of compounds.

4 Evaluation

4.1 Re-annotated Corpus

We re-annotated the entire CTB5 with our proposed word segmentation and POS tagging annotation strategies. We further re-annotated 3,000 sentences which are randomly sampled from the training set of CTB5 using our proposed dependency label set. This re-annotated set is compared with the same sentences with the original annotation in a machines translation experiment in section 4.3.

	CTB5	Re-annotated
Number of tokens	493,938	516,581
Avg. token length	1.63	1.55
Ratio of unknown words	14.67%	12.82%
Ratio of unknown word-POS pairs	15.02%	13.28%

Table 5. Statistics of the original CTB5 and our re-annotated version.

(a) Word Segmentation Results

Corpus	P	R	F
Original	97.21	97.36	97.28
Re-annotated	97.97	97.56	97.76
Re-annotated-partial	97.68	97.63	97.65

(b) Joint Segmentation and POS Tagging Results

Corpus	P	R	F
Original	93.42	93.56	93.49
Re-annotated	94.55	94.16	94.35

Table 6. Experimental results for morphological analysis on CTB5.

To evaluate the consistency of our annotation, 4 trained annotators were divided into two equal groups to perform 2-way annotation on a small subset (first 100 sentences in files 301-325), and each pair of annotators were assigned with 50 sentences. The inter-annotator agreement is 99.10% for segmentation, 98.37% for POS tagging, and 95.62% for dependency labeling.

Table 5 shows some of the statistics of the original and the re-annotated CTB5. We split CTB5 in the same data division as in previous studies (Jiang et al., 2008a; Jiang et al., 2008b; Kruengkrai et al., 2009; Zhang and Clark, 2010; Sun, 2011). The training, development and test set have 18,089, 350 and 348 sentences, respectively. Compared to the original CTB5, the re-annotated training set has a lower percentage of unknown words and unknown word-POS pairs found in the corresponding test set. This is consistent with our observation that compounds with internal structures are one of the major sources of OOV words.

4.2 Morphological Analysis Experiments

We compared the performance of a state-of-the-art joint word segmentation and part-of-speech tagging system (Kruengkrai et al., 2009) on the original and our re-annotated CTB5. We used the position-of-character (POC) tagset and the baseline feature set described in (Shen et al., 2014).

We trained all models using the averaged perceptron (Collins, 2002), which is an efficient and stable online learning algorithm. The models applied on all test sets are those that result in the best performance on the dev sets. To learn the characteristics of unknown words, we built the system's lexicon using only the words in the training data that appear at least 2 times.

We use precision, recall and the F-score to measure the performance of the systems. Precision (P) is defined as the percentage of output tokens that are consistent with the gold standard test data, and recall (R) is the percentage of tokens in the gold standard test data that are recognized in the output. The balanced F-score (F) is defined as $\frac{2 \cdot P \cdot R}{P+R}$.

We compared the performance of the morphological analyzer on the original and the re-annotated CTB5. The results of the word segmentation experiment and the joint experiment of segmentation and POS tagging are shown in Table 6(a) and Table 6(b), respectively. Each row in these tables shows the performance of the same system trained on the corresponding corpus.

For "Re-annotated-partial" in Table 6(a), we applied a different setting in order to directly compare the annotation consistency and data sparsity between the two corpora: We used the training set from the re-annotated corpus to train the system but the test set from the original corpus in the evaluation. To make the evaluation meaningful, we added an extra criterion when calculating the precision and the

System	BLEU-4
Character	31.60
Original	31.46
Re-annotated	**32.08**

Table 7. Experimental results for Chinese-Japanese machine translation on ASPEC corpus using Moses system.

System	BLEU-4
Original	32.00
Re-annotated	**32.97**

Table 8. Experimental results for Chinese-Japanese machine translation on ASPEC corpus using KyotoEBMT system.

recall: If the outmost boundaries of a sequence (two or more) of output tokens are consistent with a token in the test set, we consider that the output correctly identifies this token in the test set.

The results show that, the morphological analyzer can obtain higher accuracies in both word segmentation (0.48 points absolute in F-score) and joint (0.86 points absolute in F-score) experiments. Furthermore, in the word segmentation experiment "Re-annotated-partial" where we mapped the output of the system which is trained using the re-annotated training data to the original CTB5 test set, the accuracy is significantly higher[2] than that of the "Original", which demonstrates the better consistency in our re-annotation corpus.

4.3 Machine Translation Experiments

To show that a morphological analysis system and a dependency parsing system can both benefit from our re-annotation, we conducted two sets of Chinese-to-Japanese machine translation experiments where a morphological analyzer and a dependency parser are used respectively.

The parallel corpus we used is the Chinese-Japanese part of the Asian Scientific Paper Excerpt Corpus (ASPEC)[3], containing 672k sentence pairs. We used 2,090 and 2,107 additional sentence pairs for tuning and testing, respectively.

In the first set of experiments, we segmented the Japanese sentences using JUMAN (Kurohashi et al., 1994), and the Chinese sentences using the same morphological analyzer described in the last subsection. For decoding, we used the state-of-the-art phrase based statistical machine translation toolkit Moses (Koehn et al., 2007) with default options. We trained the 5-gram language models on the target side of the parallel corpora using the SRILM toolkit[4] with interpolated Kneser-Ney discounting. Tuning was performed by minimum error rate training (MERT) (Och, 2003), and it was re-run for every experiment.

In the second set of experiments, we used the same morphological analyzers to segment and tag the POS of Japanese and Chinese sentences as in the first set. We further parsed the dependency structures of the Japanese sentences using KNP (Kawahara and Kurohashi, 2006), a lexicalized probabilistic dependency parser, and for the Chinese sentences we used a second-order graph-based parser proposed in (Shen et al., 2012). For decoding, we used the tree-to-tree example-based machine translation framework KyotoEBMT[5] (Richardson et al., 2015) with default options.

We report results on the test set using BLEU-4 score, which was evaluated using the multi-bleu.perl script in Moses based on Juman segmentations. The significance test was performed using the bootstrap resampling method proposed by Koehn (2004).

In Table 7 we compare the performance of three Moses models: In "Character" we used a simple segmentation strategy for the Chinese sentences where we treated each character as a token; in "Original" and "Re-annotated" we segmented the Chinese sentences using the corresponding models described in

[2] $p < 0.05$ in McNemar's test.

[4] http://www.speech.sri.com/projects/srilm
[5] http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?KyotoEBMT

the last subsection. The results show, with the underlying machine translation system being the same, the segmenter trained with the original CTB5 failed to support the system to outperform the simple character-based segmentation, while on the other hand the system using the segmenter trained with our re-annotated CTB5 significantly outperformed both "Character"[6] and "Original"[7].

In Table 8 we show the result of the experiment with KyotoEBMT, a tree-to-tree machine translation system which requires unlabeled dependency annotation in the model training. 3,000 sentences with original and re-annotated dependency labels were used for training the parsers in "original" and "re-annotated" settings, respectively. The result shows that, the model "Re-annotated" which used the training set with the proposed annotation, it significantly outperformed[8] the baseline model "Original" by 0.97 point in BLEU-4 score.

5 Conclusion

We have proposed a new annotation approach for Chinese word segmentation, part-of-speech tagging, and dependency labelling. By re-annotating the CTB5 and conducting word segmentation, POS tagging and machine translation experiments, we have demonstrated that this approach has the advantages in achieving higher annotation consistency as well as less data sparsity, compared to the original annotation of CTB5. We couldn't show the comparison in dependency parsing experiments as we currently have only 3,000 annotated sentences; this experiment will be included in our future work.

Abstract

Sequence labeling architectures use word embeddings for capturing similarity, but suffer when handling previously unseen or rare words. We investigate character-level extensions to such models and propose a novel architecture for combining alternative word representations. By using an attention mechanism, the model is able to dynamically decide how much information to use from a word- or character-level component. We evaluated different architectures on a range of sequence labeling datasets, and character-level extensions were found to improve performance on every benchmark. In addition, the proposed attention-based architecture delivered the best results even with a smaller number of trainable parameters.

1 Introduction

Many NLP tasks, including named entity recognition (NER), part-of-speech (POS) tagging and shallow parsing can be framed as types of sequence labeling. The development of accurate and efficient sequence labeling models is thereby useful for a wide range of downstream applications. Work in this area has traditionally involved task-specific feature engineering – for example, integrating gazetteers for named entity recognition, or using features from a morphological analyser in POS-tagging. Recent developments in neural architectures and representation learning have opened the door to models that can discover useful features automatically from the data. Such sequence labeling systems are applicable to many tasks, using only the surface text as input, yet are able to achieve competitive results (Collobert et al., 2011; Irsoy and Cardie, 2014).

Current neural models generally make use of word embeddings, which allow them to learn similar representations for semantically or functionally similar words. While this is an important improvement over count-based models, they still have weaknesses that should be addressed. The most obvious problem arises when dealing with out-of-vocabulary (OOV) words – if a token has never been seen before, then it does not have an embedding and the model needs to back-off to a generic OOV representation. Words that have been seen very infrequently have embeddings, but they will likely have low quality due to lack of training data. The approach can also be sub-optimal in terms of parameter usage – for example, certain suffixes indicate more likely POS tags for these words, but this information gets encoded into each individual embedding as opposed to being shared between the whole vocabulary.

In this paper, we construct a task-independent neural network architecture for sequence labeling, and then extend it with two different approaches for integrating character-level information. By operating on individual characters, the model is able to infer representations for previously unseen words and share information about morpheme-level regularities. We propose a novel architecture for combining character-level representations with word embeddings using a gating mechanism, also referred to as *attention*, which allows the model to dynamically decide which source of information to use for each word. In addition, we describe a new objective for model training where the character-level representations are optimised to mimic the current state of word embeddings.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 309–318, Osaka, Japan, December 11-17 2016.

We evaluate the neural models on 8 datasets from the fields of NER, POS-tagging, chunking and error detection in learner texts. Our experiments show that including a character-based component in the sequence labeling model provides substantial performance improvements on all the benchmarks. In addition, the attention-based architecture achieves the best results on all evaluations, while requiring a smaller number of parameters.

2 Bidirectional LSTM for sequence labeling

We first describe a basic word-level neural network for sequence labeling, following the models described by Lample et al. (2016) and Rei and Yannakoudakis (2016), and then propose two alternative methods for incorporating character-level information.

Figure 1 shows the general architecture of the sequence labeling network. The model receives a sequence of tokens $(w_1, ..., w_T)$ as input, and predicts a label corresponding to each of the input tokens. The tokens are first mapped to a distributed vector space, resulting in a sequence of word embeddings $(x_1, ..., x_T)$. Next, the embeddings are given as input to two LSTM (Hochreiter and Schmidhuber, 1997) components moving in opposite directions through the text, creating context-specific representations. The respective forward- and backward-conditioned representations are concatenated for each word position, resulting in representations that are conditioned on the whole sequence:

$$\overrightarrow{h_t} = LSTM(x_t, \overrightarrow{h_{t-1}}) \qquad \overleftarrow{h_t} = LSTM(x_t, \overleftarrow{h_{t+1}}) \qquad h_t = [\overrightarrow{h_t}; \overleftarrow{h_t}] \tag{1}$$

We include an extra narrow hidden layer on top of the LSTM, which proved to be a useful modification based on development experiments. An additional hidden layer allows the model to detect higher-level feature combinations, while constraining it to be small forces it to focus on more generalisable patterns:

$$d_t = tanh(W_d h_t) \tag{2}$$

where W_d is a weight matrix between the layers, and the size of d_t is intentionally kept small.

Finally, to produce label predictions, we use either a softmax layer or a conditional random field (CRF, Lafferty et al. (2001)). The softmax calculates a normalised probability distribution over all the possible labels for each word:

$$P(y_t = k|d_t) = \frac{e^{W_{o,k} d_t}}{\sum_{\tilde{k} \in K} e^{W_{o,\tilde{k}} d_t}} \tag{3}$$

where $P(y_t = k|d_t)$ is the probability of the label of the t-th word (y_t) being k, K is the set of all possible labels, and $W_{o,k}$ is the k-th row of output weight matrix W_o. To optimise this model, we minimise categorical crossentropy, which is equivalent to minimising the negative log-probability of the correct labels:

$$E = -\sum_{t=1}^{T} log(P(y_t|d_t)) \tag{4}$$

Following Huang et al. (2015), we can also use a CRF as the output layer, which conditions each prediction on the previously predicted label. In this architecture, the last hidden layer is used to predict confidence scores for the word having each of the possible labels. A separate weight matrix is used to learn transition probabilities between different labels, and the Viterbi algorithm is used to find an optimal sequence of weights. Given that y is a sequence of labels $[y_1, ..., y_T]$, then the CRF score for this sequence can be calculated as:

$$s(y) = \sum_{t=1}^{T} A_{t,y_t} + \sum_{t=0}^{T} B_{y_t, y_{t+1}} \tag{5}$$

$$A_{t,y_t} = W_{o,y_t} d_t \tag{6}$$

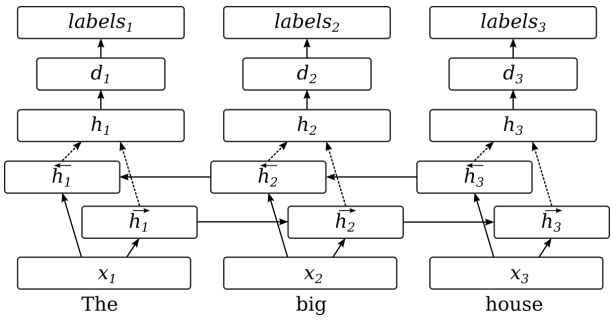

Figure 1: Neural sequence labeling model. Word embeddings are given as input; a bidirectional LSTM produces context-dependent representations; the information is passed through a hidden layer and the output layer. The outputs are either probability distributions for softmax, or confidence scores for CRF.

where A_{t,y_t} shows how confident the network is that the label on the t-th word is y_t. $B_{y_t,y_{t+1}}$ shows the likelihood of transitioning from label y_t to label y_{t+1}, and these values are optimised during training. The output from the model is the sequence of labels with the largest score $s(y)$, which can be found efficiently using the Viterbi algorithm. In order to optimise the CRF model, the loss function maximises the score for the correct label sequence, while minimising the scores for all other sequences:

$$E = -s(y) + log \sum_{\tilde{y} \in \widetilde{Y}} e^{s(\tilde{y})} \tag{7}$$

where $\widetilde{Y}$ is the set of all possible label sequences.

3 Character-level sequence labeling

Distributed embeddings map words into a space where semantically similar words have similar vector representations, allowing the models to generalise better. However, they still treat words as atomic units and ignore any surface- or morphological similarities between different words. By constructing models that operate over individual characters in each word, we can take advantage of these regularities. This can be particularly useful for handling unseen words – for example, if we have never seen the word *cabinets* before, a character-level model could still infer a representation for this word if it has previously seen the word *cabinet* and other words with the suffix *-s*. In contrast, a word-level model can only represent this word with a generic out-of-vocabulary representation, which is shared between all other unseen words.

Research into character-level models is still in fairly early stages, and models that operate exclusively on characters are not yet competitive to word-level models on most tasks. However, instead of fully replacing word embeddings, we are interested in combining the two approaches, thereby allowing the model to take advantage of information at both granularity levels. The general outline of our approach is shown in Figure 2. Each word is broken down into individual characters, these are then mapped to a sequence of character embeddings $(c_1, ..., c_R)$, which are passed through a bidirectional LSTM:

$$\overrightarrow{h_i^*} = LSTM(c_i, \overrightarrow{h_{i-1}^*}) \qquad \overleftarrow{h_i^*} = LSTM(c_i, \overleftarrow{h_{i+1}^*}) \tag{8}$$

We then use the last hidden vectors from each of the LSTM components, concatenate them together, and pass the result through a separate non-linear layer.

$$h^* = [\overrightarrow{h_R^*}; \overleftarrow{h_1^*}] \qquad m = tanh(W_m h^*) \tag{9}$$

where W_m is a weight matrix mapping the concatenated hidden vectors from both LSTMs into a joint word representation m, built from individual characters.

We now have two alternative feature representations for each word – x_t from Section 2 is an embedding learned on the word level, and $m^{(t)}$ is a representation dynamically built from individual characters in

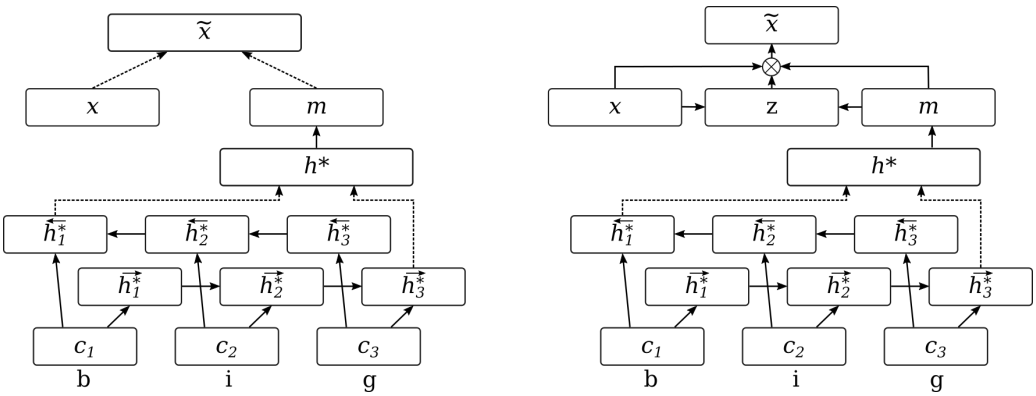

Figure 2: Left: concatenation-based character architecture. Right: attention-based character architecture. The dotted lines indicate vector concatenation.

the t-th word of the input text. Following Lample et al. (2016), one possible approach is to concatenate the two vectors and use this as the new word-level representation for the sequence labeling model:

$$\widetilde{x} = [x; m] \tag{10}$$

This approach, also illustrated in Figure 2, assumes that the word-level and character-level components learn somewhat disjoint information, and it is beneficial to give them separately as input to the sequence labeler.

4 Attention over character features

Alternatively, we can have the word embedding and the character-level component learn the same semantic features for each word. Instead of concatenating them as alternative feature sets, we specifically construct the network so that they would learn the same representations, and then allow the model to decide how to combine the information for each specific word.

We first construct the word representation from characters using the same architecture – a bidirectional LSTM operates over characters, and the last hidden states are used to create vector m for the input word. Instead of concatenating this with the word embedding, the two vectors are added together using a weighted sum, where the weights are predicted by a two-layer network:

$$z = \sigma(W_z^{(3)} tanh(W_z^{(1)} x + W_z^{(2)} m)) \qquad \widetilde{x} = z \cdot x + (1 - z) \cdot m \tag{11}$$

where $W_z^{(1)}$, $W_z^{(2)}$ and $W_z^{(3)}$ are weight matrices for calculating z, and $\sigma()$ is the logistic function with values in the range $[0, 1]$. The vector z has the same dimensions as x or m, acting as the weight between the two vectors. It allows the model to dynamically decide how much information to use from the character-level component or from the word embedding. This decision is done for each feature separately, which adds extra flexiblity – for example, words with regular suffixes can share some character-level features, whereas irregular words can store exceptions into word embeddings. Furthermore, previously unknown words are able to use character-level regularities whenever possible, and are still able to revert to using the generic OOV token when necessary.

The main benefits of character-level modeling are expected to come from improved handling of rare and unseen words, whereas frequent words are likely able to learn high-quality word-level embeddings directly. We would like to take advantage of this, and train the character component to predict these word embeddings. Our attention-based architecture requires the learned features in both word representations to align, and we can add in an extra constraint to encourage this. During training, we add a term to the loss function that optimises the vector m to be similar to the word embedding x:

Name	Task	# labels	# train tokens	# dev tokens	# test tokens
CoNLL00	Chunking	22	158,795	52,932	47,377
CoNLL03	NER	8	203,621	51,362	46,435
PTB-POS	POS	48	912,344	131,768	129,654

JNLPBA	NER	11	445,090	47,461	101,039
GENIA-POS	POS	42	397,690	52,697	50,556

Table 1: Details for each of the evaluation datasets.

$$\widetilde{E} = E + \sum_{t=1}^{T} g_t(1 - cos(m^{(t)}, x_t)) \qquad g_t = \begin{cases} 0, & \text{if } w_t = OOV \\ 1, & \text{otherwise} \end{cases} \tag{12}$$

Equation 12 maximises the cosine similarity between $m^{(t)}$ and x_t. Importantly, this is done only for words that are not out-of-vocabulary – we want the character-level component to learn from the word embeddings, but this should exclude the OOV embedding, as it is shared between many words. We use g_t to set this cost component to 0 for any OOV tokens.

While the character component learns general regularities that are shared between all the words, individual word embeddings provide a way for the model to store word-specific information and any exceptions. Therefore, while we want the character-based model to shift towards predicting high-quality word embeddings, it is not desireable to optimise the word embeddings towards the character-level representations. This can be achieved by making sure that the optimisation is performed only in one direction; in Theano (Bergstra et al., 2010), the *disconnected_grad* function gives the desired effect.

5 Datasets

We evaluate the sequence labeling models and character architectures on 8 different datasets. Table 1 contains information about the number of labels and dataset sizes for each of them.

- **CoNLL00**: The CoNLL-2000 dataset (Tjong Kim Sang and Buchholz, 2000) is a frequently used benchmark for the task of chunking. Wall Street Journal Sections 15-18 from the Penn Treebank are used for training, and Section 20 as the test data. As there is no official development set, we separated some of the training set for this purpose.

- **CoNLL03**: The CoNLL-2003 corpus (Tjong Kim Sang and De Meulder, 2003) was created for the shared task on language-independent NER. We use the English section of the dataset, containing news stories from the Reuters Corpus[1].

- **PTB-POS**: The Penn Treebank POS-tag corpus (Marcus et al., 1993) contains texts from the Wall Street Journal, annotated for part-of-speech tags. The PTB label set includes 36 main tags and an additional 12 tags covering items such as punctuation.

- **FCEPUBLIC**: The publicly released subset of the First Certificate in English (FCE) dataset contains short essays written by language learners and manual corrections by examiners (Yannakoudakis et al., 2011). We use a version of this corpus converted into a binary error detection task, where each token is labeled as being correct or incorrect in the given context.

- **BC2GM**: The BioCreative II Gene Mention corpus (Smith et al., 2008) consists of 20,000 sentences from biomedical publication abstracts and is annotated for mentions of the names of genes, proteins and related entities using a single NE class.

Table 2: Comparison of word-based and character-based sequence labeling architectures on 8 datasets. The evaluation measure used for each dataset is specified in Section 6.

- **CHEMDNER**: The BioCreative IV Chemical and Drug (Krallinger et al., 2015) NER corpus consists of 10,000 abstracts annotated for mentions of chemical and drug names using a single class. We make use of the official splits provided by the shared task organizers.

- **JNLPBA**: The JNLPBA corpus (Kim et al., 2004) consists of 2,404 biomedical abstracts and is annotated for mentions of five entity types: CELL LINE, CELL TYPE, DNA, RNA, and PROTEIN. The corpus was derived from GENIA corpus entity annotations for use in the shared task organized in conjuction with the BioNLP 2004 workshop.

- **GENIA-POS**: The GENIA corpus (Ohta et al., 2002) is one of the most widely used resources for biomedical NLP and has a rich set of annotations including parts of speech, phrase structure syntax, entity mentions, and events. Here, we make use of the GENIA POS annotations, which cover 2,000 PubMed abstracts (approx. 20,000 sentences). We use the same 210-document test set as Tsuruoka et al. (2005), and additionally split off a sample of 210 from the remaining documents as a development set.

6 Experiment settings

For data prepocessing, all digits were replaced with the character '0'. Any words that occurred only once in the training data were replaced by the generic OOV token for word embeddings, but were still used in the character-level components. The word embeddings were initialised with publicly available pretrained vectors, created using word2vec (Mikolov et al., 2013), and then fine-tuned during model training. For the general-domain datasets we used 300-dimensional vectors trained on Google News[2]; for the biomedical datasets we used 200-dimensional vectors trained on PubMed and PMC[3]. The embeddings for characters were set to length 50 and initialised randomly.

The LSTM layer size was set to 200 in each direction for both word- and character-level components. The hidden layer d has size 50, and the combined representation m has the same length as the word embeddings. CRF was used as the output layer for all the experiments – we found that this gave most benefits to tasks with larger numbers of possible labels. Parameters were optimised using AdaDelta (Zeiler, 2012) with default learning rate 1.0 and sentences were grouped into batches of size 64. Performance on the development set was measured at every epoch and training was stopped if performance had not improved for 7 epochs; the best-performing model on the development set was then used for evalua-

tion on the test set. In order to avoid any outlier results due to randomness in the model initialisation, we trained each configuration with 10 different random seeds and present here the averaged results.

When evaluating on each dataset, we report the measures established in previous work. Token-level accuracy is used for PTB-POS and GENIA-POS; $F_{0.5}$ score over the erroneous words for FCEPUBLIC; the official evaluation script for BC2GM which allows for alternative correct entity spans; and micro-averaged mention-level F_1 score for the remaining datasets.

7 Results

While optimising the hyperparameters for each dataset separately would likely improve individual performance, we conduct more controlled experiments on a task-independent model. Therefore, we use the same hyperparameters from Section 6 on all datasets, and the development set is only used for the stopping condition. With these experiments, we wish to determine 1) on which sequence labeling tasks do character-based models offer an advantange, and 2) which character-based architecture performs better.

Results for the different model architectures on all 8 datasets are shown in Table 2. As can be seen, including a character-based component in the sequence labeling architecture improves performance on every benchmark. The NER datasets have the largest absolute improvement – the model is able to learn character-level patterns for names, and also improve the handling of any previously unseen tokens.

Compared to concatenating the word- and character-level representations, the attention-based character model outperforms the former on all evaluations. The mechanism for dynamically deciding how much character-level information to use allows the model to better handle individual word representations, giving it an advantage in the experiments. Visualisation of the attention values in Figure 3 shows that the model is actively using character-based features, and the attention areas vary between different words.

The results of this general tagging architecture are competitive, even when compared to previous work using hand-crafted features. The network achieves 97.27% on PTB-POS compared to 97.55% by Huang et al. (2015), and 72.70% on JNLPBA compared to 72.55% by Zhou and Su (2004). In some cases, we are also able to beat the previous best results – 87.99% on BC2GM compared to 87.48% by Campos et al. (2015), and 41.88% on FCEPUBLIC compared to 41.1% by Rei and Yannakoudakis (2016). Lample et al. (2016) report a considerably higher result of 90.94% on CoNLL03, indicating that the chosen hyperparameters for the baseline system are suboptimal for this specific task. Compared to the experiments presented here, their model used the IOBES tagging scheme instead of the original IOB, and embeddings pretrained with a more specialised method that accounts for word order.

It is important to also compare the parameter counts of alternative neural architectures, as this shows their learning capacity and indicates their time requirements in practice. Table 3 contains the parameter counts on three representative datasets. While keeping the model hyperparameters constant, the character-level models require additional parameters for the character composition and character embeddings. However, the attention-based model uses fewer parameters compared to the concatenation approach. When the two representations are concatenated, the overall word representation size is increased, which in turn increases the number of parameters required for the word-level bidirectional LSTM. Therefore, the attention-based character architecture achieves improved results even with a smaller parameter footprint.

8 Related work

There is a wide range of previous work on constructing and optimising neural architectures applicable to sequence labeling. Collobert et al. (2011) described one of the first task-independent neural tagging models using convolutional neural networks. They were able to achieve good results on POS tagging, chunking, NER and semantic role labeling, without relying on hand-engineered features. Irsoy and Cardie (2014) experimented with multi-layer bidirectional Elman-style recurrent networks, and found that the deep models outperformed conditional random fields on the task of opinion mining. Huang et al. (2015) described a bidirectional LSTM model with a CRF layer, which included hand-crafted features specialised for the task of named entity recognition. Rei and Yannakoudakis (2016) evaluated a range of neural architectures, including convolutional and recurrent networks, on the task of error detection in learner writing. The word-level sequence labeling model described in this paper follows the previous work, combining useful design choices from each of them. In addition, we extended the model with two alternative character-level architectures, and evaluated its performance on 8 different datasets.

Character-level models have the potential of capturing morpheme patterns, thereby improving generalisation on both frequent and unseen words. In recent years, there has been an increase in research into these models, resulting in several interesting applications. Ling et al. (2015b) described a character-level neural model for machine translation, performing both encoding and decoding on individual characters. Kim et al. (2016) implemented a language model where encoding is performed by a convolutional network and LSTM over characters, whereas predictions are given on the word-level. Cao and Rei (2016) proposed a method for learning both word embeddings and morphological segmentation with a bidirectional recurrent network over characters. There is also research on performing parsing (Ballesteros et al., 2015) and text classification (Zhang et al., 2015) with character-level neural models. Ling et al. (2015a) proposed a neural architecture that replaces word embeddings with dynamically-constructed character-based representations. We applied a similar method for operating over characters, but combined them with word embeddings instead of replacing them, as this allows the model to benefit from both approaches. Lample et al. (2016) described a model where the character-level representation is combined with word embeddings through concatenation. In this work, we proposed an alternative architecture, where the representations are combined using an attention mechanism, and evaluated both approaches on a range of tasks and datasets. Recently, Miyamoto and Cho (2016) have also described a related method for the task of language modelling, combining characters and word embeddings using gating.

9 Conclusion

Developments in neural network research allow for model architectures that work well on a wide range of sequence labeling datasets without requiring hand-crafted data. While word-level representation learning is a powerful tool for automatically discovering useful features, these models still come with certain weaknesses – rare words have low-quality representations, previously unseen words cannot be modeled at all, and morpheme-level information is not shared with the whole vocabulary.

In this paper, we investigated character-level model components for a sequence labeling architecture, which allow the system to learn useful patterns from sub-word units. In addition to a bidirectional LSTM operating over words, a separate bidirectional LSTM is used to construct word representations from

individual characters. We proposed a novel architecture for combining the character-based representation with the word embedding by using an attention mechanism, allowing the model to dynamically choose which information to use from each information source. In addition, the character-level composition function is augmented with a novel training objective, optimising it to predict representations that are similar to the word embeddings in the model.

The evaluation was performed on 8 different sequence labeling datasets, covering a range of tasks and domains. We found that incorporating character-level information into the model improved performance on every benchmark, indicating that capturing features regarding characters and morphmes is indeed useful in a general-purpose tagging system. In addition, the attention-based model for combining character representations outperformed the concatenation method used in previous work in all evaluations. Even though the proposed method requires fewer parameters, the added ability of controlling how much character-level information is used for each word has led to improved performance on a range of different tasks.

Abstract

Previous studies on Thai Sentence Boundary Detection (SBD) mostly assumed a sentence ends at a space and formulated the task SBD as a disambiguation problem, which classified a space either as an indicator for Sentence Boundary (SB) or non-Sentence Boundary (nSB). In this paper, we propose a word labelling approach which treats the space character as a normal word, and detects SB between any two words. This removes the restriction for SB to be occurred only at spaces and makes our system more robust for modern Thai writing. It is because in modern Thai writing, the space is not consistently used to indicate SB. As syntactic information contributes to better SBD, we further propose a joint Part-Of-Speech (POS) tagging and SBD framework based on Factorial Conditional Random Field (FCRF) model. We compare the performance of our proposed approach with reported methods on ORCHID corpus. We also performed experiments of FCRF model on the TaLAPi corpus. The results show that the word labelling approach has better performance than previous space-based classification approaches and FCRF joint model outperforms LCRF model in terms of SBD in all experiments.

1 Introduction

Sentence Boundary Detection (SBD) is a fundamental task for many Natural Language Processing (NLP) and analysis tasks, including POS tagging, syntactic, semantic, and discourse parsing, parallel text alignment, and machine translation (Gillick, 2009). Most research on SBD focus on languages that already have a well-defined concept of what a sentence is, typically indicated by sentence-end markers like full-stops, question marks, or other punctuations. However, as we study more contexts of language use (e.g. speech output which lacks punctuations) as well as look at many more different languages, the assumption of clearly-punctuated sentence boundary becomes less valid. One such language is Thai.

In prior research on Thai, the space character has been regarded as a very important element in Thai SBD (Pradit *et al.*, 2000; Paisarn *et al.*, 2001; Glenn *et al.*, 2010). These regard that space characters are always present between sentences. However, in actual fact, as prescribed by Thai linguistic authorities (www.royin.go.th) as well as what can be observed in real texts, spaces do exist in Thai texts not only in such sentence-end contexts. There is some pressure from linguistic authorities (Wathabunditkul, 2003) to set orthographic standards in Thai, prescribing the use of spaces in the context of certain words, following the rules of the Thai Royal Institute Dictionary[1]. Examples of these rules include: using of the space before and after an interjection or an onomatopoeiac word โอ๊ย (Ouch!), อุ๊ย (ow!); before conjunctions และ (*and*), หรือ (*or*), and แต่ (*but*); before and after a numeric expression: มีนักเรียน 20 คน (have 20 students), เวลา 10.00 น. (time 10.00 a.m.). Unfortunately, the rules are not strictly followed in practice and the use of spaces between words, phrases, clauses and sentences vary across different users of the Thai language. According to TaLAPi (Aw et al. 2014), a news domain corpus, it has about 23% sentences ending without a space character. One example of the Thai text from TaLAPi corpus is

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 319–327, Osaka, Japan, December 11-17 2016.

shown in Figure 1, in which the space character is used within a sentence, but not as a sentence-end indicator.

In view of this complexity of spaces in Thai in light of the SBD task, we propose a word-based labelling approach which regards Thai SBD as a word labelling problem instead of a space classification problem. The approach treats the space as a normal word and labels each word as SB or nSB (non-Sentence Boundary). Figure 2 illustrates the space-based classification approach versus the word-based labelling approach.

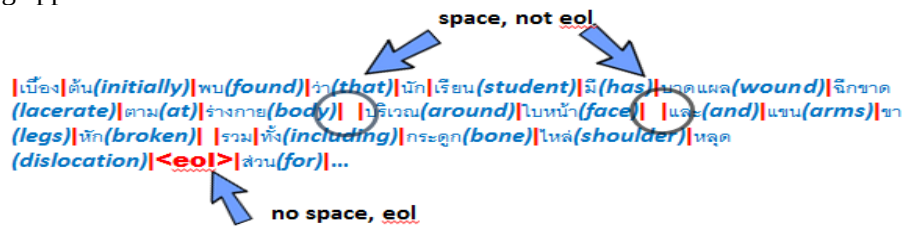

Figure 1. Example of a written Thai text in which there are two space characters within the first sentence, but there is no space character at the end of the sentence, i.e., at highlighted <eol>". "eol" refers to end-of-line.

The proposed word labelling approach formulates SBD as a typical sequence labelling task, i.e., labelling each word including spaces as a SB or nSB. It is tested on ORCHID corpus and demonstrates higher accuracy on SB than previous methods (Pradit *et al.*, 2000; Paisarn *et al.*, 2001; Glenn *et al.*, 2010). Furthermore, the contribution of POS in this task is investigated and a Joint framework for POS tagging and SBD is formulated. The results on TaLAPi corpus show that POS information can improve the accuracy of SBD, for both the sequential task of POS tagging followed by SBD and the proposed joint framework. Moreover, in the joint framework, we propose a two-layer classification for POS tagging, which is called as "2-step" Joint approach in the following paper. For comparison, the joint approach in which POS tagging realized in one step is called as "1-step" Joint approach. The proposed "2-step" Joint approach runs considerable faster and achieves similar performance when compared with the Cascade approach and "1-step" Joint approach of POS tagging and SBD. By adding enhanced features, the "2-step" Joint approach yields better SBD accuracy and comparable POS tagging accuracy.

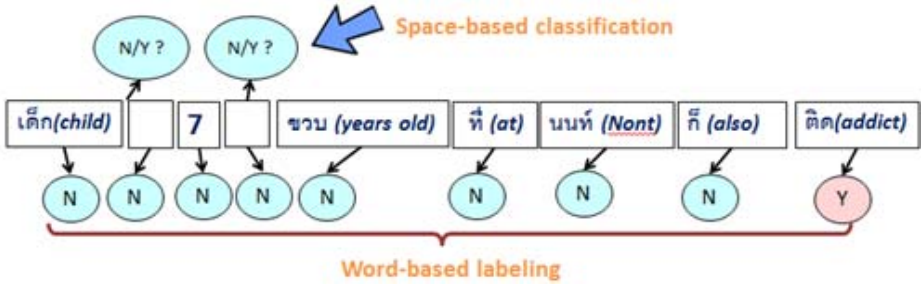

Figure 2. Space-based SBD vs word-based labelling SBD. Space-based SBD detects spaces and assigns Y (SB) or N (nSB) to each space. Word-based labelling assigns Y(SB) or N(nSB) to every word. In this case, the space character is considered as a word.

The rest of the paper is organized as follows. Section 2 reviews the previous studies on Thai SBD. Section 3 describes the proposed word labelling framework and the approaches. Section 4 compares the performance between the proposed word-based methods and reported space-based methods on ORCHID corpus (Sornlertlamvanich *et al.*, 1997), and also studied the different frameworks of word-based approaches. Section 5 concludes the paper.

2 Previous Studies

There have been limited studies carried out in Thai SBD over the past twenty years. Longchupole (1995) presented a method to segment a paragraph into small units and then used verbs to estimate the number of sentences. That was a grammatical rule based approach to extract sentences from paragraphs. The reported SBD accuracy was 81.18% (Longchupole, 1995). Pradit *et al.* (2000) applied the statistical POS tagging technique (Brants, 2000) on the detection of SB. They considered SB and non-

SB as POS tags and distinguished SB from other POS tags based on a trigram model. Their method yielded an accuracy of 85.26% on ORCHID corpus. Paisarn *et al.* (2001) utilized the Winnow algorithm to extract features from the context around the target space. The Winnow functioned like a neuron network model where a few nodes were connected to a target node. Each node examined only two features for simplicity. In total, there were 10 features including words around target space and their POS information. The space-correct accuracy for the Winnow on ORCHID was 89.13%. Later, Glenn *et al.* (2010) proposed to use maximum entropy classifier to distinguish each space as SB or non-SB and their results were shown to be consistent with the Winnow (Paisam *et al*., 2001).

Nearly all Thai SBD studies are based on the assumption that there is a space at the position of the SB. While we have shown in the Introduction part that sentence break is not always indicated by a space, especially in modern Thai writing. That inspired us to propose the word-based approach to consider a space as a word and treats SBD as a word labelling task instead of a space disambiguation problem

The word-based approach is further enhanced to label POS tags and SB jointly using joint inferencing. The advantages of this approach are: 1) it relies on contexts instead of spaces to detect SB, 2) it solves SBD and POS tagging jointly to relax the dependency of POS tagging for SBD, 3) it demonstrates higher accuracy on SBD than previous methods (Pradit *et al.*, 2000; Paisarn *et al.*, 2001; Glenn *et al*., 2010).

3 The Models

CRFs (Lafferty *et al.*, 2001; Sutton *et al*., 2011) have demonstrated their strengths of sequence labelling in NLP tasks (McCallum *et al.*, 2003; Liu *et al*., 2005; Sun *et al.*, 2011). They rely on the capacity to capture the sequence's observation O_n {i=1,2…n} (abbreviated as O) and at the same time the local dependency L_i {i=1,2,…n} (abbreviated as L) among nodes in the sequence (see Figure 3 for the example of linear-chain CRF (LCRF) (Sutton et al., 2011)). Conditioned on observations O, dependencies of L form the chain. In the model, the probability of labelling an observed input O with a label sequence L is defined by a conditional probability as in Equation (1):

$$p_\lambda(L \mid O) = \frac{1}{Z(O)} \exp\left(\sum_t \sum_k \lambda_k f_k(O, L, t)\right) \quad (1)$$

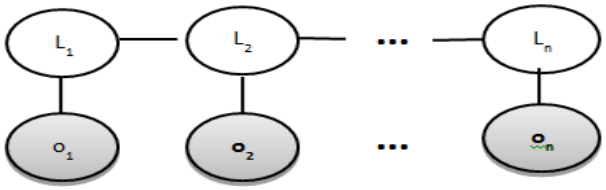

Figure 3. Linear-chain graph CRF (LCRF)

where $\{f_k\}$ is a set of feature functions defined over the observation O and label sequence L at each position t, together with the set of corresponding weights $\{\lambda_k\}$; z(O) is a normalization factor.

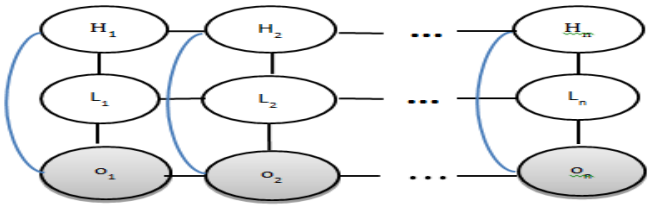

Figure 4. Two-layer Factorial CRF (FCRF)

Dynamic CRF (DCRF) (Sutton *et al.,* 2004; Sutton *et al*., 2011) is a generalization of LCRF, which supports any arbitrary structure graph. It is formally defined as in Equation (2):

$$p_\lambda(L \mid O) = \frac{1}{Z(O)} \exp\left(\sum_t \sum_{c \in C} \sum_k \lambda_k f_k(O, L_{(c,t)}, t)\right) \quad (2)$$

where C is a set of cliques indices which connect the nodes in a sequence in a single layer or among different layers. As a special case of DCRF, Factorial CRF (FCRF) model allows multiple layers' la-

belling simultaneously for a given sequence. The graphical illustration of two-layer FCRF is shown in Figure 4 where *H* indicates the 1st layer labels and *L* indicates the 2nd layer labels. *O* is the observation sequence. Through the connections between different layers of labels and the given observation, joint conditional distributions of the labels are learnt.

3.1 Isolated and Cascade SB and POS Tagging

We use LCRF for the single task of SB detection or POS tagging. In this scenario, as Thai SB is to detect word sequence and find the end of each sentence, we consider this to be similar to a sentence-end punctuation prediction task with only two labels. Words are labelled with SB if they are at the beginning of a sentence otherwise, they will be labelled as nSB. For POS tagging, we use all the 35 sub-categories as described in Aw et al. (2014).

Feature Template	Window Size
w_0	3 or 5
$w_{-1}+w_0$	3 or 5
$w_{-1}+w_0+w_1$	3
$wtype_0$	3 or 5
$wtype_{-1}+wtype_0$	3 or 5
$wtype_{-1}+wtype_0+wtype_1$	3

Table 1. The feature template for Isolated SBD and POS tagging. Window size 3 is used for Isolated SBD and POS tagging. Window size 5 is used in "2-step" Joint model (vii and viii) in Table 6.

Considering POS tagging has much more labels to recognize than SBD, it will increase the memory use for system training, therefore the number of the features and feature template have to be carefully selected. It is essential to use a simple feature set, as shown in Table 1, to make a comparison between Isolated models, Cascade models and the Joint models. It is important for "1-step" Joint model as more features make the process run extremely slow. In Table 1, w_i refers to the word at the i^{th} position relative to the current node; window size is the maximum span of words centered at the current word that the template covers, e.g., $w_{-1}+w_0$ with a window size of 3 refers to $w_{-2}+w_{-1}$, $w_{-1}+w_0$, and w_0+w_1; $wtype_i$ indicates the word type at the i^{th} position relative to the current node; In total, five word types are defined, i.e., English, Thai, punctuation, digits and spaces, for the data used in our experiments.

Feature Template	Window size
pos_0	3 or 5
$pos_{-1}+pos_0$	3
$pos_{-1}+pos_0+pos_1$	3

Table 2. The additional feature template for Cascade models, besides the feature templates in Table 1. Window size 5 is used in Cascade model (iv) in Table 6.

As POS tag provides additional syntactic and some semantic information to the word, they are utilized as additional features to the Cascade approach for detecting the sentence boundary. Besides the features listed in Table 1, more POS features listed in Table 2 are used in the Cascade models.

	Original POS	Pseudo POS	Total No.		Original POS	Pseudo POS	Total No.
1	NN,NR,PPER,PINT, PDEM	NPs	104271	7	CL	CL	5747
2	REFX	REFX	1357	8	OD,CD	OCD	8453
3	DPER,DINT,DDEM, PDT	DPs	7267	9	FXN, FXG, FXAV, FXAJ	FXs	13887
4	JJA, JJV	JJs	14335	10	P, COMP, CNJ	PCs	50301
5	VV, VA, AUX	VVs	72769	11	FWN,FWV,FWA,FWX	FWs	24
6	ADV,NEG	ADs	12275	12	PAR, PU, IJ, X	Os	6270

Table 3. The mapping from original POS to Pseudo POS tags

3.1.1. "1-step and "2-step" Joint Models

The joint model realizes the 2-layer labelling of one sequence using FCRF. We consider the first layer as labels of SBD, and the second layer as labels of POS tagging (see Table 3). However, due to the large number of POS tags, combining the feature templates of both tasks increases the search space tremendously and has a large impact on the processing speed. To address this problem, we propose a "2-step" Joint-model in which we first predict 12 top categories of the POS tags as classified in (Aw *et al.*, 2014) and then restore the pseudo POS tags back to the original POS tags (see Figure 5). On the other side, the "1-step" Joint model uses all the 35 POS tags to realize POS tagging in the 2nd layer of FCRF.

To train the "2-step" Joint model, all train data are labelled with two SB labels (i.e., SB and nSB) and 12 pseudo POS tags. The 12 pseudo POS tags are obtained by combining similar POS tags into one category as illustrated in Table 3. The Original POS column lists the original 35 POS tags and the Pseudo POS column lists the corresponding 12 pseudo POS tags. To restore the pseudo POS tags back to the original tags, we train different LCRF models for each pseudo POS tag. As no restoration is required for "CL" and "REFX", a total of 10 LCRF models are built to restore the original POS tags. The diagram of the proposed "2-step" Joint model is shown as follows (Figure 5).

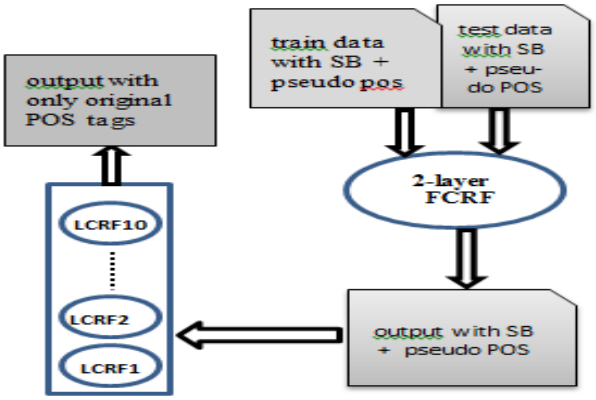

Figure 5. The proposed "2-step" Joint model for Thai SBD and POS Tagging based on two-layer FCRF and the LCRF

For fair comparison between Isolated and Joint models, we used the same feature templates in Table 1 in two of the "2-step" Joint models, i.e., (v) and (vi) in Table 6. Since the "2-step" Joint model run much faster than "1-step" Joint, more features can be added. As in Table 4 shown, name entity recognition (NER) information was added to improve the performance of the "2-step" joint models besides the feature template in Table 1.

Feature Template	Window Size
NER_0	3
NER_{-1}+NER_0	3

Table 4. The enhanced feature template for "2-step" Joint model (viii) in Table 6

4 Experimentation

4.1 Data Preparation

Our experiments were performed on the ORCHID corpus (Sornlertlamvanich *et al.*, 1997) and the TaLAPi corpus (Aw *et al.*, 2014).

The processing of the ORCHID corpus follows the work of Sornlertlamvanich *et al.* (1997) to remove all comments and concatenate all sentences and paragraphs. Different from the previous experiments, we did not insert a space at the end of sentence if it was not originally present. As such, the percentage of sentences ending without a space was almost 100% for the ORCHID corpus used in our experiment. We portioned the ORCHID data into 10 parts with equal size and used 10 fold cross validation for evaluation.

The experiments on TaLAPi corpus were performed only on the news domain which was annotated with word segmentation, POS tags and name entities. It had 3633 paragraphs, 10,478 sentences and

311,637 words. We split 80% for training and 20% for testing. During the splitting, we tried to balance the distribution of spaces and POS tags. Thus in the training data, we have a total of 282,678 words, of which 8,034 words (2.842%) are SB and 274,644 words are nSB. In the test data we have 2,091 (2.836%) SB and 71,635 nSB.

4.2 Experimental results

The GRMM toolkit (Sutton, 2006) was used in our experiments to build the 2-layer FCRF models and one layer LCRF models. To demonstrate the proposed methods, we performed 5 different experiments as follows:

Orchid Corpus

i. Isolated LCRF model to detect SBD using POS information to make it comparable with reported work.

TaLAPi Corpus

ii. Isolated LCRF model for POS tagging and SBD without POS information for SBD.
iii. Cascade LCRF model on SB utilizing same feature as (i) and POS information with different feature templates.
iv. "1-step" Joint model using same features as (ii)
v. "2-step" Joint model using same features as (ii) and with additional features and different feature configurations.

	POS-trigram(%)	**Winnow(%)**	**ME(%)**	**our work(%)**
sb-precision	74.35	92.69	86.21	93.64
sb-recall	79.82	77.27	83.50	89.84
sb-fscore	76.98	84.28	84.83	91.70
nsb-precision	90.27	91.48	93.18	99.27
nsb-recall	87.18	97.56	94.41	99.56
nsb-fscore	88.70	94.42	93.79	99.41
space correct	85.26	89.13	91.19	95.91

Table 5. Comparison of our word-labelling approach based on LCRF (last column) with previous studies on ORCHID corpus. POS-trigram (Pradit *et al*., 2000); Winnow (Paisarn *et al*., 2001); ME (*Glenn et al.*, 2010). Space correct =(#correct sb+#correct nsb)/(total # of space tokens). '#' indicate the number of items followed.

In the ORCHID corpus experiment, we used the features described in Table 1 and Table 2. Table 5 shows the result of the word-labelling approach and its comparison with reported methods. Compared to the reported results (Glenn *et al.*, 2010), our word-labelling approach yielded consistent improvement on precision, recall, F-score for both SB and non-SB and also "space correct". Our SB precision is 1% higher than Winnow method and our recall is 6.3% higher than ME method. The F-score is 7% higher than Winnow and ME. As mentioned in 4.1, not all sentence boundaries in ORCHID are indicated by space. To have a fair comparison, we consider all sentence boundaries as a "space" when calculating "space correct" (Glenn *et al.*, 2010). In Table 5, the short form "sb" and "nsb" refers to the sentence break and non-sentence break respectively.

For the experiments on TaLAPi corpus, we study the performance in Isolated, Cascade and Joint model. The same experiment can be run on ORCHID corpus, but due to time and space limitation, we only show the results of the experiments on TaLAPi corpus in Table 6.

Comparing Cascade with Isolated Model

All Cascade models have higher F-score than the Isolated model. The best F-score of the Cascade model is 67.29% when we used 18 features in the experiment (iv). The experiment affirms that POS information is helpful in sentence boundary detection.

Comparing Isolated, Cascade with Joint Model

With the same set of features as in (i), "1-step" Joint (v) yields 3% increase on recall and 2% increase on F-score for SBD when compared to the Isolated model in (i). Comparing (vi) with (i), a similar in-

crease in accuracy for SBD, with the same features, is observed. These results demonstrate that SBD can benefit from the other layer's label information, i.e., POS tagging labels, in the Joint model (v). When compared to Cascade models, "1-step" Joint shows comparable SB detection performance with the Cascade model (iii) that uses additional 3-gram POS features. By enhancing the feature set for SB detection in the Cascade model (iv), we yielded 1% increase on F-score when compared to the Cascade model (iii).

	Description	**POS**	**SBD**		
		Accuracy	**Precision**	**Recall**	**F-score**
i	Isolated without pos information for SB	94.24	82.67	53.37	64.86
ii	Cascade with same features as (i) and 1-gram POS		81.93	54.85	65.71
iii	Cascade with same features as (i) and 3-gram POS		80.26	56.38	66.24
iv	Cascade with same features as (iii) and window size of 5		79.12	58.53	67.29
v	"1-step" Joint with same features as (i)	94.64	81.72	56.24	66.63
vi	"2-step" Joint with same features as (i)	95.46	82.29	55.57	66.34
		94.49			
vii	"2-step" Joint with same features as (vi) and window size of 5	95.63	80.52	58.29	67.62
		94.99			
viii	"2-step" Joint with same features as (vii) and NER	95.64	80.36	60.26	68.87
		94.99			

Table 6. Comparison of our methods based on FCRF and LCRF on TaLAPi corpus.

Comparing "1-step" with "2-step"

While the Cascade models and "1-step" Joint model was limited by the running speed due to the number of POS tags, the "2-step" Joint model was therefore proposed to improve the running speed and not degrade the accuracy. With the same set of features, the "2-step" Joint (vi) run much faster than "1-step" Joint (v), while yielded almost the same SBD F-score as (v). The run time comparison can be found in Table 7. Experiments were run on Intel(R) Xeon(R) 8 core processor E5-2667 V2 3.30GHz, 25M cache with multi-thread 16.

Different models	**Train time (s)**	**Test time (s)**	**All process (**hr)
Isolated SB (i)	389.1	4.012	0.11
Isolated POS (i)	33230.8	98.2	9.26
Cascade (ii)	33938.2	101.3	9.46
Cascade (iii)	33992.7	102.4	9.48
Cascade (iv)	34181.3	103.8	9.54
"1-step" Joint (v)	41009.8	125.79	11.43
"2-step" Joint (vi)	12895.7	60.147	3.61
"2-step" Joint (vii)	16543.8	74.065	4.62
"2-step" Joint (viii)	18210.2	76.080	5.08

Table 7. Comparison of speed among different methods (test time does not include the serializing time).

The "2-step" Joint (vi) reduces more than half of the running time, compared to "1-step" Joint (v). This decrease in processing time enables us to include more feature set to further improve the performance of SBD in the "2-step" Joint model. By increasing window size from 3 to 5 (i.e., from (vi) to (vii)), (vii) yields 1.3% increase on F-score for SBD, compared to (vi). To further improve the performance, we added NER information with different grams on top of experiment (vii) and found that NER information with unigram (i.e., NER_0) and bigram (i.e., $NER_{-1}+NER_0$) improves the performance, i.e., (viii) shown in Table 6. Undoubtedly, with increased features, the running time of "2-step" Joint model (viii) is more than (vi) and (vii), but it is still faster than the "1-step" Joint model (v). More importantly, it achieved 2% increase on F-score for SBD. Compared to Cascade model (iv), it saved 50% time and achieved 1.6% increase on F-score for SBD.

5 Conclusion

In this paper, we have demonstrated for the first time a word-based labelling approach to Thai SBD. The word-based labelling approach achieved very good performance compared to reported results on ORCHID data. The Cascade model is to use evaluated POS information as features to help SB detection. Higher accuracy in the POS information will yield better accuracy in the Thai SBD. In fact, we also used manually annotated POS tags in SB detection, and it yielded better accuracy, i.e., 79.31% in precision, 62.70% in recall and 70.03% in F-score, compared to the Cascade approach (iv).

Different from Cascade models, Joint models are supposed to make SBD benefit from POS tagging labels in the second layer. Different features are tried in our experiments. Additional features do not always yield better accuracy. For example, when we use more features, e.g., "w_{-1}+w_1" and "$wtype_{-1}$+$wtype_1$, on the top of "2-step" Joint (viii), it does not improve the performance. We noticed that the pseudo-POS tagging performance was not improved in the same way as SBD when more features were added. Besides, more experiments will be explored in the future to see how word boundary information, POS and sentence boundary information affect each other.

In this paper, we demonstrated for the first time a word-based labelling approach to Thai SBD. The word-based labelling approach was proposed to leverage LCRF to do sequence labelling which achieved very good performance compared to reported results on ORCHID data. Furthermore, the performance of SBD with the help of POS tagging was investigated on the corpus TaLAPi. Cascade models and Joint models were compared and the "2-step" Joint POS tagging with SB detection was proposed. This proposed model saved more than half of the time, while obtaining almost the same accuracy for SBD as "1-step" Joint model, when using the same feature set. With increased speed, more features were therefore used to improve SBD and yields comparable POS tagging performance.

Assigning Fine-grained PoS Tags based on High-precision Coarse-grained Tagging

Abstract

We propose a new approach to PoS tagging where in a first step, we assign a coarse-grained tag corresponding to the main syntactic category. Based on this high-precision decision, in the second step we utilize specially trained fine-grained models with heavily reduced decision complexity. By analyzing the system under oracle conditions, we show that there is a quite large potential for significantly outperforming a competitive baseline. When we take error-propagation from the coarse-grained tagging into account, our approach is on par with the state of the art. Our approach also allows tailoring the tagger towards recognizing single word classes which are of interest e.g. for researchers searching for specific phenomena in large corpora. In a case study, we significantly outperform a standard model that also makes use of the same optimizations.

1 Introduction

When a part-of-speech (PoS) tagger assigns word class labels to tokens, it has to select from a set of possible labels whose size usually ranges from fifty to several hundred labels depending on the language. Especially for new domains or under-resourced languages, there is usually not enough training data to reliably learn all the subtle differences between a large set of labels. We thus propose to split the PoS tagging task into two steps. A first high precision step, where we only assign a coarse-grained tag which can be reliably learned also with rather limited training data, and which benefits from additional unlabeled data in the form of clusters or embeddings. And a second step, where we apply specialized tagging models that only have to choose from a much smaller set of possible labels.

Figure 1 gives an overview of our approach using, in the first step, a coarse-grained tagset (similar to the universal tagset (Petrov et al., 2012)) and in the second step the fine-grained PTB tagset (Marcus et al., 1993). In the figure, we can see how knowing the coarse-grained tag informs the second step. For example, if we already know that *beautiful* is an adjective, we only have to choose between three possible tags (`JJ`, `JJR`, or `JJS`) instead of 45 tags for the full PTB tagset.

Our approach requires that the coarse tagging in the first step is more accurate than using fine-grained tagging itself, as we will loose some accuracy through error propagation between the steps. We will thus first analyze how well coarse tagging can actually be done, and also focus on whether coarse-grained models transfer better between different kinds of texts, as e.g. Ritter et al. (2011) shows that a fine-grained tagger trained on newswire data doesn't work well on social media.

Creating robust and accurate coarse-grained taggers is a worthwhile task on its own, as many NLP applications actually do not require fine-grained distinctions. For example, the popular TextRank algorithm (Mihalcea and Tarau, 2004) for keyphrase extraction uses coarse grained PoS tags to build the underlying co-occurrence graph, or Benikova and Biemann (2016) use coarse-grained tags to annotate semantic relations between nominals.

Another advantage of our approach is that the second tagging step can be easily customized for specific needs, e.g. if a scholar wants to analyze the usage of a specific PoS tag. In this case, we can use fine-grained models with additional features that are informative for this sub-problem, but might not be helpful for the overall tagging task.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 328–336, Osaka, Japan, December 11-17 2016.

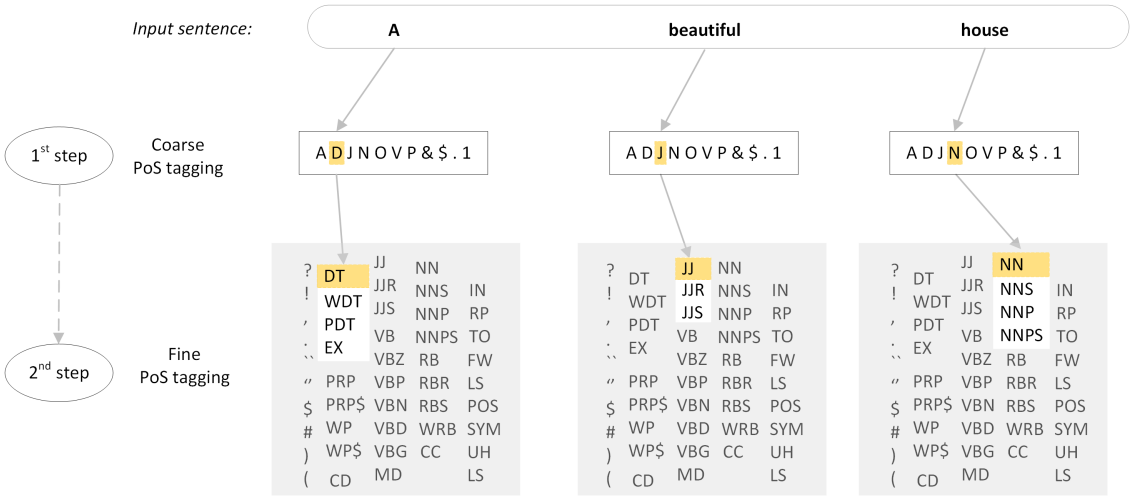

Figure 1: PoS tagging in two steps: The first step assigns a coarse tag (main word class) of a word. The second step determines the fine PoS tag based on the coarse PoS tag of the first step.

Related Work We are not aware of prior work using a similar approach. Some rule-based approaches (Brill, 1992; Hepple, 2000) assign the most probable tag to each token and then use transformation rules to correct the initial assignment. However, both steps use the same granularity and the initial assignment only reflects the prior probability but is not usable in itself.

There is also relatively little research on coarse-grained tagging. Gimpel et al. (2011) developed a tagger for Twitter data that uses a specialized coarse-grained tagset which is equivalent to our first step, but they do not aim at refining these assignments further as we do in the second step. Most approaches do fine-grained tagging first, and then map back to the universal set in order to make the different tagsets compatible. For example, Horsmann et al. (2015) use a coarse tagset to evaluate PoS tagging models using a set of corpora that are annotated with different fine-grained PoS tags.

2 Coarse-grained Tagging

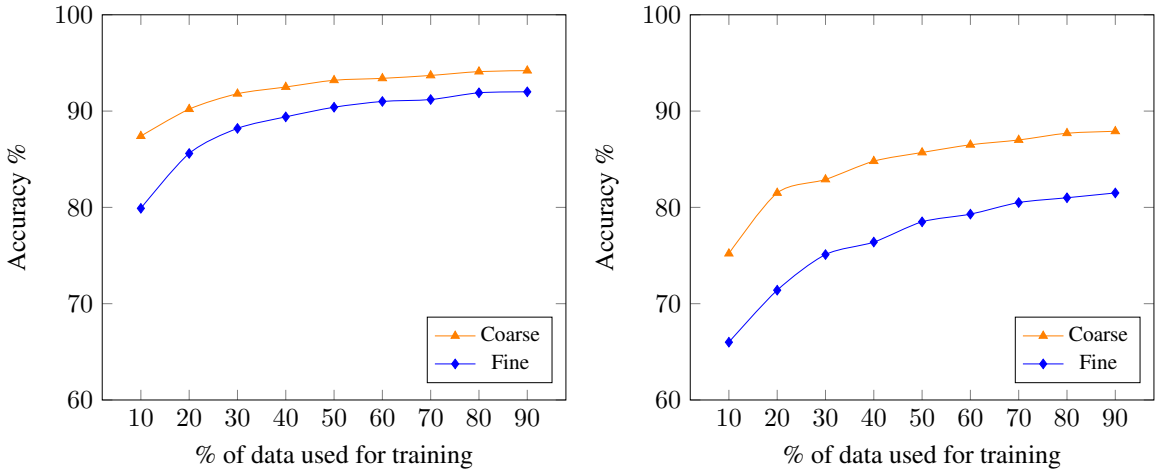
The first thing we need for our approach is a robust and highly accurate coarse PoS tagging. For domains or languages with little training data, accuracy is mainly limited by out-of-vocabulary tokens. In such situations, it seems easier to first assign a highly generalizing model that can be learned from relatively little training data instead of forcing the model to make an uninformed fine-grained decision. Thus, in this section we explore how well coarse-grained tagging actually works.

For our experiments, we use corpora from different genres (*News*, *Web*, *Chat*, and *Twitter*) in order to ensure that results are not bound to text properties only. Newswire text has a formal nature and contains few language errors, as it is usually carefully edited. Text from the web is (on average) less formal containing informal expressions and orthographic errors. Chat conversations are highly informal and often similar to spoken language, as the communication takes place between a smaller group of people with many non-standard abbreviations and orthographic errors. Twitter contains highly diverse text, as the platform is used for all kinds of purposes ranging from chat-like discussions to formal announcements. As *News* corpus, we use 46k tokens of the Wall Street Journal (WSJ) (Marcus et al., 1993), for *Web* we use 44k tokens from the GUM corpus (Zeldes, 2016) containing semi-formal text from various Wiki-platforms, as *Chat* corpus we use the NPS (Forsyth and Martell, 2007) chat corpus with 32k tokens, and for *Twitter* we use the 15k tokens Twitter messages provided by Ritter et al. (2011).

For our purposes, we need to map the fine-grained tags in these corpora to an inventory of coarse grained tags. We rely on the mappings provided by DKPro Core (Eckart de Castilho and Gurevych, 2014). We train our models using Conditional Random Fields (Lafferty et al., 2001) as implemented in FlexTag (Zesch and Horsmann, 2016) which relies on the machine learning framework DKPro TC (Daxenberger et al., 2014). As basic feature set which is common to all our models we use use ± 2 tokens

	Accuracy (%)			
	News	**Web**	**Chat**	**Twitter**
fine	92.0	88.6	86.8	80.2
coarse	94.2*	92.5*	91.4*	87.2*

Table 1: Accuracy of fine tagging vs. coarse tagging. Marked values are statistically significant against the fine-grained baseline (McNemar's test, $p < 0.05$)



(a) News

(b) Twitter

Figure 2: Learning curves for 'cleanest' dataset vs. 'noisiest' dataset

as local context, the 1,000 most frequently occurring character 2-grams to 4-grams over all tokens, and whether the target token contains capitalized characters, numeric values, or special characters.

Table 1 shows the results of 10-fold cross validation on each of the four corpora. We find that coarse tagging outperforms fine tagging on all datasets (statistically significant, McNemar's test, $p < 0.05$). As expected, the size of the gain is connected to the type of corpus, ranging from 2.2 percent point on *News* to 7.0 points on *Twitter*. The improvement can almost exclusively be attributed to intra-class errors of the fine-grained model, i.e. our coarse model is differentiating between the coarse grained classes as well as the fine-grained system, but isn't forced to make an uninformed decision. In the next section, we will investigate if this gives us enough head start to improve overall performance, but before that we further investigate the properties of our coarse tagger.

2.1 Amount of required training data

A practical benefit of coarse tagging should be that the amount of required training data is considerably lower than for fine tagging, as fewer labels should need less data to be learned. We thus adapted our 10-fold cross validation experiment to train on decreasing numbers of chunks, i.e. instead of training on 9 chunks and test on the remaining chunk, we train only on 8 and test on the 10th chunk, then train on 7 and test on the 10th chunk, and so on.

Figure 2 shows the results of this learning curve experiment on *News* (our 'cleanest' corpus) and *Twitter* (the 'noisiest'). For *News*, we see the expected behavior of a larger advantage of coarse tagging for smaller amount of training data, while for *Twitter* the distance between coarse and fine tagging does not change much. Note that we have much less data for *Twitter* than for *News*, so that we could still see a similar behavior for *Twitter* if more annotated data was available.

2.2 Word class performance

So far, we have seen that coarse tagging yields in general higher accuracy than fine tagging, but it would also be interesting to see which word classes benefit the most. The possible increase in performance

	Word class	# Token 10^3	Accuracy fine	coarse
News	Adjective	0.3	77.6	78.1
	Adverb	1.6	84.4	84.2
	Conjunction	1.1	99.0	98.9
	Determiner	4.2	98.6	98.5
	Noun	14.3	89.9	93.5
	Numeral	1.4	96.2	95.0
	Preposition	6.0	96.6	97.4
	Pronoun	1.5	98.3	98.9
	Punctuation	6.0	99.7	99.8
	Verb	6.6	86.4	93.4
	Other	0.4	95.3	96.9
		46.4	92.0	94.2

	Word class	# Token 10^3	Accuracy fine	coarse
Twitter	Adjective	0.7	58.6	57.7
	Adverb	0.8	80.1	80.9
	Conjunction	0.3	94.3	95.6
	Determiner	0.9	92.4	95.1
	Noun	3.5	69.1	84.1
	Numeral	0.3	74.1	69.5
	Pronoun	1.4	92.6	96.3
	Preposition	1.5	87.5	92.2
	Punctuation	2.0	96.5	98.7
	Verb	2.5	76.6	88.3
	Other	1.5	75.4	79.9
		15.0	80.2	87.2

Table 2: Coarse tagging results by coarse word class

is linked to at least two factors: (i) the size of the remaining fine-grained label set, and (ii) how well the remaining labels can be separated. For example, the set of fine-grained labels for the noun class is rather small (four tags: `NN`, `NNS`, `NNP`, `NNPS`) and the singular/plural noun decision is rather simple in English. However, the remaining problem to differentiate between normal nouns and proper nouns is far from trivial because the distinction is often not syntactically realized, but relies on world knowledge and context. For example, *I bought an apple.* vs. *I bought an Apple.* can only be decided based on capitalization, but especially in the social media datasets this signal is not very reliable. In contrast to nouns, we do not expect adjectives to improve much, as comparative and superlative can be quite easily distinguished from the base form of the adjective and from each other.

Table 2 shows the results per coarse-grained word class, where fine-grained results are mapped to the corresponding coarse-grained value for evaluation. Again, for space reasons, we only show *News* and *Twitter* as the most extreme representatives of our evaluation datasets. As expected, nouns and verbs are responsible for most of the improvement, as they are the bigger classes and the difficult decision faced in both classes are deferred to the second step.

2.3 Cross-domain performance

So far, we have conducted all our experiments in an in-domain setting, i.e. we train and test on the same kind of data (although of course not on exactly the same data). Since for new domains there usually is no training data in the first place, it is common to fall back on models trained on the more easily available *News* corpora. In this section, we want to evaluate the difference between fine and coarse tagging in such a setting. We will train on *News* enriched with additional training data and external resources in order to create a competitive model. We then evaluate this enhanced *News* model on the remaining datasets *Web*, *Chat*, and *Twitter*.

Fine Baseline Model In order to create a strong baseline, we augment our fine-grained tagger with more training data and external knowledge. We use the same feature set as before and train the model on the WSJ sections 0-21 and additional 250k tokens taken from the Switchboard corpus. We add distributional knowledge in form of Brown clusters (Brown et al., 1992) that we trained on 100 million tokens of English tweets crawled between 2011 and 2016. When we evaluate on the WSJ sections 22-24, we achieve an accuracy of 96.4% which is on par with the state of the art for fine-grained tagging which ranges from 96.5% (Brants, 2000) to 97.6% (Huang et al., 2015) according to the ACL wiki.[1]

Coarse Model Our coarse model is also trained on the WSJ section 0-21. An advantage of using coarse tags is the availability of many annotated corpora that can be easily mapped to coarse tags regardless of

[1] http://aclweb.org/aclwiki/index.php?title=POS_Tagging_(State_of_the_art)

	Accuracy (%)		
	News → Web	**News → Chat**	**News → Twitter**
fine	92.3	73.6	80.8
coarse	96.0*	88.9*	90.6*

Table 3: Accuracy of a fine trained and coarse trained model for tagging across domains. Marked values are statistically significant against the baseline (McNemar's test, $p < 0.05$)

the actually used fine tags. This immensely extends the pool of annotated training data that we can choose from. We thus additionally add 250k tokens of the Switchboard corpus as well as a PoS dictionary feature based on the three most frequent coarse tags of each word derived from the British National corpus (Clear, 1993). Furthermore, we add additional annotated Twitter data (Owoputi et al., 2013) to inform our classifier about phenomenons found in the social media domain. Please note that neither of these extension is possible for the baseline model because the tagsets are not compatible on the fine-grained level. However, we can use those resources for coarse grained tagging by mapping the fine tags to the same coarse tagset.

Table 3 shows the results of tagging the *Web*, *Chat*, and *Twitter* datasets, while we exclude *News* as we have been using it for training the models.[2] We find that in this cross-domain setting, our coarse-grained tagger significantly outperforms the fine-grained version for all three datasets. Especially the results on the *Chat* dataset are informative, as the news-trained model can obviously not be transferred well to chat data. In contrast, our coarse-grained version performs even better on *Chat* than on *Twitter* showing that it generalizes well.

3 Fine-grained Tagging

As we have shown in the previous section, we can assign coarse tags with higher accuracy than fine tags. This gives us the necessary head start for our second tagging step, as errors from the first stage will be propagated into the second stage and cannot be corrected anymore. For example, if we wrongly assigned the coarse tag `N` to a verb in the first step, we will in the second step apply the specialized classifier for nouns that has no chance of assigning a verb tag.

We implement the fine tagging by using a dedicated model which assigns fine PoS tags belonging to one coarse word class. For this step, we use a Support Vector Machine (Joachims, 1998) as implemented in Weka (Holmes et al., 1994), because this sub-task is not easily implemented as a sequence classification task. We use the same feature set as before and train the second step models on the WSJ considering only words belonging to the same coarse word class. Two coarse word classes (conjunction and numbers) do not have further fine-grained specializations in the PTB tagset, i.e. they can be mapped one-to-one to their fine PoS tag.

In order to assess the full potential of our approach, we will first ignore error propagation between the two tagging stages. This means, we assume an oracle condition that assigns correct coarse-grained tags. Afterwards, we will evaluate our full model with error propagation and check against the hypothetical performance of the oracle.

We show the results of fine tagging under oracle condition in Table 4 in comparison to our fine baseline. Marked values show statistically significant improvements against the baseline (McNemar's test, $p < 0.05$). Under oracle condition our model performs significantly better on all our for evaluation corpora. In the last row of Table 4, we show the results of our two-step approach, where errors made in the coarse step are propagated to the fine-grained tagging. Our results are on par with the state-of-the-art fine baseline for three out of four datasets, and are significantly better for the *Chat* corpus.

In order to better understand the influence of coarse errors, we simulate a certain level of error propa-

[2]Dataset with additional tags not occurring in the training data pose special problems. We treat the few unknown tags as always correct in order not to influence the relative difference between the fine and coarse setup too much.

	Accuracy (%)			
	News	**Web**	**Chat**	**Twitter**
Fine baseline	96.4	92.3	73.6	80.8
Oracle 100%	98.4*	95.8*	83.0*	89.3*
Two-step	96.1	92.4	75.8*	81.9

Table 4: Accuracy of fine-grained tagging using oracle coarse-grained tagging and two-step tagging. Marked values are statistically significant against the baseline (McNemar's test, $p < 0.05$)

gation by using an oracle that only returns the correct tag with a certain probability (uniformly sampled over all tags). Figure 3 shows the resulting relationship between a certain level of coarse-grained accuracy and the resulting fine-grained accuracy. We see that both are in a similar linear relationship for all datasets. Measuring the slope, we can approximate that a 1 percent point improvement in coarse accuracy translates into an improvement between .8 and .9 percent points in fine-grained accuracy. The accuracy of our two-step tagging is marked by a black dot. Its location is always on or very close to the hypothetical performance of the oracle. We can thus conclude that our predictions are quite accurate and better coarse performance will really lead to better fine performance. On *Chat* our approach performs slightly better than predicted, which we take as an indicator that our error propagation experiment is a rather conservative lower-bound for the impact of coarse tagging errors.

4 Tag-specific Optimization

While it is hard to optimize the tagging accuracy for a specific fine-grained tag using traditional taggers, our approach offers a straightforward way to train a second stage model that is tailored towards such a task. For example, a scholar might be only interested in finding past participle verbs (word class `VBN` in the PTB tagset). However, they are easily confused with past tense verbs (word class `VBD`) due to their identical word surface form as in the example below.

> *Mr. Smith was arrested/VBN and **charged/VBN** along with the others when he returned to Namibia this month*

A tagger is easily mislead to tag the second VBN (bold faced) as past tense verb rather than past participle, because the auxiliary is outside a narrowly defined ± 2 context window. Note that the past tense decision might even be correct in a very similar context like *Mr. Smith was arrested/VBN and **went/VBD** along anyway.* So the tagger either needs to learn the compositional semantics of 'charged along' from a large number of annotated examples or by using additional external knowledge. We thus argue that for our specialized `VBN` classifier it is easier than in a global setting to utilize a wider context window and use more lexical features.

If we wish to optimize the detection accuracy for VBN in our approach, we can ignore the performance on the other tags. Thus, we transform the problem into a one vs. all classification, i.e. we further reduce the decision complexity in the second tagging step to a binary decision between `VBN` and $\neg$`VBN`. In order to avoid a class bias, we ensure a balanced distribution of both classes in the training data and train our model again on the WSJ. We extend the feature set to provide additional hints for the classifier that one of the words outside of the ± 2 context window is an inflected form of *have*, *be*, or a modal verb.

Table 5 shows the results of our optimization experiment. We evaluated the accuracy of tagging only the word class VBN. We report accuracy for the fine baseline and our two-step model in (i) standard configuration and (ii) the `VBN` optimized version. The first thing to notice is that without optimization our standard two-step model performs worse than the fine-grained baseline. However, our optimized two-step model significantly outperforms the fine-grained baseline on all datasets. This shows that our separation of the tagging process in two steps allows for an easy way of customizing a PoS tagger towards specific needs by incorporating linguistically motivated features.

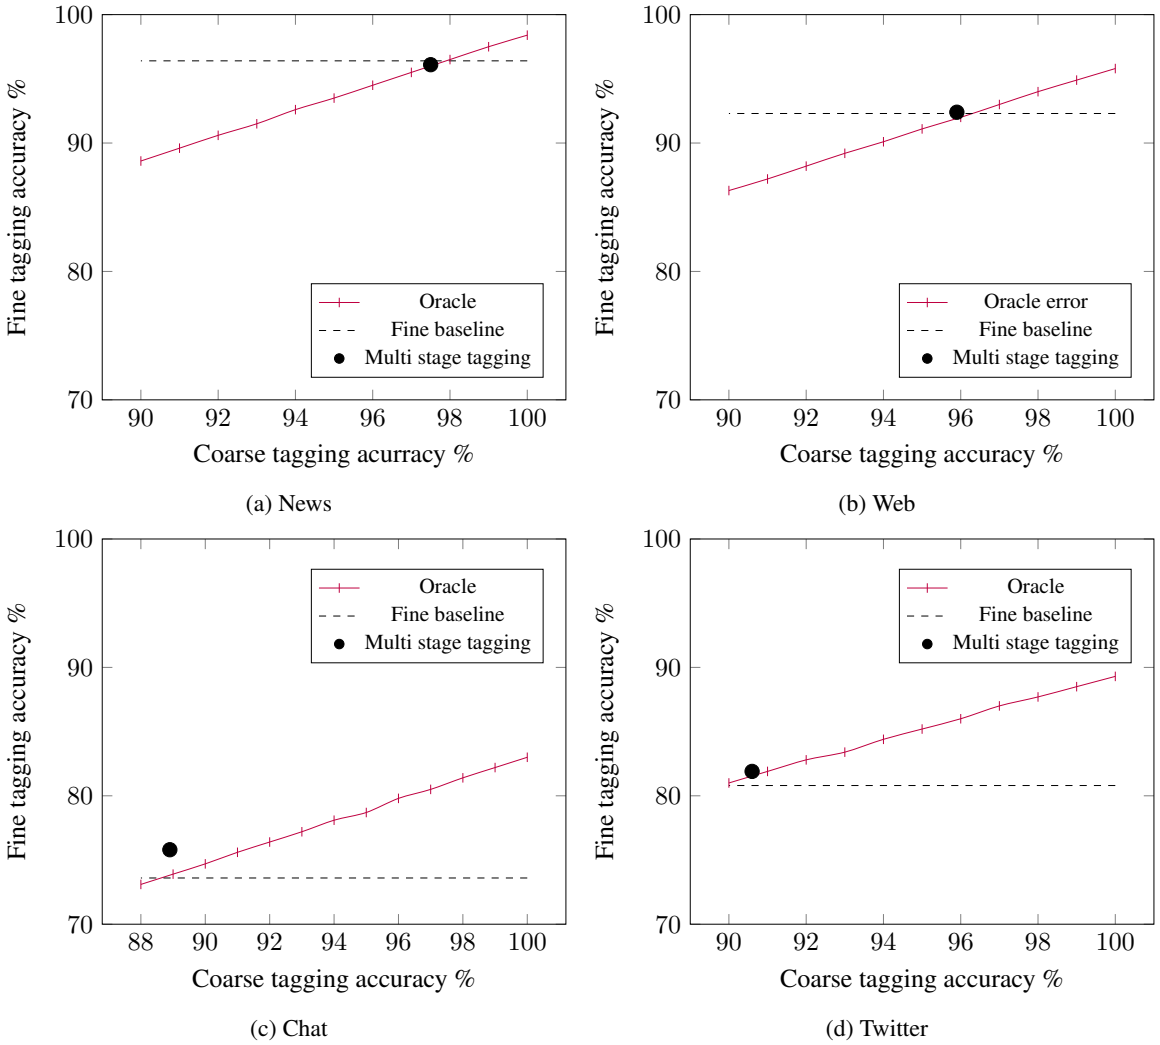


Figure 3: Relationship between fine-grained accuracy and error-level of the coarse-grained tagging. The horizontal dashed line shows the baseline performance and the black dot shows the accuracy of our two-step PoS tagging.

	VBN Accuracy (%)							
	News		**Web**		**Chat**		**Twitter**	
	w/o	w	w/o	w	w/o	w	w/o	w
fine	86.7	87.4	81.2	82.4	75.7	77.0	70.0	76.4
two-step	84.6	90.7*	79.0	86.7*	74.0	81.3*	64.3	81.4*

Table 5: Results for detecting **VBN** with and without optimization. Marked values are statistically significant against the fine-grained baseline (McNemar's test, $p < 0.05$)

5 Conclusions

We introduce a new two-step PoS tagging approach, where first a coarse-grained tag is assigned with high precision, and in a second step a specialized fine-grained classification with heavily reduced decision complexity is applied. We show that the accuracy of coarse-grained tagging is significantly higher when directly learning a coarse model compared with a fine-grained model. This especially holds in a cross-domain setting where coarse models generalize much better than fine models. As many NLP applications rely on coarse-grained tags, this finding has a huge potential for practical improvements in downstream tasks. If we evaluate the fine-grained accuracy, we find that our two-step approach performs on par

with the classical single-step paradigm, except for the especially challenging chat messages where it is significantly better. Using an oracle for coarse-grained tagging, we show that our approach has a huge potential for improving the overall accuracy, as improving coarse-grained accuracy translates almost directly into coarse-grained accuracy. In the common setting that a researcher is only interested in the performance of a specific fine-grained tag, we show that our approach can be easily optimized and then significantly outperforms the classical approach that does not improve even if the same optimizations are used.

In future work, we aim to further improve coarse grained tagging, as our analysis shows that coarse-grained improvements nearly linearly translate into fine-grained improvements. We also aim at further improving fine-grained tagging, as we see large potential for further specializing the feature sets used for different word classes.

Abstract

Parsing texts into *universal dependencies (UD)* in realistic scenarios requires infrastructure for *morphological analysis and disambiguation (MA&D)* of typologically different languages as a first tier. MA&D is particularly challenging in *morphologically rich languages (MRLs)*, where the ambiguous space-delimited tokens ought to be disambiguated with respect to their constituent morphemes. Here we present a novel, language-agnostic, framework for MA&D, based on a transition system with two variants, word-based and morpheme-based, and a dedicated transition to mitigate the biases of variable-length morpheme sequences. Our experiments on a Modern Hebrew case study outperform the state of the art, and we show that the morpheme-based MD consistently outperforms our word-based variant. We further illustrate the utility and multilingual coverage of our framework by morphologically analyzing and disambiguating the large set of languages in the UD treebanks.

1 Problem Statement

A decade following the emergence of statistical parsers for English (Charniak, 1996; Bod, 1995), the CoNLL data sets presented a new challenge: the development of data-driven statistical parsers that can be trained to parse any language given an appropriately annotated treebank (Buchholz and Marsi, 2006; Nivre et al., 2007). These data sets facilitated the development of accurate, language-agnostic, dependency parsers (Nivre et al. (2006), McDonald (2006) etc.), but not without shortcomings: they require that input tokens be *morphologically analyzed and disambiguated* in advance.

This latter assumption breaks down in realistic parsing scenarios where the morphological analysis of an input token may consist of multiple syntactic words to participate in the parse tree (Tsarfaty et al., 2010). The *universal dependencies (UD)* initiative aims to remedy this by presenting a harmonized set of treebanks, now 54 and counting, with a unified annotation scheme and multilayered annotation. Specifically, UD data distinguishes the input space-delimited tokens from the (morpho)syntactic words that participate in the parse tree (Nivre et al., 2016).

Efforts towards parsing texts into *universal dependencies* in realistic scenarios thus require language-agnostic infrastructure for automatic *morphological analysis and disambiguation (MA&D)* of data from typologically different languages. MA&D is particularly challenging in *morphologically rich languages (MRLs)*, where space-delimited input tokens may have multiple analyses, only one relevant in context. This *morphological ambiguity* of a token is typically represented as a lattice. The term *Morphological Disambiguation* (MD) refers to selecting a single path through the *morphological analysis* (MA) lattice.

In Semitic languages, MD is particularly challenging (Adler, 2007; Bar-haim et al., 2008; Shacham and Wintner, 2007; Pasha et al., 2014; Habash and Rambow, 2005). To illustrate, Figure 1 shows the MA lattice of the Hebrew phrase 'bclm hneim'[1] (literally: in-shadow-of-them the-pleasant, meaning: in their pleasant shadow). Different paths in the lattice represent different disambiguation decisions. In

[1] We transliterate as in Sima'an et al. (2001).

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 337–348, Osaka, Japan, December 11-17 2016.

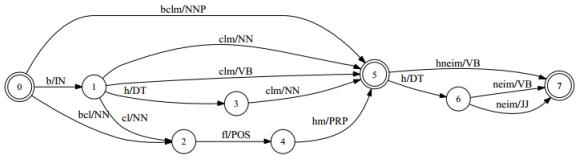

Figure 1: An example of an MA lattice of the phrase "bclm hneim" ("in their pleasant shadow") in transliterated Hebrew. Edges mark syntactic words, and double circles mark white spaces.

the context of 'bclm hneim', the correct path of 'bclm' is 'b-cl-(fl)-hm', "in-shadow-(of)-them". In the context of another sentence, the token 'bclm' may be "Betzelem", the name of a famous organization.

In MRLs, MD is also more subtle than simply segmenting the space-delimited tokens. Many MRLs are fusional, and clitics may be fused into hosts. In Figure 1, in the phrase 'b-cl-(fl)-hm' (literally: in-shadow-(of)-them), the possessive 'fl' (of) is fused into the pronoun 'hm' (them) and remains implicit in the surface form. Such fusion results in an ambiguous number of morphosyntactic nodes that participate in the analysis, impacting downstream applications as syntactic and semantic parsing, translation, etc.

Previous work on MA&D in MRLs, and in Semitic languages in particular (Adler, 2007; Bar-Haim et al., 2005; Shacham and Wintner, 2007; Pasha et al., 2014), relied on language-specific lexica and cannot be executed cross-linguistically. General CRF implementations, such as MarMoT (Müller et al., 2013), that can be applied across languages, assume an unrealistic, gold pre-segmented setting (Bjorkelund et al., 2013). For generic morphological segmentation, Morfessor (Smit et al., 2014) uses a max-likelihood in semi-supervised settings, but it cannot handle the rich labeling of morphological segments.

In this paper we present a general, language-agnostic solution the for the MA&D task. We target *joint* morphological segmentation and tagging, as has been advocated in monolingual cases (Zhang and Clark, 2011; Bar-haim et al., 2008; Adler and Elhadad, 2006; Habash and Rambow, 2005), in *universal* settings. Our technical approach extends the transition-based framework for structured prediction of Zhang and Clark (2011). We define and implement two MD variants: word-based and morpheme-based. We present the best MA&D results to date, and demonstrate that the morpheme-based variant consistently outperforms our word-based one, while providing state-of-the-art results on full-fledge, fine-grained, MD of Hebrew. Furthermore, our MA&D framework is intentionally designed with language independence in mind. Devoid of requiring language-specific resources, we show robust and competitive MA&D performance on MRLs and non-MRLs alike, for circa 50 languages in the most recent release of UD treebanks (Nivre et al., 2016).

2 Challenges and Formal Settings

We propose a data-driven framework for MA&D of MRLs and non-MRLs alike. The MA component implements a function that maps each input sentence to its MA lattice, and the MD component implements a transition-based model that accepts the lattice as input and returns a selected path as output.

Formally, our transition system is a quadruple $S = (C, T, c_s, C_t)$, where C is a set of configurations, T is a set of transitions, c_s is an initialization function, and $C_t \subseteq C$ is a set of terminal configurations. A transition sequence y of length n, $y = c_0, t_1(c_0), ..., t_n(c_{n-1})$, starts with an initial configuration $c_0 = c_s(x)$ for the input sentence x and ends with a terminal configuration $c_n \in C_t$, where $t_i \in T$ and $c_n = t_n(c_{n-1}) \in C_t$. We employ an objective function F where x is the input sentence and $GEN(x)$ is the set of possible transition sequences for x:

$$F(x) = argmax_{y \in GEN(x)} Score(y) \quad (1)$$

To compute $Score(y)$, $y \in GEN(x)$ is mapped to a global feature vector $\Phi(y) \in N_d$, where each feature is a count of occurrences of a pattern defined by a feature function ϕ. The feature vector $\Phi(y)$ is defined via a set of d feature functions $\{\phi_i\}_{i=1}^{d}$. The way Φ is defined effectively determines the quality of the parser, since the feature model captures linguistic information to which the model learns to assign

weights. Given this vector, $Score(y)$ is computed by multiplying $\Phi(y)$ with a weights vector $\vec{\omega} \in R^d$.

$$Score(y) = \Phi(y) \cdot \vec{\omega} = \sum_{c_j \in y} \sum_{i=1}^{d} \omega_i \phi_i(c_j) \quad (2)$$

Following Zhang and Clark (2011), our system learns the weights vector $\vec{\omega} \in R^d$ via the generalized perceptron, using the early-update averaged variant of Collins and Roark (2004). The algorithm iterates through a gold-annotated corpus, each sentence is disambiguated (decoded) with the last known weights, and if the decoded result differs from the gold standard, the weights are updated. As in Zhang and Clark (2011), decoding is based on the beam search algorithm, where a number of possible parse sequences are evaluated concurrently to mitigate irrecoverable prediction errors. At each step, the transition system applies all valid applicable transitions to all candidates. The B highest scoring expanded candidates are maintained and passed on to the next step. Those that don't make the B mark, fall off the beam.

Our MRL setting (cf. Tsarfaty et al. (2010)) poses three technical challenges to this general scheme:
(i) the formal challenge: how should we define a transition system for MA&D?
(ii) the learning challenge: how can we define feature functions that learn morphological phenomena?
(iii) the decoding challenge: how can we effectively compare morpheme sequences of variable length?

3 Our Proposed Solution

Let $x = x_1...x_k$ be an input sentence of k tokens and $L = MA(x_1), ..., MA(x_k)$ be the morphological ambiguity lattice for x, where L is a contiguous series of word-lattices $L_i = MA(x_i)$ connected top to bottom, as illustrated in Figure 1. Each word lattice L_i is a set of sequences of morphemes, and each sequence is a single disambiguated analysis for x_i. We define the *morphosyntactic representation* (MSR) of an arc in the lattice as a tuple $m = (s, e, f, t, g)$ with lattice nodes s and e marking the start and end of a morpheme, a form f, a part-of-speech tag t, and a set g of attribute:value grammatical properties.

Defining Configurations. A configuration for the MD transition system is a quadruple (L, n, i, M) where $L = MA(x)$ is the sentence-lattice, n is a node in L, i is the 0-based index of a word-lattice in L, and M is a set of disambiguated morphemes (i.e., selected arcs). The terminal configuration is defined to be $C_t = \{(L, top(L), tokens(L), M)\}$ for any L, M, where $tokens(L)$ is the number of word-lattices that form L. The initial configuration function c_s concatenates the L_i lattices of the tokens into a single structure $L = MA(x_1) + ... + MA(x_k)$, and sets $n = bottom(L)$, $i = 0$ and $M = \emptyset$.

Defining Transitions. There are two conceivable ways to make morphological disambiguation decisions, in a *word-based* (WB), and in a *morpheme-based* (MB), fashion, in the terminology of Tsarfaty and Goldberg (2008). In WB models (a.k.a *token-level* in the UD terminology), the disambiguation decision determines a complete path of morphemes between token-boundaries. In the lattice, this refers to selecting a path between two token-boundary nodes (double circles). MB disambiguation decisions (also termed *lexical-level*, or *word-level* in UD) occur at any node in the lattice indicating a morpheme boundary, with more than one outgoing arc, choosing a specific arc m among them.

Interim: Word-Based or Morpheme-Based? WB and MB strategies face contradicting, and complementary, challenges. In WB models, disambiguation decisions are complex, and learning how to score them is expected to suffer from data sparseness. MB models, on the other hand, over-generalize in terms of possible morphological combinations, and learning to score combinations may fail to generalize and be prone to over-fitting. On top of that, morpheme sequences are longer than word sequences, which, in a transition-based system, is known to be more error prone. Finally, variable-length sequences introduce length biases which negatively impact performance. Since MA&D is the base for the NLP pipeline, it is critical to settle this debate empirically and establish the basis for downstream tasks.

Parameterizing Transitions. A transition system is required to distinguish between all possible decisions it can make at a given point. At the same time, the model should be able to generalize from seen decisions to unseen ones, and effectively learn to disambiguate open-class words and out-of-vocabulary

items. To satisfy these desiderata, we define a *delexicalization projection* for a pre-defined set of parts-of-speech tags O capturing open-class categories. Simply put, this projection neutralizes the lattice-nodes specific indices, and, for any tag $t \in O$, it further neutralizes the lexical form. Formally:

$$DLEX_O(m) = \begin{cases} (\_, \_, \_, t, g) & \text{if } t \in O \\ (\_, \_, f, t, g) & \text{otherwise} \end{cases} \quad (3)$$

3.1 Word-Based Modeling

The Transition System For word-based (WB) modeling, a single transition morphologically disambiguates whole word-lattices such that the node n of a configuration is always at a word boundary (a node that is a bottom, top, or both, of word-lattices of L). We define the transitions in the WB system as an open set of transitions termed MD_s, specifying the parameter s as a single path:

$$MD_s : (L, n, i, M) \rightarrow (L, q, i+1, M \cup \{m_0, .., m_j\}) \quad (4)$$

Here, $\{m_0, ..., m_j\} \in L$ form a contiguous path of arcs, where m_0 starts at node n, m_j ends at node q (they can be the same arc), and s is the projected paths $s = DLEX_O(m_0), ..., DLEX_O(m_j)$. A terminal configuration will therefore contain the union of contiguous paths of word-lattices in L, together forming a complete morphological disambiguation of the ambiguous tokens of the input sentence.

Learning We define three types of word-lattice properties: o - the surface form of the token itself, a - the $DLEX$-projected lattice (all MSRs projected by the delexicalization function), and p - a chosen disambiguated path, which only exists for previously processed lattices. Using these properties, we define baseline feature templates modeled after POS tagging: unigram, bigram, and trigram combinations of o and a, and p-based features, which predict the next disambiguation decision based on the previous one(s).

3.2 Morpheme-Based Modeling

The Transition System For morpheme-based (MB) modeling, a single transition chooses an outgoing arc of the current node n in the lattice, requiring a disambiguation decision if (and only if) there is more than one outgoing arc. Again we define the transitions as an open set of transitions termed MD_s, now specifying s as a single *arc*:

$$MD_s : (L, n, i, M) \rightarrow (L, q, j, M \cup \{m\}) \quad (5)$$

Here, m is a morpheme $(n, q, f, t, g) \in L$, and $s = DLEX_O(m)$. If node q is at a word boundary, then $j = i + 1$, otherwise $j = i$. For a terminal configuration, each $m \in M$ is an outgoing arc of the end node of another arc in M (with the exception of the first morpheme, starting at $bottom(L)$) forming a contiguous path that disambiguates x.

Learning In the MB model we can access specific information concerning the current node inside the word-lattice. We define the properties f, t and g, corresponding to arcs' form, part-of-speech and morphological attribute:value pairs. We use these properties in various unigram, bigram, and trigram combinations, in parallel with the WB model. As in the WB model we also define the property p as the path in the previously disambiguated word-lattices. We define the property n to be the set of $DLEX$-projected outgoing morphemes of the current node (this parallels the property a of WB models, but at morpheme granularity). Similarly to the WB case, we use unigram, bigram, and trigram combinations of these properties as well.

Decoding Since the number of arcs in lattices' paths for x may vary, so do the number of transitions in our morpheme-based transition system. This violates a basic assumption of standard beam search decoding — that the number of transitions is a deterministic function of the input.

There are two inherent biases in varied-length transition sequences driven by the general perceptron algorithm. The beam search algorithm tests the best candidate after each step for goal fulfillment. A short

sequence may temporarily be the best candidate and fulfill the goal, while longer (and possibly correct) sequences are incomplete and may be lost. On the other hand, long sequences have more features, therefore their score may be arbitrarily inflated. So the score may be higher for longer paths, even though a shorter one may be correct and may fall off the beam.

To address these challenges we introduce a special transition we call *ENDTOKEN (ET)*, that explicitly increments i, instead of implicitly in MD_s. So, in equation (4) we set $j = i$ and apply:

$$ET : (L, n, i, M) \rightarrow (L, n, i + 1, M) \tag{6}$$

ET is required to occur exactly once at the end of the word-lattice, when n is the top of some word-lattice in L. Set aside from other transitions, ET has its own set of features. Other than incrementing i, ET has no effect on configurations, but it does cause a re-ordering of candidates in the beam during decoding, at each token boundary. Note that ET kicks in only for variable length lattices. On same-length lattices, ET is skipped and equation (4) remains as is — the process essentially falls back on the standard, same-length decoding.

An MD transition sequence thus becomes the union of disjoint sets of configurations $y = y_{md} \cup y_{et}$, and changes $Score$ in Equation (2), where $|y_{et}|$ is the # of tokens in L with variable length paths. :

$$\sum_{i=1}^{d} \omega_i^{md} \phi_i^{md}(y_{md}) + \sum_{j=1}^{d} \omega_j^{et} \phi_j^{et}(y_{et}) = \sum_{c_k \in y_{md}} \sum_{i=1}^{d} \omega_i^{md} \phi_i^{md}(c_k) + \sum_{c_l \in y_{et}} \sum_{j=1}^{d'} \omega_j^{et} \phi_j^{et}(c_l) \tag{7}$$

While the number of morphemes, and therefore $|y_{md}|$, can vary, $|y_{et}|$ is deterministic per lattice. Using this anchor, the features of the ET transition provide a counter-balance to the effects of varied-length sequences by scoring fully disambiguated paths of each word-lattice individually, occuring a fixed amount of times for all paths.

ENDTOKEN vs. IDLE transitions Variable-length sequences in beam search also exist in the structured prediction of constituency trees. Zhu et al. (2013) introduced an IDLE transition (also adopted in Honnibal and Johnson (2014) and Zhang et al. (2014)) that, like ET, has no effect on configuration, but unlike ET, occurs only at the end of the parsing sequence, an arbitrary number of times, until all parsing sequences are complete.

While IDLE transitions make sense when applied after a complete hierarchical structure is predicted — where they may learn to rerank candidates based on features that are visible at the top of the structure (the root) — it is futile to use last-seen features that arbitrarily exist at the end of a morphological disambiguation (linear) sequence, to rerank candidates again and again. This is because at the end of the sequence, we can no longer save candidates that were lost earlier on due to length discrepancies .

To mitigate this, one might try to create IDLE padding with global features spanning the entire disambiguated path. Even then, the learned model parameters would not generalize well, since these features will be applied an arbitrary number of times — the maximal length of an occasional word lattice we are at — which has no linguistic significance, and may arbitrarily inflate certain scores.

ET transitions, in contrast, occur right when they are needed — at the boundary of a word-lattice. This position enables the reordering of candidates right after a length discrepancy may have been introduced. Moreover, ET scores are counted against the global score a fixed number of times per lattice, for all, any length, candidates. This enables a fair comparison of all paths per lattice.

4 Empirical Evaluation

We empirically evaluate the proposed models, and investigate their strengths, weaknesses, and bounds. We start with a detailed investigation of MA&D in the Semitic language Modern Hebrew, which is known for its rich morphology and significant ambiguity. We then verify the cross-linguistic coverage of the models on the set of UD treebanks (Nivre et al., 2016), to validate their efficacy.

We implement *yap* (*yet another parser*), a general-purpose transition-based framework for structured prediction, based on beam search and the generalized perceptron. We extend it with the models described herein. We implement the WB, MB variants, ET transitions, and evaluate different feature settings.

(a)

	Word-Based				
	unigram	+bigram	+trigram	+next unigram	+next with bigram
	85.73 (86.72)	86.9 (87.88)	86.7 (87.66)	**92.19 (92.76)**	91.98 (92.59)
+ET	89.09 (89.81)	89.93 (90.71)	90 (90.85)	**93.39 (93.94)**	92.84 (93.46)

	90.67 (91.41)	91.12 (91.88)	90.09 (91.82)	93.56 (94.16)	**93.89 (94.49)**
+ET	92.68 (93.36)	92.74 (93.55)	92.64 (93.47)	94.27 (94.92)	**94.33 (94.9)**

Table 1: Dev. set results for Word-Based (a) and Morpheme-based (b) MD: F_1 for full morphological disambiguation (form, part of speech, morphological properties). (n parenthesis: F_1 for form and POS only. The +ET lines indicate a variant that employs the ENDTOKEN transition at token boundaries.

We report the F_1 metric comparing the MSRs of *predicted* vs. *gold* lattice arcs, for full morphological disambiguation (segmentation, POS tags, and all morphological properties), and for segmentation and POS tags only. For comparison with previous work, we also report token-level accuracy (while F_1 awards partial success on word-lattices, token-level accuracy requires exact match on a whole path per token).

4.1 The Case for Modern Hebrew

Setup We evaluate MA&D performance on the Modern Hebrew section of the SPMRL 2014 Shared Task (Seddah et al., 2014), which has been derived from the Unified-SD treebank of Tsarfaty (2013). We updated the treebank to provide consistent theories for the treebank annotation and lexicographic resources (Itai and Wintner, 2008), a consistency that we found lacking in the SPMRL 2014 Hebrew section. We use the standard split, and train on the standard train set (5k sentences). Here we provide results and in-depth analysis on *dev* and confirm our findings on *test*.

A pre-condition for the execution of our MD models is an $MA(x)$ function that generates word-lattices for x (§2). We start off with a morphological analyzer that we implemented, called HEBLEX, which relies on the Ben-Gurion Hebrew Lexicon used by Adler and Elhadad (2006). The lexicon contains full analyses for 567,483 words and 102 prefixes. HEBLEX uses the lexicon to determine the various combinations of prefixes and words that form valid tokens. This process is far from trivial due to morphological *fusion*, as some morphemes are implicit (§1).

Although the lexicon is quite large, there are still tokens which are *out-of-vocabulary (OOV)*. OOV tokens may be of two types: it may be that an entire string is out of the lexicon (mostly proper nouns) or that the affixes and the open class items are seen, but their combination has not yet been encountered. We address OOV by assigning proper noun analyses to entire tokens, as well as to all arcs combined with seen affixes. This adds ambiguity to the lattices, but gives the MD the chance to select a correct path.

In our experiments we aim to quantify exactly the effect of lexical coverage of the MA on MD accuracy. To this end, we add an option to *infuse* missing gold analyses into the MA lattices provided by HEBLEX and present two sets of results: once disambiguating lattices with infused gold analyses (ideal MA), and once without infusing gold analyses (realistic MA).

Results Tables (1a), (1b) present our investigation of the WB and MB models on the dev test, respectively, with different feature templates. Our results show that the MB disambiguation consistently outperforms our WB variant, in various feature template settings. Moreover, the ET transition consistently improves performance, with best results for Hebrew at F_1 scores of 94.3 (94.9) for full MD (seg/POS only). The token-level accuracy for our best results are 93.07 (93.9) for full MD (seg/POS).

These results were obtained on *infused* lattices, that include the gold path as one of the alternatives. In order to gauge the effect of incomplete lexical coverage, we disable infusion of the gold analyses into the HEBLEX lattices. We then observe a drop to F_1 scores of 89.62 (92.06) and token accuracy of 87.72(90.85). To set our results in context, we applied our best model in "English-like" settings for tagging, with gold pre-segmented text. F_1 then increases to 96.82 (97.44). That is, in "English-like" settings, our tagging accuracy (97.44) is as high as state-of-the-art English tagging (Manning, 2011).

MarMoT (Müller et al., 2013), a state of the art CRF tagger, obtains F_1 93.38 on full MD on this set.

Next we aim to verify that ET transitions indeed act as intended. We classify a sequence length error as either an overshoot (predicted morphological disambiguation sequence is longer than gold) or undershoot (predicted shorter than gold). Without ET, in the infused setting, 36.8% of sentences have incorrect length and the overshot:undershoot ratio is 6.6:1. Adding ET transitions results in 31.8% length errors, correcting 20.62% of the overshoot errors, resulting in ratio of 4:1. In the un-infused setting, 41.4% of the sentences have incorrect length with a ratio of 6.39:1. Adding ET results in 36% length errors, correcting 20.67% of the overshoot errors, resulting in ratio of 3.7:1.

Hebrew previous results are non-trivial to compare to due to significant changes of the treebank along the way and unavailable code of previous work. The most relevant results to ours are by Adler (2007), who reports state-of-the-art results for Modern Hebrew in realistic (non-infused) setting, with self-reported token accuracy of 90% (93%) on a different evaluation set. For his prediction on our dev set, F_1 evaluation yields 85.74 (87.95), much lower than ours. Segmentation F_1 for Adler is 96.35, while ours is 97.6. We confirm our findings on the test set, for which Adler F_1 yields 82.91 (85.56). Our best model now yields 86.23 (88.85) and 92.96 (93.73) in realistic and infused settings, respectively.

4.2 The Case for Universal Dependencies

Setup We evaluate the cross-linguistic coverage of our MD models on the UD set. We parse 48 UD treebanks from the UD1.3 release (Nivre et al., 2016), training on the *train* set and evaluating on *test*.[2]

We implement a *universal* data-driven morphological analyzer, that can be trained out-of-the-box along with our MD models for any treebank in the CoNLL-U format. We generate a dictionary for each language from its train set by collecting all seen analyses of each token in the training data, where an analysis is composed of MSRs that contain a lemma, POS, and the full set of morphological features. The dictionary maps each token to a set of MSR sequences, which then compose their ambiguous MA lattices. For out-of-vocabulary (OOV) tokens, the MA pre-computes the cardinality of each coarse POS — the number of unique tokens per coarse POS — and consider the top 5 POS as "open-class". For these top 5 POS, the MA computes the 50 highest-frequency MSRs (POS + morph. properties) to be used as the OOV lattice of an OOV token. When applying MA to the training set, we add the OOV lattice to tokens whose known analysis contains an open-class POS. The model thus encounters during training a larger space of states than the observed one, and learns to accurately apply transitions in OOV circumstances at test time.

Results Table 2 reports F_1 accuracy for full MD and seg/POS for UD languages that do not require segmentation. For most large train sets ($> 200k$ tokens), we observe 2-3 points absolute drop from infused (ideal) to uninfused (realistic) setting. This suggests that when large train sets exist, our data-driven MA is a viable economic alternative to costly hand-crafted monolingual lexical resources. To scrutinize our realistic results we also report non-OOV-only F_1 for 5k limited uninfused setting. Here we see that for ~80% of languages, our results are on a par with a state-of-the-art tagger, MarMot, retrained on these data, within 0.035 (or less) points gap. This demonstrates that our disambiguation capacity is on-par with MarMot, where performance gaps come mostly from our OOV strategy (which is intentionally restrained, to allow handling of MRL segmentation that is handled by MarMot). Table 3 shows results for UD MRLs that require segmentation, contrasting results on gold pre-segmented input and un-segmented raw data. For raw data we see a minor, ~0.02, drop in F_1, compared to gold-segmented settings. That is, our model still retains the competitive MA&D performance, in a *single, universal, trainable* model — we attribute this to our *joint* segmentation and tagging strategy, which overcomes error propagation.[3]

[2] We do not present results for 6 languages: cs,kk,es_ancora,en_esl,pt_br,ja_ktc, as some or all form fields are empty.

[3] Shortly before submitting this article, UDPipe (Straka et al., 2016), a tool for tokenization, morphological analysis, tagging and parsing, had been released. As its name suggests, UDPipe is a pipeline implementation packaging together separate tools for different tasks. Our approaches and ultimate goals are rather different. We present *joint* morphological segmentation and tagging, as opposed to a pipeline. Moreover, our framework can be extended into a *single* transition-based system performing all tasks jointly, overcoming overheads and error propagation, as we intend to address next.

Table 3: MA&D in segmented languages: F_1 scores of the languages in UD which require morphological segmentation. The upper line indicate full MD, the lower line indicates segmentation and POS only. The left hand side shows results for GOLD segmentation, the right hand side for input lattices. MM columns are results for MarMoT. Results in parentheses are F_1 scores for non-OOV-only tokens.

5 Conclusion

We present an MD transition-based system that can effectively cope with extreme morphological ambiguities in MRLs. To the best of our knowledge, this is the first joint framework for MRL segmentation and tagging in a transition-based setup. Moreover, we present the best MA&D results for Modern Hebrew to date, and the first ever set of MA&D results for the most recent release of UD treebanks (UD1.3).[4] Our system provides a first tier for dependency parsing in real-world scenarios, dispensing with the need of external pre-processing. Furthermore, this transition-based model can be extended into a *joint* model for *complete* morphological and syntactic analysis, as has been previously advanced in phrase-based parsing (Tsarfaty, 2006; Goldberg and Tsarfaty, 2008; Cohen and Smith, 2007; Green and Manning, 2010).

[4]Upon publication we will make our source code, executables and trained models available at `https://github.com/habeanf/yap`.

Abstract

Development of hand crafted rule for syllabifying words of a language is an expensive task. This paper proposes several data-driven methods for automatic syllabification of words written in Manipuri language. Manipuri is one of the scheduled Indian languages. First, we propose a language-independent *rule-based* approach formulated using *entropy* based phonotactic segmentation. Second, we project the syllabification problem as a sequence labeling problem and investigate its effect using various sequence labeling approaches. Third, we combine the effect of sequence labeling and rule-based method and investigate the performance of the hybrid approach. From various experimental observations, it is evident that the proposed methods outperform the baseline rule-based method. The entropy based phonotactic segmentation provides a word accuracy of 96%, CRF (sequence labeling approach) provides 97% and hybrid approach provides 98% word accuracy.

1 Introduction

Manipuri language, one of the scheduled Indian languages, belonging to a Tibeto-Burman languages family(Chelliah, 1990) is syllabic in nature. In general, a syllable follows *onset-nucleus-coda* (consonant-vowel-consonant) structure, where nucleus is the core component defined by a vowel. The preceding and following consonants defined by the onset and coda respectively may or may not be present in a syllable. However every syllable must have a nucleus. Formation of an onset, nucleus and coda, while producing an uninterrupted syllabic sound, greatly affects the pronunciation of a language. For various applications such as Text-to-Speech Synthesis (TTS) (Kishore and Black, 2003; Bellur et al., 2011), Automatic Speech Recognition (ASR) (Wu et al., 1998) etc., proper syllabification of a word is one of the important core issues, especially for syllabic Indian languages. Though there have been several studies in this direction for the rich resource Indian languages such as Hindi, Bengali, Tamil, Telegu, Malayalam, Marathi (Bellur et al., 2011; Narendra et al., 2011; Kurian et al., 2011), only very few studies have been reported for low resource Manipuri language (Abbi and Awadhesh, 1985; Chelliah, 1990). To the best of our knowledge, no corpus is available for Manipuri language in UTF-8 to study various aspects of corpus-based linguistic understanding. This has motivated us to generate Manipuri corpus in UTF-8 and analyse various characteristics such as onset and coda distributions, syllable formulation and syllabification rules etc.

Manipuri language is written generally using two scripts; *Bengali scripts* and *Meitei Mayek* [1]. At present, majority of the Manipuri documents are written using Bengali scripts and, hence the investigation in this paper focuses on Manipuri words written using Bengali script. Further, processing of Bengali scripts poses more challenges than processing Meitei Mayek because of the phoneme imbalance. Bengali script has 55 symbols to represent 38 phonemes in Manipuri language (Singh et al., 2007).

One of the major challenges in syllabifying Indian languages such as Hindi, Urdu, Bengali, Marathi, Kashmiri, Punjabi, Gujarati is the *schwa* deletion in their written forms (Kishore and Black, 2003;

[1] http://www.unicode.org/L2/L2000/00259-MeeteiMayek.pdf

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 349–357, Osaka, Japan, December 11-17 2016.

Choudhury et al., 2004). Majority of the existing studies for syllabifying Indian languages are based on hand crafted rules built on language characteristics. Building such rules requires domain knowledge and it is an expensive task. Further, such rules often fail to capture *heteronym* (word having same spelling, but different pronunciations).

In general, languages evolves over time. New vocabularies are added. One language borrows vocabularies from other languages and become parts of the regular usage. For example, words like `institution`, `election`, `daddy` etc. have become more preferred words than their Manipuri counterparts. While syllabifying such borrowed or loan words, the rules crafted using the characteristics of the native language often fail to capture the syllabic structures of such word.

In this paper, we first explored two rule-based approaches which are *Baseline System* (C*VC* structured) and *Entropy Based Phonotactic Segmentation* (EPS). Secondly, we transform the syllabification problem as a *sequence labeling problem* and investigate the effect of two state-of-art methods, namely *Conditional Random Field* (CRF) (Sutton and McCallum, 2006) and *Maximum Entropy Markov Model* (MEMM) (McCallum et al., 2000). The intuition behind such transformation is that with an appropriate training set, these models can learn the inherent dependencies automatically and address the problem of *schwa*, *heteronym* and *loan* words. Another advantage of such machine learning methods is the language independent model. Given an appropriate annotated dataset, these methods can syllabify with reasonable accuracy without the knowledge of the underlying language. In summary, this paper has the following five contributions.

- Generate Manipuri corpus in UTF-8.
- Statistical analysis of the syllabified corpus for understanding syllable components (i.e. onset, nucleus and coda).
- Development of a data driven rule-based syllabification methods by exploring entropy distribution.
- Investigating the syllabification performance of CRF, MEMM and comparing with rule-based counterparts.
- Evaluating CRF model over Assamese language dataset.

2 Related Works

Two approaches are mainly considered for automatic syllabification of a language.

(i) **Rule-based approach**

(a) **Obligatory Onset Principle** (Hooper, 1972), or **Principle of Maximum Open Syllabicity** (Pulgram, 1970): It is one of the simplest principles, which is based on the assumption that open syllable i.e., a syllable with no coda, is significance. This is in fact very naive approach and it is impractical for Manipuri as it has various legal consonant clusters other that just CV syllable structure.

(b) **Sonority principles** (Selkirk, 1984): In this method, syllabification depends on sonority of each phoneme i.e., its quality of being sonorous. Sonorous is the capability of giving out sound especially resonance, deep sound. This principle assigns numerical values to every phoneme of a syllable depending on its sonority level where vowels have the highest value followed by nasals, fricatives, and plosives. The main disadvantage of sonority information is the position dependency of phonemes. The same phoneme present at a different location of a syllable may have different sonorous property. There exists several instances where phoneme does not fit its typical sonority rules.

(c) **The legality principle** (Goslin and Frauenfelder, 2001): Syllabification is based on the validation of the syllable structure considering its onsets and codas. It also considers the legality of the consonant clusters to detect its splitting points. It allows consonant clusters to be valid if they appear in some syllables. Legality principle requires a big corpus to study the legality of

its constituents structures. Its main problem arises when several valid splitting instances of a consonant cluster are possible resulting on ambiguous syllabification rules.

(d) **Maximum onset principle** (MOP) (Kahn, 2015): It is very similar to legality principle. Here, if multiple legal splits are possible, it gives preference to longer onsets irrelevant of the legality of the syllable coda.

Rule-based approaches are language dependent. A prior knowledge of the syllable structure and phonotactics of the language is necessary to derive such rules. Further, syllabification purely based on rule-based approached is mostly inadequate due to the presence of various ambiguities. There are various instances where correct syllabification cannot be obtained by a definite rule or may even break the conventional syllabification principle.

(ii) **Data driven approach**

(a) Zhang and Hamilton (1997) suggested Learning English Syllabification Rules system that learn rules using a symbolic pattern recognition approach.

(b) Adsett and Marchand (2009) provide a comparison between various data-driven syllabification algorithms namely, IB1 (94.36%) and Look-up Procedure (91.44%) algorithms along with Hidden Markov Support Vector Machines (95.17%), Liangs algorithm (95.48%) and Syllabification by Analogy (96.70%) which incorporate structure information.

(c) (Marchand et al., 2009; Adsett and Marchand, 2009) showed that rule-based approaches perform poorly as compared to the data driven approaches.

To the best of our knowledge, there have not been any work related to corpus-based machine learning approach using sequence labeling method for syllabifying Manipuri words. In the similar line of approach, Dinu et al. (2013) used CRF using two level tagging (phone boundary and phone distance) to perform syllabification for Romanian language. However, unlike their study, our approach uses only one level tagging as discussed in the section 5.2.

Further, Rogova et al. (2013) proposed a language-independent probabilistic syllabification of phonetic transcriptions of words using Segmental Conditional Random Fields (SCRF). This method works with phonetic transcriptions of word as input. Due to the existance of inherent $schwa$ in the script, phonetic transcriptions of a word may not be correct for Manipuri words.

3 Corpus generation

One of the challenges working with low resource Manipuri language is the unavailability of UTF-8 data sources. To create UTF-8 textual corpus for this study, we have identified two Manipuri local newspapers [2]. The local Manipuri newspapers written in Bengali script are not unicode compatible. The news articles are published and archived on the news website in PDF format. In order to generate unicode compatible text corpus, we deploy a Bengali OCR [3]. However, the accuracy of the OCR is very poor i.e., 52.6% words accuracy. We, therefore, manually correct the text extracted from the OCR. Thus, our corpus consists of 733 documents with 89,084 words and 26,203 unique words covering all possible Manipuri phone types.

4 Statistical analysis of Manipuri syllables

The 26,203 unique words present in the corpus are manually syllabified to study their characteristics. Each syllable is annotated with its positional information (`beg`, `mid` and `end`). For each word, the beginning syllable is marked as `beg`, ending syllable as `end` and all syllables that are between `beg` and `end` as `mid`. For example, the word *particular* is divided into *par*_`beg`, *ti*_`mid`, *cu*_`mid` and *lar*_`end`. Analysis of the distribution of onset, nucleus, and coda over different syllabic positions is important for understanding various linguistic aspects of a language. For the proposed rule-based approach for

syllabifying Manipuri word, we study distributional characteristics of onset, nucleus, and coda as one of the core parameters.

Table 1 shows the types of syllable structure with their percentage distribution of syllabic position (i.e. `beg`, `mid`, `end`) present across words in the corpus where C and V represent consonant and vowel respectively. The dashed line is the partition between the typical 9 syllable structures of Indian languages (covering almost 99.78%) over the nontypical syllable structures found in this corpus. All the root patterns of Manipuri language, as describe in Abbi and Awadhesh (1985), are found in the corpus. The appearance of the nontypical structures are due to the presence of loan words such as *headquarters*, *match*, *annual*, etc.

In Table 1, we observed that CV structure is the most commonly used syllabic structure with more than 59.43% of occurrences, followed by CVC with about 26.1%. We also observed that some syllable structures have dominant positional distribution. For example, V and CVC dominate with `beg`, while CV dominates with `mid` and CCV with `end` syllable position.

4.1 Phonotactics

Phonotactics is an important area of research in phonology which explores the rules governing the phoneme sequence of a language. To understand phonotactics of Manipuri language, we explore the distribution of onset, nucleus and coda across the syllables at different positions.

Figure 1[a,b,c] show the probability of onset and coda distribution for consonant phones at different syllabic positions (beg, mid and end) and their entropy i.e. the information contain in onset and coda probability distribution. A consonant with low entropy shows its structural bias toward either onset or coda. The figures show that a significant number of consonants have structural (onset or coda) as well as positional bias. Further, Figure 1[d] shows the probability distribution of nucleus vowel phones across different syllabic positions (beg, mid and end). It clearly shows that some vowels such as /a/, /au/, /ai/ have positional bias towards `beg`. In the proposed EPS method, discussed in section 5.1.2, the entropy

distribution is used to determine syllable boundary.

5 Proposed Methods

In this paper, we propose three different corpus-based automatic syllabification methods; (i) Rule-based approach, (ii) Sequence labelling approach and (iii) Hybrid of rule-based and sequence labelling approaches.

5.1 Rule-based approach

In this section, we discuss two rule-based approaches: (i) Purely based on C*VC* rule of the language and (ii) Corpus driven EPS. Both of them depends on the legality of syllable structures and consonant clusters by checking each phone along with its adjacent units until a legal split point is obtained. These two approaches differ only when a current phone α to be checked is consonant. When α is a dependent vowel and if its previous phone is a consonant then add α to the current syllable phone sequence else there is spelling error in the syllabifying word. When α is an independent vowel, then add it to the current syllable phone sequence only if it satisfies one of the following conditions.

a) If previous phone is one of the following short vowels {/a/, /aa/, /i/, /ii/} and followed by either /u/ or /uu/.

b) If previous phone is a short vowels /aa/ and followed by /o/.

c) If previous two phones do not satisfy condition (a) and previous phone is one of the following vowels {/a/, /aa/, /u/, /uu/, /o/} and followed by either /i/ or /ii/.

Table 2: Types of consonants and vowels and their orthographic phoneme representation

Otherwise, mark α as the beginning phone of the new syllable.

5.1.1 Baseline System

Since pure consonant cannot be a stand-alone phone, it must always be merged to either previous or following phone. Assumption in this approach is that a diacritic character (such as halant or virama) is properly placed to distinguish pure consonant from full consonant phone. Table 2 shows different types of consonants and vowels, and their corresponding orthographic representations. In this approach, if the input phone α is a pure consonant and not followed by one of the following semivowels {/y/, /r/, /l/, /w/}, then add α to the current syllable phone sequence, otherwise mark it as the beginning phone of the new syllable. We consider this approach as a *baseline* model to compare with other proposed methods.

5.1.2 Entropy Based Phonotactic Segmentation (EPS)

As the problem of schwa deletion exists in the script, the assumption made for the baseline system does not happen in reality. The proposed approach (described in algorithm 1), is an improvement over the baseline to handle the schwa deletion problem, by using the entropy estimate of phone and cluster of phones. It is designed as a generalized recursive algorithm where the baseline approach is treated as terminating case. Initially for each α, the two parameters β and γ, which are the preceding and following phones or string of phones of α, are taken as `NULL` value.

- `H(x,y)` calculate the cluster entropy of `x` and `y` when both are not `NULL`. If one of them is `NULL`, then the entropy of onset-coda distribution for the other is calculated.
- P_{split}`(x,y)` and P_{merge}`(x,y)` give the probability of splitting and merging respectively when `x` and `y` appear together.
- `CheckSplit(x,y)` function either split or merge `x` and `y` based on P_{split}`(x,y)` and P_{merge}`(x,y)` score.
- x^* represents the expansion of x by adding more context information.
- θ represents a threshold of the entropy.
- `MAX` = 5, since the typical syllable structures are not greater that 5.

5.2 Sequence labeling approach

In this section, we transform the problem of segmenting a word into its syllable units as a problem of sequence labeling task. To apply sequence labeling task on a word in the corpus, every letters present in each word are tagged as `C` or `S` where `C` denotes *continuous character* and *S* denotes *splitting character*. In each manually syllabified word, all letters except the last letter in a syllable are tagged as `C` and the last letter as `S`. For example, the word `Manipuri` which is syllabified as `ma ni pu ri` is tagged as `m/C a/S n/C i/S p/C u/S r/C i/S`.

EPS(β,α,γ)
if Length($\beta + \alpha + \gamma$) $\leq$ MAX then
  if *H(β,α)* $\leq \theta$ **then**
    CheckSplit(β,α)
  end
  else if *H(α,γ)* $\leq \theta$ *and* $P_{split}(\alpha,\gamma) < P_{merge}(\alpha,\gamma)$ **then**
    EPS(β,α + γ,NULL)
  end
  else
    EPS(β^*,α,γ^*)
  end
end
else
  Baseline(α)
end

Algorithm 1: EPS: If α is consonant

Now, considering the observed input sequence $o_1, o_2, ..., o_k$ (a Manipuri word), where o_i denotes an alphabet of Manipuri language (Bengali script in this study), the task is to find the best state sequence i.e., $s_1, s_2, ..., s_k$ that might have resulted the observed sequence where $s_i \in \{C, S\}$. For the word `Manipuri`, the desire output is the sequence $\{$`C S C S C S C S`$\}$.

In this study, we have considered two state-of-art sequence labeling methods namely CRF (Sutton and McCallum, 2006) and MEMM (McCallum et al., 2000). For this experiment, each phone that occurs less than 5 times in the corpus is considered as a rare phone. Each phone that occurs more than 2 times in the corpus will be a feature with their corresponding tags. Those features having a frequency less than 2 will be ignored. The rare phone features having a frequency less than 10 will be ignored and the common phone where feature frequency is more than 250 will form an equivalent class. For improving iterative scaling, 100 iterations have been used and to avoid the overfitting problem L1 regularizer have been employed.

5.3 Hybrid approach

The sequence labeling approach does not verify its output syllable structure with the phonotactic structure of the underlying language. In the proposed hybrid approach, the output of the sequence labeling method is passed to the proposed EPS method to verify the phonotactic structure and rectify the possible error.

6 Syllabification Results

This section discusses the experimental results of different syllabification methods proposed in this paper. 5-fold cross validation has been used to investigate the performance of different labeling methods. *Precision*, *Recall*, *F-measure* and *word accuracy* have been used as the evaluation metrices.

Table 3 compares the performance of different methods in terms of word accuracy, Precision, Recall and F1 measure and shows the distribution of wrongly syllabified words among the loan words and Manipuri words. It clearly shows that all the proposed methods outperform the baseline method. The EPS outperforms the baseline at least by 8.5% in accuracy. Similarly, CRF outperforms both baseline and EPS of about 9.6% and 1% respectively. Interestingly MEMM underperforms all other methods because of the existance of structural bias i.e. label bias problem. EPS and CRF can overcome this problem because they can generalize the global context information. It is also evident from the table that hybrid approach further enhanced the classification accuracy over CRF and EPS of about 0.5% and 1.6%. All the proposed approaches in this paper, were able to handle most of the schwa deletion and loan words problems.

Table 3: Evaluation for different methods

Manipuri Dataset				
Methods	Word Accuracy	Precision	Recall	F1 Score
Baseline	0.875	0.92950	0.93577	0.93212
EPS	0.95992 (+0.085)	0.98007	0.98004	0.98
MEMM	0.73225 (-0.143)	0.80968	0.80519	0.80603
CRF	0.97080 (+0.096)	0.98293	0.98343	0.98287
Hybrid	0.97576 (+0.101)	0.98624	0.98731	0.98653

Assamese Dataset				
Methods	Word Accuracy	Precision	Recall	F1 Score
MEMM	0.33808	0.55486	0.54891	0.54817
CRF	0.95258	0.97798	0.97777	0.97745

Evaluation for different types of word in Manipuri Dataset					
Methods	Word type	Word accuracy	Precision	Recall	F1 Score
Baseline	Loan	0.3227	0.6218	0.6518	0.6339
	Manipuri	0.8909	0.9389	0.9443	0.9412
EPS	Loan	0.7773	0.8791	0.9027	0.8890
	Manipuri	0.9657	0.9846	0.9825	0.9832

	Manipuri	0.8100	0.8869	0.8814	0.8828
CRF	Loan	0.7864	0.8874	0.8950	0.8888
	Manipuri	0.9772	0.9868	0.9867	0.9865
Hybrid	Loan	0.8182	0.8961	0.9117	0.9022
	Manipuri	0.9805	0.9894	0.9897	0.9894

6.1 Language Independency

To investigate the capability of CRF handling across different languages, we have further considered another publicly available Assamese dataset consisting of 17,925 unique words. Second part of the Table 3 shows the response of CRF and MEMM over this dataset. It clearly shows that CRF provides a word accuracy of 0.95, while MEMM provides just 0.34.

7 Conclusion

In this paper, we first present generation of Manipuri text corpus using Bengali OCR for linguistics studies. Using the corpus generated from the news articles, we analysed phone characteristics across structural and positional properties. Using the observation from this study, we proposed entropy based phonotactic segmentation (EPS) method (a corpus driven rule based automatic syllabification method) for automatic segmentation of Manipuri words. This approach achieves a word accuracy of 96%. Further, the effect of CRF has been investigated and found to provide a word accuracy of 97%. Then, we combine both the CRF and EPS to enhance the classification accuracy and achieve an accuracy of 98%.

Abstract

In the context of natural language processing, representation learning has emerged as a newly active research subject because of its excellent performance in many applications. Learning representations of words is a pioneering study in this school of research. However, paragraph (or sentence and document) embedding learning is more suitable/reasonable for some tasks, such as sentiment classification and document summarization. Nevertheless, as far as we are aware, there is relatively less work focusing on the development of unsupervised paragraph embedding methods. Classic paragraph embedding methods infer the representation of a given paragraph by considering all of the words occurring in the paragraph. Consequently, those stop or function words that occur frequently may mislead the embedding learning process to produce a misty paragraph representation. Motivated by these observations, our major contributions in this paper are twofold. First, we propose a novel unsupervised paragraph embedding method, named the essence vector (EV) model, which aims at not only distilling the most representative information from a paragraph but also excluding the general background information to produce a more informative low-dimensional vector representation for the paragraph. We evaluate the proposed EV model on benchmark sentiment classification and multi-document summarization tasks. The experimental results demonstrate the effectiveness and applicability of the proposed embedding method. Second, in view of the increasing importance of spoken content processing, an extension of the EV model, named the denoising essence vector (D-EV) model, is proposed. The D-EV model not only inherits the advantages of the EV model but also can infer a more robust representation for a given spoken paragraph against imperfect speech recognition. The utility of the D-EV model is evaluated on a spoken document summarization task, confirming the practical merits of the proposed embedding method in relation to several well-practiced and state-of-the-art summarization methods.

1 Introduction

Representation learning has gained significant interest of research and experimentation in many machine learning applications because of its remarkable performance. When it comes to the field of natural language processing (NLP), word embedding methods can be viewed as pioneering studies (Bengio et al., 2003; Mikolov et al., 2013; Pennington et al., 2014). The central idea of these methods is to learn continuously distributed vector representations of words using neural networks, which seeks to probe latent semantic and/or syntactic cues that can in turn be used to induce similarity measures among words. A common thread of leveraging word embedding methods to NLP-related tasks is to represent a given paragraph (or sentence and document) by simply taking an average over the word embeddings corresponding to the words occurring in the paragraph. By doing so, this thread of methods has recently

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 358–368, Osaka, Japan, December 11-17 2016.

enjoyed substantial success in many NLP-related tasks (Collobert and Weston, 2008; Tang et al., 2014; Kageback et al., 2014).

Although the empirical effectiveness of word embedding methods has been proven recently, the composite representation for a paragraph (or sentence and document) is a bit queer. Theoretically, paragraph-based representation learning is expected to be more suitable for such tasks as information retrieval, sentiment analysis and document summarization (Huang et al., 2013; Le and Mikolov, 2014; Palangi et al., 2015), to name but a few. However, to the best of our knowledge, unsupervised paragraph embedding has been largely under-explored on these tasks. Classic paragraph embedding methods infer the representation of a given paragraph by considering all of the words occurring in the paragraph. Consequently, those stop or function words that occur frequently in the paragraph may mislead the embedding learning process to produce a misty paragraph representation. In other words, the frequent words or modifiers may overshadow the indicative words, thereby drifting the main theme of the semantic content in the paragraph. As a result, the learned representation for the paragraph might be undesired. In order to address this shortcoming, we propose a novel unsupervised paragraph embedding method, named the essence vector (EV) model, which aims at not only distilling the most representative information from a paragraph but also excluding the general background information to produce a more informative and discriminative low-dimensional vector representation for the paragraph.

On a separate front, with the popularity of the Internet and the increasing development of the digital storage capacity, unprecedented volumes of multimedia information, such as broadcast news, lecture recordings, voice mails and video streams, among others, have been quickly disseminated around the world and shared among people. Consequently, spoken content processing has become an important and urgent demand (Lee and Chen, 2005; Ostendorf, 2008; Liu and Hakkani-Tur, 2011). Obviously, speech is one of the most important sources of information about multimedia (Furui et al., 2012). A common school of processing multimedia is to transcribe the associated spoken content into text or lattice format by an automatic speech recognizer. After that, well-developed text processing frameworks can then be readily applied. However, such imperfect transcripts usually limit the associated efficacy. To bridge the performance gap between perfect and imperfect transcripts, we hence extend the proposed essence vector model to a denoising essence vector (D-EV) model, which not only inherits the advantages of the EV model but also can infer a more robust representation for a given spoken paragraph that is more resilient to imperfect speech recognition.

The remainder of this paper is organized as follows. We first briefly review two classic paragraph embedding methods in Section 2. Section 3 sheds light on our proposed essence vector model and its extension, the denoising essence vector model. Then, a series of experiments are presented in Section 4 to evaluate the proposed representation learning methods. Finally, Section 5 concludes the paper.

2 Literature Review

In contrast to the large body of work on developing various word embedding methods, there are relatively few studies concentrating on learning paragraph representations in an unsupervised manner (Huang et al., 2013; Le and Mikolov, 2014; Chen et al., 2014; Palangi et al., 2015). Representative methods include the distributed memory model (Le and Mikolov, 2014) and the distributed bag-of-words model (Le and Mikolov, 2014; Chen et al., 2014).

2.1 The Distributed Memory Model

The distributed memory (DM) model is inspired and hybridized from the traditional feed-forward neural network language model (NNLM) (Bengio et al., 2003) and the recently proposed word embedding methods (Mikolov et al., 2013). Formally, given a sequence of words, $\{w^1, w^2, \cdots, w^L\}$, the objective function of feed-forward NNLM is to maximize the total log-likelihood,

$$\sum_{l=1}^{L} \log P(w^l | w^{l-n+1}, \cdots, w^{l-1}). \quad (1)$$

Obviously, NNLM is designed to predict the probability of a future word, given its $n-1$ previous words. The input of NNLM is a high-dimensional vector, which is constructed by concatenating (or

taking an average over) the word representations of all words within the context (i.e., $w^{l-n+1}, \cdots, w^{l-1}$), and the output can be viewed as that of a multi-class classifier. By doing so, the n-gram probability can be calculated through a softmax function at the output layer:

$$P\left(w^l \middle| w^{l-n+1}, \cdots, w^{l-1}\right) = \frac{\exp(y_{w^l})}{\sum_{w_i \in V} \exp(y_{w_i})}, \tag{2}$$

where y_{w_i} denotes the output value for word w_i, and V is the vocabulary.

Based on the NNLM, the notion underlying the DM model is that a given paragraph also contributes to the prediction of the next word, given its previous words in the paragraph (Le and Mikolov, 2014). To make the idea work, the training objective function is defined by

$$\sum_{t=1}^{\mathrm{T}} \sum_{l=1}^{L_t} \log P(w^l | w^{l-n+1}, \cdots, w^{l-1}, D_t), \tag{3}$$

where T denotes the number of paragraphs in the training corpus, D_t denotes the t-th paragraph, and L_t is the length of D_t. Since the model acts as a memory unit that remembers what is missing from the current context, it is named the distributed memory (DM) model.

2.2 The Distributed Bag-of-Words Model

Opposite to the DM model, a simplified version is to only rely on the paragraph representation to predict all of the words occurring in the paragraph (Le and Mikolov, 2014; Chen et al., 2014). The training objective function can then be defined by maximizing the predictive probabilities all over the words occurring in the paragraph:

$$\sum_{t=1}^{\mathrm{T}} \sum_{l=1}^{L_t} \log P(w^l | D_t). \tag{4}$$

Since the simplified model ignores the contextual words at the input layer, the model is named the distributed bag-of-words (DBOW) model. In addition to being conceptually simple, the DBOW model only needs to store the softmax weights, whereas the DM model stores both softmax weights and word vectors (Le and Mikolov, 2014).

3 Learning to Distill: The Proposed Essence Vector Modeling Framework

3.1 The Essence Vector Model

Classic paragraph embedding methods infer the representation of a paragraph by considering all of the words occurring in the paragraph. However, we all agree upon that the number of content words in a paragraph is usually less than that of stop or function words. Accordingly, those stop or function words may mislead the representation learning process to produce an ambiguous paragraph representation. In other words, the frequent words or modifiers may overshadow the indicative words, thereby making the learned representation deviate from the main theme of the semantic content expressed in the paragraph. Consequently, the associated capacity will be limited. In order to complement such deficiency, we hence strive to develop a novel unsupervised paragraph embedding method, which aims at not only distilling the most representative information from a paragraph but also diminishing the impact of the general background information (probably predominated by stop or function words), so as to deduce an informative and discriminative low-dimensional vector representation for the paragraph. We henceforth term this novel unsupervised paragraph embedding method the essence vector (EV) model.

To turn the idea into a reality, we begin with an assumption that each paragraph (or sentence and document) can be assembled by two components: the paragraph specific information and the general background information. This assumption also holds in the low-dimensional representation space. Accordingly, the proposed method consists of three modules: a paragraph encoder $f(\cdot)$, which can automatically infer the desired low-dimensional vector representation by considering only the paragraph-specific information; a background encoder $g(\cdot)$, which is used to map the general background information into a low-dimensional representation; and a decoder $h(\cdot)$ that can reconstruct the original paragraph by combining the paragraph representation and the background representation.

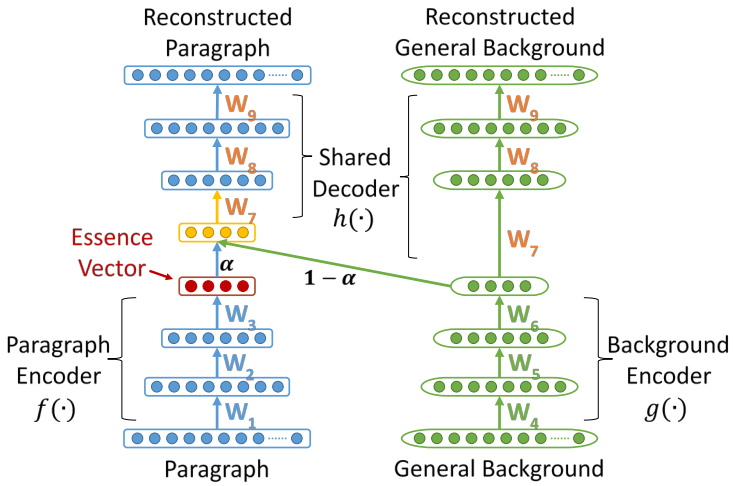

Figure 1: Illustrations of the essence vector model.

More formally, given a set of training paragraphs $\{D_1, \cdots, D_t, \cdots, D_T\}$, in order to modulate the effect of different lengths of paragraphs, each paragraph is first represented by a bag-of-words high-dimensional vector $P_{D_t} \in \mathbb{R}^{|V|}$, where each element corresponds to the frequency count of a word/term in the vocabulary V, and the vector is normalized to unit-sum. Then, a paragraph encoder is applied to extract the most specific information from the paragraph and encapsulate it into a low-dimensional vector representation:

$$f(P_{D_t}) = v_{D_t}. \tag{5}$$

At the same time, the general background is also represented by a high-dimensional vector with normalized word/term frequency counts, $P_{BG} \in \mathbb{R}^{|V|}$, and a background encoder is used to compress the general background information into a low-dimensional vector representation:

$$g(P_{BG}) = v_{BG}. \tag{6}$$

Both $f(\cdot)$ and $g(\cdot)$ are fully connected deep networks with different model parameters θ_f and θ_g, respectively. It is worthy to note that $f(\cdot)$ and $g(\cdot)$ can have same or different architectures. Since each learned paragraph representation v_{D_t} only contains the most informative/discriminative part of P_{D_t}, we assume that the weighted combination of v_{D_t} and v_{BG} can be mapped back to P_{D_t} by a decoder $h(\cdot)$:

$$h(\alpha_{D_t} \cdot v_{D_t} + (1 - \alpha_{D_t}) \cdot v_{BG}) = P'_{D_t}, \tag{7}$$

where $h(\cdot)$ is also a fully connected multilayer neural network with parameter θ_h, and the interpolation weight can be determined by an attention function $q(\cdot,\cdot)$:

$$\alpha_{D_t} = q(v_{D_t}, v_{BG}). \tag{8}$$

The attention function can be realized by a trainable network or a simple linear/non-linear function. Further, to ensure the quality of the learned background representation v_{BG}, it should also be mapped back to P_{BG} by $h(\cdot)$ appropriately:

$$h(v_{BG}) = P'_{BG}. \tag{9}$$

In a nutshell, the training objective function of the proposed essence vector model is to minimize the total KL-divergence measure:

$$\min_{\theta_f, \theta_g, \theta_h} \sum_{t=1}^{T} \left(P_{D_t} \log \frac{P_{D_t}}{P'_{D_t}} + P_{BG} \log \frac{P_{BG}}{P'_{BG}} \right). \tag{10}$$

The activation function used in the EV model is the hyperbolic tangent, except that the output layer in the decoder $h(\cdot)$ is the softmax (Goodfellow et al., 2016), the cosine distance is used to calculate the

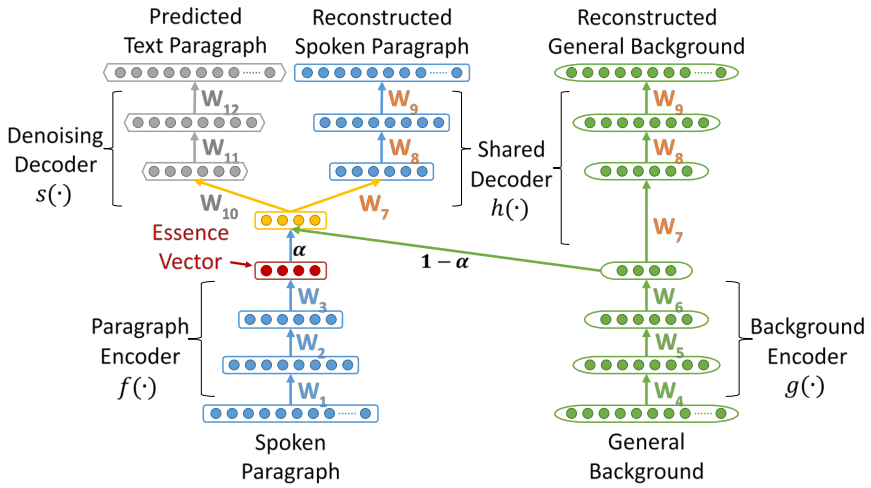

Figure 2: Illustrations of the denoising essence vector model.

attention coefficients, and the Adam (Kingma and Ba, 2015) is employed to solve the optimization problem. At test time, a given paragraph can obtain its own representation by being passed through the paragraph encoder (i.e., $f(\cdot)$). Figure 1 illustrates the architecture of the EV model.

3.2 The Denoising Essence Vector Model

Next, we turn to focus on learning representations for spoken paragraphs. In addition to the stop/function words and modifiers, the additional challenge facing spoken paragraph learning is the imperfect transcripts generated by automatic speech recognition. Therefore, our goal is not only to inherit the advantages of the EV model, but also to infer a more robust representation for a given spoken paragraph that withstands the errors of imperfect transcripts. The core idea is that the learned representation of a spoken paragraph should be able to interpret its corresponding manual transcript paragraph as much as possible. With the intention of equipping the ability that can distill the *true* information from a given *spoken* paragraph, we further incorporate a multi-task learning strategy in the EV modeling framework. To put the idea into a reality, an additional module, a denoising decoder $s(\cdot)$, is introduced on top of the EV model. More formally, given a set of training spoken paragraphs $\{D_1, \cdots, D_t, \cdots, D_{\mathrm{T}}\}$ and their manual transcripts $\{D_1^m, \cdots, D_t^m, \cdots, D_{\mathrm{T}}^m\}$, the EV model can first be constructed by referring to each pair of D_t and the general background information (cf. Section 3.1). Since we target at making the learned paragraph representation v_{D_t} contain the true information of D_t^m, we assume that the weighted combination of v_{D_t} and v_{BG} can also be well mapped back to $P_{D_t^m}$ by the decoder $s(\cdot)$:

$$s\left(\alpha_{D_t} \cdot v_{D_t} + \left(1-\alpha_{D_t}\right) \cdot v_{BG}\right) = P'_{D_t^m}, \tag{11}$$

where $s(\cdot)$ is a fully connected neural network with parameter θ_s. The activation function used in $s(\cdot)$ is the hyperbolic tangent, except that the last layer is the softmax. We will henceforth term this extended unsupervised paragraph embedding method the denoising essence vector (D-EV) model. The training objective of the D-EV model is to minimize the following total KL-divergence measure:

$$\min_{\theta_f,\theta_g,\theta_h,\theta_s} \sum_{t=1}^{\mathrm{T}} \left(P_{D_t} \log \frac{P_{D_t}}{P'_{D_t}} + P_{D_t^m} \log \frac{P_{D_t^m}}{P'_{D_t^m}} + P_{BG} \log \frac{P_{BG}}{P'_{BG}} \right). \tag{12}$$

Figure 2 illustrates the architecture of the proposed D-EV model.

4 Experimental Setup & Results

4.1 Experiments on the EV Model for Sentiment Analysis

At the outset, we evaluate the proposed EV model on the sentiment polarity classification task. Four widely-used benchmark multi-domain sentiment datasets are used in this study[1] (Blitzer et al., 2007). They are product reviews taken from Amazon.com in four different domains: Books, DVD, Electronics, and Kitchen. Each of the reviews, ranging from Star-1 to Star-5, were rated by a customer. The reviews with Star-1 and Star-2 were labelled as Negative, and those with Star-4 and Star-5 were labeled as Positive. Each of the four datasets contains 1,000 positive reviews, 1,000 negative reviews, and a number of unlabeled reviews. Labeled reviews in each domain are randomly split up into ten folds (with nine folds serving as the training set and the remaining one as the test set). All of the following results are reported in terms of an average accuracy of ten-fold cross validation. The linear kernel SVM (Chang and Lin, 2011) is used as our classifier and all of the parameters are set to the default values. All of the unlabeled reviews are used to obtain the general background information and train the EV model.

In this set of experiments, we first compare the EV model with PCA (Bengio et al., 2013), which is a standard dimension reduction method. It is worthy to note that PCA is a variation of an auto-encoder (Bengio et al., 2013) method; thus it can be treated as our baseline system. All of the experimental results are listed in Table 1. As expected, the proposed EV model consistently outperforms PCA in every domain by a significant margin. The reason might be that PCA maps data to a low-dimensional space by maximizing the statistical variance of data, but the implicitly denoising strategy and the linear formulation limit its model capability. On the contrary, the proposed EV model is designed to distill the most useful information from a given paragraph and exclude the general background information explicitly; it thus can deduce a more informative and discriminative representation.

Next, we make a step forward to compare the EV model with other baseline systems based on literal bag-of-words features, including unigrams and bigrams. The results are also shown in Table 1. Several observations can be drawn from the results. First, although bigram features (denotes as Bigrams in Table 1) are believed to be more discriminative than unigram features (denotes as Unigrams in Table 1), the results indicate that Unigrams outperform Bigrams in most cases. The reason might be probably due to the curse of dimensionality problem. Second, as expected, the combination of unigram and bigram features (denotes as Unigrams+Bigrams) achieves better results than using Unigrams and Bigrams in isolation for all cases. Third, both the proposed EV model and PCA can make further performance gains when paired with Unigrams, Bigrams, and their combination. Fourth, the proposed EV model demonstrates its ability in the sentiment classification task since it consistently outperforms PCA for all cases in the experiments.

Table 2: Experimental results of multi-document summarization achieved by the proposed EV model and several state-of-the-art summarization methods.

4.2 Experiments on the EV Model for Multi-Document Summarization

We further investigate the capability of the EV model on an extractive multi-document summarization task. In this study, we carry out the experiments with the DUC 2001, 2002, and 2004 datasets[2]. All the documents were compiled from newswires, and were grouped into various thematic clusters. The summary length was limited to 100 words for both DUC 2001 and DUC 2002, and 665 bytes for DUC 2004. The general background information was inferred from the LDC Gigaword corpus[3] (including Associated Press Worldstream (AP), New York Times Newswire Service (NYT), and Xinhua News Agency (XIN)). The most common belief in the document summarization community is that relevance and redundancy are two key factors for generating a concise summary. In this paper, we leverage a density peaks clustering summarization method (Rodriguez and Laio, 2014; Zhang et al., 2015), which can take both relevance and redundancy information into account at the same time. That is, a concise summary for a given document set can be automatically generated through a one-pass process instead of an iterative process. Recently, the summarization method has proven its empirical effectiveness (Zhang et al., 2015). For evaluation, we adopt the widely-used automatic evaluation metric ROUGE (Lin, 2003), and take ROUGE-1 and ROUGE-2 (in F-scores) as the main measures following Cao et al., (2015).

We compare the proposed EV model with two baseline systems (the vector space model (VSM) (Gong and Liu, 2001) and the LexRank (Erkan and Radev, 2004) method), the best peer systems (including Peer T, Peer 26, and Peer 65) participating DUC evaluations, and the recently elaborated DNN-based systems (including CNN and PriorSum) (Cao et al., 2015). Owing to the space limitation, we omit the detailed introduction to these summarization methods; interested readers may refer to Penn and Zhu (2008), Liu and Hakkani-Tur (2011), Nenkova and McKeown (2011), and Cao et al., (2015) for more in-depth elaboration. It is worthy to note that the proposed EV model, the two baseline systems, and the best peer systems are unsupervised methods, while the DNN-based systems are supervised ones. The experimental results are listed in Table 2. Several interesting observations can be concluded from the results. First, the proposed EV model outperforms VSM by a large margin in all cases, and performs comparably to other well-designed unsupervised summarization methods. Second, both LexRank and EV (with the density peaks clustering method) take pairwise information into account globally, so their results are almost the same. Third, although the proposed EV model is an unsupervised method and is

not specifically designed toward summarization, it almost achieves the same performance level as the complicated DNN-based supervised methods (i.e., CNN and PriorSum), which confirms the power of the EV model again.

4.3 Experiments on the D-EV Model for Spoken Document Summarization

In order to assess the utility of the proposed D-EV model, we perform a series of experiments on the extractive spoken document summarization task. All of experiments are conducted on a Mandarin benchmark broadcast new corpus[4] (Wang et al., 2005). The MATBN dataset is publicly available and has been widely used to evaluate several NLP-related tasks, including speech recognition (Chien, 2015), information retrieval (Huang and Wu, 2007) and summarization (Liu et al., 2015). As such, we follow the experimental setting used in previous studies for speech summarization in the literature. The vocabulary size is about 72 thousand words. The average word error rate of the automatic transcripts of these broadcast news documents is about 38%. The reference summaries were generated by ranking the sentences in the manual transcript of a broadcast news document by importance without assigning a score to each sentence. Each document has three reference summaries annotated by three subjects. For the assessment of summarization performance, we adopt the commonly-used ROUGE metric (Lin, 2003), and take ROUGE-1, ROUGE-2 and ROUGE-L (in F-scores) as the main measures. The summarization ratio is set to 10%. An external set of about 100,000 text news documents, which was assembled by the Central News Agency (CNA) during the same period as the broadcast news documents to be summarized (extracted from the Chinese Gigaword Corpus[5] released by LDC), is used to obtain the background representation.

To begin with, we compare the performance levels of the proposed EV and D-EV models and two classic paragraph embedding methods (i.e., DM and DBOW) for spoken document summarization. All the models are paired with the density peaks clustering summarization method. The results are shown in Table 3, from which several observations can be drawn. First, DBOW outperforms DM in our experiments, though DBOW is a simplified version of DM. Second, the proposed EV model outperforms DM and DBOW by a large margin, as expected. The results confirm that EV can modulate the impact of those stop or function words when inferring representations for paragraphs. That is to say, the proposed paragraph embedding method EV can indeed distill the most important aspects of a given paragraph and meanwhile suppress the impact of the general background information for producing a more discriminative paragraph representation. Thus, the relevance degree between any pair of sentence and document representations can be estimated more accurately. Third, the D-EV model consistently outperforms other paragraph embedding methods, including our own EV model. The outcome reveals that, although EV can achieve better performance than other classic paragraph embedding methods, the recognition errors inevitably make the inferred representations deviate from the original semantic content of spoken paragraphs. Accordingly, the results signal that the D-EV model can complement the

[4] http://slam.iis.sinica.edu.tw/corpus/MATBN-corpus.htm
[5] https://catalog.ldc.upenn.edu/LDC2011T13

deficiency of the EV model in spoken document summarization; we thus believe that it is more suitable for use in spoken content processing.

In the last set of experiments, we compare the results mentioned above with that of several well-practiced, state-of-the-art unsupervised summarization methods, including the graph-based methods (i.e., the Markov random walk (MRW) method (Wan and Yang, 2008) and the LexRank method (Erkan and Radev, 2004)) and the combinatorial optimization methods (i.e., the submodularity-based (SM) method (Lin and Bilmes, 2010) and the integer linear programming (ILP) method (Riedhammer et al., 2010)). Among them, the ability of reducing redundant information has been aptly incorporated into the submodular-based method and the ILP method. Interested readers may refer to Penn and Zhu (2008), Liu and Hakkani-Tur (2011), and Nenkova and McKeown (2011) for comprehensive reviews and new insights into the major methods that have been developed and applied with good success to a wide range of spoken document summarization tasks. The results are also listed in Table 3. Several noteworthy observations can be drawn from the results of these methods. First, although the two graph-based methods (i.e., MRW and LexRank) have similar motivations, MRW outperforms LexRank by a large margin. Second, although both SM and ILP have the ability to reduce redundant information when selecting indicative sentences to form a summary for a given document, ILP consistently outperforms SM. The reason might be that ILP performs a global optimization process to select representative sentences, whereas SM chooses sentences with a recursive strategy. Comparing the results of these strong baseline systems to that of the paragraph embedding methods (including DM, DBOW, EV, and D-EV) paired with the density peaks clustering summarization method, it is clear that all the paragraph embedding methods are better than the baseline methods. The results corroborate that, instead of only considering literal term matching for determining the similarity degree between a pair of sentence and document, incorporating concept (semantic) matching into the similarity measure leads to better performance. In particular, the proposed D-EV model is the most robust among all the methods compared in the paper, which supports the important notion of the proposed "*learning to distilling*" framework. We also want to note that the proposed methods (i.e., EV and D-EV) can also be incorporated with the graph-based methods and the combinatorial optimization methods. We leave this exploration for future work.

5 Conclusions

In this paper, we have proposed a novel paragraph embedding framework, which is embodied with the essence vector (EV) model and the denoising essence vector (D-EV) model, and made a step forward to evaluate the proposed methods on benchmark sentiment classification and document summarization tasks. Experimental results demonstrate that the proposed framework is the most robust among all the methods (including several well-practiced or/and state-of-the-art methods) compared in the paper, thereby indicating the potential of the new paragraph embedding framework. For future work, we will first focus on pairing the (denoising) essence vector model with other summarization methods. Moreover, we will explore other effective ways to integrate extra cues, such as speaker identities and relevance information, into the proposed framework. Furthermore, we also plan to extend the applications of the proposed framework to information retrieval and language modeling, among others.

Abstract

This paper introduces a continuous system capable of automatically producing the most adequate speaking style to synthesize a desired target text. This is done thanks to a joint modeling of the acoustic and lexical parameters of the speaker models by adapting the CVSM projection of the training texts using MR-HMM techniques. As such, we consider that as long as sufficient variety in the training data is available, we should be able to model a continuous lexical space into a continuous acoustic space. The proposed continuous automatic text to speech system was evaluated by means of a perceptual evaluation in order to compare them with traditional approaches to the task. The system proved to be capable of conveying the correct expressiveness (average adequacy of 3.6) with an expressive strength comparable to oracle traditional expressive speech synthesis (average of 3.6) although with a drop in speech quality mainly due to the semi-continuous nature of the data (average quality of 2.9). This means that the proposed system is capable of improving traditional neutral systems without requiring any additional user interaction.

1 Introduction

It is clear that in recent times there has been an increase in the penetration rates of speech technologies and applications based in speech recognition or speech synthesis are more and more common. Speech synthesis systems in particular have improved greatly in terms of speech intelligibility, speech quality or naturalness in neutral read speech situations regardless of the technology (Barra-Chicote, 2011). The problem appears when one needs to develop applications such as dialogue systems or robotic interfaces, for which a more expressive way of speaking is more appropriate.

One of the main problems regarding expressive speech synthesis is the vast amount of possibilities that have to be taken into account. Human expressiveness is not a discrete space but a continuous one, and speaking styles vary greatly from person to person and even from time period to time period. As such, obtaining enough data to cover all the requirements can become a very difficult task and scalability a significant problem. This is why statistical parametric speech synthesis is better fitted to the task. While unit-selection based systems have been proven to be more than capable of providing good quality

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 369–376, Osaka, Japan, December 11-17 2016.

expressive speech (Adell et al., 2012; Andersson et al., 2010), the adaptability of HMM-based systems allows us to better face the scalability problem.

The objective of the present paper is to introduce a complete TTS system capable of predicting the most adequate speaking style in order to automatically adapt the produced voice to the target text. For that objective we propose a continuous system based both in Continuous Vector Space Modeling (CVSM) (Tonta and Darvish, 2010; Klein et al., 2011) and Multi-regression HMM (MR-HMM) (Fujinaga et al., 2001), CVSM to model the expressive training texts as a continuous space and MR-HMM to make use of that continuous space as auxiliary features for the HMM modeling. This results in a system capable of characterizing input texts as a vector, which at the same time ends up producing the adequate acoustic model associated to the input text. As such, as long as sufficient variety in the training data is available, we would be able to model a continuous lexical space into a continuous acoustic space.

The rest of the paper is organized as follows. In section 2 we describe corpus considered for training the system. Section 3 gives a theoretical background to the proposed system and then explains in detail the proposed method. Then, section 4 describes the perceptual evaluations environment, whose results are described in section 4.1. Finally in section 5 we present the conclusions to be drawn from this paper together with some ideas for future work.

2 Speech Corpus

For the present research we wanted to combine text processing techniques and speech synthesis techniques, so the considered corpus had to not only cover a number of speaking styles with a reasonable amount of text data, but also consist of speech from a single speaker, so that the synthesis models could provide high quality synthetic speech. For that reason we utilized our self-designed and recorded database: Spanish Speaking Styles.

2.1 Spanish Speaking Styles

Spanish Speaking Styles (SSS) is a speaking styles corpus recorded for a single male professional speaker in 4 different speaking styles, with about 1 hour of speech per speaking style. The 4 speaking styles (news broadcasting, interviews, live sports broadcasts and political speech) cover a large spectrum of the expressive map (as can be seen in the F0-rhythm map that we can see in figure 1) while being recognizable.

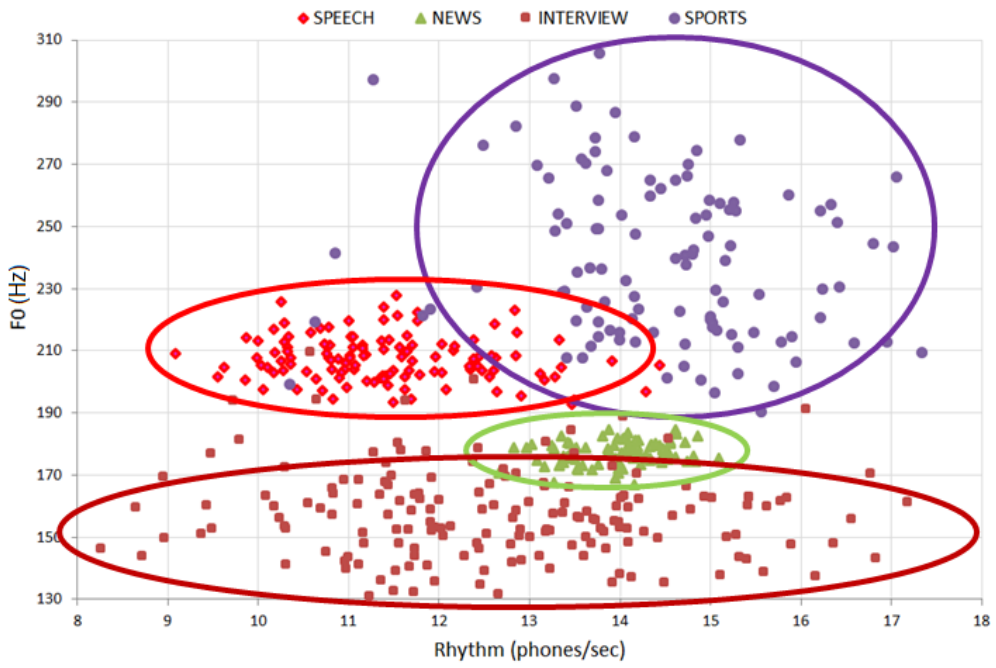

Figure 1: F0 vs. rhythm map of the 4 recorded speaking styles in SSS.

Two of the speaking styles (news and political speech) are scripted and the other two (live sports broadcasts and interviews) unscripted. A summary of the database can be seen in table 1.

Speaking Style	Train set	Test set
NEWS	102 utts, 1h3min	21 utts, 11min
INTERVIEW	332 utts, 45min	21 utts, 7min
SPORT	200 utts, 56min	21 utts, 7min
POLITICAL SPEECH	116 utts, 56min	21 utts, 11min
TOTAL	750 utts, 3h40min	84 utts, 36min

Table 1: Detailed description of the SSS database.

3 Expressive Speech Synthesis based on CVSM and MR-HMM

The ideal expressive TTS system should be able to handle any kind and any number of expressiveness without requiring costly labeling or manipulations every time we want to add any new one. With this purpose in mind the concept of a continuous system (i.e. a system in which expressiveness is treated as a complete space instead of as discrete entities) fits perfectly. That is, in real life expressiveness present overlap between them because there are not clear frontiers, so being able to take into account those overlaps in the shape of a dynamic synthesizer would be ideal.

3.1 Continuous Vector Space Modeling

Traditional information retrieval techniques such as TF-IDF (Fautsch and Savoy, 2010) are commonly based on the assumption that all the terms of the vocabulary lists of the documents do not have any relationship to each other, which is ultimately false as language has semantic relationships that we should be able to model (Tonta and Darvish, 2010; Klein et al., 2011). With that consideration in mind Latent Semantic Analysis (LSA) (Deerwester et al., 1990; Landauer et al., 2013), nowadays referred to as Continuous Vector Space Modeling (Krishnamurthy and Mitchell, 2013; Andreas and Ghahramani, 2013) was born.

CVSM aims to exploit the relationships between terms t_i and documents d_j by transforming them into an alternate "semantic" vector space, where both terms and documents are described by vectors of similar dimensionality and directions, enabling direct comparisons (Olmos et al., 2013; Cosma and Joy, 2012).

Typically this step is done by means of Singular Value Decomposition (SVD) (Golub and Reinsch, 1970; Henry et al., 2010), through which the latent semantic structure of the WTDM is shown.

3.2 Multi-Regression HMM

Multi-regression HMM is a particular kind of adaptation in which the model parameters are adapted depending on auxiliary features instead of the acoustic features themselves. Initially this was developed to exploit the correlation between F0 and the spectral features (Fujinaga et al., 2001), which significantly improved isolated word recognition rates in a speech recognition task. Numerically speaking, the multi-regression formula for M auxiliary features is defined as follows:

$$\mu = r_0 + r_1\epsilon_1 + \ldots + r_1\epsilon_M \tag{1}$$

Where $r_{0\ldots M}$ are the regression coefficients and $r_{\epsilon\ldots M}$ the M auxiliary features. This particularity can be exploited in speech synthesis to model additional information in the speaker models such as speaking styles or emotions (Nose and Kobayashi, 2012; Ling et al., 2013), and it has been used for applications as varied as generating walking motion models (Niwase et al., 2005).

3.3 Proposed System

Figure 2 shows the proposed flowchart for the continuous, MRHMM-based system. There we can see many fundamental differences with the discrete and semi-continuous approach, both at training time and at synthesis time.

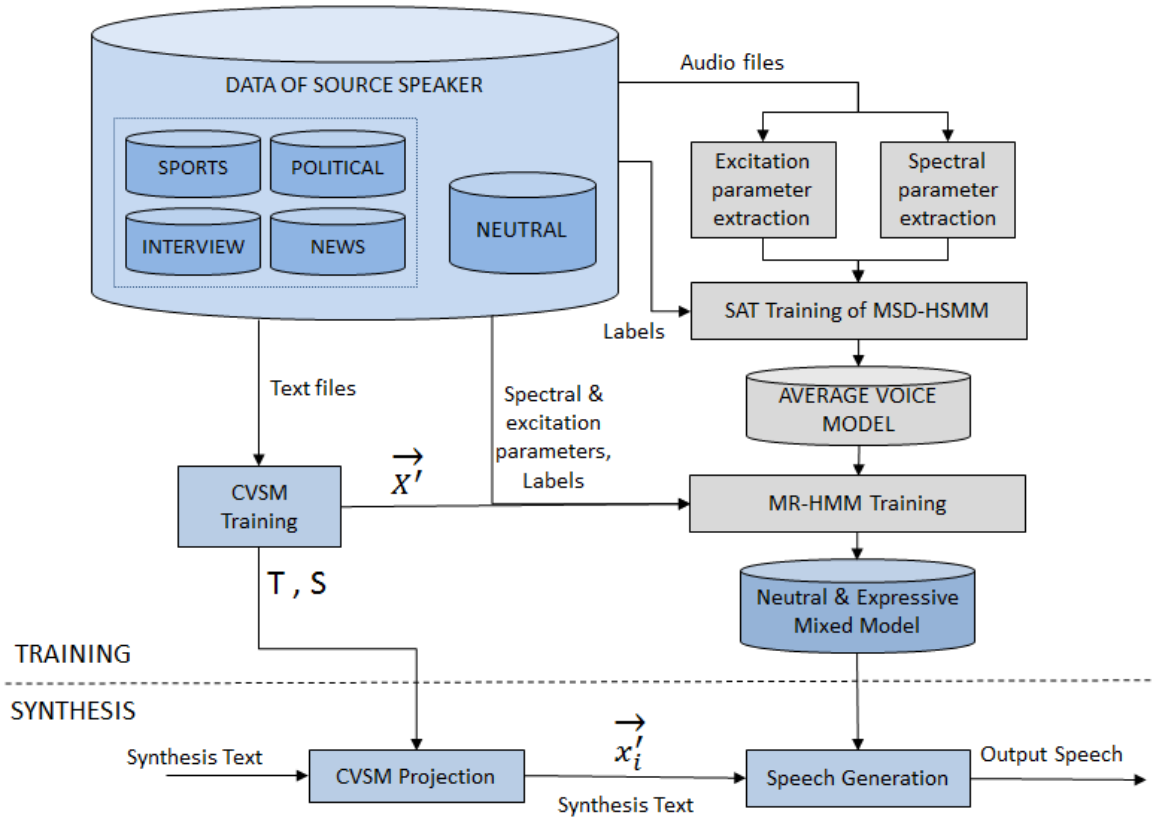

Figure 2: Schematic of the proposed continuous approach to the expressive TTS system.

Most notably, there is no traditional adaptation process involved in the system, but a MR-HMM adaptation that takes the CVSM projections of each training text file as the control vector $\vec{x}'$ for a training process that outputs a new model that combines both neutral and expressive information. Also we can see how there is no need for a centroid estimation, as there is no genre prediction carried out at synthesis time. Instead, only the CSVM matrices are kept as the output so that at synthesis time the synthesis text can be projected to obtain $\vec{x}'_i$, which will be used directly at the speech generation process. This process is then capable of producing an expressive speech output without relying in any genre prediction system, only in the CVSM projections of the synthesis texts.

4 Perceptual Evaluation

For the proposed perceptual evaluation we considered two approaches to the continuous modeling: a first one that directly utilized the CVSM-projected vectors $\vec{x}'$ and a second one that normalized each component by the maximum of their respective component $\vec{\bar{x}}' = \{v_1/v_{MAX1}, \ldots, v_4/v_{MAX4}\}$ where $v_{MAXi} = max\,(v_i)\,\forall v_i$ in the training data. The second approach was considered in case reducing the dispersion of the control vector values helped the MR-HMM re-estimation process. The same normalization was applied to the synthesis control vectors. In total 8 systems were evaluated (2 versions with 4 speaking styles each), which following the Latin Square approach (Gao, 2005), meant that we needed 8 different utterances to be synthesized for all the systems to be presented to the listeners in a random order without repetitions.

The test itself was carried out by means of a web interface, where the evaluator was presented with a button to play the audio sample and the transcription of the uttered texts. The samples could be played as many times as desired. Then, the listener was asked to rate the utterances in the traditional 5 point MOS evaluation in terms of adequacy of the utterance to the text (from not adequate to very adequate), speech quality (from very bad to very good) and perceived expressive strength when comparing to a hypothetical neutral version (very low to very high).

Regarding the speaker models, the whole train section of SSS database and the neutral speech of the same speaker present in SEV database (Barra-Chicote et al., 2008) were modeled into an average voice model (AVM) by applying Speaker Adaptive Training (SAT) (Anastasakos et al., 1997) with three feature streams with their Δ and Δ^2 coefficients: logarithm of the fundamental frequency (1 coefficient), mel-cepstral analysis coefficients (MCEP, 60 coefficients) and aperiodicity bands (25 coefficients). The models were adapted by means of the CSMAPLR algorithm (Yamagishi et al., 2009).

In terms of the statistical significance of the results, we applied the Wilkoxon Signed-Rank Test for a 95% confidence ratio in order to obtain the error margins. 16 subjects took part in each evaluation to guarantee double coverage of the Latin square matrix.

4.1 Evaluation Results

Figures 4 to 3 show the results for both continuous system evaluations (C_Normalized for the normalized version and Continuous for the non-normalized one), together with neutral speech (N), traditional emotional system (S) and natural voice (NAT). The results for the non-continuous systems have been extracted from other works to serve as a reference. It is important to emphasize that this evaluation considered only utterances that could be synthesized, which represented a 65% for the normalized version and 60% for the non-normalized one, details for each system-style interaction can be seen in table 2.

Synth. Rate	C_Normalized	Continuous
Interview	48%	43%
News	81%	67%
Speech	81%	90%
Sports	52%	38%
Average	65%	60%

Table 2: Percentage of synthesizable test sentences for each system-style pair. C_Normalized represents the normalized implementation of the continuous system and Continuous the non-normalized one.

Speech quality (figure 3) does show some bad results, an average quality of 2.93 for the basic system and 2.73 for the normalized system, which is significantly worse than all other systems. This is supposed to be mainly because the continuous system introduces a large amount of artifacts. This effect was somewhat expected due to the inherent semi-continuous nature of the SSS database: the professional speaker was asked to interpret the four speaking styles showing as little variation as possible so that they were clear representatives of their paralinguistic characteristics, so modeling them in a continuous fashion is not possible without additional data. More varied data or a more naturally continuous task is expected to fare better for the continuous system.

On the other hand, in the adequacy results (figure 4) we can see how the system provides significant increases when compared to traditional neutral systems. In the case of the normalized system, the average adequacy is 3.47 and 3.60 for the non-normalized version, not significantly worse than the 3.78 of the traditional expressive synthesis. Interviews, due to its extremely conversational nature was not modeled adequately.

Finally perceived expressive intensity results (figure 5) show a similar image to adequacy. Significantly better than using a neutral system, both proposed continuous systems show a 3.51 average perceived expressive intensity, which is once again comparable to the 3.65 of the non-predictive speech synthesis. Even so the systems are far from the 4.07 of natural speech and are much better than the 2.51 of neutral speech.

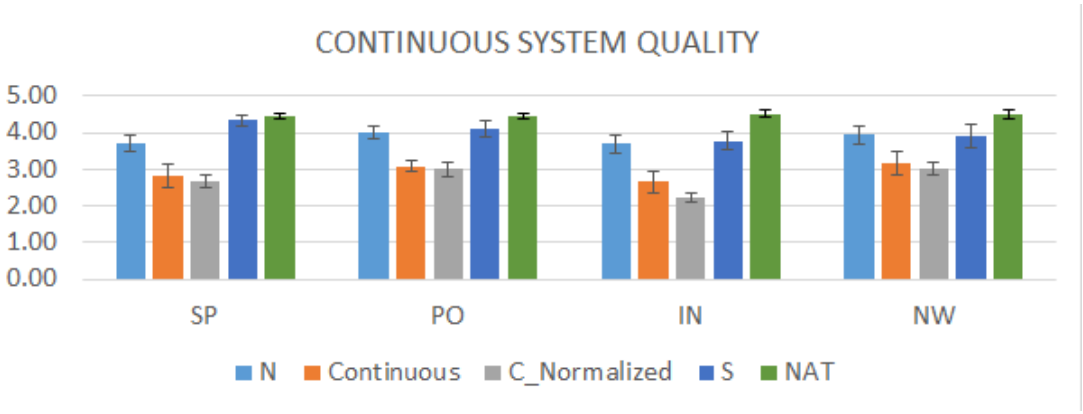

Figure 3: Results in MOS scale of the quality evaluation for the continuous system.

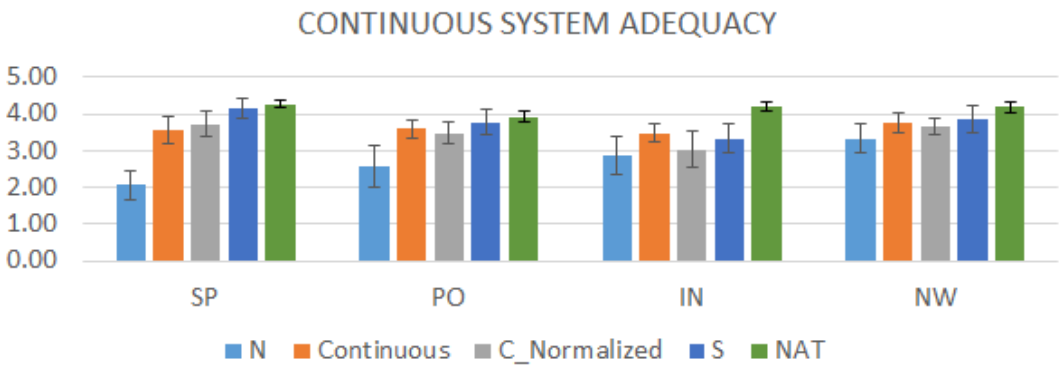

Figure 4: Results in MOS scale of the adequacy evaluation for the continuous system.

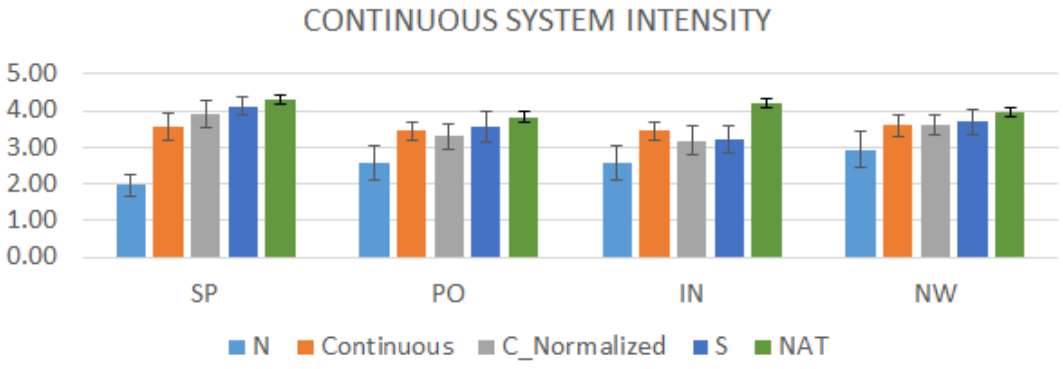

Figure 5: Results in MOS scale of the expressive intensity evaluation for the continuous system.

5 Conclusions and Future Work

We have introduced a complete TTS system is capable of synthesizing the most adequate expressiveness to the target text without relying in genre prediction techniques, just by making use of the CVSM projection of the input text as a control factor of the speaker model, which vastly increases the versatility of the system as we remove the need for labeling the training data genre. This system proved to be capable of conveying the correct expressiveness (average adequacy of 3.6) with an expressive strength comparable to oracle traditional expressive speech synthesis (average of 3.6) although at a significant drop in speech quality mainly due to the semi-continuous nature of the data (average quality of 2.9).

All in all we have introduced a different approach to expressive speech synthesis where the system automatically adjusts the produced speaking style according to the text to be synthesized without requiring any output from the user besides providing adequate training data. The system has shown that it is capable of significantly improving the traditional neutral speech synthesis systems in the task, and also of providing similar adequacy and perceived expressive strength rates than those of natural voice.

For future work we want to consider a broader array of expressiveness, in order to find a problem where the continuous modeling fits naturally: a more complete speaking styles collection, or even considering sub-spaces of speaking styles, including more conversational speaking styles in an attempt to solve the problems that arose with interviews. Another field that we want to work on is on bringing our systems into the DNNs and RNNs world. This task will prove challenging as there is still not many researches underway on DNN-based expressive speech synthesis. Finally, carrying out evaluations in real life systems such as car navigation systems or robotic assistants in scenarios not as constrained as the ones we evaluated would provide much needed information on how research systems fare in the real world, which would undoubtedly give hints on where more to focus our efforts.

Abstract

Speech prosody is known to be central in advanced communication technologies. However, despite the advances of theoretical studies in speech prosody, so far, no large scale prosody annotated resources that would facilitate empirical research and the development of empirical computational approaches are available. This is to a large extent due to the fact that current common prosody annotation conventions offer a descriptive framework of intonation contours and phrasing based on labels. This makes it difficult to reach a satisfactory inter-annotator agreement during the annotation of gold standard annotations and, subsequently, to create consistent large scale annotations. To address this problem, we present an annotation schema for prominence and boundary labeling of prosodic phrases based upon acoustic parameters and a tagger for prosody annotation at the prosodic phrase level. Evaluation proves that inter-annotator agreement reaches satisfactory values, from 0.60 to 0.80 Cohen's kappa, while the prosody tagger achieves acceptable recall and f-measure figures for five spontaneous samples used in the evaluation of monologue and dialogue formats in English and Spanish. The work presented in this paper is a first step towards a semi-automatic acquisition of large corpora for empirical prosodic analysis.

1 Introduction

Speech prosody is known to be central in advanced communication technologies. It is decisive in structuring the message, stressing parts of the message that the interlocutor considers important, and revealing information about the interlocutor's attitude and affection state (Nooteboom, 1997; Wennerstrom, 2001). However, despite the advances of theoretical studies in speech prosody, so far, no sufficiently large, well-annotated prosody material has been created to support empirical studies and drive the research on empirical techniques for analysis and generation of prosodic cues, especially for application in human-computer interaction technologies. Common annotation conventions, such as the ToBI convention (Beckman et al., 2005), provide a descriptive framework of intonation contours and phrasing based upon labels that are language-dependent and rather subjective, which makes it difficult to reach a satisfactory inter-annotator agreement for creating gold standard annotations to train and evaluate algorithms.

It is, therefore, not surprising that empirical research is still based upon rather small laboratory experiments. A further consequence of the lack of sound universal prosody annotation conventions is that current methodologies applied to speech prosody segmentation are still based upon textual and linguistic units (usually words or syntax) rather than on acoustic and phonological units (prosodic phrases and prosodic words). These limitations become an insurmountable barrier for technologies that aim at grasping prosodic cues in spontaneous speech, where many complex prosodic, linguistic and affective phenomena occur (hesitations, incoherent discourse structure, false starts, continuation rising tunes for holding the floor, expression of emotions, speech acts, prosodic disambiguation, etc.). These inherent characteristics of oral language cannot be dealt with using strategies that belong to written language. For instance, sentences with false starts including a filled pause (e.g., *They've never . . . mmm well, my brother's been to Barcelona*).

To overcome the limitations of the current annotation practice and advance in the derivation of more meaningful communicative units from speech as well as in the generation of more natural synthesized speech in the field of human-machine interaction technologies, we need:

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 377–386, Osaka, Japan, December 11-17 2016.

- a parametric language-independent annotation schema of prosody at the acoustic level that can be used by computational models for automatic segmentation and prominence detection;
- prosody taggers and acoustic feature extractors that distill acoustic features from raw speech signals.

In what follows, we address both tasks. First, we present an annotation schema that is implemented as a modular script, deployed as an extended version of the Praat software (Boersma, 2001) into which a functionality for feature annotation and retrieval is incorporated. Such a feature annotation functionality contributes to the independent modular structure and also helps visualization and manual revision of the output within the same Praat environment. Then, we introduce our prosody tagger. Results on inter-annotator agreement and tagger performance compared to a baseline using only F0 cues show that our work is a relevant contribution to the state of the art in the field of speech prosody processing.

The rest of the paper is structured as follows. Section 2 provides an overview of the theoretical approaches in speech prosody, existing automatic tools for labeling prosody and a brief description of the Praat software used for the implementation of our prosody tagger. Section 3 describes the adapted methodology, which is based on theoretical studies of hierarchical prosody and the annotation schema used for manual annotation and for the implementation of the automatic prosody tagger. Section 4 covers the architecture and technical description of the prosody tagger and Praat's extended functionality developed for feature annotation. Section 5 discusses the inter-annotator agreement and evaluation of the performance of our methodology for automatic segmentation and prominence labeling at the prosodic phrase level. Finally, conclusions and future work are drawn in Section 6.

2 Related Work

Theoretical studies of speech prosody have claimed since the 1980's the hierarchical nature of prosodic events in self-contained units (Selkirk, 1984; Ladd, 2008; Gussenhoven, 1984). They describe intonation as a suprasegmental feature, which goes beyond textual segments and has its own structure and phonology. These theoretical studies, especially the one by Selkirk (1984), describe prosody as a hierarchical entity composed of embedded prosodic levels. In our work, we focus on the prosodic phrase (PPh) and the phenomenon of prominence at the PPh level. Our interest in the PPhs stems from the fact that the PPh level has been shown to correlate with the extended thematic structure advocated by Mel'čuk (2001); see, e.g., Domínguez et al. (2014).[1] This correlation proved to be instrumental for the prediction of expressive prosodic contours (Domínguez et al., 2016a).

Recently, a series of models for a computational representation of the intonation contour have been developed and made available in an open initiative for their comparison and further study under the Common Prosody Platform (CPP)[2] (Prom-On et al., 2016): the *Command-Response* (CR) model, the *Autosegmental-Metrical* (AM) model, the *Task-Dynamic* (TD) model and the *Target Approximation* (TA) model. However, these models are limited to a representation of fundamental frequency (F0) contours, which is known to be only one element of speech prosody (Tseng, 2004).

Regarding automatic annotation for prosody involving machine learning techniques, AuToBI[3] (Rosenberg, 2010) was the first publicly available tool to automatically annotate intonation (again, mainly F0 contours and also breaks) with ToBI labels (Silverman et al., 2010). However, AuToBI has several limitations. Thus, it outputs word-by-word annotation, which is a handicap for obtaining a higher-level representation. Furthermore, it is trained on an English corpus of broadcasting radio news, making it domain- and language-specific. In line with AuToBI, ANALOR[4] (Avanzi et al., 2008) is a tool for semi-automatic annotation of French prosodic structure, trained on a small corpus of radio broadcast.

[1] Contrary to other theories of information structure based upon simple theme-rheme division (Steedman,), Mel'čuk (2001)'s extended thematic structure allows embeddedness of thematicity spans and propositions.

[2] http://commonprosodyplatform.org/

[3] http://eniac.cs.qc.cuny.edu/andrew/autobi/

[4] http://www.lattice.cnrs.fr/Analor.html?lang=fr

Like AuToBI, it is domain- and language-specific, but it allows segmentation of an utterance into major prosodic units.

Praat (Boersma, 2001) is an open-source platform for phonetic research widely used by the speech community for annotation, analysis and synthesis purposes. Praat allows the annotation of sound files by means of tiers. Each tier, which is mapped to the whole time-stamp of the associated sound file, includes interval or point annotations that cannot overlap. Each annotation has a label and this label is the only information that can be included into any annotation. Since the labels cannot be extracted as objects in the main Praat window, no action can be scripted based upon smaller units than tiers. Notwithstanding, Praat is a powerful tool, user-friendly, programmable, freely available, running on many platforms, and actively maintained (Mertens, 2004). Due to all these characteristics, a number of Praat-based tools have appeared over the last decade, among them, e.g., ProsodyPro (Xu, 2013). However, many of these tools create a set of parallel tiers, assigning different labels to these tiers, and then, output extracted acoustic features in a text format for further processing using other platforms. For example, Praaline (Christodoulides, 2014) process the *txt* file externally using the R statistical package.

3 Methodology

The main goal of the present work is the development and implementation of a methodology that serves as a scaffolding upon which further improvements and empirical studies can be built upon. One of the requirements, as introduced before, is that this methodology is versatile in the sense that it is language-independent and is able to describe prosodic cues in natural language using a parametric approach. A second goal of our work is to implement a prosody tagger embedded into a Praat-based platform that allows feature annotation and retrieval of any segment below the tier level. In what follows, we introduce the methodology used in the annotation and implementation of a prosody tagger following a discrete representation based upon normalized acoustic parameters (see Section 3.1). The specific annotation guidelines for manual annotation are detailed in Section 3.2. A technical specification of the implementation of the prosodic tagger is outlined in Section 4.

3.1 Acoustic Parameters in Prosodic Units

A key element in our methodology is the concept of prosody as a multidimensional acoustic entity, which involves F0, intensity, and duration acoustic elements. Our methodology involves a combination of normalized acoustic parameters that has been proven by recent studies to yield better results in the task of the prediction of prosodic labels (Domínguez et al., 2016b).

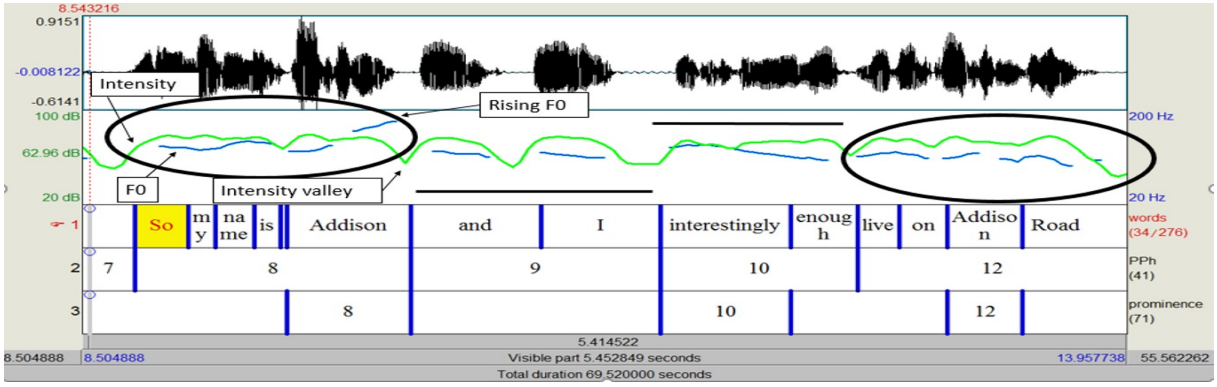

Figure 1: Example of prosodic units.

Figure 1 shows a snapshot of an instance of an utterance containing two propositions (in Mel'čuk (2001)'s terminology). The snapshot corresponds to a continuation rise (L H-H% according to the ToBI convention (Silverman et al., 2010)) in the first proposition and a typical falling tune (H H-L%) in the second. Looking at the graphic representation of the intonation and intensity contours provided by the Praat algorithm, we can clearly observe how these lines form a homogeneous picture (marked by an

ellipse in Figure 1) that corresponds exactly with the PPh division. Nevertheless, as we are dealing with spontaneous speech, there are some areas where the division is not that clear, as can be observed in the central part of the utterance. This homogeneity observed in Figure 1 (which is also auditorily perceived by an expert annotator) can be translated into a vector of normalized acoustic values, which are computed at different levels.

For the representation of the vectors, we adopt a practical approach based upon the actual functions already provided by Praat for speech signal processing. We establish different levels of abstraction, which do not strictly correspond to theoretical representations as such, but follow the idea that prosodic units to be tagged must follow a certain parametric logic in terms of positive or negative deviations at each level in their associated segments. Consequently, we consider as Level 1 (L1) the whole utterance or speech sample; as Level 2 (L2) each voiced segment within the utterance; Level 3 (L3) PPhs once they are segmented. Domínguez et al. (2016b) describe boundary tones in terms of a combination of normalized acoustic parameters, showing also that such a combination performs better than each acoustic element individually for the prediction of prosodic cues.

3.2 Annotation Guidelines

In this section, a set of guidelines for the annotation of prominence and boundaries at the PPh level is introduced. Since the corpus used for evaluation is spontaneous speech, which has inherent difficulties especially for segmentation, specific notes on how to proceed in controversial points are included in these guidelines.

A PPh is defined as a prosodic unit that forms a homogeneous unit in terms of F0 and intensity curves and is signaled by one or a combination of acoustic parameters as outlined in the previous section. A PPh is marked according to the following criteria:

- In case there is one or (usually) a combination of the following conditions: pause, final rising intonation, lengthening of the last word, sharp fall in intensity, a PPh boundary is to be marked.
- In terms of content packaging, a PPh must contain at least one complete concept (usually a predicate with its arguments) of a considerable length relative to the whole utterance and associated voiced segment respectively.
- In spontaneous speech, disfluencies such as disruptions, truncated phrases and hesitations may influence manual labeling of prosodic units. Therefore, all these events are to be included in the closest PPh, unless a pause precedes or follows such disfluencies.
- If the contour following an unvoiced phoneme (with *undefined* F0 value) is perceived as a continuation of the previous F0 contour (forming an homogeneous unit), no boundary is to be inserted. On the contrary, if the F0 contour is significantly different after the F0 phonemic disruption, a boundary is to be marked.

Prominence within each PPh is marked in accordance with the following criteria:

- Prominent words are defined as a combination of one or (usually) several of the following parameters: F0 peak, high intensity, longer duration within its PPh.
- At least one word must be labeled as prominent within each PPh.
- Perceived relevant content must not be used as a criterion to label prosodic prominence (e.g., in noun compounds, an element tends to be perceived more prominent as it carries the semantic meaning of the unit).
- If a combination of acoustic parameters occurs within a word,[5] this word should have more weight than another word showing, for example, an F0 peak and no other acoustic cue.

[5]We refer to textual units in this case, as we are not aiming at segmenting prosodic words yet

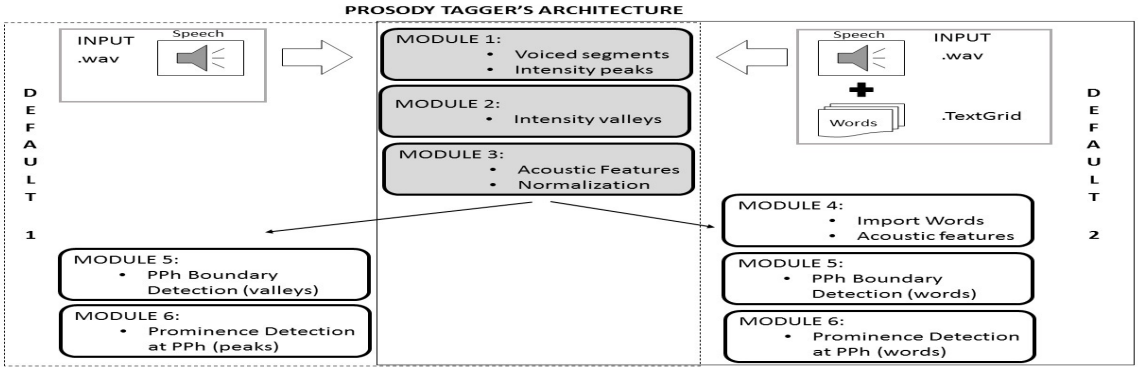

Figure 2: Prosody tagger's architecture.

4 Prosody Tagger Implementation

Our prosody tagger is available as a web service.[6] Any speech sample in *wav* format and associated *TextGrid* with word division can be uploaded, such that the segmentation into PPhs and prominence within the segmented PPhs is displayed on screen and also for download in TextGrid format. All scripts and the extended Praat version for feature annotation are also available under a Creative Common's license[7].

The architecture of the prosody tagger has been conceived as a modular platform such that its optimization and further development (including prosodic word detection) can be attained focusing on specific intermediate steps within the whole pipeline. Acoustic information extracted from different modules is annotated in terms of feature vectors in each segment, including computed z-scores within different prosodic units (so far, from Levels 1 to 3), as introduced in previous sections. Those features can be visualized, retrieved and used for processing at any stage thanks to the extension for feature annotation performed on Praat. Acoustic parameters include, but are not limited to, F0, intensity and duration elements, as Praat allows extraction of a wider range of acoustic parameters (such as jitter, shimmer and pulses, among others).

Figure 2 sketches the modular architecture of the prosody tagger with two possible configurations: (i) Default 1: using only raw audio (as wav file), and (ii) Default 2: using both raw audio (wav file) and importing external word segmentation (in TextGrid format), which must be uploaded by the user. For the Default 2 configuration presented in this study, we have used for word segmentation the proprietary Automatic Speech Recognition system *Scribe*[8] by Vocapia Research.[9] The output of Scribe is converted from xml into TextGrid format. In what follows, a description of each module's functionality is outlined and annotated acoustic features are specified at each stage.

Module 1 uses the wav file and creates a TextGrid using the built-in function in Praat *To TextGrid (silences)*, which automatically detects unvoiced and voiced segments as intervals. Then, a pitch object and an intensity object are extracted from the sound file. The function *To IntensityTier (peaks)* is performed on the intensity object to select salient peaks. The F0 information is extracted at standard frame rates from the pitch object to associate extracted intensity peaks to the ones that involve F0; the distance between these peak candidates is also considered for syllable nuclei detection. A point tier is created and points matching the combination of intensity, F0 and time distance within each voiced segment are annotated. As features, absolute intensity, F0 and the associated voiced interval are stored in each point segment.

Module 2 makes use of the intensity object created in Module 1 to extract intensity valleys using the Praat function *To IntensityTier (valleys)*. Standard intensity frames are selected if their intensity z-score

[6] http://kristina.taln.upf.edu/praatweb/

[9] http://www.vocapia.com/

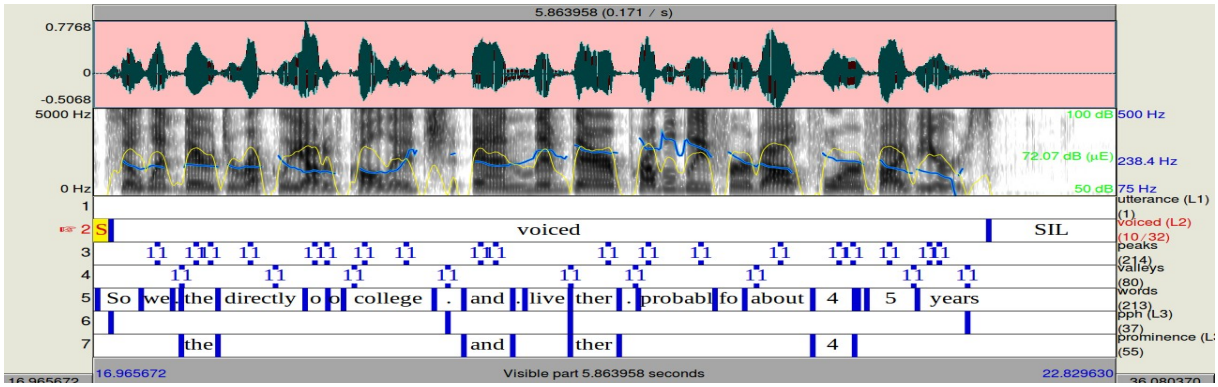

Figure 3: All modules' output for calculation.

(relative to L1) is lower than 0. Then, the lowest values in intensity relative to each voiced fragment (L2) are labeled in a new point tier taking into account the distance between them. Annotated features from this module are: intensity z-score relative to the whole sound (L1) and intensity z-score relative to the associated voiced segment (L2) at each valley point.

Module 3 extracts acoustic values, computes z-scores at available levels, and annotates results as features in each segment. At L1, mean and standard deviation of intensity and F0, together with duration for the whole file, are annotated. These values serve for calculation of z-scores at lower levels in the hierarchy. At L2, annotated features include both absolute values for F0, intensity and duration for further calculation of z-scores in peak and valley tiers (created in Module 1 and 2 respectively) and z-scores derived from L1 values. In the peak and valley tiers, the distance to the previous point is also annotated as a feature. For the first point in the tier, the distance to the boundary of its associated voiced segment is specified as reference.

If a TextGrid with the word segmentation is available, Module 4 exports this tier and annotates features at each marked interval. Consequently, prominence predicted in Module 6 outputs prominent words if these segments are provided by the user. Extracted acoustic parameters and annotated features in this module include: (i) z-scores relative to their associated L2 voiced interval (the z-score values for intensity and F0 are extracted and annotated as features for each word segment obtained by Module 1); (ii) time landmarks, i.e., time of minimum value of intensity and maximum F0 within each word; (iii) duration: absolute duration of the word, and relative duration to the corresponding voiced segment and to the whole sample.

Module 5 uses voiced segments and valleys to predict PPh boundaries. They are derived from the information extracted in the L2 voiced/silence segments detected by Module 1 and from the valleys marked in Module 2. Valleys and peaks contained in each L2 voiced segment are looped in to find the smallest z-score values of intensity within each voiced range and measuring the distance of these valleys to the closest peaks. If the distance of one of the closest peaks is greater than or equal to 0.2 seconds, the z-score is among the minimum in the range, and F0 value is *undefined*, then a PPh boundary is marked.

Finally, Module 6 performs prominence detection on each PPh predicted in the previous module. If no word alignment is available, only syllable peaks predicted in Module 1 are used. Consequently, this module outputs prominent points that correspond to peak points in configuration 1 and prominent word intervals in configuration 2. For calculation of prominence, a combination of F0, intensity and duration cues are taken into account as described in Section 3. Figure 3 displays all tiers created by each module as described above for computation and the final output with the tagging of PPh boundaries and prominent words after the whole pipeline has been executed running a default 2 configuration.

5 Evaluation

A total of five different spontaneous speech samples are used in the evaluation, both for inter-annotator agreement and the prosody tagger's performance: three dialogues in Spanish and two monologues in

American English. Table 1 shows the specific information details for each sample. Dialogues in Spanish are set in a medical context; a male doctor is involved in all of them talking to a patient. Gender is represented in all file names with the convention "f" and "m" for female and male respectively. Files "es_01mm" and "es_02mm" include the same speakers in the same conversational context, where a patient complains to the doctor, but in "es_01mm", the doctor shows a negative response, while in "es_02mm", he acts in a comprehensive and pro-active way. Monologues in English are biographical introductions of the speakers (birthplace, family, recent activities, etc.). Original sound files, transcripts and annotations used in this evaluation will be made available upon request to the authors and acceptance of associated license terms.

		Length	
Filename	Format	Seconds	Words
es_01mm	dialogue	36	196
es_02mm	dialogue	28	150
es_03fm	dialogue	152	545
en_04m	monologue	70	213
en_05f	monologue	30	282
	TOTAL	**316**	**1386**

Table 1: Corpus used in evaluation.

Filename	Prominence	Boundary
es_01mm	0.55	**0.98**
es_02mm	**0.63**	**0.72**
es_03fm	0.51	**0.78**
en_04m	**0.72**	**0.93**
en_05f	**0.69**	**0.70**

Table 2: Inter-annotator agreement Cohen's kappa.

Two expert annotators, proficient in both English and Spanish, have independently labeled both speech samples following the guidelines outlined above in Section 3.2. Cohen's kappa (Cohen, 1960) has been calculated for inter-annotator agreement for each prominence and boundary labeling task. Evaluation is performed on the Default 2 configuration using word segmentation to facilitate the computation and objectiveness of the validation process. A baseline pipeline using only duration and F0 parameters for the same task has been implemented. Inter-annotator kappa results are presented in Section 5.1. The tagger's accuracy, precision and recall compared to the baseline is reported in Section 5.2.

5.1 Inter-annotator agreement

Table 2 provides kappa values for PPh boundary and prominence labeling of our corpus. If annotators label words that are part of the same prosodic word (e.g, they coincide in the final initial word boundary or are separated by a function word, which is usually unstressed), we count this as a partial match for the kappa computation. In order to count matches automatically under Praat, annotators are asked to insert interval boundaries duplicating the word boundaries which are automatically marked, so that we can compare boundary times for the computation of matches.

A kappa within the range of 0.6-0.8 (within a scale between 0 and 1) is considered *satisfactory*, and above 0.8 *perfect* (Cohen, 1960). In Table 2, kappa values that are in line with these thresholds are highlighted in bold for each task (i.e., prominence and boundary labeling within PPh level). Results prove that agreement ranges from 0.51 and 0.98. A higher agreement is observed in the boundary labeling task for all voice samples. No significant differences are observed between English and Spanish samples in boundary detection. However, in prominence labeling, two Spanish samples (files "es_01mm" and "es_-03fm") only reach a *moderate* agreement of 0.55 and 0.51 respectively and, in the overall picture, kappa values for prominence in Spanish are lower than those for English, which might be due to the dialogue format of the samples with shorter interventions, affective states displayed by participants (perceived emotional behavior conveyed by prosody) and quick turn movements between speakers. Nevertheless, we cannot infer that prominence annotation could be language-dependent as such: the corpus we use for evaluation is simply too small for such conclusions. Further research could exploit these techniques, or even a combination of semi-automatic annotation using the prosody tagger presented in this paper, to explore how linguistic parameters such as the discourse type (dialogue in Spanish versus monologue in English), register, gender or speaker idiosyncrasies may affect inter-annotator agreement and tagger's performance in this respect.

5.2 Automatic prosody labeling performance

In order to evaluate the performance of the automatic prosody tagger, we count as full matches those matches that have been labeled as full either by one or by both annotators. For prominence labeling only, we include into the match count also partial matches, i.e., words that coincide in one interval boundary or belong to the same prosodic word – as already done in the inter-annotator agreement exercise. Boundaries that match with a time margin of ± 0.25 seconds are considered to be partial matches. For PPh boundaries, we count it as a match (or true positive), if the automatic tool labels a boundary which has only been labeled by one annotator. Table 3 presents the accuracy, precision, recall and F-measure scores for full matches (F) and full and partial matches (F&P), both for the baseline and our tagger (recall that the baseline uses F0 only).

	Accuracy		Precision		Recall		F-Measure	
	P	B	P	B	P	B	P	B
baseline (F)	0.83	0.89	0.49	0.88	0.22	0.28	0.30	0.42
tagger (F)	**0.84**	0.88	**0.52**	0.58	**0.32**	**0.43**	**0.36**	**0.55**
baseline (F&P)	0.90	0.90	0.84	0.88	0.37	0.28	0.51	0.42
tagger (F&P)	**0.91**	0.89	0.80	0.63	**0.49**	**0.49**	**0.61**	**0.55**

Table 3: Automatic prosody tagger's accuracy, precision and recall.

Table 3 shows that the prosody tagger performs at accuracy rates higher than 0.84 in both prominence (P) and boundary (B) detection tasks. The baseline achieves higher precision figures (especially in boundary detection) than our tagger. A closer look at the output reveals that the baseline marked only those boundaries that included a clear pause, i.e., "safe" candidates. In contrast, the tagger marked not only those clear pauses, but also more subtle boundaries that involved an intensity decrease and not necessarily a pause. On the other side, the tagger reaches considerably higher recall figures than the baseline for both prominence and boundary detection tasks. The F-measure figures show that overall, the tagger performs better. Still, since our methodology is based upon the deviation of normalized values, neutral speech might pose a problem when trying to tag both prominence and boundaries, as there is a tendency towards less variable prosodic cues in this register. Further empirical studies using a semi-automatic approach and optimization of the tagger are needed to have a deeper insight into this and other issues.

6 Conclusions

The integration of a parametric prosody annotation methodology into speech signal processing research is essential in order to reach a close to natural segmentation of spontaneous speech samples and to facilitate the task of the annotation of large corpora for training algorithms for the generation of expressive synthesized speech.

We presented an annotation schema that facilitates a hierarchical acoustic representation of prosody and a tagger that automatically tags speech samples in accordance with this schema. The rather high inter-annotator agreement figures show that our annotation schema is coherent and objective, i.e., does not depend on potentially subjective criteria of the individual annotators. Recall results surpassing the baseline prove that our automatic prosody tagger is flexible enough to support language independent speech signal analysis and detection of prominence and boundaries at the PPh level using a combination of acoustic features, rather than merely F0 contours, as previous empirical and theoretical studies claimed. Improved recall scores also indicate that the number of true positives from the total number of words which actually belong to the positive class, i.e., labeled as positive by the manual annotators, is much higher than the baseline's.

The present implementation may be extended for other applications or further smaller prosodic unit detection (such as prosodic words) due to its modular architecture and open-source philosophy. Moreover, this paper briefly presents an extended Praat functionality for feature annotation to provide easy access and manual revision of the tagger's output as well as retrieval of annotated features at any stage of the computation process. The modularity and prosodically-oriented methodology used in the development of the tagger provides a suitable framework for the deployment of more complex data-driven

approaches, which are able to learn from prosodic units instead of textual units, and thus, get closer to more natural and expressive results when applied to generation of prosodic cues.

All in all, the presented methodology and implementation serves as a platform upon which further research lines and experiments can be run to increase the knowledge in the area of speech technologies and test advanced implementations for human-machine interaction technologies. In the future, we plan to explore the re-implementation of the tagger as a neural network application. Extracted acoustic features combined with linguistic features such as part of speech tag, syntactic dependencies and communicative structure, will be put to the test to observe whether prediction is enhanced, as previously suggested by empirical studies such as (Domínguez et al., 2016b).

Abstract

Popular techniques for domain adaptation such as the feature augmentation method of Daumé III (2009) have mostly been considered for sparse binary-valued features, but not for dense real-valued features such as those used in neural networks. In this paper, we describe simple neural extensions of these techniques. First, we propose a natural generalization of the feature augmentation method that uses $K + 1$ LSTMs where one model captures global patterns across all K domains and the remaining K models capture domain-specific information. Second, we propose a novel application of the framework for learning shared structures by Ando and Zhang (2005) to domain adaptation, and also provide a neural extension of their approach. In experiments on slot tagging over 17 domains, our methods give clear performance improvement over Daumé III (2009) applied on feature-rich CRFs.

1 Introduction

There are often multiple types of data that share common characteristics. For example, in this work we are interested in slot tagging of user queries under as many as 17 different domains. Correctly labeling a given query requires the knowledge of the domain that the query is in. A word such as "home" can be labeled as either `contact_name` under the COMMUNICATION domain, `place_type` under the PLACES domain, or `home_screen` under the XBOXENTERTAINMENTSEARCH domain. On the other hand, a function word such as "the" is labeled as `others` across all domains.

Ideally, we would like to train on all sources of data in order to learn about words that are shared across domains, but naively combining these sources for training does not work well since this ignores label inconsistencies across domains. The other extreme is to only use data only from the domain of interest, but it misses out opportunities to learn global patterns shared by multiple domains. The goal of domain adaptation is precisely to address this conundrum: how can we learn from multiple sources of data but retain the integrity of individual domains?

There has been much progress in domain adaptation. A notable example is the feature augmentation method of Daumé III (2009), whose key insight is that if we partition the model parameters to those that handle *common patterns* and those that handle *domain-specific patterns*, the model is forced to learn from all domains yet preserve domain-specific knowledge. The method of Daumé III (2009) is usually considered for sparse binary-valued features which underlie conventional NLP systems. With such features, the parameter partitioning can be achieved with trivial data preprocessing: by conjoining feature types with domain indicators and using them alongside the original feature types. But it is not clear how this approach can be extended to dense real-valued feature values, which are used in many recent NLP systems based on neural networks.

In this paper, we describe natural generalizations of such domain adaptation techniques to neural networks. First, we propose a neural extension of the feature augmentation method of Daumé III (2009)

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 387–396, Osaka, Japan, December 11-17 2016.

in which we achieve the effect of model partitioning by having a global LSTM used across all domains and independent LSTMs used within individual domains, and then combining their outputs in the top layer. Second, we propose using the framework for learning predictive structures by Ando and Zhang (2005) for domain adaptation which has not previously been considered for this task (the original work only considers multi-tasking in the context of semi-supervised learning): we likewise consider a neural extension of this framework.

We perform slot tagging experiments on 17 different personal digital assistant domains that Cortana handles (Tur, 2006; Anastasakos et al., 2014; Kim et al., 2015a; Kim et al., 2015c; Kim et al., 2015b; Kim et al., 2016a; Kim et al., 2016b). Our methods give clear performance improvement over naive baselines such as training K independent models on individual domains or training one model on the union of all domains. Our methods also significantly outperform the feature augmentation method of Daumé III (2009) with standard sparse binary features implemented with conditional random fields (CRFs).

The rest of the paper is organized as follows. In Section 2, we discuss related works. In Section 3, we provide background information on domain adaptation and sequence modeling. First, we review the feature augmentation method of Daumé III (2009) (Section 3.1). Then we review the framework for learning predictive structures by Ando and Zhang (2005) and observe how it can be naturally considered for domain adaptation (Section 3.2). We also give a brief introduction to neural networks for sequence modeling (Section 3.3). In Section 4, we present a neural extension of the feature augmentation method. In Section 5, we present a neural extension of the framework of Ando and Zhang (2005). In Section 6, we give experimental results.

2 Related Works

Domain adaptation and multi-taking with neural networks have been an active research area. We discuss some examples of previous works and how our work differs.

Many past approaches to domain adaptation simply augment the network with a parameter that activates on the current domain. For instance, Alumäe (2013) and Tilk and Alumäe (2014) tackle multi-domain neural language modeling, with both feedforward and recurrent networks, by introducing a domain-indicator parameter. Similarly, Ammar et al. (2016) address multi-lingual dependency parsing with the stack LSTM by introducing a language-indicator parameter that exploits various resources for the given language such as the language identity and WALS typological properties.

Our work is distinguished from these works in that we use a *global* $(K+1)$-th model that captures general patterns across K domains, rather than just K models augmented with domain indicators. This explicit modeling of domain-independent patterns is more in the spirit of the original feature augmentation method of Daumé III (2009). The problem of adapting a general network to particular task has been studied in the context of speech recognition acoustic models (Yao et al., 2012; Mirsamadi and Hansen, 2015).

A task closely related to domain adaptation is multi-tasking: training a single model to perform different tasks (not just different domains) in hope to exploit common properties across tasks. Multi-tasking has also been investigated extensively in the NLP neural network community, notably the "NLP from scratch" work by Collobert et al. (2011) in which various sequence labeling tasks are tackled by a single network with convolution and CRF layers, and its numerous followup studies such as Yang et al. (2016).

3 Background

3.1 Domain Adaptation by Feature Augmentation

Daumé III (2009) propose the following simple approach to domain adaptation. Suppose there are K distinct domains, and let d denote the total number of feature types. The usual setting in NLP is that these features are high-dimensional, sparse, and binary-valued. For example in a CRF, a feature type may ask if the current word is "apple" and the previous word is "company": it takes value 1 if the answer is yes and 0 otherwise. Thus without distinguishing domains, a feature vector takes the form $x \in \{0,1\}^d$ for any domain $k \in \{1 \dots K\}$.

Now, consider learning a naive model $f : \{0,1\}^d \rightarrow \Omega$ over all K domains where Ω denotes an output space. Without domain adaptation, the model f receives a feature vector $x \in \{0,1\}^d$ and simply outputs the value $f(x) \in \Omega$ no matter which domain x corresponds to. The proposal of Daumé III (2009) is that we train a model $f^{aug} : \{0,1\}^{(K+1)d} \rightarrow \Omega$ that instead uses an *augmented* feature vector $x^{aug} \in \{0,1\}^{(K+1)d}$ defined as

$$x^{aug} = (x, 0, \ldots, x^k, \ldots, 0)$$

where $x^k \in \{0,1\}^d$ is a feature representation of x under the k-th domain. In other words, we expand the feature space by $K+1$ times by duplicating the original feature x for K times: then given an input from the k-th domain, we only use the original x and the corresponding domain representation x^k.

Note that this essentially partitions the model parameters to those that handle the representation x used across all domains and those that handle x^k for individual domains $k \in \{1 \ldots K\}$. In the sparse binary feature regime, this can be achieved by conjoining the original feature types with a domain indicator. For example, the i-th feature value of x^k can look like

$$x_i^k = \begin{cases} 1 & \text{if the current word is "apple"} \\ & \text{AND the previous word is "company"} \\ & \text{AND the domain is } k \\ 0 & \text{otherwise} \end{cases}$$

This can be also thought of as data preprocessing in which we duplicate the data in each domain and mark one copy with the domain identity.

3.2 Shared Structure Learning Framework

Ando and Zhang (2005) propose learning a shared structure across multiple related classification tasks. Specifically, they consider K binary classification tasks each of which has its own linear classifier $f_k : \mathbb{R}^d \rightarrow \mathbb{R}$ mapping a d-dimensional feature vector $x \in \mathbb{R}^d$ to a classification score

$$f_k(x) := (u_k + \Theta v_k)^\top x = u_k^\top x + v_k^\top \Theta^\top x$$

Here, $u_k \in \mathbb{R}^d$ and $v_k \in \mathbb{R}^m$ are task-specific parameters but $\Theta \in \mathbb{R}^{d \times m}$ is a global parameter shared by all classifiers $f_1 \ldots f_K$. In particular, if Θ is zero then each classifier is an independent linear function $u_k^\top x$. The predicted label is the sign of the classification score $f_k(x)$.

The parameter sharing makes the estimation problem challenging, but Ando and Zhang (2005) develop an effective alternating loss minimization algorithm using a variational property of singular value decomposition (SVD). The original work applied this framework to semi-supervised learning and achieved strong empirical results. But note that it can be viewed as domain adaptation where the K classification tasks are different "domains" and we aim to learn a global parameter Θ shared across the domains.

3.3 Neural Networks for Sequence Modeling

Recently, there has been much success in tackling sequence modeling problems using neural networks. By far the most popular network for sequence modeling is long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997), which is a special case of more general recurrent neural network (RNN) architecture. An RNN extends a traditional feedforward network by recursively receiving inputs generated by the model itself. This essentially defines a feedforward network in which the same set of parameters are used multiple times and is well-suited for sequential data. But a simple RNN suffers from the vanishing gradient problem and does not model long-term dependency very well (Pascanu et al., 2013). An LSTM addresses this issue by introducing a memory cell in RNN architecture that can control how much past information to retain or to forget. This modification has been shown to be crucial in practice. Many recent works in NLP have achieved state-of-the-art results using variants of LSTM, for example in dependency parsing (Dyer et al., 2015) and machine translation (Bahdanau et al., 2014).

4 A Neural Extension of the Feature Augmentation Method

We now describe a neural extension of the feature augmentation method for domain adaptation (Daumé III, 2009). Our model consists of $K + 1$ LSTMs: one LSTM θ is used on all domains, and the remaining K LSTMs $\theta^1 \dots \theta^K$ are used only for the corresponding domains. More specifically, we predict one of L labels at the t-th time step in a given user query in domain $k \in \{1 \dots K\}$ as follows. The common LSTM θ produces an output vector $h_t \in \mathbb{R}^d$ and the domain-specific LSTM θ^k produces an output vector $h_t^k \in \mathbb{R}^d$. The output dimension d of these LSTMs is empirically chosen. The model has parameters $W \in \mathbb{R}^{L \times d}$ and $W^k \in \mathbb{R}^{L \times d}$ at the top layer and combines the LSTM outputs as $z_t^k \in \mathbb{R}^L$ where

$$z_t^k = [W\ W^k] \begin{bmatrix} h_t \\ h_t^k \end{bmatrix} = W h_t + W^k h_t^k \tag{1}$$

which is a direct analogue of the feature augmentation method with sparse binary-valued features:

$$x^{aug} = (x, 0, \dots, x^k, \dots, 0)$$

This combined representation (1) is put through a softmax function to produce a distribution over L labels. Figure 1 (a) provides an illustration of the proposed architecture The model can be trained by maximizing the log likelihood of correct predictions in the training data:

$$J(W, W^1 \dots W^k, \theta, \theta^1 \dots \theta^k) = \sum_t \log \left(\frac{\exp [z_t]_{ans(t)}}{\sum_{l=1}^{L} \exp [z_t]_l} \right) \tag{2}$$

where $ans(t) \in \{1 \dots L\}$ is the ground-truth label for the t-th training example. Note that we do not consider the sentence-level log likelihood (which requires an additional CRF layer for global normalization) for simplicity.

5 A Neural Extension of the Shared Structure Learning Framework

We describe a neural extension of the shared structure learning framework of Ando and Zhang (2005). Recall that Ando and Zhang (2005) consider K binary classifiers $f_k : \mathbb{R}^d \to \mathbb{R}$ with a global parameter $\Theta \in \mathbb{R}^{d \times m}$:

$$f_k(x) = u_k^\top x + v_k^\top \Theta^\top x \tag{3}$$

The model can be seen as combining the given input x (the first term) and a transformed input $\Theta^\top x$ (the second term) where the transformation is learned across K tasks.

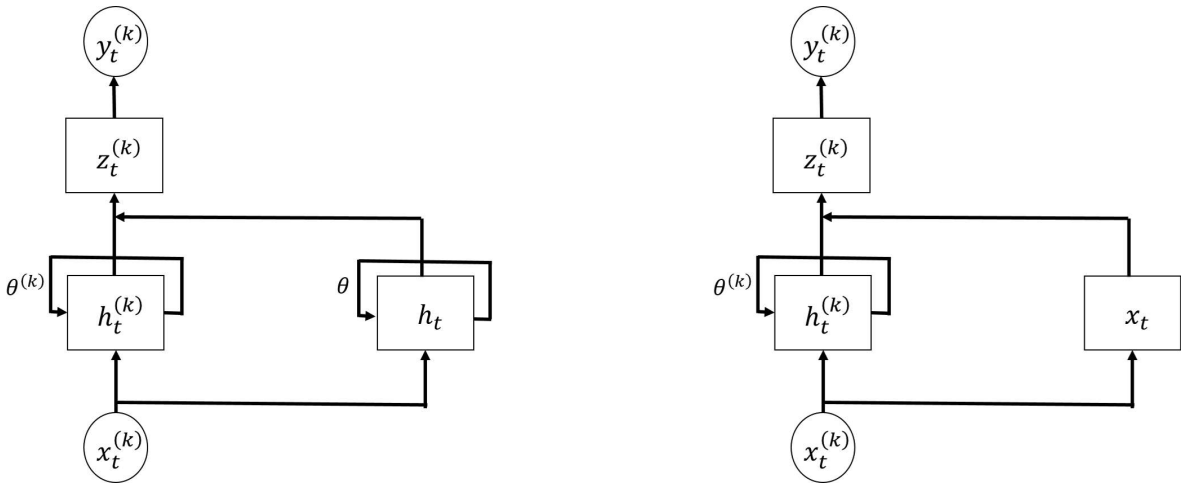
We extend this framework with the following model. The model consists of K LSTMs $\theta^1 \dots \theta^K$ corresponding to K domains. At the t-th time step in a given user query in domain $k \in \{1 \dots K\}$, we compute a direct analogue of (3) by adding the output vector of the k-th LSTM θ^k on the input vector (word embedding) x_t to the original input vector to create

$$z_t^k = W x_t + W^k \theta^k(x_t)$$

where $\theta^k(x_t) \in \mathbb{R}^d$ denotes the output vector of the k-th LSTM on input x_t.

Figure 1 (b) provides an illustration of the proposed architecture This combined representation is put through a softmax function to produce a distribution over L labels. The model can be trained by maximizing the log likelihood of correct predictions in the training data similarly in (2).

Note that the proposed extensions of Daumé III (2009) and Ando and Zhang (2005) only differ in how the domain-independent information is derived. In particular, the extension of Ando and Zhang (2005) can be seen as a weaker version of the extension of Daumé III (2009) since the domain-independent information is used as is (i.e., x_t) in the former while first transformed by a domain specific LSTM in the latter (i.e., h_t).



(a) Feature augmentation method

(b) Shared structure learning framework

Figure 1: Illustration of the proposed neural extensions of Daumé III (2009) and Ando and Zhang (2005).

6 Experiments

In this section, we turn to experimental findings to provide empirical support for our proposed methods. First, we note that our experimental settings are rather different from previously considered settings for domain adaptation in many aspects:

- *Sufficient target data:* In a typical setting for domain adaptation, one generally assumes that the source domain has a sufficient amount of labeled data but the target domain has an insufficient amount of labeled data. However, we have sufficient amounts of labeled data for all domains: our goal is to effectively utilize all of them.
- *Variant output:* In a typical setting for domain adaptation, the label space is invariant across all domains. Here, the label space can be different in different domains, which is a more challenging setting. See Kim et al. (2015d) for details of this setting.
- *Multiple source domains:* In most previous works, only a pair of domains (source vs. target) have been considered, although they can be easily generalized to $K > 2$. Here, we experiment with $K = 17$ domains.

To test the effectiveness of our approach, we apply it to the slot sequence tagging task in a suite of 17 personal assistant domains. The goal is to find the correct semantic tagging of the words in a given user utterance. For example, a user could say *"reserve a table at joeys grill for thursday at seven pm for five people"*; then the model needs to tag *"joeys grill"* with `restaurants`, *"thursday"* with `date`, *"seven pm"* with `time`, and "five" with `numberpeople`. The data statistics and the short descriptions of the domains are shown in Table 1. As the table indicates, the domains have very different attributes. We have 131 unique labels across these domains (a different subset of these labels is used in each domain). The total numbers of training, development and test queries across domains are 2640K, 129K and 64K, respectively.

6.1 Setting

In all our experiments, we train our models using stochastic gradient descent (SGD) with Adam (Kingma and Ba, 2015)—an adaptive learning rate algorithm. We use the initial learning rate of 2×10^{-4} and leave all the other hyperparameters as suggested in Kingma and Ba (2015). Each SGD update is computed using a minibatch of size 128. We use the dropout regularization (Srivastava et al., 2014) with the keep probability of 0.5. The dimension of the hidden layer is $d = 100$. For simplicity, we use simple forward-directional LSTMs rather than bi-direction LSTMs, as we observed that they yielded similar results on

the development set in preliminary experiments. To initialize word embedding, we used word embedding trained on 6 billion tokens (6B-200d) from Wikipedia 2014 plus Gigaword 5 (Pennington et al., 2014). These configurations were selected by observing the models performance on held-out development set.

We compare the following methods for the slot tagging tasks:

- *NoAdapt*: train a feature-rich CRF only on target training data.
- *Union*: train a feature-rich CRF on the union of source and target training data.
- *Daume*: train a feature-rich CRF with the discrete feature duplication method of Daumé III (2009).
- *1D&E*: train a domain specific LSTM with a generic embedding on all domain training data, shown on the right in Figure 2.
- *1D&L*: train a domain specific LSTM with a generic LSTM on all domain training data, shown on the left in Figure 2.
- *KD&E*: train domain specific K LSTMs with a generic embedding on all domain training data, shown on the right in Figure 1.
- *KD&L*: train domain specific K LSTMs with a generic LSTM on all domain training data, shown on the left in Figure 1.

The methods *1D&E* and *1D&L* are slight variants of the main proposed neural networks *KD&E* and *KD&L* in Figure 1. These only use a single LSTM for K domains in addition to a common LSTM: it is mostly presented for comparison purposes. Note that we have a single model to tag all domains (except for *NoAdapt* with which we have K models).

6.2 Results

For non-neural models, we use conditional random fields (CRFs) (Lafferty et al., 2001) with a rich set of binary-valued features such as lexical features, gazetteers, Brown clusters (Brown et al., 1992) and context words. For parameter estimation, we used L-BFGS (Liu and Nocedal, 1989) with 100 as the maximum iteration count and 1.0 for the L2 regularization parameter.

Their results are shown in Table 2. A few observations: the model without domain adaptation (*Noadapt*) is already very competitive because we have sufficient training data. However, simply training a single model with aggregated queries across all domains significantly degrades performance (*Union*). This is because in many cases the same query is labeled differently depending on the domain and the

context. This is also because the amounts of training data are widely different across different domains. For example, slots (e.g. `app name`) in other domains are overwhelmed by slots in PLACES domain such as `place name` since our PLACES domain is the largest in terms of number of slot types and 2nd largest in terms of dataset size. Finally, the feature augmentation method of Daumé III (2009) dramatically improves performance across all domains, achieving the average F1 score of 94.04.

94.04	Average	92.74	94.16	94.90	94.69	**95.50**

Table 3: F1 scores for Daumé III (2009) and LSTM model variants across seventeen personal assistant domains.

The results with our proposed LSTM domain adaptation models are also shown in Table 3. For easy comparison, the results with Daumé III (2009) applied on feature-rich CRFs are duplicated at the leftmost column.

The *NoAdapt* yields 92.74% average F1-measure which is higher than the performance of CRFs without the rich hand-crafted features. We consistently and significantly improve performance by using adaptation techniques. First, the *1D&E* improves F1 performance to 94.16%. Using not generic embedding, but generic LSTM *(1D&L)* boosts the performance up to 94.9%. Also, having K domain specific LSTMs with generic embeddings (*KD&E*) which is very close to Ando and Zhang (2005) achieves performance gain from *1D&E*, but fail to provide any improvement from 1D&L. Finally, KD&L, which is directly inspired by Daumé III (2009), achieves the best performance of 95.5%, indicating that having K different domain specific LSTMs and a generic LSTM yields significant gains on most of the domains.

7 Conclusion

In this work, we described novel neural approaches to domain adaptation. Adding to the rich history of works in domain adaptation and multi-tasking with neural networks, we proposed a neural analogue of the well-established feature augmentation method of Daumé III (2009) and the shared structure learning framework of Ando and Zhang (2005). Our extensions are natural and simple. In experiments on slot tagging over 17 domains, we demonstrated the effectiveness of our methods by delivering clear performance gains over both naive and strong baselines.

Abstract

In Computational Linguistics, Hindi and Urdu are not viewed as a monolithic entity and have received separate attention with respect to their text processing. From part-of-speech tagging to machine translation, models are separately trained for both Hindi and Urdu despite the fact that they represent the same language. The reasons mainly are their divergent literary vocabularies and separate orthographies, and probably also their political status and the social perception that they are two separate languages. In this paper, we propose a simple but efficient approach to bridge the lexical and orthographic differences between Hindi and Urdu texts. With respect to text processing, addressing the differences between their texts would be beneficial in the following ways: (a) instead of training separate models, their individual resources can be augmented to train single, unified models for better generalization, and (b) their individual text processing applications can be used interchangeably under varied resource conditions.

To remove the script barrier, we learn accurate statistical transliteration models which use sentence-level decoding to resolve word ambiguity. Similarly, we learn cross-register word embeddings from the harmonized Hindi and Urdu corpora to nullify their lexical divergences. As a proof of the concept, we evaluate our approach on the Hindi and Urdu dependency parsing under two scenarios: (a) resource sharing, and (b) resource augmentation. We demonstrate that a neural network-based dependency parser trained on augmented, harmonized Hindi and Urdu resources performs significantly better than the parsing models trained separately on the individual resources. We also show that we can achieve near state-of-the-art results when the parsers are used interchangeably.

1 Introduction

Hindi and Urdu are spoken primarily in northern India and Pakistan and together constitute the third largest language spoken in the world.[1] They are two standardized registers of what has been called the Hindustani language, which belong to the Indo-Aryan language family. Masica (1993) explains that, while they are different languages officially, they are not even different dialects or sub-dialects in a linguistic sense; rather, they are different literary styles based on the same linguistically defined sub-dialect. He further explains that at the colloquial level, Hindi and Urdu are nearly identical, both in terms of core vocabulary and grammar. However, at formal and literary levels, vocabulary differences begin to loom much larger (Hindi drawing its higher lexicon from Sanskrit and Urdu from Persian and Arabic) to the point where the two styles/languages become mutually unintelligible. In written form, not only the vocabulary but the way Urdu and Hindi are written makes one believe that they are two separate languages. They are written in separate orthographies, Hindi being written in Devanagari, and Urdu in a modified Perso-Arabic script. Given these differences in script and vocabulary, Hindi and Urdu are

[1] see http://www.ethnologue.com/statistics/size and https://en.wikipedia.org/wiki/List_of_languages_by_number_of_native_speakers

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 397–408, Osaka, Japan, December 11-17 2016.

socially and even officially considered two separate languages. These apparent divergences have also led to parallel efforts for resource creation and application building in computational linguistics. The Hindi-Urdu treebanking project is one such example where the influence of differences between Hindi and Urdu texts have led to the creation of separate treebanks for Hindi and Urdu (Bhatt et al., 2009; Bhat et al., 2015). However, pursuing them separately in computational linguistics makes sense. If the two texts differ in form and vocabulary they can not be processed with same models unless the differences are accounted for and addressed. In this paper, we aim to remove these differences between Hindi and Urdu texts. We learn accurate machine transliteration models for the common orthographic representation of their texts. To resolve their lexical divergences, we learn cross-register word embeddings from the harmonized Hindi and Urdu corpora. So as to evaluate our approach, we empirically demonstrate the impact of text harmonization on the dependency parsing of both Hindi and Urdu under varied supervised training conditions. We show that a neural network-based parser trained on cross-register word embeddings sets the new benchmark for dependency parsing of Hindi and Urdu. A summary of our overall contributions is provided as follows:

- **Common Representation:** To remove the orthographic differences between Hindi and Urdu texts, we evaluate Devanagari and Perso-Arabic scripts for their common representation. We propose accurate statistical transliteration models which use sentence-level decoding on n-best transliterations to resolve word ambiguity. We empirically show that the Devanagari script is better suited for automatic text processing of both Hindi and Urdu. We show significant gains in accuracy in different modules of Hindi and Urdu dependency parsing pipeline when the training and evaluation data are represented in Devanagari instead of Perso-Arabic.
- **Resource Sharing and Augmentation:** To facilitate resource sharing and augmentation, we use statistical transliteration to harmonize the orthographic differences between Hindi and Urdu texts, while their lexical divergences are resolved by learning cross-register word embeddings. We augment their harmonized treebanks and train neural network-based parsing models using different supervised domain adaptation techniques. We empirically show that our augmented models perform significantly better than the models trained separately on individual treebanks. Moreover, we also demonstrate that the individual parsing models trained on harmonized Hindi and Urdu resources can be used interchangeably to parse both Hindi and Urdu texts and give near state-of-the-art results.

2 Experimental Setup

To experiment on resource sharing and augmentation between Hindi and Urdu, we need to mitigate their orthographic and lexical differences. To that end, we propose a simple approach which uses machine transliteration and distributional similarity-based methods (see §3 and §4). After script harmonization, we learn distributed word representations to project Hindi and Urdu lexicon in the same distributional space. To make effective use of these word representations, we employ the non-linear neural network architecture for transition-based dependency parsing proposed by Chen and Manning (2014). We use a similar architecture for sequence labeling as well.

2.1 Parsing Models

Our parsing model is based on transition-based dependency parsing paradigm (Nivre, 2008). Particularly, we use an arc-eager transition system, which is one of the famous transition-based parsing systems. Arc-eager algorithm defines four types of transitions to derive a parse tree namely: 1) Shift, 2) Left-Arc, 3) Right-Arc, and 4) Reduce. To predict these transitions, a classifier is employed. We follow Chen and Manning (2014) and use a non-linear neural network to predict these transitions for any parser configuration. The neural network model is the standard feed-forward neural network with a single layer of hidden units. The output layer uses softmax function for probabilistic multi-class classification. The model is trained by minimizing cross entropy loss with an $l2$-regularization over the entire training data. We also use mini-batch Adagrad for optimization and apply dropout (Chen and Manning, 2014).

From each parser configuration, we extract features related to the top four nodes in the stack, top four nodes in the buffer and leftmost and rightmost children of the top two nodes in the stack and the leftmost

child of the top node in the buffer. For each node, we use the distributed representation of its lexical form, POS tag, chunk tag and/or dependency label. We use the Hindi and Urdu monolingual corpora to learn the distributed representation of the lexical units. The Hindi monolingual data contains around 40M raw sentences, while the Urdu data is comparatively smaller and contains around 6M raw sentences. The distributed representation of non-lexical units such as POS, chunk and dependency labels are randomly initialized within a range of -0.01 to +0.01 (Chen and Manning, 2014).

To decode a transition sequence, we use dynamic oracle recently proposed by Goldberg and Nivre (2012) instead of the vanilla static oracle. Dynamic oracle allows training by exploration that helps to mitigate the effect of error propagation. We use the same value for the exploration hyperparameter as suggested by Goldberg and Nivre (2012).

2.2 Sequence Labeling Models

For the training of POS tagging and chunking models, we use a similar neural network architecture as discussed above. Unlike Collobert et al. (2011), we do not learn separate transition parameters. Instead we include the structural features in the input layer of our model with other lexical and non-lexical units. For POS tagging, we use second-order structural features, 2 words to either side of the current word, and last 3 letters of the current word. Similarly, for chunking we use POS tags of the current word and the 2 words surrounding it on the either side, in addition to the features used for POS tagging.

2.3 Hindi and Urdu Treebanks

We use the annotations in the Hindi and Urdu treebanks (henceforth HDTB and UDTB) for conducting all the experiments. Both treebanks are multi-layered and multi-representational (Bhatt et al., 2009). They contain three layers of annotation namely **dependency structure (DS)** for annotation of modified-modifier relations, **PropBank-style annotation** for predicate-argument structure, and an independently motivated **phrase-structure annotation**. For our experiments, we only need annotations in the first layer of the treebanks i.e., annotations in the DS layer. Dependency Structure involves dependency analysis based on the Pāṇinian Grammatical framework (Bharati et al., 1995). In addition to dependency analysis, the sentence annotation also includes morphological analysis, part-of-speech (POS) tagging and chunking. POS tagging and chunking are based on Indian Language Machine Translation (ILMT) guidelines (Bharati et al., 2006). There are around 32 POS tags and 11 chunk tags used in the treebanks, while the dependency labels are around 82.

We split the treebank data with a ratio of 80:10:10 for training, testing and tuning separate models for POS tagging, chunking and parsing. For both treebanks, the internal structure of annotation files is preserved. However, we randomly distribute the files across training, testing and development sets. Each document or annotation file mainly contains newswire articles. Statistics about the data are provided in Table 1.

Count of	Hindi			Urdu		
	Training	Testing	Development	Training	Testing	Development
Tokens	3,47,744	43,556	43,556	1,53,317	19,065	19,065
Chunks	1,87,029	23,418	23,417	72,319	9,010	9,010
Sentences	16,629	2,077	2,077	5,432	677	677

Table 1: Statistics of training, testing and development sets used in all the experiments reported in this paper.

3 Common Representation

Despite their similarities, we can not use Hindi text processing tools for Urdu as such and vice versa as they are written in two different scripts. To address this problem, we need to represent both Hindi and Urdu texts in a single script. For this purpose, we can either use Devanagari or Perso-Arabic script. We can transliterate Hindi texts in Devanagari to Perso-Arabic or Urdu texts in Perso-Arabic to Devanagari. Either way, transliteration between these two scripts is a non-trivial task. There are genuine cases of character ambiguity due to one-to-many character mappings in both directions of transliteration. A detailed description of the challenges in Hindi-Urdu transliteration can be found in the works of Malik et al. (2008) and Lehal and Saini (2014). In addition to character ambiguity, Perso-Arabic to Devanagari

transliteration has to deal with missing short vowels in Urdu texts also. In Urdu writing, short vowels are hardly represented, even though the Perso-Arabic script has the provision for their representation. A major drawback of dropping short vowels in Urdu writing is that it generates homographs. For example, without an appropriate short vowel on the first letter, ہوا could mean 'air' (ہَوا) or 'become' (ہُوا) depending on the context. These homographs would lead to ambiguity in the Devanagari script. There would be more than one genuine Devanagari representation for such homographs, since Devanagari represents each phoneme uniquely and explicitly. Usually word-level transliteration models do not deal with word ambiguity and leave it unresolved. However, we need our transliteration model to pick a transliteration that best fits the sentential context.

It should be noted that both Devanagari and Perso-Arabic scripts are a natural choice for the common representation. The use of a third script (e.g. Roman script) for this purpose would be computationally expensive, as we need to transliterate both Hindi and Urdu resources. Moreover, the transliteration errors would also double. More importantly, if we choose a third script, we have to manually develop a reasonably-sized corpus of transliteration pairs for training the transliteration models. On the other hand, transliteration pairs in Devanagari and Perso-Arabic scripts can be automatically extracted from the corpora available in these scripts (see §3.1.1 for more details).

To measure the suitability of both scripts for the common representation of Hindi and Urdu texts, we perform extrinsic evaluation on the dependency parsing pipeline which involves POS tagging, chunking and dependency parsing. The script that maximizes the accuracy across the pipeline would imply its feasibility for uniformly representing the Hindi and Urdu texts for computational purposes.

3.1 Hindi-Urdu Transliteration

Hindi and Urdu transliteration has received a lot of attention from the NLP research community of South Asia (Malik et al., 2008; Lehal and Saini, 2012; Lehal and Saini, 2014). It has been seen to break the barrier that makes the two look different. Most of the existing works on Hindi-Urdu transliteration have considered basic rule-based models which use character tables coupled with a set of heuristics to resolve ambiguous mappings. Statistical approaches have hardly been explored (Sajjad et al., 2011). Unlike rule-based systems, statistical approaches are more robust and efficient. Among data-driven approaches, machine learning methods like noisy-channel model and structured prediction algorithms have been widely used for machine transliteration (Knight and Graehl, 1998; Zelenko and Aone, 2006). In this work, we model Hindi-Urdu transliteration as a structured prediction problem using a linear model. We use the structured perceptron (DHMM) of Collins (Collins, 2002) to learn the parameters of our transliteration model. Given an input training data of aligned character sequences $D = d_1 ... d_n$, a vector feature function $\vec{f}(d)$, and an initial weight vector $\vec{w}$, the algorithm performs two steps for each training example $d_i \in D$: (1) **Decode**: $\hat{t} = \underset{t_1 \cdots t_n}{\arg\max}(\vec{w} \cdot \vec{f}(d))$, and (2) **Update**: $\vec{w} = \vec{w} + \vec{f}(d) - \vec{f}(\hat{t})$. We use Viterbi-search for decoding in case of Devanagari to Perso-Arabic transliteration, while we use beam-search for Perso-Arabic to Devanagari transliteration to decode the best letter sequence in the target script. The latter is used to extract n-best transliterations for resolving word ambiguity.

In case of Perso-Arabic to Devanagari transliteration, to resolve the word ambiguity as discussed above, we perform sentence-level decoding on the n-best transliterations from the perceptron model. We use a noisy channel model and exact Viterbi search to find the most likely Hindi (Devanagari) sentences. The noisy-channel model can be formally defined as follows:

$$\mathbf{h}^* = \arg\max \; p(h) \times p(h|u) \tag{1}$$

$p(h)$ is the language model score which gives a prior distribution over the most likely sentences in Hindi and $p(h|u)$ is the perceptron score which indicates how likely the Hindi (Devanagari) sentence h is a word by word transliteration of the Urdu sentence u. Since $p(h|u)$ is not a probability score, we assign uniform probabilities to all the transliteration options. Thus redefining our model without $p(h|u)$ as:

$$\mathbf{h}^* = \arg\max \; p(h) \tag{2}$$

Thus, our model only relies on language model to find the best sentence from the n-best transliterations. We use trigram language model learned from 40M multi-domain Hindi corpus with Kneser-Ney smoothing. Here, it should be noted that it is plausible to score Urdu sentences in Devanagari using a language model trained on Hindi data, since there is a considerable overlap in the Hindi and Urdu grammar and vocabulary.

3.1.1 Transliteration Pair Extraction and Character Alignment

Like any other supervised machine learning approach, supervised machine transliteration requires a strong list of transliteration pairs to learn the model parameters. We use the sentence aligned ILCI Hindi-Urdu parallel corpora (Jha, 2010) to extract the transliteration pairs. Initially, the parallel corpus is word-aligned using GIZA++ (Och and Ney, 2003). We extract all the word pairs which occur as 1-to-1 alignments in the word-aligned corpus as potential transliteration equivalents. We extracted a total of 54,035 translation pairs from the parallel corpus of 50,000 sentences. To further complement the translation pairs, we also extracted 66,668 pairs from IndoWordNet (Narayan et al., 2002) synset mappings.[2] A rule-based approach with edit distance metric is used to extract the transliteration pairs from these translation pairs. To compute the edit distances, we use the Hindi-Urdu character mappings presented in (Lehal and Saini, 2014). We compute the levenshtein distance between the translation pairs based on insertion, deletion and replace operations. The distance scores are normalized by dividing them with the length of the longest string in a translation pair. Translation pairs with a normalized score of less than a small threshold of $\sim$0.1 are considered as transliteration pairs. Using this procedure, we extracted 21,972 unique transliteration pairs from the Hindi-Urdu parallel corpus and 24,614 unique transliteration pairs from the Hindi-Urdu synsets. After mining the transliteration pairs, we character align them using Giza++ for training and testing the transliteration models.

3.1.2 Experiments and Results

We train two structured perceptron models on the transliteration pairs discussed above. We maintain 80:10:10 data split for training, testing and tuning both models. Additionally, we also manually transliterate 1000 Urdu sentences in Devanagari script to tune and evaluate our noisy-channel model which we use on top of the Perso-Arabic to Devanagari transliteration system to resolve word ambiguity. The parameters such as number of training iterations, order of ngram context, number of transliterations for noisy-channel model are tuned on the respective development sets. We found that the top 5 transliterations gave the best results.

To compare our results with the existing systems, we choose HUMT, Malerkotla (MAL) and SANGAM available on the Internet,[3] while choosing the SMT-based transliteration as a baseline. The baseline model is a phrase-based machine translation system (PSMT) for transliteration built using the Moses toolkit.[4] We train the system with the default settings with the distortion limit set to 0. We list the performance of all these systems in Table 2 for comparison. The performance of our noisy-channel models is reported in Table 3.

System	Devanagari → Perso-Arabic	Perso-Arabic → Devanagari
PSMT	96.23%	74.30%
HUMT	90.34%	40.75%[5]
MAL	93.78%	78.23%
SANGAM	97.38%	87.56%
DHMM	**98.03%**	**88.03%**

Table 2: Comparison of type-level accuracies of the available systems on the Internet with our system.

[2] http://www.cfilt.iitb.ac.in/~sudha/bilingual_mapping.tar.gz

[3] http://www.sanlp.org/HUMT/HUMT.aspx, translate.malerkotla.co.in/ and http://sangam.learnpunjabi.org/

[4] http://www.statmt.org/moses/

[5] HUMT system performed worst on Perso-Arabic to Devanagari transliteration because it relies on diacritical marks in Urdu texts for correct transliteration.

System	Testing Set	Development Set
DHMM	94.21%	94.63%
+Noisy-channel Model	**96.37%**	**96.72%**

Table 3: Token-level performance of noisy-channel model in resolving word ambiguity in Perso-Arabic to Devanagari transliteration.

As shown in Table 2, we have established a new best system for the transliteration of Hindi and Urdu texts bidirectionally. Our Devanagari to Perso-Arabic system outperforms SANGAM by 0.65%. There is also an improvement of 0.47% over SANGAM in case of Perso-Arabic to Devanagari transliteration. Out of the two transliteration models, Perso-Arabic to Devanagari performs worst because of the missing vowels in the Urdu texts. Our noisy-channel model improved the results of our basic perceptron model for Perso-Arabic to Devanagari transliteration. It improved the accuracy by an absolute 2% on the test set. This clearly shows how often homographs are generated due to missing vowels in Perso-Arabic script.

3.1.3 Extrinsic Evaluation

As we already mentioned, the script that fares well in an extrinsic evaluation on a dependency parsing pipeline will be chosen for the common representation of Hindi and Urdu texts. For training and evaluation in each script, we made two copies of Hindi and Urdu training and evaluation sets. For each module, we trained two models–one in each script. In Table 4, we report the results on the respective evaluation sets in both scripts. Besides using predicted POS and chunk tag features for chunking and parsing, we also conduct experiments using the gold features. This is important for capturing the impact of orthographic representation on each module independently.

Data	POS tagging	Chunking	Parsing (LAS)
		Gold Features	
Hindi Devanagari	**96.48**	**98.40**	91.70
Hindi Perso-Arabic	96.00	98.35	91.52
Urdu Perso-Arabic	93.13	96.62	88.08
Urdu Devanagari	**93.42**	**96.65**	88.38
		Predicted Features	
Hindi Devanagari	-	**97.84**	**88.32**
Hindi Perso-Arabic	-	97.58	87.95
Urdu Perso-Arabic	-	95.60	81.67
Urdu Devanagari	-	**96.03**	**82.28**

Table 4: Performance of different modules of a dependency parsing pipeline trained and evaluated on Hindi and Urdu treebank data in Devanagari and Perso-Arabic scripts.

The results presented in Table 4 clearly favor Devanagari script over Perso-Arabic for the orthographic representation of Hindi and Urdu texts. For all the modules, accuracy decreases in Perso-Arabic script, while there is a significant increase in accuracy in Devanagari script. The reason mainly lies in the fact that Devanagari represents information explicitly while Perso-Arabic script does not. Devanagari is a phonetic script which represents phonemes uniquely and explicitly. Perso-Arabic on the other hand is not a phonetic script. The better results in Devanagari script clearly would, therefore, be due to the less ambiguous representation of words in this script as can be seen in Table 5. The table represents the impact of transliteration on lexical and POS-tag merging.

Script	**Lexical Merging** (%)	**Tag Ambiguity** (%)
Hindi in Perso-Arabic	-11.87	+3.12
Urdu in Devanagari	+11.26	-2.51

Table 5: Comparison of lexical and POS-tag merging rates in Devanagari and Perso-Arabic transliterated data.

We define *lexical merging rate* as the amount of percentage drop in the size of the vocabulary after transliteration. Similarly *tag ambiguity* captures the increase in ambiguity of POS categories due to lexical merging. Both *lexical merging* and *tag ambiguity* rates are higher in the case of Devanagari to Perso-Arabic transliteration, which explains the drop in accuracies when the models are trained and evaluated on data represented in Perso-Arabic script. There is an 11% drop in type counts when we transliterate HDTB data in Perso-Arabic, while on the other hand, there is a similar percentage increase in

vocabulary when UDTB in represented in Devanagari. Interestingly, not all the lexical merging/expansion leads to/resolves syntactic ambiguity. In HDTB, Perso-Arabic script created 3% homographs which are syntactically ambiguous, while Devanagari scripts resolves ambiguity for around 3% words in UDTB. Given these statistics, it seems reasonable to conclude that Devanagari is better suited for automatic text processing of Hindi and Urdu texts. However, it is also interesting that the POS models are able to resolve most of the syntactic ambiguity created by Perso-Arabic script.

4 Resource Sharing and Augmentation

In the above section, we empirically showed that the Devanagari script can serve as a common representation for both Hindi and Urdu texts without harming the performance of text processing applications such as a POS tagger and a parser. Given the fact that Hindi and Urdu are syntactically or grammatically similar, resource sharing and augmentation should become feasible just by removing the script barrier. A common orthographic representation would, however, only affect that part of Hindi and Urdu vocabularies which is shared. It will not fill the lexical gaps. It is the lexical differences between Hindi and Urdu texts that leave them mutually unintelligible (Masica, 1993). The severity of lexical differences can be clearly seen by comparing the OOV rates of Hindi and Urdu evaluation sets. As shown in Table 6, almost half of the tokens in both Hindi and Urdu development sets are missing from the Urdu and Hindi training sets respectively. Such excessive OOV rates would worsen the problem of lexical data sparsity for any statistical model.

Training	Development	OOV (%)
Hindi	Urdu	**51.6**
Urdu	Urdu	15.40
Urdu	Hindi	**62.76**
Hindi	Hindi	22.06

Table 6: OOV rates of Hindi and Urdu development sets. Both Hindi and Urdu data sets are represented in Devanagari.

Lexical data sparseness is considered as one of the major challenges in tackling the problem of data sparsity in data-driven approaches to natural language processing. A common approach to bridge the lexical gaps between the source and the target data is to use distributional similarity-based methods. The distributional similarity methods exploit Harris' distributional hypothesis which states that words that occur in the same contexts tend to have similar meanings (Harris, 1954). To address the lexical differences between Hindi and Urdu, distributional similarity-based methods seem as an appropriate choice. Consider a case of **pratikshā** and **intizār**, both words are semantic equivalents and have the same meaning i.e., **wait**. **pratikshā** is a Sanskrit word used in Hindi texts, while **intizār** is its Perso-Arabic equivalent used in Urdu texts. In both Hindi and Urdu, **pratikshā** and **intizār** form complex predicates with similar light verbs. One such complex predicate is **pratikshā/intizār kar** 'wait do'. The complex predicate takes a genitive-marked theme argument, licenses ergative case on its agentive argument in perfective aspect and can take similar tense, aspect and modal auxiliaries. Even though, **pratikshā** and **intizār** are different word forms, they have identical syntactic distributions which could be used as an approximation of their semantic similarity.

To capture the similarity between Sanskrit and Perso-Arabic words in Hindi and Urdu vocabularies, we could apply distributional similarity methods on the union of harmonized (represented in same script) Hindi and Urdu corpora. Augmenting source domain corpus with the target domain data to learn distributional representation of words is a common practice to address lexical sparseness encountered in domain adaptation tasks (Candito et al., 2011; Plank and Moschitti, 2013). We could also use bilingual word clustering or word embedding approaches which have been used to address the loss of lexical information in delexicalized parsing (Täckström et al., 2012; Xiao and Guo, 2014). In case of Hindi and Urdu, the former approach is more simple and direct way to capture the distributional similarity. The similar grammar and partially shared vocabularies would ensure semantically similar words of Hindi and Urdu are assigned similar distributional representations. The cross-lingual approaches, on the other hand, are computationally complex, while capture the distributional similarity indirectly using a seed bilingual

lexicon.

The distributional similarity can be incorporated in a statistical model either by using word clusters or word vectors (Turian et al., 2010). Similar to Collobert et al. (2011) and Chen and Manning (2014), we represent lexical units in the input layer of our neural network model by the word embeddings instead of one-hot vectors. We augment Hindi monolingual data with the transliterated Urdu data and use word2vec toolkit[6] to learn the word embeddings. The toolkit provides an efficient implementation of the continuous bag-of-words (CBOW) and skip-gram (SG) approaches of Mikolov et al. (2013) to compute distributed representation of words. To learn distributed word representations, we considered context windows of 2 to 5 words to either side of the central element. We varied vector dimensionality within the 50 to 100 range in steps of 10. The model choice, window size and vector dimensionality were selected on the development set in a POS tagging task. The optimal parameters are: learning algorithm as skip-gram, window size as 1, embedding dimensionality as 50 and minimum word frequency as 2.

Once we have represented both Hindi and Urdu texts in same distributional space, we model sharing and augmentation of their resources as a supervised domain adaptation task. Supervised domain adaptation assumes the availability of annotated data in both source and target domains to improve model performance in the target domain. We discuss the best practices in supervised domain adaptation and evaluate their performance for Hindi and Urdu resource sharing and augmentation. An overview of the supervised domain adaptation methods can be found in (Daumé III, 2007), which we repeat here briefly.

- The SRCONLY method trains a single model on the source data while ignoring any target data.
- The TGTONLY method trains a single model only on the target data and acts as the baseline.
- In the ALL method, we simply train our model on the union of the Hindi and Urdu training sets.
- In the WEIGHTED method, we weight the instances of a data set with larger instances to train a single unbiased model. The weights are appropriately chosen by cross-validation.
- In the LININT method, we train SRCONLY and TGTONLY models and linearly interpolate their predictions at the inference time. The interpolation weights are tuned via cross-validation.
- PRIOR method relies on the use of SRCONLY model as a prior on the weights of the target model while training. In our neural network model, we simply replace the regularization term with $\lambda||w - w^s||_2^2$ where w^s is the weight vector from the SRCONLY model.

Among these supervised methods, SRCONLY will address resource sharing, while WEIGHTED, LININT and PRIOR are the methods for resource augmentation.

4.1 Experiments and Results

In any non-linear neural network model, we need to tune a number of hyperparameters for an optimal performance. Tuning these parameters is usually as cumbersome as designing appropriate feature combinations in a linear model. The hyperparameters include number of hidden units, choice of activation function, learning rate, dropout, dimensionality of input units, etc. Furthermore, we had to tune these parameters for each individual task separately. Interestingly, we found that the hyperparameters take similar optimal values for all the three tasks. This could be due to the fact that POS tagging, chunking and parsing are correlated to each other. There is, however, some variation in learning rate and dropout. The optimal parameters include: 200 hidden units, rectilinear activation function, 20 batch size, 20 dimensional non-lexical input units, 0.01 learning rate for POS tagging and chunking and 0.3 for parsing, and 15 training iterations.

After tuning the hyperparameters of our neural network models, we trained multiple models for both Hindi and Urdu to evaluate the performance of each domain adaptation method. To use uniform POS and chunk features, we used 10-fold jackknifing to assign these features to the training data instead of using gold features. For chunking, we used the auto POS features from the best performing POS tagger. Similarly for parsing, we used the best POS and chunk taggers to generate these features. The results of our experiments are reported in Table 7.

[6] https://code.google.com/p/word2vec/

Source	Target	SRCONLY	TGTONLY	ALL	WEIGHTED	LININT	PRIOR
POS tagging							
Hindi	Urdu	89.34	93.42	93.74	93.77	**93.93**	93.52
Urdu	Hindi	86.06	96.48	96.50	96.54	**96.61**	96.22
Chunking							
Hindi	Urdu	92.53	96.03	96.40	96.31	**96.52**	96.13
Urdu	Hindi	90.27	97.64	**97.77**	97.63	97.71	97.44
Dependency Parsing							
Hindi	Urdu	78.93	82.28	82.64	82.53	**82.65**	82.32
Urdu	Hindi	75.12	88.32	**88.41**	88.37	88.39	88.18

Table 7: Results of different supervised domain adaptation methods on Hindi and Urdu resource sharing and augmentation.

For resource augmentation, it is encouraging to note that all the methods led to some improvement over the TGTONLY baseline. Surprisingly, PRIOR method did not perform well in our case. It was one of the best methods reported by Daumé III (2007) when used with a linear model. On the other hand, LININT consistently performed better than other methods. Nevertheless, we achieved substantial improvements in accuracies in all the three tasks for both Hindi and Urdu. Particularly, improvements in Urdu are more prominent. Our augmentation results clearly show that Hindi and Urdu annotations can be complementary to each other. In our case, large number of annotations in HDTB proved useful for parsing of Urdu, which comparatively has a smaller-sized treebank.

The SRCONLY models, under resource sharing experiments, did not perform at par with the TGTONLY baseline models. The performance is still better for Urdu (as a target domain) than it is for Hindi which again could be attributed to the sheer size of the Hindi training data. The larger gaps in accuracies between the SRCONLY and TGTONLY models can be attributed to domain shift problem inherent in data-driven approaches. To empirically verify it, we explored the impact of domain shift on the Hindi tagger and parser trained on newswire data by applying it on Hindi texts other than news articles. For this task we used annotated data from four different domains of Hindi which include cricket, recipes, gadgets and box office. Each domain contains around 500 hundred sentences annotated with POS, chunk and dependency structures. The accuracies of the Hindi parser and tagger on these domains is shown in Table 8. If we compare the accuracies of the Hindi POS tagger and parser on Urdu and the four domains, it appears that the performance on the Urdu test set is comparable. The tagging and parsing accuracies on gadget and recipe data are lower than the accuracies on the Urdu test data. This encourages us to suggest that we can consider Hindi and Urdu as two separate domains representing the same language at least in computational sense and use their tools interchangeably instead of building tools for them separately.

Domains	Parsing			POS tagging
	UAS	LS	LAS	
Cricket	87.90	85.26	79.72	94.02
Box-office	86.64	83.43	78.98	89.55
Gadget	83.27	81.30	75.35	85.93
Recipe	81.12	79.31	71.37	88.95
Urdu	86.13	83.15	78.93	89.34

5 Related Work

Recently, there have been several attempts at leveraging the similarity between Hindi and Urdu for sharing and interoperability of their individual resources. Most of the works suggest that Hindi and Urdu resources can be used interchangeably with some modifications (Sinha, 2009; Visweswariah et al., 2010). Sinha (2009) show that an English-Urdu machine translation system can be easily build by using Hindi as a bridge language. Urdu translations of English sentences are derived from the output of an existing English-Hindi MT system. They use lexical mappings between Hindi and Urdu words, lexical and syntactic disambiguation rules, and a transliteration module for converting the MT output to Urdu.

Adeeba and Hussain (2011) used a transliteration-based approach to create an Urdu WordNet from an existing Hindi WordNet (Narayan et al., 2002). They used a rule-based transliteration system to convert

the lexical database of the Hindi WordNet to Urdu (Perso-Arabic). They manually pruned typical Sanskrit words that are not used in Urdu texts and added additional entries specific to Urdu. Similarly Ahmed and Hautli (2010) proposed to use a simple transliteration-based approach to access Hindi WordNet for Urdu texts, instead of creating a separate Urdu WordNet.

Mukund et al. (2010) have explored the use of Hindi specific POS tagger and chunker on Urdu text. Both training and testing data are transliterated to a common form for model transfer. They show that Hindi POS tagger performs worst on Urdu text which suffered an absolute loss of 32.5% in accuracy from an Urdu specific tagger. Their observation is same for chunking, however the results are not reported due to lack of an evaluation set. Visweswariah et al. (2010) explore complementary role of linguistic resources present in Hindi and Urdu for better system performance. They show improvements in machine translation, bitext alignment and POS tagging.

Besides these empirical studies that show Hindi and Urdu can mutually benefit from sharing their individual resources, there are also arguments against any such endeavour (Riaz, 2009; Mukund et al., 2010; Prasad et al., 2012). In a theoretical study, Riaz (2009) argues that lexical divergences between Hindi and Urdu hinder the interoperability of their computational resources. On the basis of the extensive variation in their vocabularies, he argues that any method that relies on maximum likelihood estimation may not work jointly for both Hindi and Urdu.

Our work differs from these related works in multiple ways. Firstly, we showed that Urdu text processing suffers substantially by the use of an ambiguous script. For computational purposes, we argued to represent Urdu texts in Devanagari instead of Perso-Arabic. To that end, we proposed an efficient and accurate transliteration method that resolves the lexical ambiguity due to missing short vowels and ambiguous characters in Perso-Arabic writing. Secondly, in addition to resource sharing, we also showed that resource augmentation can improve the performance of individual text processing modules of Hindi and Urdu. Furthermore, to mitigate the effect of lexical sparsity, we also used distributional similarity-based method besides transliteration.

6 Conclusion

In this paper, we explored the possibility of sharing and augmenting annotation resources of Hindi and Urdu to improve the performance of their individual text processing modules. To bridge the script and lexical differences between their texts, we proposed a simple and efficient technique based on script transliteration and distributional similarity. We showed that we can easily abstract away from the orthographic differences between Hindi and Urdu texts by representing their lexicons in a same distributional space. As a proof-of-the-concept, we showed that by bridging their script and lexical differences we can enhance the performance of Hindi and Urdu dependency parsers by simply merging their training data. Moreover, our experimental results suggest that Hindi and Urdu parsers can even be used interchangeably with reasonable accuracies.

In the future, we would like to explore the possibility of merging the semantic role annotations in HDTB and UDTB for training a better semantic role labeler. It would also be interesting to see whether our observations related to resource sharing between Hindi and Urdu would hold for applications other than parsing.

Deeper syntax for better semantic parsing

Abstract

Syntax plays an important role in the task of predicting the semantic structure of a sentence. But syntactic phenomena such as alternations, control and raising tend to obfuscate the relation between syntax and semantics. In this paper we predict the semantic structure of a sentence using a deeper syntax than what is usually done. This deep syntactic representation abstracts away from purely syntactic phenomena and proposes a structural organization of the sentence that is closer to the semantic representation. Experiments conducted on a French corpus annotated with semantic frames showed that a semantic parser reaches better performances with such a deep syntactic input.

1 Introduction

FrameNet (Baker et al., 1998) is an English resource containing a set of inter-related semantic frames, each frame containing a set of semantic roles (*frame elements* in FrameNet's terminology). Frames offer semantic generalizations over individual predicates, since different lexical units can evoke the same frame, and semantic roles offer generalizations over syntactic arguments. Hence FrameNet parsing can be viewed as mixing predicate disambiguation and semantic role labelling.[1]

Although FrameNet is more semantically-oriented than other semantic role labeling resources such as PropBank (Palmer et al., 2005), syntactic information has been shown to be decisive for predicting (FrameNet) semantic roles since the early days of the task (Gildea and Jurafsky, 2002). Linking regularities provide the theoretical justification of this result: there exist regularities in how semantic arguments are realized in syntax. Yet it is well known that the mapping from syntactic arguments to semantic ones is not straightforward. First, lexical idiosyncrasies can come into play, for instance the *Addressee* of communication verbs may correspond to the indirect object for verbs like *to say* and to the direct object for a verb like *to inform*. Second, it is also well known that surface syntax exhibits variation that can obfuscate regularities. For instance though the *Speaker* is generally the subject of communication verbs, this does not hold when the verb is passivized. This difference disappears if syntactic alternations are neutralized, and the "canonical" diathesis of a verb is made explicit: the *Speaker* is the canonical subject in both active and passive voices.

In this paper, we investigate the syntax-semantic interface in FrameNet annotated data, and study the impact of using "deeper" syntactic features to predict semantic frames and roles. More precisely, we take advantage of a deep syntactic dependency graphbank for French (Candito et al., 2014b; Ribeyre et al., 2014), which provides a level of representation that abstracts away from purely syntactic variation. The main contributions of the paper are (i) a comparison of the syntax/semantic regularities observed when using plain "surface" syntax to those observed when using deep syntax and (ii) a study of how and why the switch from surface to deep syntax impacts FrameNet semantic parsing. In the remaining of the

[∗] All of his work has been done during his PhD at Alpage.

[1] In the following, we will use shorter terms than those of FrameNet terminology : we use the term *trigger* for a lexical unit that can evoke a frame, the term *role* for frame element, and *role filler* for the sequence of words that instantiates a role.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 409–420, Osaka, Japan, December 11-17 2016.

paper we will use the terms Surface Syntactic Representations (SSR) and Deep Syntactic Representations (DSR) to refer to surface syntactic trees and deep syntactic graphs.

Using abstract syntactic representations as an intermediate representation level between syntax and semantics has been proposed in different theoretical frameworks, such as derived trees of Tree Adjoining Grammars (Joshi and Schabes, 1997) or deep syntactic structures of the Meaning Text Theory (Mel'čuk, 1988). But we only found few works showing, empirically, that using such representations can effectively help predict the semantic roles of predicates.Two of them concern PropBank semantic role labeling. The early (Gildea and Hockenmaier, 2003) work shows that using CCG-derived predicate-argument features predicted by a CCG parser improves the identification of core PropBank arguments. Vickrey and Koller (2008) investigate the use of simplified syntactic paths and report a slight improvement when applying transformation rules to simplify phrase-structure parses.

As far as FrameNet parsing is concerned, we don't know of any work using more abstract syntactic input than plain "surface" syntactic trees, whether phrase-structure (Gildea and Jurafsky, 2002) or dependency trees (Johansson and Nugues, 2007; Das et al., 2014). We focus on French, first because of the availability of the afore-mentioned DSR, and second because in the French FrameNet corpus (Djemaa et al., 2016) the annotated semantic roles are restricted to essential arguments. On the contrary, both essential ("core") and non essential participants are annotated in the English FrameNet, including modifiers such as time, location, purpose etc... But syntactic variation such as syntactic alternations, VP coordination, control etc... does concern primarily the most salient grammatical functions (subject, direct object, indirect object etc...), which are typically the ones that essential arguments bear. Hence, neutralizing syntactic variation is expected to have an impact primarily on essential semantic roles.

The structure of the paper is the following: in section 2, we present (i) the French FrameNet corpus that we use, (ii) the deep syntactic representations whose impact for FrameNet parsing we wish to investigate, (iii) we compare the syntax/semantic interface when using surface dependency trees and deep dependency graphs and (iv) we compare such deep representations to other deep representations proposed mainly for English. Section 3 and 4 are devoted to the frame-semantic parser and the deep-syntactic parsing architecture we used. We present and discuss the frame-semantic parsing experiments in section 5, and conclude in section 6.

2 Deep syntax and frame semantics

2.1 French FrameNet corpus

The French FrameNet annotated corpus (Djemaa et al., 2016) was produced within the ASFALDA ANR project on French shallow semantic parsing[2]. Two corpora have been annotated with frames and roles: the French Treebank (Abeillé and Barrier, 2004) (hereafter FTB) and the Sequoia Treebank (Candito and Seddah, 2012b). The first one contains $18,535$ sentences from the *Le Monde* newspaper. The second one is much smaller and was originally created for domain adaptation experiments for statistical parsing. It contains $3,099$ sentences from a regional newspaper, from Europarl, from the European Medicine Agency and from the French Wikipedia.

The French FrameNet corpus annotation is restricted to four semantic domains: commercial transactions, cognitive stances, verbal communication and causality. For all lexical items of the lexicon, associated with frames pertaining to these domains, the first 100 occurrences have been annotated. For each occurrence to annotate, annotators were proposed the pertaining frames, plus a special null frame for the cases in which the occurrence evoked a sense not pertaining to the four domains. We provide quantitative characteristics of the corpus in Table 1. The semantic annotations cover 105 frames, and the lexicon extracted from the annotations contains 1112 frame/lemma pairs (i.e. senses). The corpus contains $15,990$ annotated frame occurrences (plus 8727 occurrences of the null frame[3]), 56.2% of which correspond to verbal triggers and 33.0% to noun triggers.

[2]Version 1.0, https://sites.google.com/site/anrasfalda/

[3]The null frame is used to annotate words that would trigger a frame that has not been defined yet. Note that trigger occurrences ahead of the first 100 occurrences do not bear any frame at all, and are not to be considered.

Nb. Sentences	21 634	Nb. annot. frame occurrences	15 990
Nb. Tokens	625 951	Nb. annot. role occurrences	24 147
Nb. distinct annot. frames	105	Mean nb. annot. frames per lemma	18.3
Nb. distinct annot. lemma/frame pairs	1112	Median nb. annot. frames per lemma	6

Table 1: Quantitative characteristics of the French FrameNet annotated corpus (excluding the null frame).

2.2 Deep syntactic representations

We now turn to the deep syntactic graphbank that we use as an alternative syntactic representation for FrameNet parsing. DSRs are available for the two corpora that were annotated with frames and roles (the Sequoia corpus and the French Treebank). The development set of the Sequoia corpus was used to set up the deep syntactic annotation scheme, as well as a surface-to-deep syntax conversion module (Ribeyre et al., 2014) based on a graph-rewriting tool (Ribeyre et al., 2012). While the DSRs were manually validated for the full Sequoia corpus, those for the FTB sentences were automatically obtained using this surface-to-deep syntax conversion module, described in section 4. The quality of the resulting DSRs is high enough to use them as a reference for evaluation[4].

Candito et al. (2014b) define DSRs as dependency graphs which abstract away from purely syntactic variations, as far as verbal and adjectival predicates are concerned, making explicit their predicate-argument structure. SSR and DSR differ on three aspects:

- **Saturation:** The predicate-argument structure of all verbs is saturated for verbs that are not the head of a saturated clause (e.g. coordinated verbs, infinitival verbs). Any element that does not locally depend on the verb but that would do so if the verb were the head of a clause is added as (deep) dependent of the verb. First, this means that arguments shared by several verbs, e.g. in elliptic coordinations or control verb constructions, are attached to all their deep governors. For instance in *Paul loves to eat pies*, *Paul* is the subject of both *loves* and *eat*, and in *Paul loves and often eats pies*, the two coordinated predicates *loves* and *eats* share the same subject *Paul* and direct object *pies*. Second, noun-modifying verbs get the noun as deep syntactic dependents. For instance in *People born before 1969 fear the moon*, the verb *born* gets *People* as subject.
- **Syntactic alternations:** Productive syntactic alternations are neutralized. Syntactic arguments of verbs get their *canonical* grammatical function, which may differ from the observed grammatical function. The most frequent alternations are the passive alternation, then middle and neuter alternations, each marked with a *se* clitic. Other more marginal alternations are impersonal, impersonal passive and causatives. Note that alternations frequently interact with predicate-argument structure saturation. For instance, in *Paul would like to get an interview and then be hired*, *Paul* is added as canonical subject of *get* but canonical object of *hired*. In noun-modifying participial clauses, if the verb is transitive, the past participle is analyzed as a passive. For instance in *People hired after march are few*, the verb *hired* gets *People* as canonical direct object (see also the verb *poussée (urged)* in figure 1).
- **Abstraction:** Most grammatical markers are discarded. Auxiliaries in particular are replaced by deep features on the lexical verb. Empty prepositions and complementizers are bypassed For instance in *Le chat sourit à la souris (The cat smiles to the mouse)*, the preposition *à* is discarded, and the indirect object of the verb is the NP *la souris (the mouse)*.

By extension, the subjects[5] of adjectives are made explicit in the DSRs.

The DSRs are closer to predicate-argument structures than SSRs are, yet predicates are not disambiguated, and thus canonical grammatical functions are used and not semantic roles.

Figure 1 shows the SSR, DSR and FrameNet annotations for one sentence (the role fillers are reduced to their syntactic head, cf. section 2.3). It can be seen, for instance, that the past participle *poussée*

[4]Ribeyre et al. (2014) report a 98.4 Fscore evaluated on manually validated DSRs for 200 sentences from the FTB.

[5]The subject of the adjective is either the noun it modifies in case of an attributive adjective, or the subject of the copular verb in case of a predicative adjective.

(urged) modifies the proper noun *EDF* in both syntactic representations, but the noun is its canonical direct object in the deep representation.

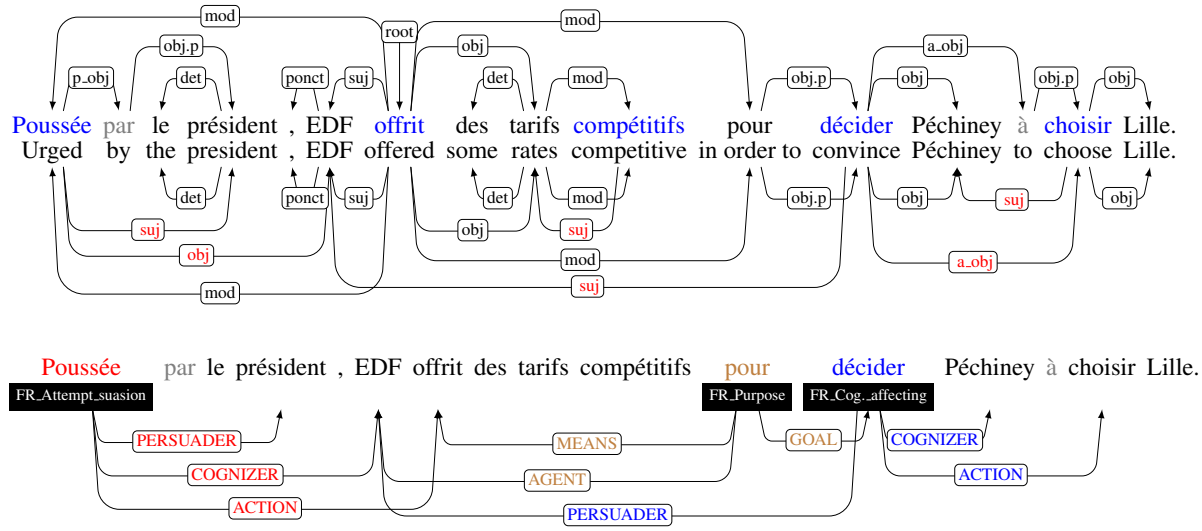

Figure 1: Example of syntactic and semantic annotations for a sentence. **Top**: Surface and deep syntactic representations (edges above: SSR, edges below: DSR). Verbs and adjectives are in blue. Tokens discarded in the DSR are in gray. Grammatical functions added and/or normalized when switching from SSR to DSR are in red. **Bottom**: frame and role annotations (from trigger to syntactic head of role fillers), for three triggers (2 verbs and 1 preposition).

2.3 Syntax semantics interface

As already mentionned in the introduction, syntax is a major feature when predicting semantic roles. Reducing the variety of syntactic features might therefore help fighting against data sparsity and improve this prediction task. Because they are meant to neutralize syntactic variations, DSRs are good candidates for such a reduction. In all the following, we will use as syntactic features the syntactic paths that link a frame trigger to the syntactic head of each of its role fillers (the head is taken as the leftmost root of the subtrees composing the role filler). In this section we will measure how much the use of DSRs helps to reduce the variety of syntactic paths. In order to do so, we will compute the entropy of the probability distribution of the syntactic paths that correspond to a role. Two entropies will be compared: the *surface* syntactic entropy and the *deep* syntactic entropy.

Before defining surface and deep syntactic entropy, we need to define precisely the notions of semantic path: deep syntactic path (DSP) and surface syntactic path (SSP). Given sentence S that contains an occurrence of frame F having word t as trigger and which role R is filled by a sequence of tokens W (the role filler, which may be discontinuous). We will call the tuple (t, R, W) a semantic path of S.

We associate to every semantic path $p = (t, R, W)$ of sentence S a surface syntactic path $SSP(p)$ and a deep syntactic path $DSP(p)$, which link the trigger to the head of the role filler W, noted $h(W)$.

$SSP(p)$ is the shortest path linking t and $h(W)$ in the SSR of S. The SSR being a tree, such a path exists and is unique, it is the sequence of dependencies that link t to $h(W)$. We represent it formally as a sequence of tuples *(direction,label)*, where *direction* is + if a dependency is traversed from the governor to the dependent and - otherwise.

Defining DSP is not as straigtforward: the DSR being a graph, there can be several shortest paths[6] from t to $h(W)$. We select a unique shortest path using the following hierarchy of grammatical functions to rank paths of length one: $suj > obj > ats/ato > a\_obj > de\_obj > p\_obj > mod$.[7] The left part of Table 2 shows the five most frequent syntactic paths, when the trigger is a verb, using either surface or

[6] Actually, since deep syntax can form non connected oriented graphs, there can be no path at all between t and $h(W)$ (due to errors in deep syntax or in semantic annotations). We use the special tag *__no_path__* in such cases.

[7] With $a > b$ meaning a has priority over b and a/b meaning a has the same priority as b.

surface syntax		deep syntax	
(+suj)	25.02%	(+suj)	33.1%
(+obj)	17.01%	(+obj)	32.79%
(-mod)	8.04%	(+a_obj)	4.73%
(+obj,+obj.cpl)	4.42%	(-mod)	3.15%
(+a_obj,+obj.p)	4.09%	(+mod,+obj.p)	2.46%
Total	58.58%	Total	76.23%

role	synt. head	syntax	path
PERSUADER	*EDF*	surface	(-obj.p,-mod,+suj)
		deep	(+suj)
COGNIZER	*Péchiney*	surface	(+obj)
		deep	(+obj)
ACTION	*choisir*	surface	(+a_obj,+obj.p)
		deep	(+a_obj)

Table 2: **Left**: Most frequent gold syntactic paths in training corpus, when the trigger is a verb. **Right**: surface and deep paths for the *FR_cognizer_affecting* frame evoked by *décider* in the sentence of Figure 1.

deep syntax. We can see that the distribution of paths is much more compact when using deep syntax : the first five paths represent more than 76% of deep paths, compared to 58% for surface paths. (obj) and (suj) paths represent 42.03% of SSP but 65.89% of DSP (in order to reach that coverage with SSP, the 8 most frequent SSP are needed).

The right part of Table 2 shows the deep and surface paths corresponding to the roles of the *FR_cognizer_affecting* frame evoked by *décider* in the sentence of Figure 1.

In order to measure the reduction of the variety of the syntactic realization when moving from surface to deep syntax, we have computed the average entropy over all roles R of the probability distributions $P(p|R)$ where p is a path. These distributions have been estimated on the training corpus. The average entropy when computed on surface syntax is equal to 1.65 and to 1.32 when computed on deep syntax. This decrease is a direct measure of the normalizing effect of the deep syntactic frame we used. Note though that an entropy reduction could be artificially obtained by neutralizing meaningful syntactic distinctions. Yet, the DSRs were designed following syntactic principles and experiments in section 5 are intended to check that such a normalization is indeed beneficial for downstream semantic parsing.

2.4 Comparison with other deep representations

There has been various previous works proposing deeper syntactic annotation schemes that can represent information absent in plain constituency or dependency trees, such as long-distance dependencies, subjects of control verbs, subjects of coordinated verbs etc. This additional information is sometimes viewed as pertaining to semantic representations, sometimes retained as still syntactic.

English has been the first focus language, along with Czech thanks to the Prague Dependency Treebank (Hajič et al., 2006). For English, several works automatically convert Penn Treebank constituency trees into deeper representations, based on lexicalized grammar formalisms such as LFG, CCG or HPSG. Cahill et al. (2004) automatically construct LFG f-structures from PTB trees, a work adapted for various other languages including French (Schluter and van Genabith, 2008). Hockenmaier and Steedman (2007) extracted a corpus of CCG derivations and dependency structures from the Penn Treebank. These two kinds of deeper representations do capture long distance dependencies, subjects of non finite verbs, argument sharing between coordinated verbs. When compared to the DSRs we use though, the main missing trait is the neutralization of syntactic alternations, which we believe is a major source for the syntactic path normalization effect described in section 2.3[8].

The Stanford dependencies (SD, De Marneffe and Manning (2008)) constitute another proposal for obtaining dependencies not directly present in surface syntactic trees. The stanford parser comprises a dependency extraction system, which can output several variants of typed word-to-word dependencies, from plain dependency trees to more semantically-oriented graphs. The deepest variant ('collapsed with propagation of conjunct dependencies' variant) does cope with some of the aforementioned phenomena such as subject of infinitival verbs or coordinated verbs. Compared with the DSRs for French, the major differences are that syntactic alternations are not neutralized, and that all prepositions are collapsed and injected in the labels (while only void prepositions are collapsed in the French DSRs).[9]

[8]Passive alternations is by far the most frequent alternation, and also happens to be rather easy to identify, so we hypothesize that using such representations on top of passive neutralization would be an alternative to the DSRs we use.

[9]We actually did some unfruitful experiments on the English FrameNet data, comparing the use of syntactic features ex-

Taking a further step towards semantic representations, predicate-argument structure graphs such as those used for the Broad-Coverage Semantic Dependency Parsing task at SemEval 2014 (Oepen et al., 2014) are also very close to the DSRs we use, with respect to the covered linguistic phenomena. The three datasets used in this shared task are (i) predicate-argument semantic graphs extracted from the HPSG-grounded DeepBank of Flickinger et al. (2012), (ii) predicate-argument structures from the Enju HPSG Treebank [10], and (iii) the Prague Czech-English Dependency Treebank (Hajič et al., 2012). These three datasets differ in how far they differ from syntactic representations. While some traits are common to the DSRs we use, one major difference lies in the more semantically-oriented labelling of the word-word dependencies: the semantic arguments are simply numbered (arg0, arg1, etc...). We believe that in the absence of word sense disambiguation at the level of predicates, this plain numbering obfuscates syntactic clues that are crucial for FrameNet semantic role labelling. If we take a French example, the verb *convenir* has two senses (among others), in which the arguments bear different FrameNet roles, and which can be disambiguated by the canonical subcategorization frame: we have *X(subject) convenir à Y(a-object)* meaning "X suits Y" versus *X(subject) convenir de Y(de-object)* meaning "X admit to Y".

To sum up, while the various deep representations cited above do capture the topology of predicate-argument structures, by coping with major phenomena such as control verbs or coordinated verbs, the DSRs are appealing for framenet parsing for two reasons: first they are still syntactic in nature (they are thus recoverable deterministically from surface syntax, cf. section 4), while a semantic graph would represent a too sophisticated input for the task. Second, the DSRs use canonical grammatical functions, which are both more abstract than surface grammatical function labels, but do not obfuscate important syntactic clues for predicate and role disambiguation.

3 Semantic parser

The semantic prediction system (FastSem) is a baseline system based on a cascade of linear classifiers[11]. For every word w of a sentence, we proceed in two steps. A *frame* identification step (which frame (if any) does w trigger?) followed by a *role* identification step (which role (if any) is w the head of?). This architecture is based on two strong independence hypotheses: frames are independent from one another in a sentence and roles inside a frame are independent[12].

We chose to use a simple architecture as our focus here is to assess whether normalized syntactic paths help semantic parsing. It remains to be proved, although it can be easily supposed, that it would also help with less naive hypotheses.

In the first step we use for each lexical unit a different linear classifier, each using the following features: the fine- and coarse-grained PoS of the target word t, and for each word w of the sentence, its lemma, its PoS (fine and coarse) and the syntactic path that links t to w. The classifier used for the second step is frame specific. To predict the role of word f, we use as features the lemma and PoS (coarse and fine) of f, t's lemma and fine-grained PoS, the syntactic path between t and f, plus the combination of the syntactic path and the lemma of t.

4 Predicting deep syntax

In order to evaluate the impact of deep syntax on semantic parsing in realistic conditions, we need to obtain predicted deep syntactic representations. Although directly training a graph parser would be an option (as in (Ribeyre et al., 2016)), we retain the rule-based architecture that was used to bootstrap the deep syntactic annotations. Our motivation is to be able to apply the surface-to-deep rewriting rules step-by-step, in order to study the impact of each phenomenon.

tracted from two variants of SD (basic versus collapsed with propagation of conjunct dependencies). We concluded that the collapsed dependencies are not adapted for our purpose: they no not neutralize syntactic alternations, and multiply labels by collapsing all prepositions. We could measure that this has the result of actually increasing the entropy of the syntactic paths that correspond to a role. Preposition collapsing has a negative impact on predicting non essential semantic roles, such as temporal or locative modifiers.

[10] See http://kmcs.nii.ac.jp/enju

[11] The classifier library used is LIBLINEAR (Fan et al., 2008).

[12] These hypothesis are known to be too strong. For instance Das et al. (2014) show that collectively predicting all role fillers of a given frame occurrence improves performance.

	Surface dependency parser		Conversion to deep syntax			
			on predicted surf. parses		on gold surf. parses	
	UAS	LAS	UF1	LF1	UF1	LF1
trainjk	86.9	83.5	83.5	80.4	99.7	99.5
dev	87.5	84.1	84.1	81.0	99.7	99.4
test	86.6	83.3	83.5	80.5	99.7	99.5

Table 3: Parsing performance. Columns 2 and 3: unlabeled and labeled attachment scores of the (surface) dependency parser. Last four columns: unlabeled and labeled F-scores after classification of *il/se* clitics and conversion to deep syntax, applied either on the predicted surface dependency parses (columns 4 and 5) or on the gold dependency parses (last 2 columns). Results on the training set are obtained using a 10-fold jackknifing. Results on the dev and test set are obtained using training on the full training set.Punctuation tokens are taken into account.

The surface-to-deep syntax conversion module of Ribeyre et al. (2014) takes as input surface dependency trees in which a few linguistic phenomena have already been made explicit, because they were considered difficult to capture by a rule-based approach. This is in particular the case for the status of the *il* and *se* clitics, which results from complex syntactic and lexical factors. In order to do so, we designed two classifiers that predict the status of these clitics. We omit to describe here these classifiers as well as their evaluation, for reason of lack of space.

The architecture of our deep syntactic parser is to apply sequentially **(i)** part-of-speech tagging and lemmatization, **(ii)** surface dependency parsing and **(iii)** surface-to-deep syntax rewriting rules.

Tagging and syntactic parsing were performed with MACAON (Nasr et al., 2011), a tool suite for standard NLP tasks. The tagging is based on a CRF model whereas the dependency parser is a second order graph-based parser, with standard features. We report parsing performance in Table 3 (first two colums). The scores are comparable to the baseline scores obtained by the SPMRL shared task participants on French (Björkelund et al., 2013), without any special handling of multi-word expressions.

The last step consists in applying the surface-to-deep syntax conversion module (Ribeyre et al., 2014). This module uses OGRE (Ribeyre et al., 2012), a deterministic two-stage graph rewriting system.

The first stage follows the Single Pushout Approach (SPO) (Rozenberg, 1997), a widely used method when dealing with graph rewriting system. This stage identifies graph patterns and applies rewriting operations such as adding an edge, removing an edge, changing a label, and so on. This is done in one pass and contrary to the SPO approach, the first stage is executed only once.

The second stage is a propagation step. During the first stage, the rewriting rules may have left what we call *triggers* on edges. Those are special actions that, given a specific edge configuration, apply a serie of rewriting steps using a fixed-point algorithm: when all possible rewritings have been done, the algorithm terminates. It is especially helpful in case of linguistic phenomena interacting with each other. In the SSR of the sentence *John seems to want to give a book to Mary*, for example, *John* is the subject of *seems* and *want* is a dependent of *seems* and *give* a dependent of *want*. Ultimately, in the DSR, *John* is the subject of both *want* and *give*. The interaction between raising and control verbs is obtained through the propagation of rules of the form "if V_1 taking V_2 as complement has or gets a final subject X then add X as final subject of V_2". Moreover, the two-stage rewriting system ensures that the algorithm terminates and the system is confluent. See (Ribeyre, 2016) for more details and proofs.

The surface-to-deep syntax module applies sequentially 5 sets of rewriting rules:

1. The first set converts tense auxiliaries into mood and tense features on the lexical verb.
2. The second set distributes dependents of coordinated predicates and identifies the final subject of non finite verbs and by extension, of adjectives also, whether used as predicative complements or noun modifiers.
3. Syntactic alternations are mainly handled in the third set, which identifies the canonical grammatical functions for arguments of verbs (whether already present in the surface tree, or added by the second

	Prec.		Recall		F-measure		Prec.		Recall		F-measure	
Input	SSR	DSR	SSR	DSR	SSR	DSR	SSR	DSR	SSR	DSR	SSR	DSR

module).

4. The fourth set handles comparative and superlative constructions mostly.
5. The last set exclusively deals with bypassing the semantically empty words.

We provide the performance evaluation of DSR prediction step in Table 3. Columns 4 and 5 show the result of the whole parsing architecture, where steps (i), (ii) and (iii) are predicted. The last two columns show the result of applying step (iii) on gold SSR. Not surprisingly, the DSR built from gold SSR are almost perfect. This is due to the fact that the deep syntactic corpus contains gold DSR for the small Sequoia part only, the other part, which corresponds to the FTB, is made of pseudo-gold DSR obtained by the application of step (iii) on gold SSR ! The table shows the sharp drop in quality when DSR are computed on predicted SSR.

5 Experiments and discussion

We now turn to FrameNet parsing experiments, meant primarily to compare the use of surface versus deep syntactic paths as features. All experiments were used using the same split.[13] Feature engineering was performed on the development set.

5.1 Evaluation metrics

The train, dev and test examples are made of the set of annotated frame occurrences of the train, dev and test sets, including the null frame cases. For each setting, we trained word specific classifiers for the frame selection step and frame specific classifiers for the role selection step. But, since selecting the null frame is a rather easy task, we chose to evaluate each of the two steps using two different metrics. For frame selection, we first evaluate the task of deciding whether a word triggers an actual frame or the null frame. The results are reported in lines "trigger detection" of Table 4. The "frame selection" lines report the precision, recall and F-scores of choosing a frame, computed when setting aside the triggers whose gold frame is the null frame.

For role labeling, prediction and evaluation is made on heads of role fillers only. It is also broken in two: we first evaluate the task of deciding whether a word plays a role or not with respect to the trigger (reported in the "role detection" lines in the result tables). Then, for words that are actually head of role fillers in gold data, we compute precision, recall and F-score of the head and role pairs predicted by our semantic parser (reported in the "role selection" lines in the tables). Note that in both cases, the role is counted as incorrect if the frame was not predicted correctly.

5.2 Results and discussion

The experiments conducted vary according to two dimensions: the use of surface vs. deep syntactic paths (SSP or DSP) and whether they are predicted or gold. The predicted SSP are obtained using predicted PoS, lemmas, morphological features and surface dependency syntax. The predicted DSP are obtained by applying *il/se* classification and rewriting rules on predicted surface dependency trees (cf. section 4). All results are computed on the test set.

The left part of Table 4 shows results using gold syntactic structure, whether surface or deep. As can be seen, the results for the first three metrics slightly increase when switching from SSP to DSP, but

[13]The training set is the concatenation of the usual training sets of the Sequoia and FTB corpus. Same for the development and test sets.

	Prec.		Recall		F-measure		Prec.		Recall		F-measure

	SSP	DSP				
		all	alt	byp	subj	coo
gold	68.5	74.3	70.6	69.1	69.3	70.2
predicted	61.3	68	63.3	63.1	62.4	63.1

Table 6: FastSem F-measure for role selection with application of deep rewriting rule sets in isolation, for verbal triggers. Rules are applied on SSP that are either gold (first row) or predicted (last row). The first column reports the results when using SSP. The second when using DSP with all rules applied. See text for description of the rule sets (alt) to (coo).

we obtain a 4.2 point improvement for the overall result of role selection when using DSP instead of SSP (63.9 to 68.1). Because our DSR focus on the predicate argument structure of verbs and adjectives, and because the number of adjectival triggers is marginal in the French FrameNet corpus, we chose to provide, in Table 5, the same metrics as in Table 4, computed on verbal triggers only. As one can see, using deep syntax provides substantial help for predicting roles: we obtain a 6.4 point improvement for role selection for verbal triggers (68.5 to 74.9).

We now turn to a more realistic setting in which all features for the semantic parser are predicted: lemmas, PoS, SSP and DSP. Not surprisingly, the results shown in Table 4 (all triggers) and 5 (verbal triggers) are overall lower than when using gold features. However, switching from surface to deep syntax leads to higher gain for predicted data than for gold data: 5.1 points (56.7 to 61.7) for all trigger, instead of 4.2 for gold data and 6.7 points (61.3 to 68) instead of 6.4 on gold data for verbal triggers. These results clearly show the benefit of using deep syntactic features.

The differences between SSP and DSP are of various kinds, as seen in section 2.2. We propose to study the impact of each phenomenon, by applying in isolation each set of graph-rewriting rules of the surface-to-deep syntax conversion module. More precisely, we applied in isolation (alt) the rules for syntactic alternations, (byp) the bypassing of empty prepositions and complementizers, (subj) the addition of subjects for non finite verbs and adjectives and (coo) the distribution of dependents to coordinated predicates. We provide the results in Table 6, for the role selection task, computed on verbal triggers only. It shows that every rule set contributes to a better prediction of the semantic structure.

5.3 Error analysis

In order to perform error analysis, we analyzed the changes in role selection when switching from SSP to DSP (table 7). The number of corrected errors (W→C) is more than four times the number of introduced errors (C→W). We reproduce below three cases of errors that were corrected when switching from surface to deep syntax. They correspond to syntactic alternation (1), coordination of VPs (2) and control verb (3). The trigger is in capital letters, and the (head of) role fillers we focus on are in bold:

	C→C	C→W	W→C	W→W
predicted	1163	47	218	481
gold	1362	48	203	316

Table 7: Improvements and degradations for role selection when switching from SSP to DSP, using either gold syntax (first row) or predicted syntax (second row). Break-down of the non-null gold roles of the dev set, when frames are correctly identified by both systems. C stands for correct, W stands for wrong.

freq. range	G1 (frequent) $> 10\%$		G2 (medium) $< 10\%$ and $> 1\%$		G3 (rare) $< 1\%$	
	Prop.	F1	Prop.	F1	Prop.	F1
SSR	42.1%	89.2	33.1%	78.3	24.8%	38.3
DSR	65.9%	92.3	14.3%	75	19.8%	23.5

Table 8: Role selection task results on the dev set, using gold frames triggered by verbs: break-down by frequency (in the training set) of the gold syntactic path. "Prop." columns provide the proportion of each sub-group.

1. *Cette **thérapie** a été DÉCIDÉE par le **gouvernement***
   (This therapy has been decided by the government.)
   thérapie: DSP=(+obj) SSP=(+subj) **gouvernement**: DSP=(+subj) SSP=(+p_obj,+obj.p)

2. ***Grandier** avait publié un pamphlet et S'OPPOSAIT fermement à la destruction des murailles.*
   Grandier had published a pamphlet and was firmly opposed to the destruction of the walls.
   Grandier: DSP=(+subj) SSP=(-dep.coord,-coord,+subj)

3. ***Ils** ont essayé de les PERSUADER de bouleverser le calendrier.*
   They have tried to them persuade to change the schedule.
   Ils: DSP=(+subj) SSP=(-obj.p, -de_obj, +subj)

We also took a closer look at the introduced errors. They mostly correspond to cases in which the role filler has same surface and deep syntactic path, the path being rather unusual for the role filler. This may indicate that increased regularity of the DSP makes role fillers with unusual syntactic path more difficult to detect. We tried to assess this hypothesis by breaking-down the performance of the role selection task by frequency of the syntactic paths between the head of the role filler and the trigger. Results are shown in table 8. The frequent paths (G1) lead to better role prediction than the other two groups, and this is even more true when using DSRs than SSRs (92.3 versus 89.2). This explains most of the improvements, since this group represents a higher proportion when using DSRs than SSRs (65.9 versus 42.1). For less frequent paths (G2 and G3), results are either slightly (G2) or much (G3) better when using SSRs than DSRs, but these two groups represent a much lower proportion in the DSR paths than in the SSR paths. To sum up, frequent paths are even more frequent when using DSRs, and thus lead to better role prediction, whereas the non frequent paths exhibit the opposite trend.

6 Conclusion

In this paper we showed that frame semantic structure prediction can benefit from a deeper syntactic representation, in which the syntactic paths between a verb and its arguments are normalized. This reduces the variety of the syntactic realization of semantic roles, which we assessed by measuring a decrease of the entropy of the syntactic paths of a given role. We then showed that a FrameNet semantic parser can take advantage of this simpler syntax/semantic interface and reach better performance when switching from surface syntax to deep syntax.

Abstract

We present a dependency to constituent tree conversion technique that aims to improve constituent parsing accuracies by leveraging dependency treebanks available in a wide variety in many languages. The technique works in two steps. First, a partial constituent tree is derived from a dependency tree with a *very simple* deterministic algorithm that is both language and dependency type independent. Second, a complete high accuracy constituent tree is derived with a constraint-based parser, which uses the partial constituent tree as external constraints. Evaluated on Section 22 of the WSJ Treebank, the technique achieves the state-of-the-art conversion F-score 95.6. When applied to English Universal Dependency treebank and German CoNLL2006 treebank, the converted treebanks added to the human-annotated constituent parser training corpus improve parsing F-scores significantly for both languages.

1 Introduction

State-of-the-art parsers require human annotation of a training corpus in a specific representation, e.g. constituent structure in Penn Treebank (Charniak and Johnson, 2005; Petrov and Klein, 2007) or dependency relations in a dependency treebank (Yamada and Matsumoto, 2003; McDonald et al., 2005) . Creation of human-annotated treebanks, however, is knowledge and labor intensive and it is desired that one can improve parsing performance by leveraging treebanks annotated in representations of a wide variety.

While there have been quite a few papers on automatic conversion from dependency to constituent trees and vice versa (Wang et al., 1994; Collins et al., 1999; Forst, 2003; de Marneffe et al., 2006; Johansson and Nugues, 2007; Xia et al., 2008; Hall and Nivre, 2008; Rambow, 2010; Wang and Zong, 2010; Zhang et al., 2013; Simkó et al., 2014; Kong et al., 2015) , very few papers address the issue of whether or not the converted treebank actually improves the performance of the target parser when added to the human-annotated gold treebanks for parser training. In addition, much of the work on dependency to constituency conversion relies on dependency trees automatically derived from the Penn Treebank (Marcus et al., 1993) via head rules and assumes that the head-modifier definitions are consistent between the constituent and dependency trees (Xia et al., 2008). However, such techniques cannot easily generalize to dependencies that diverge from the Penn Treebank in head-modifier definitions and dependency labels, e.g. Universal Dependency (Nivre et al., 2015) in Figure 1(b), and the dependencies of a wide variety available in CoNLL shared tasks.

In this paper, we propose a *very simple* dependency to constituent tree conversion technique which is applicable to any languages and any dependencies, e.g. Universal Dependency (UD), CoNLL dependencies (CoNLL), Stanford dependencies (Stanford), while achieving the state-of-the-art conversion accuracy. The technique works in two steps. We first derive a partial constituent tree from a dependency tree according to a simple deterministic algorithm without any external knowledge sources such as head rules. The partial constituent tree retains the gold part-of-speech tags (POStags) and partial contituent brackets inferred from the dependency tree (in Section 2). We then recover the complete constituent

(a) Penn Treebank Constituent Tree

(b) Universal Dependency

(c) CoNLL Dependency

(d) Stanford Dependency

Figure 1: Penn Treebank Constituent Tree (a), Universal Dependency (b), CoNLL Dependency (c) and Stanford Dependency (d) representations for *Retailers see pitfalls in environmental push*. The preposition *in* is the head of *push* in the Penn Treebank, CoNLL and Stanford Dependency, whereas it is the modifier of *push* in the Universal Dependency. None of the dependency labels overlap with the Penn Treebank phrase labels. A dependency arrow goes from a head to its modifier.

structure and labels by a constraint-based parsing which uses the gold POStags and partial brackets as parsing constraints (in Section 3).

Evaluated on WSJ-22 for conversion accuracy, the proposed technique achieves the labeled F-score of 95.62 for conversion from the Stanford (de Marneffe et al., 2006) basic dependency (in Section 4). When applied to the English Universal Dependency (UD) treebank and German CoNLL2006 treebank, the converted treebanks added to the human-annotated constituent parser training corpus improve the F-scores of BerkeleyParser [1] (Petrov and Klein, 2007) and Maximum Entropy (MaxEnt) parsers significantly for both languages (in Section 5). While most of the previous work applies dependency to constituent tree conversion on the dependencies automatically derived from the Penn Treebank, the current work applies the technique to human-annotated English UD treebank as well. The constituent parser performance improvement due to the addition of converted treebanks is the first reported for English and German (in Section 6).

Throughout the paper, we use the notation CTree for a constituent tree, DTree for a dependency tree and UDTree for a universal dependency tree. We use the term 'constituent' and 'phrase' interchangeably. Conversion and parsing accuracies are reported in labeled F-scores.

2 Dependency to Partial Constituent Tree Conversion

We first derive a partial constituent tree from the source dependency tree. The partial constituent tree retains all of the human annotated part-of-speech tags and partial constituent brackets inferred from the source dependencies. Figure 2 is the deterministic algorithm that derives a partial CTree from any given DTree, where the dependency span of a word is a consecutive word sequence reachable from the word by head modifier relations.

Note that the algorithm in Figure 2 does not require any external knowledge sources such as head rules learned from the target CTrees. It applies to any DTrees that make a reasonable linguistic assumption on head-modifier relations regardless of languages and dependency types. This *simplicity* sets the current proposal apart from all of the previous proposals that rely on linguistic rules, as in (Xia et al., 2008), statistical model utilizing manually acquired head rules and the phrase labels of the target constituent treebank, as in (Kong et al., 2015), or a scoring function that computes the similarity between the source DTree and the nbest parsing output of the DTree sentences by the target constituent parser, as in (Niu et al., 2009).

[1] https://github.com/slavpetrov/berkeleyparser

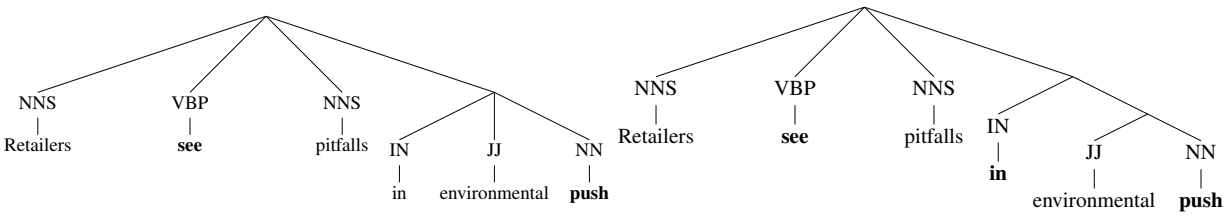
input: DTree (labeled or unlabeled) with *n* input words
output: Unlabeled CTree with gold POStags and partial constituent brackets

Step 1: Identify the dependency span D_i of each word w_i
if *the word* w_i *does not have any dependent* **then**
  D_i is length 1, containing only w_i itself;
else
  D_i subsumes all of its dependents recursively;

Step 2: Convert a dependency span D_i to a constituent C_i
Vertex of C_i dominates the immediate dependents of the head word and the head word itself.

Step 3: Remove all constituent brackets containing only one word.

Figure 2: DTree to unlabeled partial CTree Conversion Algorithm



(a) Partial CTree derived from UDTree in Figure 1(b)

(b) Partial CTree derived from DTrees in Figure 1(c, d)

Figure 3: Partial CTrees derived from the DTrees in Figure 1 according to the algorithm in Figure 2

The UDTree in Figure 1(b) is converted to the partial CTree in Figure 3(a) and the DTrees in Figure 1(c, d) are converted to the partial CTree in Figure 3(b) according to the algorithm in Figure 2. The head word of each constituent is in bold-face. Similarity of the head-modifier definitions between the target CTree and the source DTree is reflected on the partial CTrees. The partial CTree in Figure 3(a) derived from the UDTree leaves more ambiguity within the prepositional phrase covered by *in environmental push* than the one derived from CoNLL or Stanford DTrees. Similarity between a given DTree representation and the Penn Treebank CTree is reflected on the conversion accuracy reported in Section 4.

3 Constraint-based Maximum Entropy Parsing

To derive the fully specified labeled CTree from a partial CTree, we parse the input sentence with a constraint-based constituent parser that utilizes the gold POStags and partial brackets as model external constraints.

We implement the constraint-based parsing algorithm on the maximum entropy parser of (Ratnaparkhi, 1997; Ratnaparkhi, 1999), which works robustly regardless of the grammar coverage of the baseline parsing model and therefore well-suited for constraint-based parsing of partial CTrees derived from out-of-domain as well as in-domain DTrees.

3.1 Baseline Maximum Entropy Parser

The baseline MaxEnt parser takes one of the four actions to parse an input sentence: *tag* , *chunk* , *extend* and *reduce*. Four models corresponding to each action are built separately during training.

The model score in (1) is integrated into the parser scoring function (2). In (1) and (2), a_i is an action from *tag*, *chunk*, *extend* or *reduce*, and b_i is the context for a_i.

$$q(a_i|b_i) = p_{a_i}(a_i|b_i) \quad (1)$$

$$score(T) = \prod_{a_i \in deriv(T)} q(a_i|b_i) \quad (2)$$

deriv(T) in (2) is the derivation of a parse *T*, which may not be complete. Given the scoring function (2), a beam search heuristic attempts to find the best parse T^*, defined in (3) where *trees(S)* are all the complete parses for an input sentence *S*.

input: Input sentence with partial CTree
output: Complete labeled CTree

Parser Initialization;
M = 20 & K = 80 & Q = 0.95;
C = ¡empty heap¿ h_0 = ¡input sentence¿;
while —C— ¡ M **do**

Figure 4: Constraint-based parsing algorithm

Constraints	WSJ-22	BOLT-DF
Baseline w/o constraints	88.57	82.43
Gold POStag	89.50	85.09
Gold bracket	98.52	96.88
Gold POStag+bracket	98.74	98.02

Table 1: Impact of model external constraints on parsing F-scores. The constraints Gold POStag, Gold bracket denote the POStags and constituent brackets read off from the human annotated gold CTrees. Combination of gold brackets and gold labels are equivalent to gold CTrees.

$$T^* = arg \max_{T \in trees(S)} score(T) \tag{3}$$

The parser explores the top K scoring parses and terminates when M complete parses are found or all hypotheses are exhausted. Possible actions $a_1 a_n$ on a derivation are sorted according to the model score $q(a_i|b_i)$. Only the actions $a_1 a_m$ with the highest probabilities are considered.

3.2 Constraint-based Maximum Entropy Parsing

In constraint-based parsing, the parser actions are based not only on the trained model scores but also on external constraints, which aim to improve the parsing qualities not achievable by parsing models alone.

The model external constraints include gold (i.e. human annotated) POStags, gold constituent brackets and/or gold labels. We enforce the parser to choose the gold tags, gold constituent brackets and labels over those selections made by the parsing model scores. When gold tags are provided as constraints, the tag action accepts the gold tag as the output. When gold constituent brackets (and labels) are given, the parser $chunk$, $extend$ and $reduce$ actions accept the gold constituent spans and their labels over the highest scoring model hypotheses. Figure 4 shows the constraint-based parsing algorithm.

The parameters M, K are described in Section 3.1. C denotes the heap of completed parses. h_i contains the derivations of length i. h_c contains the derivation with a constraint. Q is the probability pruning threshold. Advance applies relevant actions to a derivation d and returns a list of new derivations $d_1 d_n$. If there is a model external constraint for an action, it returns the derivation with the constraint d_c. Otherwise, it returns the derivations with the highest probabilities until the probability mass of the actions is greater than the threshold Q. Insert inserts a derivation d in heap h. Extract returns a derivation in h. Completed returns true if and only if d is a complete derivation.

Applying the constraint-based parsing algorithm in Figure 4 to the input sentence *Retailers see pitfalls in environmental push* with the partial CTrees in Figure 3 as the constraints, the parser produces the labeled CTree in Figure 1(a). Impact of model external constraints on parsing F-scores is shown in Table 1. The constraints Gold POStag, Gold bracket denote the POStags and constituent brackets read off from the human annotated gold CTrees. Combination of gold brackets and gold labels are equivalent to gold CTrees. Note that gold constituent brackets alone lead to very high F-scores for WSJ-22, 98.52 and BOLT-DF, 96.88. Our proposal capitalizes on the effectiveness of human annotated gold POStags

Techniques	Dependencies	F-score
(Xia et al., 2008)	CoNLL	89.4
(Niu et al., 2009)	Unlabeled	93.8
Current 2-stage	CoNLL	95.5
Current 2-stage	Stanford-v1.6.8	95.6

Table 2: DTree to CTree conversion F-scores on WSJ-22

Dependencies	DevSet	EvalSet
Stanford-v1.6.8	92.88	92.06
CoNLL	92.50	91.74
Universal Dependency	91.22	90.48

Table 3: DTree to CTree conversion F-scores on EWT according to various dependencies

and constituent brackets on parsing even when they are provided only partially, and utilize the partial CTrees derived from human annotated DTrees to recover the complete CTrees.

4 Conversion Accuracy

To compare the performance of the current conversion technique (Current 2-stage) with the previous work, all of which use the DTrees automatically derived from the Penn Treebank as the source dependency, we show the conversion accuracy on WSJ-22 in Table 2. The proposed 2-stage technique achieves the state-of-the-art conversion F-score 95.6 without relying on language and/or target treebank specific head rules. The constraint-based MaxEnt parser is trained on WSJ02-21.[2]

We also show the conversion accuracy of the current technique on English Web Treebank (EWT, LDC2012T13) from three types of dependencies in Table 3: Stanford basic dependency converted from the Penn Treebank by Stanford parser v1.6.8, CoNLL dependency converted from the Penn Treebank by pennconverter.jar[3], and human-annotated UD of (Nivre et al., 2015)[4]. MaxEnt parser for the constraint-based parsing is trained on English Ontonotes-5 treebank. The EWT train/development/evaluation data partitions are the same as those available from the UD.[5] Conversion F-scores are computed with `evalb`, excluding punctuations.

5 Parsing Experimental Results

Our ultimate goal is to improve constituent parsing accuracy by leveraging dependency treebanks available in a wide variety. To achieve this objective, we first convert dependency treebanks into constituent representations using the proposed conversion technique. Then we merge the converted treebanks with the human-annotated constituent treebank to enlarge the training set of constituent parser. We finally re-train the constituent parsers with the enlarged training set. We report the parsing experimental results for English and German.

English parser training and evaluation data sets from Ontonotes-5 (LDC2013T19) and EWT are shown in Table 4. Ontonotes-5 is the biggest constituent treebank available in English and includes sub-corpora from 7 genres. German parser training and evaluation data sets are shown in Table 5.

We experiment with two constituent parsers. The MaxEnt parser which we adapted for the constraint-based parsing and the BerkeleyParser. We measure the labeled F-scores including punctuations so that all sentences are scored correctly even when there is a mismatch of punctuation tags between the reference and machine parses.[6]

5.1 English Results

We train the baseline parser on the Ontonotes-5 training corpus only (Baseline in Tables 6 and 7). UD treebank corresponding to the training portion of EWT is converted to CTrees, using the proposed conversion technique with the constraint-based MaxEnt parser, and the converted treebank is added to the Ontotnotes-5 treebank for parser training (+Converted in Tables 6 and 7). We also train parsers on both Ontonotes-5 treebank and the EWT training corpus (+Gold in Tables 6 and 7).

[2] (Niu et al., 2009) automatically derive their dependencies from the Penn Trees using head percolation table.

[3] Downloaded from http://nlp.cs.lth.se/coftware/treebank-converter

[4] v1.1 downloaded from http://universaldependencies.org

[5] The gold stanford English UD was built over the source material of the EWT. That is, UD and EWT are parallel.

[6] Ontonotes-5 and EWT are quite noisy and quite a few sentences contain punctuation tag mismatches.

Table 7: English BerkeleyParser F-scores

For both MaxEnt and Berkeley parsers, addition of the converted treebank improves the F-scores of the EWT evaluation data much more than other evaluation data sets from the Ontnotes-5 treebank, as expected. The converted treebank also improves the F-scores of WB, MZ, NW, BN and PT for the MaxEnt parser and MZ, NW and BN for BerkeleyParser. Not surprisingly, addition of the gold EWT improves the parser performance more than addition of the converted treebank. When the addition of the converted treebank hurts the parser performance, we see that the same downward pattern holds even with the addition of the gold EWT, as indicated by italics in Tables 6 and 7.

5.2 German Results

Tiger constituent treebank has the corresponding CoNLL2006 dependency treebank. We split the Tiger treebank training data into two parts, one for the baseline constituent parser training, and the other for conversion from the CoNLL dependency treebank. Experimental results are shown in Table 8. We observe the same pattern of improvement as English in a bigger margin.

6 Related Work and Conclusions

In the family of DTree to CTree conversion technique, the current work is closest in spirit to (Niu et al., 2009). They generate N-best parses of the dependency treebank sentences using the constituent parser and compare the similarity between N-best constituent parses and the source dependencies by converting the N-best parses back to dependencies. They show that addition of converted Chinese dependency treebank to CTB, (Xue et al., 2005), improves the Chinese constituent parsing accuracy modestly. (Xia

MaxEnt parser	75.74	76.88	78.01
BerkeleyParser	71.88	73.42	76.12

Table 8: Contituent parsing improvement due to the DTree-to-CTree converted treebank and the gold constituent treebank

et al., 2008) propose a rule-based DTree to CTree conversion technique, assuming that the input DTree is identical to a flattened version of the desired CTree. They decompose the input DTree into multiple DTree segments, replacing each segment with the CTree counterparts and glue the CTree segments to form a complete CTree. The idea of utilizing dependency boundaries as constraints on constituent parsing has been explored in (Wang and Zong, 2010).

In the family of bi-directional conversion between CTrees and DTrees, (Hall and Nivre, 2008) present a dependency driven parser that parses both dependency and constituent structures. They automatically transform constituent representations into complex dependency representations so that they can recover the constituent structure. (Kong et al., 2015) propose a statistical model to transform DTrees into CTrees. They first convert CTrees to DTrees, which encode the rich head-modifier and phrase label information from the CTrees.[7] They train a statistical model to restore the CTrees from the feature-rich DTrees. While they report their DTree to CTree conversion accuracy on WSJ-22, their accuracy is not directly comparable to those we report in Tables 2 and 3 since their DTrees encodes head-modifier relations and phrase labels read off from the corresponding gold CTrees. (Fernández-Golzález and Martins, 2015) derive head-ordered DTrees from CTrees, train an off-the-shelf dependency parser on the DTrees, and recover the constituent information from the head-ordered DTrees. These bi-directional techniques practically reduce constituent parsing to dependency parsing and are applied to DTrees that encode the same complex information as the corresponding CTrees in order to easily recover the phrase structures.

We presented a simple DTree to CTree conversion technique that aims to improve constituent parsing accuracies by leveraging dependency treebanks available in a wide variety in many languages. Evaluated on WSJ-22, the technique achieves the state-of-the-art conversion F-score 95.6. When applied to English and German, the converted treebanks added to the constituent parser training corpus improve parsing F-scores significantly for both languages.

Abstract

Multiword expressions (MWEs) are pervasive in natural languages and often have both idiomatic and compositional readings, which leads to high syntactic ambiguity. We show that for some MWE types idiomatic readings are usually the correct ones. We propose a heuristic for an A* parser for Tree Adjoining Grammars which benefits from this knowledge by promoting MWE-oriented analyses. This strategy leads to a substantial reduction in the parsing search space in case of true positive MWE occurrences, while avoiding parsing failures in case of false positives.

1 Introduction

Multiword expressions (MWEs), e.g. *by and large*, *red tape*, and *to pull one's socks up* 'to correct one's work or behavior', are linguistic objects containing two or more words and showing idiosyncratic behavior at different levels. Notably, their meaning is often not deducible from the meanings of their components and from their syntactic structure in a fully compositional way. Thus, interpretation-oriented NLP tasks, such as semantic calculus or translation, call for MWE-dedicated procedures. Syntactic parsing often underlies such tasks, and the crucial issue is at which point the MWE identification should take place: before (Nivre and Nilsson, 2004), after (Constant et al., 2012) or during parsing (Wehrli et al., 2010; Green et al., 2013; Candito and Constant, 2014; Nasr et al., 2015; Constant and Nivre, 2016). The last, joint, approach proves the most efficient due to at least two reasons. Firstly, some MWEs coincide with word combinations that cross phrase boundaries, which is hard to detect prior to parsing, as in example (1). Secondly, while most MWEs have both an idiomatic and a compositional reading, as in examples (2)–(3), the former occurs much more frequently than the latter for large classes of MWEs. In Sec. 6 we show that, indeed, the *idiomaticity rate*, i.e. the ratio of occurrences with idiomatic reading to all occurrences in a corpus, exceeds 0.95 for verbal MWEs and compounds. This suggests that promoting MWE-oriented analyses in parsing might lead to rapidly achieved correct parses. (Wehrli, 2014) shows that, indeed, the quality of symbolic parsing significantly increases if an occurrence of a MWE is admitted as soon as the necessary syntactic constraints are fulfilled. Our goal is to apply a similar strategy, i.e. to systematically promote MWE-oriented interpretations, while parsing with Tree Adjoining Grammars (TAGs).

(1) **After all** the preparations we finally left.
(2) After being criticized, she **pulled her socks up**.
(3) When the kid shivered with cold, **she pulled its socks up**.
(4) **Acid rains** in Ghana are equally grim.

Consider the sentence in example (4). At least two competing analyses are syntactically valid for the first 4 words: *rains* is (a) a verb with the subject *acid*, or (b) the head noun of a nominal phrase. In the latter case, the nominal phrase has either (i) a compositional reading (*acid* is a regular nominal modifier) or (ii) an idiomatic one (*acids rains* is an NN compound).

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 429–439, Osaka, Japan, December 11-17 2016.

Our objective is to propose a parsing strategy which would promote analysis (b) and reading (ii). More precisely, the parser should only provide grammar-compliant MWE-oriented analyses each time they are feasible. Thus, we wish to both avoid the parsing failure for (1), and rapidly achieve the correct syntactic parses of (2)–(4), due to imposing their idiomatic interpretations. In this way, the parser's search space is reduced, with virtually no loss of correct parses, and with rare errors at the level of MWE identification, as in (3). The rate of such errors is the complement of the idiomaticity rate of the text to be parsed (here: 0.05).

Note that promoting the most probably correct analysis, whether containing MWEs or not, is the goal of probabilistic parsers in general. Thus, instead of designing a custom parsing architecture for promoting MWEs, it would be more adequate to simply train a general-purpose parser on a treebank containing MWE annotations. This solution is however hindered by data insufficiency. Firstly, many languages still lack large-size treebanks. Secondly, very few treebanks contain a full-fledged range of MWE annotations, even for English (Rosén et al., 2015). Thirdly, MWEs are subject to sparseness problems even more than single words: most existing MWEs occur never or rarely in MWE-annotated corpora (Czerepowicka and Savary, 2015), let alone treebanks. Here, we partly cope with these problems by an Earley-style A* parser using a MWE-oriented heuristic, which takes advantage of a potential occurrence of MWEs in a sentence. While it is designed to systematically promote MWEs regardless of their probabilities, the parser could be very well used with a weighted TAG and the weights assigned to individual elementary trees could be estimated on the basis of training data.

In Sec. 2 we remind basic facts about TAGs. In Sec. 3 we explain the MWE-promoting strategy in TAG parsing. In Sec. 4 we describe the parsing algorithm on a running example and we formalize its heuristics in Sec. 5. In Sec. 6 we show experimental results on a Polish TAG grammar extracted from a treebank. The choice of Polish is due to the fact that high-quality MWE resources compatible with the treebank are available for this language. In Sec. 7 we compare our approach with related work. Finally, we conclude and comment on future work.

2 Tree Adjoining Grammars

A TAG (Joshi et al., 1975) is a tree-rewriting system defined as a tuple $\langle \Sigma, N, I, A, S \rangle$, where Σ (resp. N) is a set of terminal (resp. non-terminal) symbols, I and A are sets of elementary trees (ETs), and $S \in N$ is the axiom. Trees in I are called initial trees (ITs), their internal and leaf nodes are labeled with symbols in N and in $\Sigma \cup N$, respectively. Their non-terminal leaf nodes are called substitution nodes and marked with $\downarrow$. Trees in A are called auxiliary trees (ATs) and are similar to trees in I except that they contain a leaf node (called a foot and marked with $\star$) whose label is the same as the one of the root. Consider the toy TAG in Fig. 2 covering three competing interpretations for *acid rains* in example (4). Notably, tree t_5 represents its idiomatic reading. We have $I = \{t_1, t_3, t_4, t_5, t_6\}$ and $A = \{t_2\}$.

ETs are combined to derive new trees using *substitution* and *adjunction*. Substitution consists in replacing a leaf with an ET whose root is labeled with the same non-terminal (cf. the dotted arrow in Fig. 1). Adjunction consists in inserting an AT t inside any tree t' provided that the root/foot label of t is the same as the label of the insertion point in t' (cf. the dashed arrows in Fig. 1). The result of a TAG derivation is twofold: a *derived tree*, and a *derivation tree*. The former represents the syntactic tree resulting from tree rewriting. The latter shows which ETs have been combined and how, as shown in Fig. 1(b). The derived tree of a sentence containing a syntactically regular MWE is identical to the one with its compositional reading, but their derivation trees differ. Thus, in the context of joint syntactic parsing and MWE identification (cf. Sec. 1), the derived and the derivation trees can be seen as the results of the former and of the latter task, respectively.

A TAG whose every ET contains at least one terminal leaf is called an LTAG (lexicalized TAG). The reason why we are particularly interested in LTAGs is that we consider MWEs a central challenge in NLP, and LTAGs show several advantages with respect to them (Abeillé and Schabes, 1989). Firstly, each MWE, together with the lexical and morphosyntactic constraints that it imposes, can be represented as a unique ET. Unification constraints on feature structures attached to tree nodes allow one to naturally express dependencies between arguments at different depths in the ETs (e.g. the subject-possessive

agreement in *to pull one's socks up*). This is not the case for most other grammatical formalism, which handle long-distance dependencies by feature percolation. Secondly, the so-called *extended domain of locality* offers a natural framework for representing two different kinds of discontinuities. Namely, discontinuities coming from the internal structure of a MWE (e.g. required but non-lexicalized arguments) are directly visible in elementary trees and are handled in parsing mostly by substitution. Discontinuities coming from insertion of adjuncts (e.g. *a bunch of NP*, *a whole bunch of NP*) are invisible in elementary trees but are handled by adjunction.

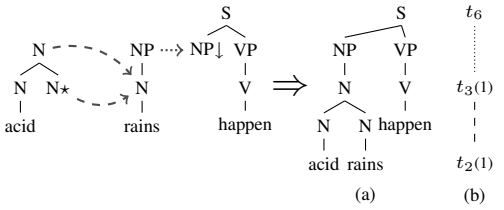

Figure 1: Tree rewriting in TAG resulting in a derived tree (a), and a derivation tree (b).

(t_1)	(t_2)	(t_3)	(t_4)	(t_5)	(t_6)

Figure 2: A toy TAG grammar converted into flat rules

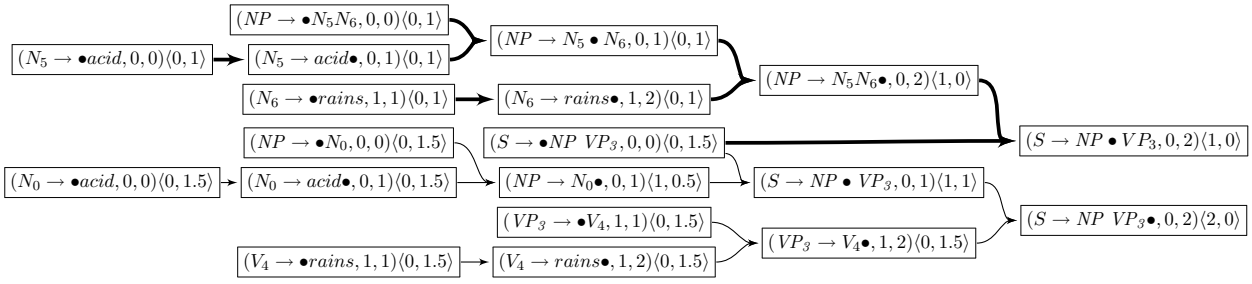

Figure 3: Hypergraph representing the chart parsing of the substring *acid rains* with ETs t_1, t_4 and t_5 from Fig. 2. The lowest-cost path representing the idiomatic interpretation is highlighted in bold.

3 Promoting MWEs in weighted TAG parsing

The fact that MWEs are represented in LTAGs as ETs allows us to propose a very simple and yet powerful strategy of promoting them in parsing. As seen in Sec. 2, parsing with an LTAG consists in combining ETs via substitution or adjunction. We define the weight of a full parse as the sum of the weights of the participating ETs. Note that the more sentence words belong to MWEs, and the longer are those MWEs, the less ETs are needed to cover the sentence. Suppose, for instance, that the sequence *acid rains* in Fig. 1 is covered by its idiomatic interpretation represented by tree t_5 from Fig. 2, instead of being handled by adjunction. In this case parsing *acid rains happen* produces the same derived tree as before but the derivation tree is smaller: it involves 2 ETs instead of 3.

This simple observation underlies our idea of promoting MWE-oriented analyses. Namely, suppose the input LTAG trivially weighted, i.e., each ET having weight 1. Then, finding analyses containing the maximum number of MWEs boils down to achieving the lowest-weight parses. Our objective is to find them more rapidly than other parses, which can be achieved by an A* algorithm using a MWE-driven heuristics, as described in the following sections. See also Sec. 8 for considerations on how this solution might generalize to non-trivially weighted grammars, notably with weights estimated on the basis of treebanks.

4 Weighted parsing with a flattened TAG

In (Waszczuk et al., 2016) we presented a TAG parsing architecture based notably on grammar flattening, subtree sharing and finite-state-based compression. Here, we sketch a simplified version of this architecture, and explain how it implements parsing as an A* graph traversal algorithm. Then in Sec. 5 we

define the heuristic implementing the MWE promoting strategy, which – to the best of our knowledge – is totally novel.

Consider again the LTAG in Fig. 2. For the sake of presentation and compression (cf. Sec. 6), we represent TAG ETs as sets of flat production rules (Alonso et al., 1999) with indexed non-terminals.[1] For instance, the two N non-terminals in t_5 receive different indexes so as to avoid spurious analyses like $[[rains]_N[acid]_N]_{NP}$. A rule headed by the root of an ET (e.g., $S \rightarrow NP\ VP_3$) is called a *top rule*. The other rules are called *inside rules*.

Suppose that only the first two words of sentence (4) are to be parsed with a grammar subset limited to t_1, t_4 and t_5. With a flattened grammar representation, TAG parsing comes close to CFG parsing (even if dedicated inference rules are needed for adjunction, which is neglected in this paper). Like for CFG, an Earley-style parsing process for TAGs defined within a deductive framework (Shieber et al., 1995), involving an *agenda* (queue of weighted items) and a *chart*, can be represented as a hypergraph (Klein and Manning, 2001), more precisely a B-graph (Gallo et al., 1993), whose nodes are items of the chart and of the agenda, and whose hyperarcs represent applications of inference rules, as shown in Fig. 3. Each item $\mathcal{I} = (r, k, l)$ contains a dotted rule r and the span (k, l) over which the symbols to the left of the dot have been parsed.[2] For instance, the hyperarc leading from $(N_5 \rightarrow \bullet acid, 0, 0)$ to $(N_5 \rightarrow acid\bullet, 0, 1)$ means that the terminal $acid$ has been scanned from position 0 to 1. The latter item can then be combined with $(NP \rightarrow \bullet N_5 N_6, 0, 0)$ to yield $(NP \rightarrow N_5 \bullet N_6, 0, 1)$, etc. $\mathcal{I}$ and r are called *passive*, if the dot occurs at the end of r, and *active* otherwise. A sentence s has been parsed if a target item has been reached (spanning over the whole sentence, with a passive top rule headed by S).

The specificity of such a hypergraph lies in the fact that it is dynamically generated as the parsing process goes on. The main objectives include the generation of the smallest possible portion of this hypergraph, while including all the requested parses. In our case those are all optimal parses[3], in the sense of the MWE-promoting strategy.

Each derivation traversing $\mathcal{I} = (r, k, l)$ and resulting in a full parse tree T can be divided into two parts: (i) $\mathcal{I}$'s *inside derivation*, i.e., the part of the derivation corresponding to a (possibly partial) subtree of T rooted at r' head and spanning over (k, l), (ii) $\mathcal{I}$'s *outside derivation*, the part of the derivation corresponding to a partial tree obtained from T but excluding $\mathcal{I}$'s *inside derivation*. The weights of $\mathcal{I}$'s best inside and outside derivations are denoted by $\beta(\mathcal{I})$ and $\alpha(\mathcal{I})$. They are calculated according to the strategy described in Sec. 3, i.e. as numbers of ETs involved.

In symbolic CFG parsing, and in deductive parsing in general, the sentence parsability problem boils down to target node B-reachability in the (gradually constructed) hypergraph, and can be solved e.g. by a depth-first search generalized to hypegraphs. In probabilistic CFG parsing, parse trees and hypergraph B-paths are scored, and discovering the best parse is equivalent to finding the shortest B-path, which can be done by Dijkstra's algorithm generalized to hypergraphs (Gallo et al., 1993). The search space of this basic algorithm can be reduced in the A* algorithm (Klein and Manning, 2003), by introducing a heuristic which estimates the distance of each node to a target node. Namely, each $\mathcal{I}$ is assigned two values: $\beta(\mathcal{I})$ and $h(\mathcal{I})$, the latter being an estimation of $\alpha(\mathcal{I})$. The parsing items are popped from agenda in increasing order of $\beta(\mathcal{I}) + h(\mathcal{I})$. The heuristic used to calculate $h(\mathcal{I})$ should be *admissible*, i.e. should never overestimate ($h(\mathcal{I}) \leq \alpha(\mathcal{I})$). Additionally, if the heuristic is *monotonic* (i.e. $\beta(\mathcal{I}) + h(\mathcal{I})$ never increases), then an item is never re-introduced into the agenda once is has been popped, and the algorithm runs faster.

We apply the A* algorithm in a slightly adapted version in that we do not search for one but for all optimal parses, i.e. those containing grammar-compliant idiomatic interpretations. Thus, we do not quit when the first target item has been reached, but only when we are sure that no more optimal derivations can be found. As long as $\mathcal{I}$ stays on the agenda, $\beta(\mathcal{I})$ has to be recalculated each time a new hyperarc with head node $\mathcal{I}$ is added. Once $\mathcal{I}$ moves to the chart, $\beta(\mathcal{I})$ remains constant. In Fig. 3, the couple $\langle \beta(\mathcal{I}), h(\mathcal{I}) \rangle$ decorates each node. Note that in case of parsing with a flattened TAG, only an ET t, not its

[1] Our proposal applies, however, to other LTAG representations as well.

[2] For simplicity, we ignore the fact that an item's span can include a gap accounting for adjunction.

[3] In probabilistic CFG parsing, the 1-best parse (Klein and Manning, 2003) or k-best parses (Pauls and Klein, 2009) are usually considered.

individual flat rules, is assigned a weight. Therefore, t's weight contributes to $\beta(\mathcal{I})$ only when t has been fully parsed, and it contributes to $h(\mathcal{I})$ otherwise. For instance, going from items $(NP \rightarrow N_5 \bullet N_6, 0, 1)$ and $(N_6 \rightarrow rains\bullet, 1, 2)$ to $(NP \rightarrow N_5 N_6 \bullet, 0, 2)$ we have completed parsing the top rule of t_5, thus the weight of this ET (1) is added to W_1. However, item $(N_6 \rightarrow rains\bullet, 1, 2)$ is decorated with $\langle 0, 1\rangle$, since no ET has been fully parsed so far but we are parsing tree t_5 (with weight 1), whose terminals fully cover the intended span $(0, 2)$.

5 MWE-driven heuristic

The proper choice of the heuristic is crucial for the performance of the A* algorithm. We propose a heuristic $h(\mathcal{I})$ specifically designed to handle MWEs and, more generally, ETs with multiple anchors, which allows to use the A* parsing algorithm with MWE-aware weighted TAG grammars. In case weight 1 is assigned to all ETs, the heuristic closely models the strategy of promoting MWEs described in Sec. 3. Namely, it admits that if a given MWE has a chance to occur in the part of the sentence that remains to be parsed (i.e., in its outside derivation), then this MWE probably occurs. More precisely, the yet unparsed portion of the sentence can be divided into two parts: (i) the terminals yet to be covered by the tree that we are currently parsing, (ii) the remaining terminals. The heuristic consists in considering each terminal s_i from (ii) separately and assuming that it will be parsed with the ET containing s_i within the longest possible MWE.

Formally, let $\mathcal{S} = s_1 s_2 \dots s_{|\mathcal{S}|}$ be the input sentence and $Pos(\mathcal{S})$ the set of positions between its words, ranging from 0 to $|\mathcal{S}|$. Since the same word can occur more than once in a sentence or a tree, we manipulate multisets of words. For a set X, a multiset over X is a set of pairs $\{(x, m(x)) : x \in X\}$, where $m(x) \in \mathbb{N}^+$ is called the multiplicity of x. We extend set notations and operators to multisets. For instance, $\{(a, 2), (b, 1)\}$ is noted as $\{a, a, b\}_{ms}$, and we have $\{a, b\}_{ms} \cup \{a\}_{ms} = \{a, a, b\}_{ms}$, $\{a, a, b\}_{ms} \setminus \{a, b\}_{ms} = \{a\}_{ms}$, $\{a, b\}_{ms} \subseteq \{a, a, b\}_{ms}$, $\{a, a, b\}_{ms} \not\subseteq \{a, b\}_{ms}$, $|\{a, a, b\}_{ms}| = 3$, etc. For any set X, let $\mathcal{M}(X)$ be the set of all multisets over X. Let $Rest(\mathcal{I})$ denote a multiset of words in the input sentence $\mathcal{S}$ outside of $\mathcal{I}$'s span, i.e., $Rest(\mathcal{I}) = \{s_1, \dots, s_k, s_{l+1}, \dots, s_{|\mathcal{S}|}\}_{ms}$.[4] Let $tree(r)$ be the ET from which r stems, and $W(t) \in [0, \infty)$ the weight of the ET t. For instance, in Fig. 2 and 3, for $r = N_5 \rightarrow acid\bullet$ we have $tree(r) = t_5$ and $W(t_i) = 1$ for $i = 1, \dots, 6$.

Let $sub(t) \in \mathcal{M}(\Sigma)$ be the multiset of terminals in tree t. For instance, $sub(t_5) = \{acid, rains\}_{ms}$. For each word w, let $minw(w)$ denote the minimal weight of scanning w by an ET, i.e., the minimum proportion of w among all terminals of a single ET. More precisely,

$$minw(w) = \min_{t:(w,i)\in sub(t)} \frac{W(t)}{|sub(t)|}. \tag{5}$$

For instance, the proportion of *acid* in the terminals of t_1, t_2 and t_5 is, 1, 1 and 0.5, respectively, so $minw(acid) = 0.5$. Similarly $minw(rains) = 0.5$.[5] Thus, with all ET weights equal to 1, the longer a MWE, the lower are the $minw$ values of its components.

Let $sub(r), super(r) \in \mathcal{M}(\Sigma)$ be the multisets of terminals occurring in $tree(r)$ inside and outside of the subtree rooted at r's head, respectively. For instance, $sub(N_5 \rightarrow acid\bullet) = \{acid\}_{ms}$ and $super(N_5 \rightarrow acid\bullet) = \{rains\}_{ms}$. Note that for any top rule r, $super(r) = \emptyset_{ms}$.

Let $\mathit{suff}(r)$ be the set of passive non-top rules headed by the symbols in r' body after the dot. For instance, $\mathit{suff}(NP \rightarrow N_5 \bullet N_6) = \{N_6 \rightarrow rains\bullet\}$ and $\mathit{suff}(S \rightarrow \bullet NP\, VP_3) = \{VP_3 \rightarrow V_4\bullet\}$. Note that if r is passive, $\mathit{suff}(r) = \emptyset$.

Finally, let $Req(\mathcal{I})$ be the multiset of words required by the yet unparsed part of the current tree, i.e.,

$$Req(\mathcal{I}) = super(r) \cup \bigcup_{p\in \mathit{suff}(r)} sub(p). \tag{6}$$

[4] In case of adjunction $\mathcal{I}$'s span includes two additional indices denoting the gap, and the words within the gap also belong to $Rest(\mathcal{I})$.

[5] Variants of the $minw(w)$ definition include distributing the weights of individual terminals in an ET proportionally to their frequencies in the corpus. Our experiments did not show any advantage of such a distribution over the uniform one.

For instance in Fig.3, for item $\mathcal{I} = (NP \rightarrow N_5 \bullet N_6, 0, 1)$ we have $super(NP \rightarrow N_5 \bullet N_6) = \emptyset_{ms}$, $sub(N_6 \rightarrow rains\bullet) = \{rains\}_{ms}$, and $Req(\mathcal{I}) = \{rains\}_{ms}$.

For any item $\mathcal{I} = (r, k, l)$ we define a primary heuristic $h_0(\mathcal{I})$ as in equation (7).

$$h_0(\mathcal{I}) = \begin{cases} \infty, \text{ if } Req(\mathcal{I}) \not\subseteq Rest(\mathcal{I}) \\ \sum\limits_{(s,i) \in Rest(\mathcal{I}) \setminus Req(\mathcal{I})} minw(s) \times i, \text{ otherwise} \end{cases} \tag{7}$$

Then the estimation for the weight of $\mathcal{I}$'s best outside derivation, i.e. $\alpha(\mathcal{I})$, is given by equation (8).

$$h(\mathcal{I}) = \begin{cases} h_0(\mathcal{I}), \text{ if } \mathcal{I} \text{ is a top-rule passive item} \\ W(tree(r)) + h_0(\mathcal{I}), \text{ otherwise} \end{cases} \tag{8}$$

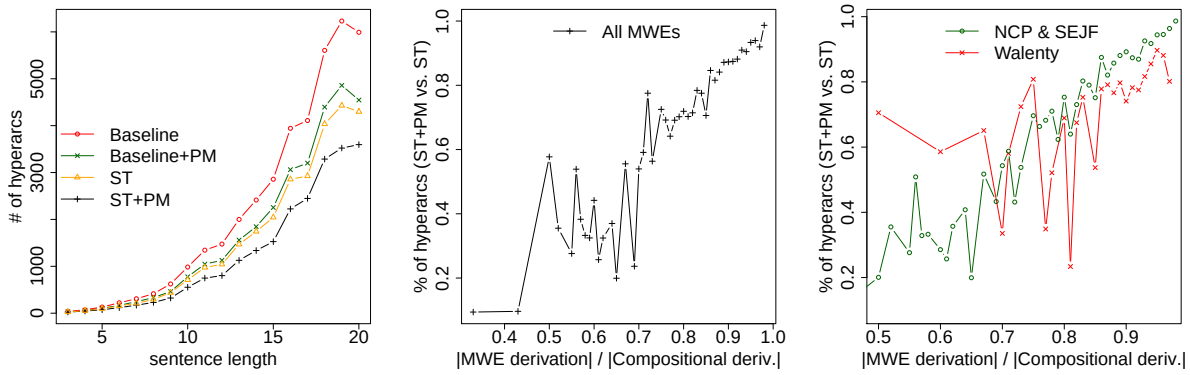
For instance, in the top-rule passive item $(NP \rightarrow N_0\bullet, 0, 1)$ we have finished parsing t_1 ($\beta(\mathcal{I}) = 1$) and we still have to consume *rains*, which implies a weight at least equal to $h(\mathcal{I}) = minw(rains) = 0.5$. In the inside-rule passive item $\mathcal{I} = (N_5 \rightarrow acid\bullet, 0, 1)$ we have $Rest(\mathcal{I}) = \{rains\}_{ms}$, $Req(N_5 \rightarrow acid\bullet) = \{rains\}_{ms}$, thus $h(\mathcal{I}) = W(t_5) = 1$. Finally, in the active item $\mathcal{I} = (NP \rightarrow N_5 \bullet N_6, 0, 1)$ we have $Rest(\mathcal{I}) = \{rains\}_{ms}$, $super(NP \rightarrow N_5 \bullet N_6) = \emptyset_{mt}$, and $Req(\mathcal{I}) = \{rains\}_{ms}$, thus $h(\mathcal{I}) = W(t_5) = 1$.

With this heuristic, and weight 1 assigned to individual ETs, the derivations containing MWEs are often reached before the paths towards compositional ones are even followed. For instance the item $(N_0 \rightarrow acid\bullet, 0, 1)$ has the estimated cost 1.5, and it will be created later than $(S \rightarrow NP\, VP_3\bullet, 0, 2)$. Thus, the hyperpath (highlighted in bold) assuming the idiomatic reading of *acid rains*, will be followed before the path assuming that *rains* is a verb.

For a given item the heuristic assumes that each remaining word w from the input sentence (with the exception of the words required by the rule underlying the item) will be scanned with the lowest possible cost, i.e. $minw(w)$ – see Eq. (5). The heuristic never over-estimates the cost of parsing the remaining part of the sentence and is thus *admissible*. All but one inference rules of the parser are also *monotonic*, in the sense that the estimation, stemming from the application of an inference rule, of the total weight $\beta(\mathcal{I}) + h(\mathcal{I})$ of an item $\mathcal{I}$ is greater or equal to the total weight, $\beta(\mathcal{I}') + h(\mathcal{I}')$, of any premise item $\mathcal{I}'$ of this rule. The sole exception concerns the inference rule – called *foot adjoin (FA)*, see (Waszczuk et al., 2016) – responsible for recognizing the so-called *gaps* over which adjoining could be performed. This is related to the fact that the weight of the item inferred with FA does not depend on the $\beta(\mathcal{I}')$ weight of its premise item $\mathcal{I}' = (r, k, l)$, where item $\mathcal{I}'$ provides an evidence that adjunction could possibly take place over span (k, l). Nonetheless, the algorithm guarantees that when item $\mathcal{I}$ is popped from the agenda, one of the hyperarcs representing an optimal derivation of $\mathcal{I}$ is already inferred, and thus the $\beta(\mathcal{I})$ value is correctly calculated.

6 Experimental results

We evaluated our parsing strategy with Składnica, a Polish treebank with over 9,000 manually disambiguated constituency trees (Świdziński and Woliński, 2010). As it contains no MWE annotations, we produced them automatically, by projecting 3 existing MWE resources: (i) the named entity (NE) layer of the National Corpus of Polish (NCP) (Savary et al., 2010) (only the multiword NEs were taken into account), (ii) SEJF, an extensional lexicon of Polish nominal, adjectival and adverbial MWEs (Czerepowicka and Savary, 2015), (iii) Walenty, a Polish valence dictionary (Przepiórkowski et al., 2014) with over 8,000 verbal MWEs. The mapping for (i) was straightforward and did not require manual validation, since Składnica is a subcorpus of the NCP, whose NE annotation and adjudication were performed manually. The mapping for (ii) and (iii), followed by a manual validation, consisted in searching for syntactic nodes satisfying all lexical constraints and part of syntactic constraints of a MWE entry. The required lexical nodes were to be contiguous for (ii) but not for (iii). As a result, 2026 idiomatic occurrences (1303 from NCP-NE, 368 from SEJF and 355 from Walenty) and 40 compositional ones (22 for SEJF and 18 for Walenty) were identified, which implies the idiomaticity rate about 0.95 (0.95 for Walenty and 0.94 for SEJF).



(a) (b) (c)

Figure 4: (a) Average number of hyperarcs explored depending on the parsing strategy (for clarity using only sentence of length < 20), (b) Average % of hyperarcs explored with the PM+ST strategy, using the ST strategy as a reference, and (c) Average % of hyperarcs explored depending on the type of MWEs.

A TAG grammar with 28652 lexicalized elementary trees was then extracted from the MWE-marked treebank, similarly to (Krasnowska, 2013) or (Chen and Shanker, 2004). Each treebank subtree marked for a MWE yielded: (i) a MWE-dedicated ET containing all paths leading to the lexical (co-)anchors, (ii) ETs covering the compositional interpretations. Various compression techniques can be applied to a flattened TAG (Waszczuk et al., 2016). We used a representation in which common subtrees and prefixes of flat rules are shared.

We assess our parser's efficiency in terms of the size of its parsing hypergraph. We believe it to be a more objective measure to compare different parsing strategies than the absolute parsing time, since each hypergraph edge corresponds to an application of an inference rule, i.e. to a basic parsing step (as in theoretical complexity considerations).[6] Conversely, the parsing time is highly dependent on the low level implementation details.[7]

The baseline hypergraph is the one generated with the full grammar, when no MWE-promoting strategy is used and all grammar-compliant parses are generated for each sentence. The MWE-promoting (PM) hypergraph, compared to this baseline, includes mainly the optimal parses (the algorithm ensures that, in PM, all optimal parses are achieved, but some sub-optimal parses may also be reached, since heuristic h is an imperfect estimation of α), i.e. those in which the maximum number of words belongs to potential MWEs.

The experiment was carried out on the same dataset from which the grammar was extracted. Therefore, for each sentence, the baseline hypergraph contained both its gold (i.e., conforming to Składnica) parse (derived tree) and its gold MWE identification (derivation tree). The PM hypergraphs, in turn, contained the correct parses for virtually 100% of the sentences,[8] and correct MWE identification for around 95% of them (due to the idiomaticity rate equal to 0.95). Thus, the parsing efficiency gain due to the PM strategy occurred with no loss of accuracy.

The PM strategy is comparable to supertagging (ST), i.e. pre-selecting, for each sentence, a subset of ETs which have good chances to be used in the derivation, in order to reduce the parsing search space. We experimented with a simple form of ST, which restricts the grammar to ETs whose terminals occur in the given sentence. Namely, we examined the ST hypergraph containing all parses for each sentence, and the one when ST was combined with PM (where mainly optimal parses were achieved).

Fig. 4a shows the absolute sizes of the hypergraphs for these 4 strategies in function of the sentence

[6]The overhead related to computing the values of the heuristic is at most linear in the size of the sentence, and may be much lower with efficient low-level optimizations.

[7]In an optimized implementation, TAG parsing time is proportional to the number of hyperarcs, as reported by (Waszczuk et al., 2016).

[8]A sanity check showed that for 54 sentences the gold parse was not found, mainly due to some abbreviation- and letter-case-related specificities, as well as to missing MWE annotations in Składnica.

length. The PM strategy brings enhancement regardless of whether supertagging is used or not. The supertagging alone outperforms, on average, the baseline MWEs-promoting strategy. Since the combination of ST and PM strategies proves the most efficient, we restrict further experiments to this version.

Note that Fig. 4a does not fully reflect the potential advantages of the PM strategy, whose behavior does not directly depend on the length of the parsed sentence, but rather on the number and the size of the MWEs potentially occurring in it. These 2 values can be together represented as the ratio of the size of the MWE-based derivation tree to the size of the corresponding compositional derivation tree (i.e. the one assuming no MWE occurrence). Expectedly, as shown in Fig. 4b, the lower this ratio (i.e. the more words in the sentence belong to MWEs, and the longer are these MWEs), the more significant the hypergraph size reductions. Moreover, the resulting graph suggests that the hypergraph size reductions are linear with respect to this ratio. Note that the vertical axis now shows the proportional gain in the hypergraph size due to the ST+PM strategy with respect to the ST strategy alone.

Finally, we investigated the behavior of the PM+ST strategy for two types of MWEs independently: verbal MWEs from Walenty and compounds from NCP and SEJF. As shown in Fig. 4c, verbal MWEs, while less frequent, prove to be better in reducing ambiguity for sentences with low number of potential MWEs. It is hard to ascertain this claim for sentences with lower gold derivation size ratio. While compounds seem to outperform verbal MWEs in this case, sentences with verbal MWEs for which this ratio is low are also very short in our dataset (of length 5, on average, for the 20 sentences with the lowest ratio), and thus exhibit low syntactic ambiguity.

7 Related work

While A* algorithms have been widely used for AI inference problems where a lightest derivation is to be found (Felzenszwalb and McAllester, 2007), this is to our knowledge the first attempt at using them within the context of MWE parsing with TAG. This work was inspired by Lewis and Steedman (2014) who applied A* to parsing with another strongly lexicalized grammar formalism, namely CCG. Unlike in this work, our grammar rules are not constrained to have a single lexical item, hence they can explicitly represent MWEs. This calls for a more elaborate heuristic, since a not yet parsed terminal can either be consumable by the currently parsed tree or not, as is the case with *rains* in item $(NP \rightarrow N_5 \bullet N_6, 0, 1)$ as opposed to $(NP \rightarrow N_0 \bullet, 0, 1)$ in Fig. 3. Distinguishing these two cases leads to a more precise weight estimation.

Angelov and Ljunglöf (2014) proposed to apply A* top-down parsing to parallel multiple context-free grammars, a formalism strictly more expressive than TAGs. In their approach weights are assigned to production rules and the grammar is not assumed to be strongly lexicalized, which complicates the design of an efficient heuristic. Their evaluation showed that a non-admissible heuristic can be orders of magnitude faster than the admissible version, at the expense of parsing quality.

Other ways of dealing with MWEs in the context of TAG would involve pre- or post-processing. A post-processing step would consist in identifying MWE interpretations in derivation structures (potentially with an additional processing cost). Regarding pre-processing, current state-of-the-art techniques are related to probabilistic supertagging (Bangalore and Joshi, 1999), as opposed to the simple symbolic supertagging applied in Sec.6. While labeling the words of a sentence with candidate ETs, one may either keep for each word the most probable ET, or all ETs whose probabilities are above a given threshold. Large MWE annotations are needed to train such supertaggers. Probabilistic treatment of contiguous MWEs has been applied to Tree-Substitution Grammar with encouraging results (Green et al., 2013). The main drawback of such probabilistic pre-processing is the fact that it can prevent the parser from finding the right derivations in case when the supertagging was wrong. This situation is avoided in A* parsing which, while requiring that candidate ETs be annotated with the corresponding probabilities, performs a filtering of unlike ET candidates on the fly.

An alternative to probabilistic supertagging has been proposed by Boullier (2003). There, an approximated CFG grammar is computed from an input TAG, and used to parse the input sentence so as to decide which ETs should be selected for TAG parsing. This approach has been enhanced by Gardent et al. (2014) to take word order into account. We consider such a supertagging technique an interesting

candidate for future work. One could indeed not only select ETs that are compatible with the sentence to parse but also distinguish ETs for literal interpretations from ETs for MWEs. Like non-statistical supertagging, using an A* algorithm has the advantage to process MWEs while keeping ambiguity as long as possible to avoid dismissing valid interpretations.

Relatively few works have explicitly addressed the idiomaticity rate of MWEs. (Savary et al., 2012) perform a straightforward matching of a Polish economic MWE lexicon, containing extensional descriptions of morpho-syntactic variants, against a corpus and obtain only 0.12%–0.21% of false positives. (El Maarouf and Oakes, 2015) examine 10 verbal MWEs in the British National Corpus and find out that the idiomaticity measure for half of them exceeds 0.95, and for 9 most frequent of them is above 0.676.

8 Conclusions and future work

We have presented a novel LTAG parsing architecture in which parses potentially containing MWEs are given higher priorities so as to be achieved faster than the competing compositional analyses. The underlying A* algorithm uses a distance estimation heuristic based on the number of terminal nodes in elementary trees. The results obtained with a Polish TAG grammar show that this strategy can considerably reduce the number of parsing items to be explored in order to generate a subset of parses very likely to contain the correct parse. The tests used a grammar extracted from a MWE-annotated treebank but the method also applies to hand-crafted grammars.

Future work includes possible enhancements of the A* heuristic. It currently does not require that, if an ET is used to scan an input terminal, then all the other terminals of this ET also have to be present. It does not require either that the terminals need to be scanned in the appropriate order. Taking such constraints into account might enhance both the parsing quality and speed. Note also that the heuristic ignores ETs which contain no lexical anchors, so it is mainly adapted to strongly lexicalized TAGs. Relieving this constraint, while preserving MWE promotion, would be worth consideration.

Another perspective is to evaluate the computational overhead of the MWE-based heuristic, as opposed to identifying MWEs in a post-parsing step. Also, a fine-grained estimation of the idiomaticity rate of different types of MWEs might give us hints as to which of them should best be identified before, during or after parsing. With such data at hand, it should be possible to construct a multi-stage MWE-aware parsing architecture, tunable for optimum trade-off between accuracy and speed.

Even with MWE lexicon mapping on a treebank, as shown in Sec. 6, sufficiently large MWE-annotated treebanks are hard to obtain, and if they do exist, they are still concerned by MWE sparseness. In the long run, we aim at a hybrid parsing architecture in which a MWE-driven parser is fed with a probabilistic TAG grammar combined with MWE lexicons. We believe that such an extension of our solution to a hybrid setting is possible due to two factors. Firstly, the heuristic described in Sec. 5 generalizes to any weighted TAG with non-negative weights assigned to individual ETs. Secondly, systematically promoting MWE-oriented analyses in probabilistic parsing can be achieved even if MWEs are underrepresented in the training corpus. Namely, MWE-oriented ETs could stem from a syntactic MWE lexicon, such as Walenty (Przepiórkowski et al., 2014), while their weights could be calculated from the weights of the ETs corresponding to their compositional analyses. Alternatively, the weights could be represented as lexicographically ordered pairs, consisting of (i) the number of ETs participating in the underlying derivations, and (ii) the actual weights stemming from the weighted grammar.

Finally, integrating feature structures and unification within this parsing framework might lead to faster pruning of spurious analyses, and enable a more precise MWE identification, especially for inflectionally rich languages like Polish.

Abstract

We present experiments in incrementally learning a dependency parser. The parser will be used in the WordsEye Linguistics Tools (WELT) (Ulinski et al., 2014a; Ulinski et al., 2014b) which supports field linguists documenting a language's syntax and semantics. Our goal is to make syntactic annotation faster for field linguists. We have created a new parallel corpus of descriptions of spatial relations and motion events, based on pictures and video clips used by field linguists for elicitation of language from native speaker informants. We collected descriptions for each picture and video from native speakers in English, Spanish, German, and Egyptian Arabic. We compare the performance of MSTParser (McDonald et al., 2006) and MaltParser (Nivre et al., 2006) when trained on small amounts of this data. We find that MaltParser achieves the best performance. We also present the results of experiments using the parser to assist with annotation. We find that even when the parser is trained on a single sentence from the corpus, annotation time significantly decreases.

1 Introduction

Although languages have appeared and disappeared throughout history, today languages are facing extinction at an unprecedented pace. Over 40% of the estimated 7,000 languages in the world are at risk of disappearing (Alliance for Linguistic Diversity, 2013). Efforts to document languages become even more important with the increasing rate of extinction. Bird (2009) emphasizes a particular need to make use of computational linguistics during fieldwork. One way the WordsEye Linguistics Tools will address this issue is by providing field linguists with the means to easily document syntax, something that is largely missing from existing documentation tools. We model our tools for documenting syntax on the tools for documenting morphology in SIL FieldWorks Language Explorer (FLEx) (SIL FieldWorks, 2014), one of the most widely-used toolkits for field linguists.

An important part of FLEx is its "linguist-friendly" morphological parser (Black and Simons, 2006), which is fully integrated into lexicon development and interlinear text analysis. The parser is constructed "stealthily," in the background, and can help a linguist by predicting glosses and morphological analyses for interlinear texts. In the same way, WELT will provide tools for specifying the syntax of sentences in the form of dependency structures and use them to train a parser in the background. The parser will provide predictions for new sentences, and, as these are corrected and approved by the linguist, they are added to the training data and the parser is incrementally improved.

This paper makes three contributions. First, we introduce a new corpus of English, Spanish, German, and Egyptian Arabic descriptions of spatial relations and motion events, which we have annotated with dependency structures and other linguistic information. We focused on spatial relations and motion because one of the other functions of WELT will be to assist field linguists with elicitation of spatial language and documentation of spatial and motion semantics. We are making the corpus available to the public. Second, we compare the performance of two existing dependency parsing packages, MSTParser (McDonald et al., 2006) and MaltParser (Nivre et al., 2006), using incrementally increasing amounts of

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 440–449, Osaka, Japan, December 11-17 2016.

this training data. Third, we show that using a parser trained on small amounts of data can assist with dependency annotation.

In Section 2, we discuss related work. In Section 3, we describe the new publicly available corpus. In Section 4, we describe the parsing experiments and discuss the results. Section 5 discusses initial experiments with nonlexical models. We discuss the annotation experiments and results in Section 6. We conclude in Section 7.

2 Related Work

There have been a number of investigations into multilingual dependency parsing. For example, Nivre et al. (2007b) presents detailed results for 11 languages using the arc-eager deterministic parsing algorithm included in MaltParser. However, results are reported only for the parser trained on the full training set and would not generalize to situations where training data is limited. Likewise, the 2006 and 2007 CoNLL shared tasks of multilingual dependency parsing (Buchholz and Marsi, 2006; Nivre et al., 2007a) relied on the existence of ample training data for the languages being investigated. Our work differs in that we are interested in the performance of a dependency parser trained on very little data.

Duong et al. (2015) approach dependency parsing for a low-resource language as a domain adaptation task; a treebank in a high-resource language is considered out-of-domain, and a much smaller treebank in a low-resource language is considered in-domain. They jointly train a neural network dependency parser to model the syntax of both the high-resource and the low-resource language. In this paper, we focus on the alternate approach of training directly on small amounts of data.

Guo et al. (2015) also investigate inducing dependency parsers for low-resource languages using training data from high-resource languages. They focus on lexical features, which are not directly transferable among languages, and propose the use of distributed feature representations instead of discrete lexical features. Lacroix et al. (2016) describe a method for transferring dependency parsers across languages by projecting annotations across word alignments and learning from the partially annotated data. However, both of these methods rely on large amounts of (unannotated) data in the target language in order to learn the word embeddings and alignments. It is unclear how well these approaches would work in the context of an endangered language where large amounts of unannotated text will not be available.

Our work also differs from the above because our goal is to incorporate a parser into tools for field linguists studying endangered languages. Currently, there are limited options for creating a syntactic parser for an endangered language. The *ParGram* project (ParGram, 2013) aims to produce wide coverage grammars for a variety of languages, but doing so requires knowledge both of the LFG formalism and the XLE development platform (Crouch et al., 2011). It is unlikely that a field linguist would have the grammar engineering skills necessary to create a grammar in this way. Similarly, the LinGO Grammar Matrix (Bender et al., 2002) is a framework for creating broad-coverage HPSG grammars. The Grammar Matrix facilitates grammar engineering by generating "starter grammars" for a language from the answers to a typological questionnaire. Extending a grammar beyond the prototype, however, does require extensive knowledge of HPSG, making this tool more feasibly used by computational linguists than by field linguists. Our work differs from both ParGram and the Grammar Matrix because we do not require the field linguist to master a particular grammar formalism. Instead, linguists will create a syntactic parser simply by labeling individual sentences, a procedure that builds easily upon an existing workflow that already includes annotating sentences with morphological information.

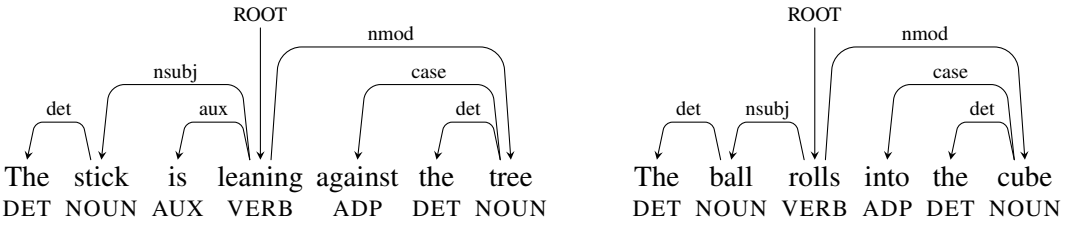
3 Corpus

To obtain a corpus that is similar to sentences that field linguists would probably analyze using WELT, we started with two stimulus kits used by field linguists to study spatial and motion language: the Picture Series for Positional Verbs (Ameka et al., 1999) and the Motion Verb Stimulus Kit (Levinson, 2001). For each picture and video clip, we elicited a one-sentence description from native speakers of English, Spanish, German, and Egyptian Arabic. We chose languages covering a range of linguistic phenomena. For example, German uses morphological case, and Spanish and Arabic both use clitics. In future work, we hope to add languages from other language families, including Chinese and Korean. Our languages

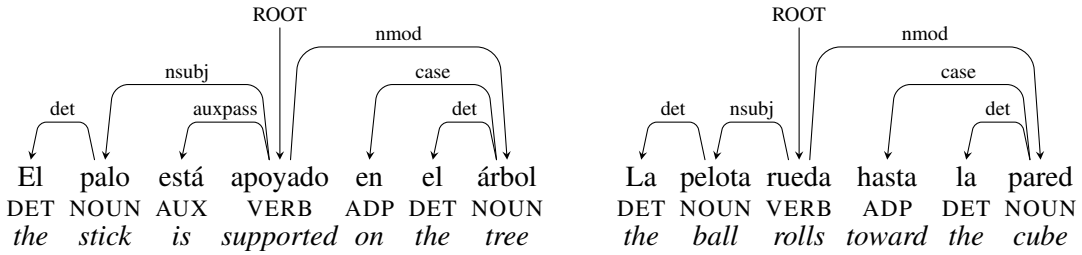
are high-resource languages because we needed to have access to linguistically trained native speakers in order to create the gold standard; however, we did not actually use any additional resources for these languages in our experiments, and we believe they can therefore stand in for low-resource languages.

	# sents	Avg. len.	# words	# lemmas	# pos tags	# features	# labels
English	163	7.21	152	135	12	26	20
Spanish	165	8.51	180	149	12	30	20
German	157	7.52	217	175	13	32	19
Arabic	158	10.04	174	117	10	37	15

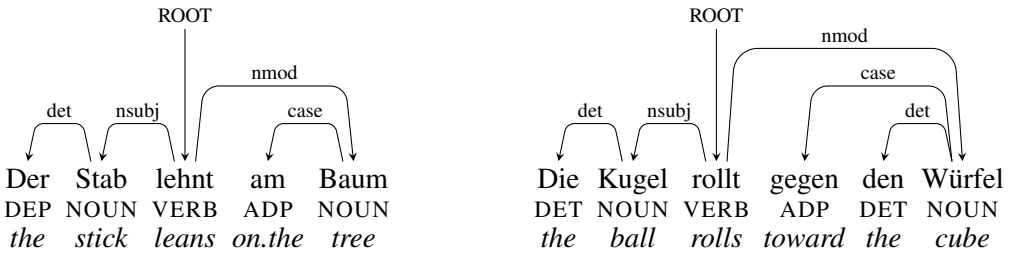
Table 1: Summary of each language in the corpus



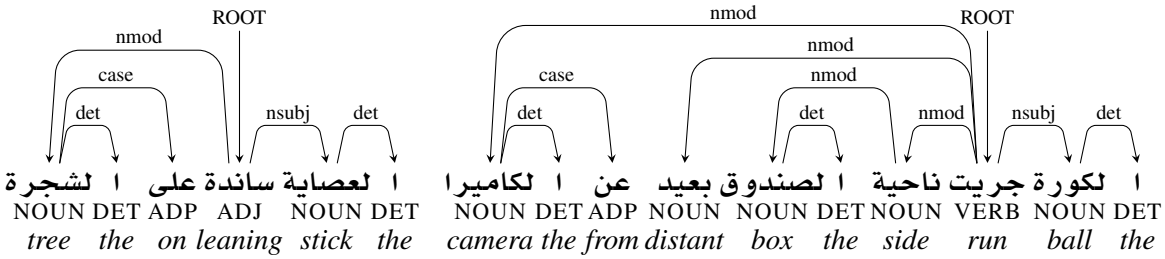
(a) English



(b) Spanish



(c) German



(d) Arabic

Figure 1: Example dependency structures

We start out by tokenizing each sentence; for Spanish and Arabic, this step includes splitting off the clitics. We then annotated each token with its lemma, morphological information, part of speech, syntactic head, and dependency label. For consistency across languages, we used part of speech tags, morphological features, and dependency labels from the Universal Dependencies project (Nivre et al., 2016) and attempted to follow the universal guidelines as closely as possible. The total number of sentences, aver-

age sentence length, and number of unique words, lemmas, part of speech tags, morphological features, and dependency labels for each language is shown in Table 1. Note the sentence count varies slightly for each language; this is because for some of the pictures and videos, the native informant gave us several possible descriptions. English and German have very similar average sentence lengths; average lengths in Spanish and Arabic are higher. German had the largest vocabulary; English had the smallest vocabulary. All languages used similar numbers of part of speech tags and dependency labels, except Arabic which used fewer of both. Arabic had the largest number of morphological features, and English the smallest. Some example sentences with dependency labels are shown in Figure 1.

4 Parsing Experiments and Results

We used four methods of training a dependency parser on our data: MSTParser (McDonald et al., 2006), two configurations of MaltParser (Nivre et al., 2006), and a baseline. All experiments used 5-fold cross validation. For each of the four training methods, we trained on a subset of the train fold ranging from 1 sentence to 100 sentences. We tested on the full test fold, and then averaged the accuracy across the five folds. Results are shown in Table 2. Arc accuracy requires selecting the correct head for a token; Lbl accuracy requires selecting the correct dependency label; Both requires that both head and dependency label are correct. The highest accuracy in each row for each metric (Arc, Lbl, Both) is shown in bold.

The baseline is determined by assigning the majority dependency label from the train data. Heads are selected using left or right attachment, whichever is more common in the train data. For most of the training sets, we did left attachment and assigned `det` as the dependency label, and the baseline usually remained constant across all train sizes. For German with train size = 2, one of the folds had a majority of right attachment, which resulted in a slight decrease in baseline accuracy. Likewise, for Arabic with train size = 1 and train size = 2, one fold used right attachment, resulting in a decrease in arc accuracy for those rows. The Arabic label accuracy was much more variable, since `nmod` was the majority label about half of the time. The Arabic baseline used for each train size and train fold is shown in Table 3.

The first parser we tested was MSTParser (McDonald et al., 2006; McDonald et al., 2005), which uses a two-stage approach to parsing: an unlabeled parser and a separate edge labeler. The parser works by finding a maximum spanning tree; the label sequence is then found using Viterbi's algorithm. MSTParser uses a combination of lexical, part of speech, and morphological features; we did not modify the default feature set.

Train size	**Fold 1**	**Fold 2**	**Fold 3**	**Fold 4**	**Fold 5**
1	det	det	nmod **(right)**	nmod	det
2	det	det	nmod **(right)**	det	nmod
5	det	det	det	nmod	nmod
10	nmod	det	det	det	nmod
25	nmod	det	nmod	nmod	nmod
50	nmod	det	det	nmod	nmod
100	det	det	det	nmod	nmod

Table 3: Arabic baseline: majority label per fold; if not otherwise indicated, the default attachment is left

We next tested MaltParser (Nivre et al., 2006), which implements a variety of deterministic parsing algorithms. A dependency structure is derived using features of the current parser state to predict the next action. Parser state is represented by a stack of partially processed tokens and a list of remaining input tokens. We tested two algorithms: Nivre arc-eager and Nivre arc-standard. The arc-eager algorithm adds arcs to the dependency tree as soon as the head and dependent are available; the arc-standard algorithm requires that the dependent already be complete with respect to its own dependents. We used the default feature sets for each of the algorithms. Like MSTParser, the feature set includes a combination of lexical, part of speech, and morphological features; MaltParser also adds dependency features (arcs and labels) from the current parser state.

Even with only one training sentence, both MSTParser and MaltParser performed well above the baseline. MaltParser consistently achieved higher accuracy than MSTParser for all languages and train sizes, especially when predicting the dependency labels. The performance of the arc-eager algorithm vs.

(d) Arabic

Table 2: Accuracy of each parsing method.

the arc-standard algorithm seems to vary by language and train size. For English, Spanish, and German, the arc-standard algorithm has higher performance on small training sets, while the arc-eager algorithm becomes superior as more training data is available. Results are more mixed for the Arabic data.

5 Initial Experiments with Nonlexical Models

One of the goals of WELT will be to encourage sharing of data and analyses among field linguists. Since stimulus packs (such as the picture series and video series that we used to create our corpus) are commonly reused across many languages, it would be helpful if a parser trained on a fully-annotated version of the data for one language could be used by a field linguist just starting out with another, potentially similar, language. To that end, we performed an initial experiment to see whether a parser trained on one language could be applied successfully to the other languages in our corpus. To test this, we used MaltParser (arc-eager algorithm) to train a parser on English data, using only nonlexical features: part of speech, morphological tags, and dependency labels/arcs. We then applied this model to the other three languages. Results are shown in Table 4. For this experiment, we used all 163 sentences from the English corpus.

Comparing these results to those in Table 2, we see that, for Spanish, the English nonlexical model performs similarly to MaltParser trained on 5 Spanish sentences. For German, the English nonlexical model performs similarly to MaltParser trained on 5-10 German sentences. For Arabic, the English nonlexical model has lower accuracy than MaltParser trained on a single Arabic sentence. This suggests that a simple nonlexical model such as this one may only be useful for linguists using WELT if an annotated corpus in a *related* language is available.

	Arc	Label	Arc+Label
Spanish	0.767	0.816	0.719
German	0.808	0.840	0.773
Arabic	0.629	0.713	0.567

Table 4: Accuracy of (English) nonlexical model applied to other languages

6 Annotation Experiments and Results

To test whether our parser would help with annotation, we performed annotation experiments using the English data. We timed how long it took an annotator to label a sentence, when the sentence is preprocessed in one of four ways. In the first method, a baseline assigns a flat structure and the dependency label `det` to all nodes. The other methods use MaltParser (Nivre arc-eager algorithm) trained on 1, 5, or 25 sentences to provide an initial parse for the annotator to correct.

Annotators labeled 5 trees for each parsing method, for a total of 20 trees. To ensure each of the four sets of 5 contained sentences with similar syntactic complexity, the sentences were chosen as follows. Each parsing method was assigned 1 sentence of each of 5 lengths: 7 words, 8 words, 9 words, 10-11 words, and 12-14 words. These were randomly selected from among all sentences of the required length. The 20 sentences were then presented to the annotator in random order. To keep the experiment consistent, all annotators labeled the same 20 sentences, in the same order.

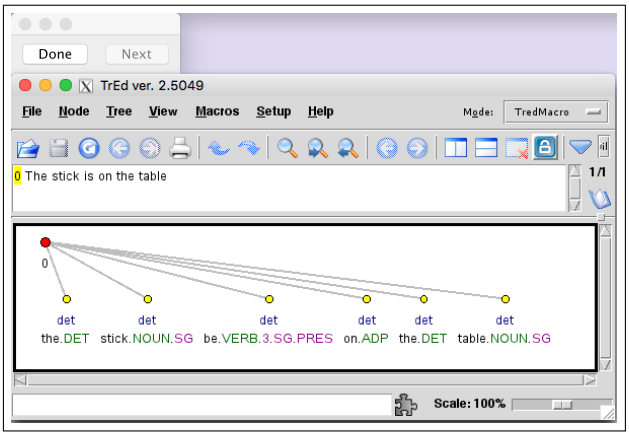

Figure 2: Screenshot of annotation software

Three annotators participated in the experiment. The first was the first author of this paper. She is an expert annotator, very familiar with the universal guidelines for dependency annotation and the annotation software. The other two annotators were undergraduate students who participated in a brief training session to familiarize them with the desired analysis and the software. They were given ref-

erence materials showing sample trees covering a variety of syntactic phenomena including: auxiliaries, copulas, coordination, secondary predication, and subordinate clauses. They were permitted to refer to this material throughout the annotation task. Before participating in the annotation task, they annotated 10 additional trees for practice.

The software used for annotation was Tree Editor (TrEd) (Pajas and Štěpánek, 2008) with a simple Java wrapper that handled opening files in TrEd and keeping track of annotation time. A screenshot of the setup is shown in Figure 2. Upon pressing the Next button, the annotator was shown the next tree in TrEd and the program recorded the start time. When the annotator finished labeling a tree, they saved the file in TrEd and pressed the Done button. The wrapper program closed the current file in TrEd and recorded the end time.

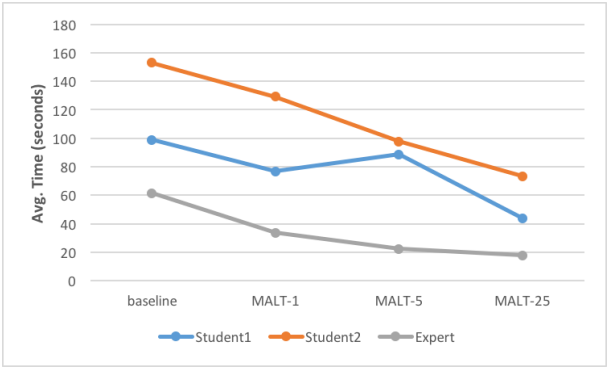

Figure 3: Annotation time across all sentence sizes

A graph showing the average time (across all sentence lengths) it took each annotator to label a tree for each of the four parsing types is shown in Figure 3. A detailed listing of the time each annotator took for each sentence size is shown in Table 5. A graph showing the average time (across annotators) for each sentence size is shown in Figure 4(a). All times are given in seconds. The accuracy of MaltParser (arc-eager) on sentences of different lengths is shown in Figure 4(b).

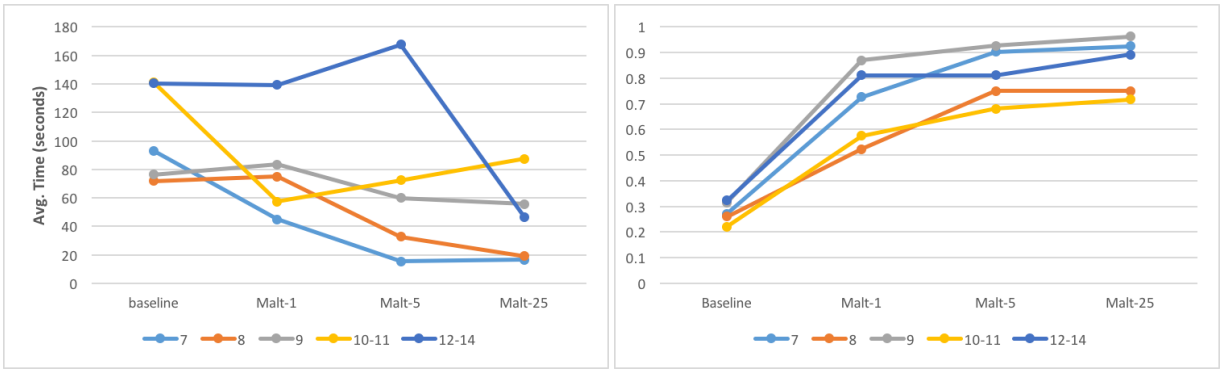
(d) Average

Table 5: Time (seconds) to annotate each sentence

Results vary slightly across annotators, but it is clear that, even when training on a single sentence, annotation time is improved. Average annotation time decreases from 104.5 seconds for the baseline parse to 79.9 seconds for the parser trained on one sentence. Using the parser trained on 5 sentences, average annotation time decreases again to 69.6 seconds. Using the parser trained 25 sentences, we see a decrease in annotation time to an average of 45 seconds. Statistical significance testing was done with a paired t-test. Significant decreases in annotation time are: between the baseline and 1 training sentence ($p = 0.034$), between the baseline and 5 training sentences ($p = 0.015$), between the baseline



(a) (b)

Figure 4: Graphs of (a) annotation time for each sentence size, across all annotators (b) parser accuracy on each sentence size

and 25 training sentences ($p = 2.51\text{e}{-5}$), and between 1 training sentence and 25 training sentences ($p = 0.018$).

There are several reasons to account for the fact that training on a single sentence significantly decreases annotation time. MaltParser works by predicting steps in a derivation, so one sentence actually translates into more than one data point. With only one sentence, the parser can learn that a determiner should be the left child of a noun, or that a noun should be the left child of the root predicate. Having these dependencies already attached reduces the work the annotator must do compared to a completely flat structure. In addition, our corpus consists only of descriptions of spatial relations and motion events, so we expect a much more limited range of grammatical constructs than one finds in other treebanks.

For very short sentences (length 7), the graph in Figure 4(b) shows a clear downward trend as the amount of training data increases. For sentences of length 8-9, we do not see improvement with one training sentence, but annotation time begins to decrease substantially when there are 5 training sentences. For longer sentences, the downward trend is less clear. This makes sense, since we can expect to find a wider range of syntactic structures in a longer sentence, and parser performance on these will require that a similar structure was seen in the train set. For sentences length 10-11, there is a substantial drop in annotation time from baseline to 1 training sentence, at which point it seems to plateau. For sentences length 12-14, average annotation time does not decrease until we have 25 training sentences.

Parser	**Student1**			**Student2**			**Expert**		
	Arc	**Lbl**	**Both**	**Arc**	**Lbl**	**Both**	**Arc**	**Lbl**	**Both**
Baseline	0.951	1.000	0.951	1.000	1.000	1.000	1.000	1.000	1.000
Malt-1	0.971	1.000	0.971	1.000	1.000	1.000	1.000	1.000	1.000
Malt-5	0.930	0.950	0.905	0.980	1.000	0.980	0.980	1.000	0.980
Malt-25	0.962	0.982	0.962	1.000	1.000	1.000	1.000	1.000	1.000

Table 6: Annotation accuracy

One concern with using a parser to assist with annotation is whether there will be any effect on overall accuracy. When presented with a mostly-correct parse, will annotators be able to see all the errors and fix them? The accuracy of the annotators for each of the four parsing types is shown in Table 6. We do see a drop in accuracy for all annotators when training on 5 sentences, especially for Student1. However, this decrease is very slight for both Student2 and Expert. We suspect there may have been several difficult sentences in this set; all annotators made errors on the sentence of length 10, and Student1 had particularly low accuracy (0.625) on the sentence of length 8.

7 Summary and Future Work

We have reported results for incrementally training a dependency parser across four languages. Our results show that such a parser can improve on baseline performance even when trained on a single

sentence, making our method particularly useful in the documentation of endangered and low-resource languages. We found that MaltParser achieved the highest accuracy overall; the arc-standard algorithm seems preferable for very small training sizes and arc-eager for slightly larger training sizes. We found that using a parser to predict each sentence before annotation did significantly improve annotation time, without a substantial decrease in accuracy.

The results of our experiments demonstrate that it is possible to extend FieldWorks' "stealthy" approach to learning a morphological parser into the realm of syntax. By providing a way to assign dependency structures to sentences, WELT will allow field linguists to incorporate syntax into language documentation. The incrementally trained parser will reduce their workload by letting them correct errors in a dependency structure rather than starting from scratch. This method of syntactic documentation does not limit the field linguist to a particular syntactic theory. We chose to use the universal labels and analyses in our corpus, but WELT users will have complete control over assignment of heads and choice of dependency labels. The only requirement is that they are consistent across sentences.

In future work, we will experiment with other parsers, such as TurboParser (Martins et al., 2010), Mate (Bohnet, 2010), and Easy-First (Goldberg and Elhadad, 2010). Furthermore, we will continue to investigate methods of re-using existing parsers and dependency annotations with new languages (see Section 5); specifically, we will investigate more effective methods of adapting existing parsers to other languages. For example, we will investigate how to combine a non-lexical model with a lexical model obtained from a small number of target language sentences. We will also investigate ways for linguists to directly specify syntactic properties that can be used by the parser, similar to the way FLEx converts morphological properties specified by users into formal rules compatible with the underlying parser. Finally, we plan to try our WELT system in actual fieldwork.

Abstract

This work focuses on the rapid development of linguistic annotation tools for resource-poor languages. We experiment several cross-lingual annotation projection methods using Recurrent Neural Networks (RNN) models. The distinctive feature of our approach is that our multilingual word representation requires only a parallel corpus between source and target languages. More precisely, our method has the following characteristics: (a) it does not use word alignment information, (b) it does not assume any knowledge about foreign languages, which makes it applicable to a wide range of resource-poor languages, (c) it provides truly multilingual taggers. We investigate both uni- and bi-directional RNN models and propose a method to include external information (for instance low level information from Part-Of-Speech tags) in the RNN to train higher level taggers (for instance, super sense taggers). We demonstrate the validity and genericity of our model by using parallel corpora (obtained by manual or automatic translation). Our experiments are conducted to induce cross-lingual POS and super sense taggers.

1 Introduction

In order to minimize the need for annotated resources (produced through manual annotation, or by manual check of automatic annotation), several research works were interested in building Natural Language Processing (NLP) tools based on unsupervised or semi-supervised approaches (Collins and Singer, 1999; Klein, 2005; Goldberg, 2010). For example, NLP tools based on cross-language projection of linguistic annotations achieved good performances in the early 2000s (Yarowsky et al., 2001). The key idea of annotation projection can be summarized as follows: through word alignment in parallel text corpora, the annotations are transferred from the *source* (resource-rich) language to the *target* (under-resourced) language, and the resulting annotations are used for supervised training in the target language. However, automatic word alignment errors (Fraser and Marcu, 2007) limit the performance of these approaches.

Our work is built upon these previous contributions and observations. We explore the possibility of using Recurrent Neural Networks (RNN) to build multilingual NLP tools for resource-poor languages analysis. The major difference with previous works is that we do not explicitly use word alignment information. Our only assumption is that parallel sentences (source-target) are available and that the source part is annotated. In other words, we try to infer annotations in the target language from sentence-based alignments only. While most NLP researches on RNN have focused on monolingual tasks[1] and sequence labeling (Collobert et al., 2011; Graves, 2012), this paper, however, considers the problem of learning multilingual NLP tools using RNN.

Contributions In this paper, we investigate the effectiveness of RNN architectures — Simple RNN (SRNN) and Bidirectional RNN (BRNN) — for multilingual sequence labeling tasks without using any word alignment information. Two NLP tasks are considered: Part-Of-Speech (POS) tagging and Super Sense (SST) tagging (Ciaramita and Altun, 2006). Our RNN architectures demonstrate very competitive results on unsupervised training for new target languages. In addition, we show that the integration of

[1]Exceptions are the recent propositions on Neural Machine Translation (Cho et al., 2014; Sutskever et al., 2014)

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 450–460, Osaka, Japan, December 11-17 2016.

POS information in RNN models is useful to build multilingual coarse-grain semantic (Super Senses) taggers. For this, a simple and efficient way to take into account low-level linguistic information for more complex sequence labeling RNN is proposed.

Methodology For training our multilingual RNN models, we just need as input a parallel (or multi-parallel) corpus between a resource-rich language and one or many under-resourced languages. Such a parallel corpus can be manually obtained (clean corpus) or automatically obtained (noisy corpus).

To show the potential of our approach, we investigate two sequence labeling tasks: cross-language POS tagging and multilingual Super Sense Tagging (SST). For the SST task, we measure the impact of the parallel corpus quality with manual or automatic translations of the SemCor (Miller et al., 1993) translated from English into Italian (manually and automatically) and French (automatically).

Outline The remainder of the paper is organized as follows. Section 2 reviews related work. Section 3 describes our cross-language annotation projection approaches based on RNN. Section 4 presents the empirical study and associated results. We finally conclude the paper in Section 5.

2 Related Work

Cross-lingual projection of linguistic annotations was pioneered by Yarowsky et al. (2001) who created new monolingual resources by transferring annotations from resource-rich languages onto resource-poor languages through the use of word alignments. The resulting (noisy) annotations are used in conjunction with robust learning algorithms to build cheap unsupervised NLP tools (Padó and Lapata, 2009). This approach has been successfully used to transfer several linguistic annotations between languages (efficient learning of POS taggers (Das and Petrov, 2011; Duong et al., 2013) and accurate projection of word senses (Bentivogli et al., 2004)). Cross-lingual projection requires a parallel corpus and word alignment between source and target languages. Many automatic word alignment tools are available, such as GIZA++ which implements IBM models (Och and Ney, 2000). However, the noisy (non perfect) outputs of these methods is a serious limitation for the annotation projection based on word alignments (Fraser and Marcu, 2007).

To deal with this limitation, recent studies based on cross-lingual representation learning methods have been proposed to avoid using such pre-processed and noisy alignments for label projection. First, these approaches learn language-independent features, across many different languages (Durrett et al., 2012; Al-Rfou et al., 2013; Täckström et al., 2013; Luong et al., 2015; Gouws and Søgaard, 2015; Gouws et al., 2015). Then, the induced representation space is used to train NLP tools by exploiting labeled data from the source language and apply them in the target language. Cross-lingual representation learning approaches have achieved good results in different NLP applications such as cross-language SST and POS tagging (Gouws and Søgaard, 2015), cross-language named entity recognition (Täckström et al., 2012), cross-lingual document classification and lexical translation task (Gouws et al., 2015), cross language dependency parsing (Durrett et al., 2012; Täckström et al., 2013) and cross-language semantic role labeling (Titov and Klementiev, 2012).

Our approach described in next section, is inspired by these works since we also try to induce a common language-independent feature space (crosslingual words embeddings). Unlike Durrett et al. (2012) and Gouws and Søgaard (2015), who use bilingual lexicons, and unlike Luong et al. (2015) who use word alignments between the source and target languages[2] our common multilingual representation is very agnostic. We use a simple (multilingual) vector representation based on the occurrence of source and target words in a parallel corpus and we let the RNN learn the best internal representations (corresponding to the hidden layers) specific to the task (SST or POS tagging).

In this work, we learn a cross-lingual POS tagger (multilingual POS tagger if a multilingual parallel corpus is used) based on a recurrent neural network (RNN) on the source labeled text and apply it to tag target language text. We explore simple and bidirectional RNN architectures (SRNN and BRNN respectively). Starting from the intuition that low-level linguistic information is useful to learn more complex taggers, we also introduce three new RNN variants to take into account external (POS) information in multilingual SST.

[2]to train a bilingual representation regardless of the task

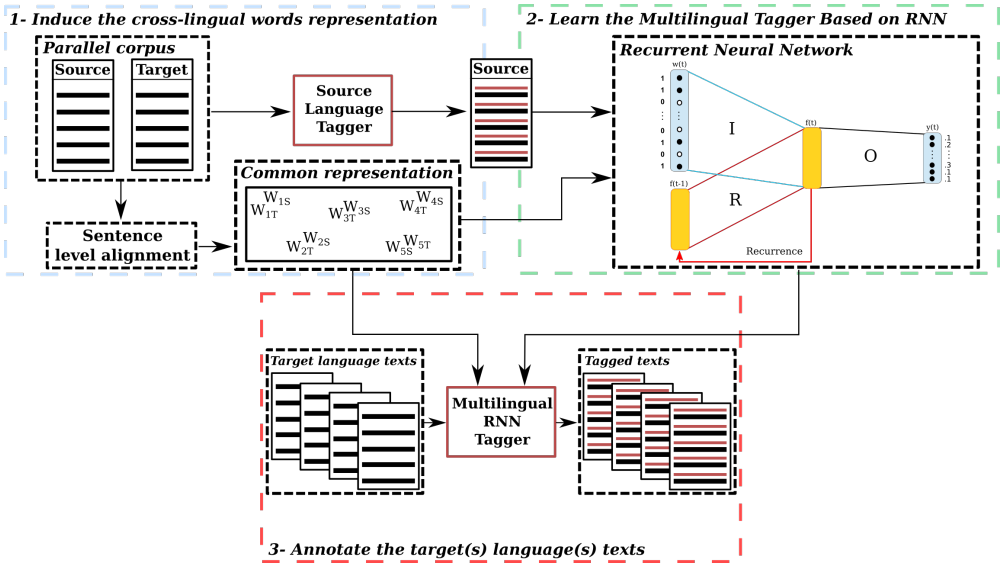

Figure 1: Overview of the proposed model architecture for inducing multilingual RNN taggers.

3 Unsupervised Approach Overview

To avoid projecting label information from deterministic and error-prone word alignments, we propose to represent the word alignment information intrinsically in a recurrent neural network architecture. The idea consists in implementing a recurrent neural network as a multilingual sequence labeling tool (we investigate POS tagging and SST tagging). Before describing our cross-lingual (multilingual if a multi-parallel corpus is used) neural network tagger, we present the simple cross-lingual projection method, considered as our baseline in this work.

3.1 Baseline Cross-lingual Annotation Projection

We use direct transfer as a baseline system which is similar to the method described in (Yarowsky et al., 2001). First we tag the source side of the parallel corpus using the available supervised tagger. Next, we align words in the parallel corpus to find out corresponding source and target words. Tags are then projected to the (resource-poor) target language. The target language tagger is trained using any machine learning approach (we use TnT tagger (Brants, 2000) in our experiments).

3.2 Proposed Approach

We propose a method for learning multilingual sequence labeling tools based on RNN, as it can be seen in Figure 1. In our approach, a parallel or multi-parallel corpus between a resource-rich language and one or many under-resourced languages is used to extract common (multilingual) and agnostic words representations. These representations, which rely on sentence level alignment only, are used with the source side of the parallel/multi-parallel corpus to learn a neural network tagger in the source language. Since a common representation of source and target words is chosen, this neural network tagger is truly multilingual and can be also used to tag texts in target language(s).

3.2.1 Common Words Representation

In our *agnostic* representation, we associate to each word (in source *and* target vocabularies) a common vector representation, namely $V_{wi}, i = 1, ..., N$, where N is the number of parallel sentences (bi-sentences in the parallel corpus). If w appears in i-th bi-sentence of the parallel corpus then $V_{wi} = 1$.

The idea is that, in general, a source word and its target translation appear together in the same bi-sentences and their vector representations are close. We can then use the RNN tagger, initially trained on source side, to tag the target side (because of our *common vector representation*). This simple representation does not require multilingual word alignments and it lets the RNN learns the optimal internal representation needed for the annotation task (for instance, the hidden layers of the RNN can be considered as multi-lingual embeddings of the words).

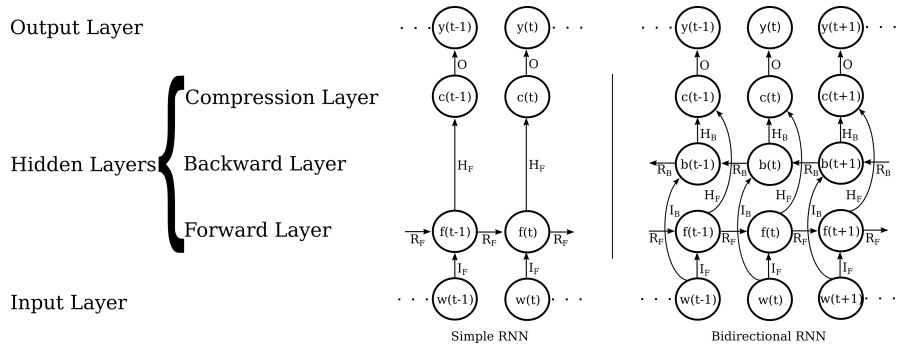

Figure 2: High level schema of RNN used in our work.

3.2.2 Recurrent Neural Networks

There are two major architectures of neural networks: Feedforward (Bengio et al., 2003) and Recurrent Neural Networks (RNN) (Schmidhuber, 1992; Mikolov et al., 2010). Sundermeyer et al. (2013) showed that language models based on recurrent architecture achieve better performance than language models based on feedforward architecture. This is due to the fact that recurrent neural networks do not use a context of limited size. This property led us to use, in our experiments, the Elman recurrent architecture (Elman, 1990), in which recurrent connections occur at the hidden layer level.

We consider in this work two Elman RNN architectures (see Figure 2): *Simple* RNN (SRNN) and *Bidirectional* RNN (BRNN). In addition, to be able to include low-level linguistic information in our architecture designed for more complex sequence labeling tasks, we propose three new RNN variants to take into account external (POS) information for multilingual Super Sense Tagging (SST).

A. Simple RNN

In the *simple* Elman RNN (SRNN), the recurrent connection is a loop at the hidden layer level. This connection allows SRNN to use at the current time step hidden layer's states of previous time steps. In other words, the hidden layer of SRNN represents all previous history and not just $n-1$ previous inputs, thus the model can theoretically represent long context.

The architecture of the SRNN considered in this work is shown in Figure 2. In this architecture, we have 4 layers: input layer, forward (also called recurrent or context layer), compression hidden layer and output layer. All neurons of the input layer are connected to every neuron of forward layer by weight matrix I_F and R_F, the weight matrix H_F connects all neurons of the forward layer to every neuron of compression layer and all neurons of the compression layer are connected to every neuron of output layer by weight matrix O.

The input layer consists of a vector $w(t)$ that represents the current word w_t in our common words representation (all input neurons corresponding to current word w_t are set to 0 except those that correspond to bi-sentences containing w_t, which are set to 1), and of vector $f(t-1)$ that represents output values in the forward layer from the previous time step. We name $f(t)$ and $c(t)$ the current time step hidden layers (our preliminary experiments have shown better performance using these two hidden layers instead of one hidden layer), with variable sizes (usually 80-1024 neurons) and sigmoid activation function. These hidden layers represent our common language-independent feature space and inherently capture word alignment information. The output layer $y(t)$, given the input $w(t)$ and $f(t-1)$ is computed with the following steps :

$$f(t) = \Sigma(w(t).I_F(t) + f(t-1).R_F(t)) \quad (1)$$

$$c(t) = \Sigma(f(t).H_F(t)) \quad (2)$$

$$y(t) = \Gamma(c(t).O(t)) \quad (3)$$

Σ and Γ are the sigmoid and the softmax functions, respectively. The softmax activation function is used to normalize the values of output neurons to sum up to 1. After the network is trained, the output $y(t)$ is a vector representing a probability distribution over the set of tags. The current word w_t (in input) is tagged with the most probable output tag.

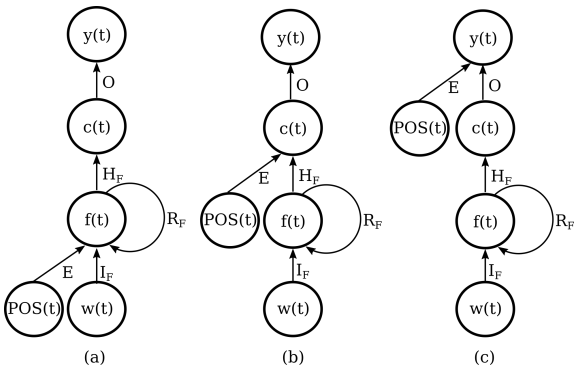

Figure 3: SRNN variants with POS information at three levels: (a) input layer, (b) forward layer, (c) compression layer.

For many sequence labeling tasks, it is beneficial to have access to future in addition to the past context. So, it can be argued that our SRNN is not optimal for sequence labeling, since the network ignores future context and tries to optimize the output prediction given the previous context only. This SRNN is thus penalized compared with our baseline projection based on TnT (Brants, 2000) which considers both left and right contexts. To overcome the limitations of SRNN, a simple extension of the SRNN architecture — namely Bidirectional recurrent neural network (BRNN) (Schuster and Paliwal, 1997) — is used to ensure that context at previous and future time steps will be considered.

B. Bidirectional RNN

An unfolded BRNN architecture is given in Figure 2. The basic idea of BRNN is to present each training sequence forwards and backwards to two separate recurrent hidden layers (forward and backward hidden layers) and then somehow merge the results. This structure provides the compression and the output layers with complete past and future context for every point in the input sequence. Note that without the backward layer, this structure simplifies to a SRNN.

C. RNN Variants

As mentioned in the introduction, we propose three new RNN variants to take into account low level (POS) information in a higher level (SST) annotation task. The question addressed here is: at which layer of the RNN this low level information should be included to improve SST performance? As specified in Figure 3, the POS information can be introduced either at input layer or at forward layer (forward and backward layers for BRNN) or at compression layer. In all these RNN variants, the POS of the current word is also represented with a vector ($POS(t)$). Its dimension corresponds to the number of POS tags in the tagset (universal tagset of Petrov et al. (2012) is used). We propose one *hot* vector representation where only one value is set to 1 and corresponds to the index of current tag (all other values are 0).

3.2.3 Network Training

The first step in our approach is to train the neural network, given a parallel corpus (training corpus), and a validation corpus (different from train data) in the source language. In typical applications, the source language is a resource-rich language (which already has an efficient tagger or manually tagged resources). Our RNN models are trained by stochastic gradient descent using usual back-propagation and back-propagation through time algorithms (Rumelhart et al., 1985). We learn our RNN models with an iterative process on the tagged source side of the parallel corpus. After each epoch (iteration) in training, validation data is used to compute per-token accuracy of the model. After that, if the per-token accuracy increases, training continues in the new epoch. Otherwise, the learning rate is halved at the start of the new epoch. Eventually, if the per-token accuracy does not increase anymore, training is stopped to prevent over-fitting. Generally, convergence takes 5–10 epochs, starting with a learning rate $\alpha = 0.1$.

The second step consists in using the trained model as a target language tagger (using our common

vector representation). It is important to note that if we train on a multilingual parallel corpus with *N* languages ($N > 2$), the same trained model will be able to tag all the *N* languages.

Hence, our approach assumes that the word order in both source and target languages are similar. In some languages such as English and French, word order for contexts containing nouns could be reversed most of the time. For example, the compound word *the European Commission* would be translated into *la Commission européenne*. In order to deal with the word order constraints, we also combine the RNN model with the cross-lingual projection model in our experiments.

3.3 Dealing with out-of-vocabulary words

For the words absent from in the initial parallel corpus, their vector representation is a vector of zero values. Consequently, during testing, the RNN model will use only the context information to tag the OOV words found in the test corpus. To deal with these types of OOV words[3], we use the CBOW model of (Mikolov et al., 2013) to replace each OOV word by its closest known word in the current OOV word context. Once the closest word is found, its common vector representation is used (instead of the vector of zero values) at the input of the RNN.

3.4 Combining Simple Cross-lingual Projection and RNN Models

Since the simple cross-lingual projection model *M1* and RNN model *M2* use different strategies for tagging (TnT is based on Markov models while RNN is a neural network), we assume that these two models can be complementary. To keep the benefits of each approach, we explore how to combine them with linear interpolation. Formally, the probability to tag a given word *w* is computed as

$$P_{M12}(t|w) = (\mu P_{M1}(t|w, C_{M1}) + (1 - \mu)P_{M2}(t|w, C_{M2})) \quad (4)$$

where, C_{M1} and C_{M2} are the context of w considered by *M1* and *M2* respectively. The relative importance of each model is adjusted through the interpolation parameter μ. The word w is tagged with the most probable tag, using the function f described as

$$f(w) = \arg\max_t(P_{M12}(t|w)) \quad (5)$$

4 Experiments

Our models are evaluated on two labeling tasks: Cross-language Part-Of-speech (POS) tagging and Multilingual Super Sense Tagging (SST).

4.1 Multilingual POS Tagging

We applied our method to build RNN POS taggers for four target languages - French, German, Greek and Spanish - with English as the source language.

In order to determine the effectiveness of our common words representation described in section 3.2.1, we also investigated the use of state-of-the-art bilingual word embeddings (using MultiVec Toolkit (Bérard et al., 2016)) as input to our RNN.

4.1.1 Dataset

For French as a target language, we used a training set of $10,000$ parallel sentences, a validation set of 1000 English sentences, and a test set of 1000 French sentences, all extracted from the ARCADE II English-French corpus (Veronis et al., 2008). The test set is tagged with the French *TreeTagger* (Schmid, 1995) and then manually checked.

For German, Greek and Spanish as a target language, we used training and validation data extracted from the Europarl corpus (Koehn, 2005) which are a subset of the training data used in (Das and Petrov, 2011; Duong et al., 2013). This choice allows us to compare our results with those of (Das and Petrov, 2011; Duong et al., 2013; Gouws and Søgaard, 2015). The train data set contains $65,000$ bi-sentences ; a validation set of $10,000$ bi-sentences is also available. For testing, we use the same test corpora as (Das and Petrov, 2011; Duong et al., 2013; Gouws and Søgaard, 2015) (bi-sentences from CoNLL shared

[3] words which do not have a known vector representation

Table 1: Token-level POS tagging accuracy for Simple Projection, SRNN using MultiVec bilingual word embeddings as input, RNN[5], Projection+RNN and methods of Das & Petrov (2011), Duong et al (2013) and Gouws & Søgaard (2015).

tasks on dependency parsing (Buchholz and Marsi, 2006)). The evaluation metric (*per-token* accuracy) and the Petrov et al. (2012) *universal tagset* are used for evaluation.

For training, the English (source) sides of the training corpora (ARCADE II and Europarl) and of the validation corpora are tagged with the English *TreeTagger* toolkit. Using the matching provided by Petrov et al. (2012), we map the TreeTagger and the CoNLL tagsets to the common *Universal Tagset*.

In order to build our baseline unsupervised tagger (based on a Simple Cross-lingual Projection – see section 3.1), we also tag the target side of the training corpus, with tags projected from English side through word-alignments established by GIZA++. After tags projection, a target language POS tagger based on TnT approach (Brants, 2000) is trained.

The combined model is built for each considered language using cross-validation on the test corpus. First, the test corpus is split into 2 equal parts and on each part, we estimate the interpolation parameter μ (Equation 4) which maximizes the *per-token* accuracy score. Then each part of test corpus is tagged using the combined model tuned on the other part, and vice versa (standard cross-validation procedure).

We trained MultiVec bilingual word embeddings on the parallel Europarl corpus between English and each of the target languages considered.

4.1.2 Results and discussion

Table 1 reports the results obtained for the unsupervised POS tagging. We note that the POS tagger based on bidirectional RNN (BRNN) has better performance than simple RNN (SRNN), which means that both past and future contexts help select the correct tag. Table 1 also shows the performance before and after performing our procedure for handling OOVs in BRNNs. It is shown that after replacing OOVs by the closest words using CBOW, the tagging accuracy significantly increases.

As shown in the same table, our RNN models accuracy is close to that of the simple projection tagger. It achieves comparable results to Das and Petrov (2011), Duong et al. (2013) (who used the full Europarl corpus while we use only a $65,000$ subset of it) and to Gouws and Søgaard (2015) (who used extra resources such as Wiktionary and Wikipedia). Interestingly, RNN models learned using our common words representation (section 3.2.1) seem to perform significantly better than RNN models using MultiVec bilingual word embeddings.

It is also important to note that only one single SRNN and BRNN tagger applies to German, Greek and Spanish; so this is a truly multilingual POS tagger! Finally, as for several other NLP tasks such as language modelling or machine translation (where standard and NN-based models are generally combined in order to obtain optimal results), the combination of standard and RNN-based approaches (*Projection+_*) seems necessary to further optimize POS tagging accuracies.

[5]For RNN models, only one (same) system is used to tag German, Greek and Spanish

4.2 Multilingual SST

In order to measure the impact of the parallel corpus quality on our method, we also learn our SST models using the multilingual parallel corpus MultiSemCor (MSC) which is the result of manual or automatic translation of SemCor from English into Italian and French.

4.2.1 Dataset

SemCor The SemCor (Miller et al., 1993) is a subset of the Brown Corpus (Kucera and Francis, 1979) labeled with the *WordNet* (Fellbaum, 1998) senses.
MultiSemCor The English-Italian MultiSemcor (MSC-IT-1) corpus is a manual translation of the English SemCor to Italian (Bentivogli et al., 2004). As we already mentioned, we are also interested in measuring the impact of the parallel corpus quality on our method. For this we use two translation systems: (a) Google Translate to translate the English SemCor to Italian (MSC-IT-2) and French (MSC-FR-2). (b) LIG machine translation system (Besacier et al., 2012) to translate the English SemCor to French (MSC-FR-1).
Training corpus The SemCor was labeled with the *WordNet* synsets. However, because we train models for SST, we convert SemCor synsets annotations to super senses. We learn our models using the four different versions of MSC (MSC-IT-1,2 - MSC-FR-1,2), with modified Semcor on source side.
Test Corpus To evaluate our models, we used the SemEval 2013 Task 12 (Multilingual Word Sense Disambiguation) (Navigli et al., 2013) test corpora, which are available in 5 languages (English, French, German, Spanish and Italian) and labeled with *BabelNet* (Navigli and Ponzetto, 2012) senses. We map BabelNet senses to WordNet synsets, then WordNet synsets are mapped to super senses.

4.2.2 SST Systems Evaluated

The goals of our SST experiments are twofold: first, to investigate the effectiveness of using POS information to build multilingual super sense tagger, secondly to measure the impact of the parallel corpus quality (manual or automatic translation) on our RNN models (SRNN, BRNN and our proposed variants). To summarize, we build four super sense taggers based on baseline cross-lingual projection (see section 3.1) using four versions of MultiSemcor (MSC-IT-1, MSC-IT-2, MSC-FR-1, MSC-FR-2) described above. Then we use the same four versions to train our multilingual SST models based on SRNN and BRNN. For learning our multilingual SST models based on RNN variants proposed in part (C) of section 3.2.2, we also tag SemCor using *TreeTagger* (POS tagger proposed by Schmid (1995)).

4.2.3 Results and discussion

Our models are evaluated on SemEval 2013 Task 12 test corpora. Results are directly comparable with those of systems which participated to this evaluation campaign. We report two SemEval 2013 (unsupervised) system results for comparison:

- **MFS Semeval 2013** : The most frequent sense is the baseline provided by SemEval 2013 for Task 12, this system is a strong baseline, which is obtained by using an external resource (the WordNet most frequent sense).
- **GETALP** : a fully unsupervised WSD system proposed by (Schwab et al., 2012) based on Ant-Colony algorithm.

The DAEBAK! (Navigli and Lapata, 2010) and the UMCC-DLSI systems (Gutiérrez Vázquez et al., 2011) have also participated to SemEval 2013 Task 12. However, they use a supervised approach [6].

Table 2 shows the results obtained by our RNN models and by two SemEval 2013 WSD systems. SRNN-POS-X and BRNN-POS-X refer to our RNN variants: *In* means input layer, *H1* means first hidden layer and *H2* means second hidden layer. We achieve the best performance on Italian using MSC-IT-1 clean corpus while noisy training corpus degrades SST performance. The best results are obtained with combination of simple projection and RNN which confirms (as for POS tagging) that both approaches are complementary.

[6] DAEBAK! and UMCC-DLSI for SST have obtained: 68.1% and 72.5% on Italian; 59.8% and 67.6 % on French

Table 2: Super Sense Tagging (SST) accuracy for Simple Projection, RNN and their combination.

We also observe that the RNN approach seems more robust than simple projection on noisy corpora. This is probably due to the fact that no word alignments are required in our cross language RNN. Finally, BRNN-POS-H2-OOV achieves the best performance, which shows that the integration of POS information in RNN models and dealing with OOV words are useful to build efficient multilingual super senses taggers. Finally, it is worth mentioning that integrating low level (POS) information lately (last hidden layer) seems to be the best option in our case.

5 Conclusion

In this paper, we have presented an approach based on recurrent neural networks (RNN) to induce multilingual text analysis tools. We have studied Simple and Bidirectional RNN architectures on multilingual POS and SST tagging. We have also proposed new RNN variants in order to take into account low level (POS) information in a super sense tagging task. Our approach has the following advantages: (a) it uses a language-independent word representation (based only on word co-occurrences in a parallel corpus), (b) it provides truly multilingual taggers (1 tagger for N languages) (c) it can be easily adapted to a new target language (when a small amount of supervised data is available, a previous study (Zennaki et al., 2015a; Zennaki et al., 2015b) has shown the effectiveness of our method in a weakly supervised context).

Short term perspectives are to apply multi-task learning to build systems that simultaneously perform syntactic and semantic analysis. Adding out-of-language data to improve our RNN taggers is also possible (and interesting to experiment) with our common (multilingual) vector representation.

Abstract

Annotation projection is a practical method to deal with the low resource problem in incident languages (IL) processing. Previous methods on annotation projection mainly relied on word alignment results without any training process, which led to noise propagation caused by word alignment errors. In this paper, we focus on the named entity recognition (NER) task and propose a weakly-supervised framework to project entity annotations from English to IL through bitexts. Instead of directly relying on word alignment results, this framework combines advantages of rule-based methods and deep learning methods by implementing two steps: First, generates a high-confidence entity annotation set on IL side with strict searching methods; Second, uses this high-confidence set to weakly supervise the model training. The model is finally used to accomplish the projecting process. Experimental results on two low-resource ILs show that the proposed method can generate better annotations projected from English-IL parallel corpora. The performance of IL name tagger can also be improved significantly by training on the newly projected IL annotation set.

1 Introduction

Annotation projection task aims to deal with low resource issues where human annotations are limited or unavailable in incident languages or domains. Since supervised learning algorithms can not work without annotation sets, annotation projection methods could automatically generate annotations from another language or domain where rich annotation sets are available, such as English.

Yarowsky and Ngai (2001) proposed a method of using parallel text with word alignment results to project annotations. Fig. 1 shows an example of entity projection with word alignment results from English to Turkish. On English side, *Voice of America Radio* and *Congo* are tagged as an organization (ORG) and a location (LOC) respectively by an English name tagger. The dashed lines represent word alignment results generated by a word alignment tool. Following alignment results, we can project labels to *Amerikann Sesi* and *Congo* on Turkish side automatically. A major problem of this framework is that it suffers from noises produced by word alignment errors. Thus, some de-noising methods have been proposed (Kim et al., 2010; Wang and Manning, 2014).

Though promising, this framework has several disadvantages. One shortcoming is that it totally depends on word alignment results. In this case, noise propagation from word alignment errors is heavily troublesome. To alleviate this problem, there are post-processing methods for annotation correction (Kim et al., 2010) and soft expectations to make use of more probabilistic information inside word alignment results (Wang and Manning, 2014). Although post-processing correction is efficient to filter out wrong labels, it can hardly find back labels which have been lost in the word alignment step. The soft expectation method leverages probabilistic information from word alignment results instead of hard labels such as one and zero. It can revive some false negative cases where true answers still have quite high rankings (but not the highest one). But this method will fail if word alignment results are totally wrong. From

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 461–470, Osaka, Japan, December 11-17 2016.

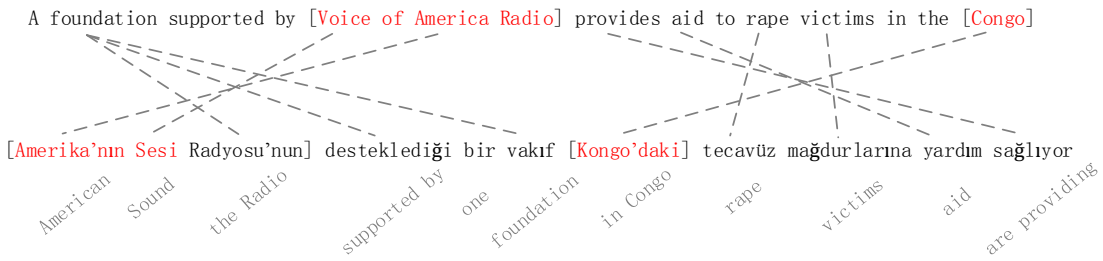

Figure 1: Errors of annotation projection with word alignment results using English and Turkish bitext.

another aspect, since word alignment task is mainly designed for the machine translation task (Och and Ney, 2003), it is not specifically tuned for other NLP tasks such as annotation projection.

Another disadvantage is that this framework depends on full-sequence word alignment where each alignment pair in the sequence will be taken into account for annotation projection. Then, the entity projection could always be disrupted by alignment errors on low-frequency word pairs and outliers, especially when the quality of bitexts cannot be guaranteed in low-resource languages. For intuition, in Fig. 1, the overall word alignment quality seems to be acceptable. But for entity projection, *Amerikann Sesi Radyosunun* is failed to be labeled completely caused by a single word alignment error on *Radyosunun*. In this circumstance, we should instead try to only focus on projecting meaningful tags, for example name tags.

In this paper, we focus on entity projection task on English-IL bitext and propose a weakly supervised framework to train a bitext name tagger and deal with issues mentioned above. The main contributions of this paper are as follows:

- We propose a new weakly-supervised framework for entity annotation projection. The framework contains two steps which can increase precision and recall step by step.
- The proposed model does not heavily depend on word alignment results. It bypasses the use of full word alignment results by taking the original English and IL data from the bitext as inputs and using training process to learn the projection. Also, the model only focuses on projecting name tags.
- We employ connections among hidden layers in recurrent neural networks to deal with sequence labeling tasks across parallel corpora.

2 Method

Given English-IL bitexts, we could start with labeling all sentences on the English side using a high-quality English name tagger [1] and find out entity names in each English sentence. For the rest of this section, our goal is to project these labeled entities from English to IL. To accomplish this goal, two separate steps are carried out. Firstly, in Sec 2.1, a **high-confidence annotation set** is generated using strict rules on parallel corpora. Secondly, in Sec 2.2, a supervised bitext name tagger is trained to recall those annotations which were lost during the first step. Besides, in Sec 2.3, we provide two different strategies to correct some errors made by the second step and give further improvements on the quality of projection.

2.1 High-confidence Annotation Projection

In order to supervise the training of the bitext name tagger, we need to firstly generate a high-quality training set out of the entire bitext. A naive way of projecting names from English to IL is to follow word alignment results [2]. Since word alignment task is not perfectly solved [3] and the performance could

[1] In our experiment, we use the Stanford NER tool (Manning et al., 2014).

[2] Here we use GIZA++ (Och and Ney, 2003)

[3] The poor alignment occurs especially when the parallel corpora is not enough (low resource issue) or the quality of bitext is poor.

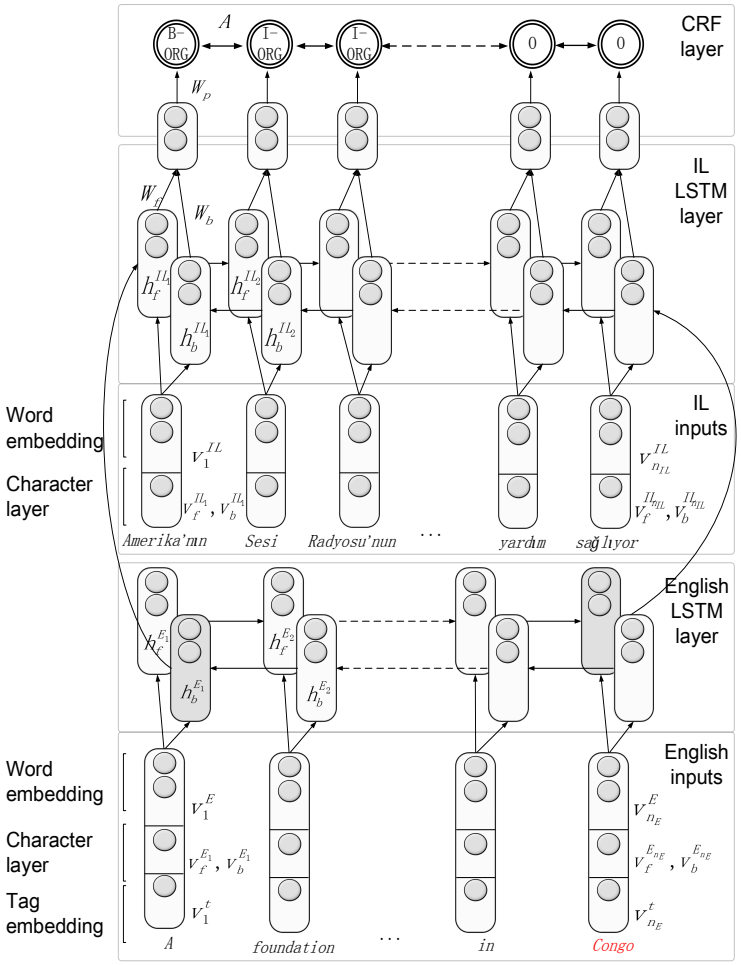

Figure 2: The framework of the bitext name tagger.

become much worse when considering the projection over low frequency phrases such as names, here we add some rules for name searching before using word alignment results.

For each labeled name in a English sentence, we search for the corresponding IL name on the IL side of the bitext as follows:

1. Firstly, if the Levenshtein distance between an IL word sequence and the English name is close enough, the word sequence will be labeled with the English name tag.

2. The second choice of measuring the similarity is to use Soundex (Raghavan and Allan, 2004).

3. If previous steps can not find the corresponding name in IL, a word-to-word translation table is used. The table is derived from GIZA++ and we only keep top 5 most credible translations for each word. And an exact word-to-word translation of entity names is carried out for string matching.

After searching steps, we use word alignment results to project names that has not been found in IL. Here we follow constraints that the number of words in a name should be the same between English and IL mentions, and words in the projected name should be contiguous. Finally, we only keep those sentence pairs where all the entity names labeled in English have been successfully projected by using previous methods.

2.2 Name Tagging on Parallel Text

In the previous section, a high-confidence annotation set is automatically generated. Using this annotation set with bitext inputs, we could train a bitext name tagger for name annotation projection. Figure

2 shows the structure of this neural-based model. Here we utilize the flexibility of recurrent neural networks to label IL sequences with the information flowing from English side. For both English and IL side, we employ bi-directional LSTM networks to handle sequence inputs of varied lengths.

Basically, our model follows the recipe of Lample et al. (2016), with several extensions designed for this task. First, there exist two sets of embedding and recurrent layers in order to handle inputs from both English and IL side. Second, to combine these two parts of signals, there are connections between two bi-directional LSTMs where the zero step of hidden layers on IL side is initialized by the last step of hidden layers on English side. Third, there are not only word and character level information, but tag sequences involved in the input signal, on both English and IL sides. Details of the bitext name tagger will be introduced in the rest of this section.

Input signal

We have three different types of input sequences for each sentence pair in the bitext:

- Word sequence $X_L = (x_1^L, x_2^L, ..., x_{n_L}^L)$, $x_i^L \in \{0, 1, ..., V_L - 1\}$, where $L \in \{E, IL\}$ represents English or IL, V_L is the size of vocabulary in L, and n_L is the number of words in the current word sequence of L.

- In order to let system know which names in English need to be projected, it is crucial to add the sequence of name types labeled by the English name tagger: $T_E = (t_1^E, t_2^E, ..., t_{n_E}^E)$, $t_i^E \in \{0, 1, ..., V_t - 1\}$, where V_t is the number of tag types. Here $V_t = 7$ since we follow the IOB format (*Inside, Outside, Beginning*) with three entity type *PERSON, LOCATION and ORGANIZATION*.

- To leverage character level information, for each word x_i^L, there is a character sequence $C^{L_i} = (c_1^{L_i}, c_2^{L_i}, ..., c_p^{L_i})$, $c_j^{L_i} \in \{0, 1, ..., V_{Lc} - 1\}$, where p is the number of characters in word X_i^L, and V_{Lc} is the number of different characters in language L.

Embeddings for each word

Then, we project these input signals from high dimensional space of token id into dense vector spaces using look-up tables. Thus, we have

$$v_i^L = W_{word}^L x_i^L,\ L \in \{E, IL\}$$

$$v_j^{L_i} = W_{char}^L c_j^{L_i},\ L \in \{E, IL\}$$

$$v_i^t = W_{tag}^E t_i^E$$

where W_{word}^L,W_{char}^L, W_{tag}^E are look-up tables for English/IL word, English/IL character, and English tag respectively.

Since character level information is helpful for name tagging task (Klein et al., 2003), we combine the word level embedding and character level embedding together by following Lample et al. (2016). For each work token, we derive a vector from the corresponding character embedding sequence using bidirectional LSTM networks as following:

$$v_f^{L_i} = LSTM_{for}^{LC}(\mathbf{v}^{L_i})[p-1],\ \ v_b^{L_i} = LSTM_{back}^{LC}(\mathbf{v}^{L_i})[0]$$

where $\mathbf{v}^{L_i} = (v_1^{L_i}, v_2^{L_i}, ..., v_p^{L_i})$, $LSTM_{for}^{LC}(\cdot)$ and $LSTM_{back}^{LC}(\cdot)$ are the forward and backward long short-term memory recurrent networks (LSTM-RNN) (Hochreiter and Schmidhuber, 1997) to encode $\mathbf{v}^{L_i}$. The output of $LSTM(\cdot)$ is a list of LSTM-RNN hidden layers.

Then, we concatenate v_i^E, $v_f^{E_i}$, $v_b^{E_i}$ and v_i^t into a vector d_i^E which represents the information of word i in each English sentence. Similarly, we concatenate v_i^{IL}, $v_f^{IL_i}$, $v_b^{IL_i}$ into a vector d_i^{IL} for each word in IL. In practice, to leverage information from rich unlabeled monolingual corpus, we initialize W_{word}^E and W_{word}^{IL} with pre-trained word embeddings using word2vec tool (Mikolov et al., 2013).

Two bi-directional LSTMs for bitext

After generating $\mathbf{d}^E = (d_1^E, d_2^E, ..., d_{n_E}^E)$ and $\mathbf{d}^{IL} = (d_1^{IL}, d_2^{IL}, ..., d_{n_{IL}}^{IL})$, we put them into English and IL bidirectional LSTM-RNNs separately:

$$\mathbf{h}_f^E = LSTM_{for}^E(\mathbf{d}^E), \;\; \mathbf{h}_b^E = LSTM_{back}^E(\mathbf{d}^E)$$

where $LSTM_{for}^E(\cdot)$ and $LSTM_{back}^E(\cdot)$ are the forward and backward LSTM-RNNs to encode $\mathbf{d}^E$. And $\mathbf{h}_f^E$ and $\mathbf{h}_b^E$ are the list of hidden layers. Similarly, for IL, we have

$$\mathbf{h}_f^{IL} = LSTM_{for}^{IL}(\mathbf{d}^{IL}, \mathbf{h}_b^E[0]), \;\; \mathbf{h}_b^{IL} = LSTM_{back}^{IL}(\mathbf{d}^{IL}, \mathbf{h}_f^E[n_E - 1])$$

To utilize information extracted from English side, we use $h_f^E[n_E - 1]$ and $h_b^E[0]$ from the last steps of bi-directional LSTM to initialize the starting states of LSTM hidden layers in IL side. Thus during training, errors can be back propagated to English side neural networks through these two vectors. The two hidden layers filled with gray color of background in Figure 2 show the intuition.

This idea is inspired by one of previous successful sequence-to-sequence deep learning method in machine translation (Sutskever et al., 2014), which encodes an input sequence into one single vector and then generates a new sequence with both the vector and the language model contained in its decoding networks. In our case, the task is much easier since we only need to predict a sequence of tag types instead of word tokens from a huge vocabulary. And the model also absorbs hints from the IL side of input sequence so it is not at all an auto-encoder.

After LSTM layers in IL, the score function is given to assess all the name types for each token in IL based on hidden layers of LSTM as follows:

$$P_i = W_p tanh(W_f \mathbf{h}_f^{IL}[i] + W_b \mathbf{h}_b^{IL}[i])$$

where P_i is a vector of dimension V_t representing scores of tags for x_i^{IL}.

Training and Projecting

Following the architecture of Lample et al. (2016), we add a first order transition matrix A on top of the previous model to simulate a CRF structure. The score function between input $\mathbf{X}$ and output tag sequence $\mathbf{y}$ is as following,

$$s(\mathbf{X}, \mathbf{y}) = s(\tilde{X}_E, \tilde{X}_{IL}, T_E, \mathbf{y}) = \sum_{i=1}^{n_{IL}} A_{y_i, y_{i+1}} + \sum_{i=1}^{n_{IL}} P_{i, y_i}$$

where $\tilde{X}_E$ and $\tilde{X}_{IL}$ represent X_E and X_{IL} with their character sequences. To normalize each score into probability, a softmax function is added,

$$p(\mathbf{y}|\mathbf{X}) = \frac{e^{s(\mathbf{X}, \mathbf{y})}}{\sum_{\tilde{\mathbf{y}} \in \mathbf{Y_X}} e^{s(\mathbf{X}, \tilde{\mathbf{y}})}}$$

Thus, the final output $\mathbf{y}_d$ for decoding is the tag sequence that has the highest probability among all possible tag sequences $\mathbf{Y_X}$.

During training, our goal is to maximize $\log p(\mathbf{y}_c|\mathbf{X})$ for the correct (high-confidence annotation) tag sequence $\mathbf{y}_c$. Stochastic gradient descent (SGD) is employed with dropout strategy [4].

Using the trained bitext tagger in this section, we can complete the name projection task by annotating the rest of sentence pairs not covered in the high-confidence annotation set, and generate the final annotation set in IL by combining both high-confidence annotation set and annotations found by the bitext tagger.

[4]For the detailed training strategy, please read the training section in Lample et al. (2016)

2.3 Error Correction Strategies

Sec 2.1 and Sec 2.2 have already introduced the main content of the proposed framework. In this section, we make use of an overlooked information to further improve the quality of the projection.

According to Sec 2.1, to generate the high-confidence annotation set, we omit those sentence pairs whose names labeled in English are not completely projected in IL. For example, we will exclude a sentence pair in the first step if the number of names in English is three while only two names are projected to IL. However, these two projected names are still *high-confidence*. So if these names can be properly utilized, the quality of projection could be further improved. Here we introduce two different strategies to make use of this information:

Post-processing strategy

Since there are two annotation results on each of these omitted sentence pairs: annotations generated by the first step and annotations generated by the second step, it is natural to implement a post-processing step and integrate these two annotation results. Compared with the second step, although the annotations from the first step is not complete, they should be more reliable if rules in Sec 2.1 are strict enough. So here we follow this assumption and force the final projected annotations to maintain names produced in the first step and add names from the second step only when there is no conflict between them.

High-confidence annotations as one of inputs

A disadvantage of the post-processing method is that the assumption that annotations from the first step are more trust-worthy is not always true. When the annotated names produced by the first step are wrong, they will not only introduce noise, but also ruin annotations from the second step if there are conflicts between them. So a better idea is to feed all the information we have to neural networks and let the model speaks the truth.

To provide information of annotations produced by the first step, we add another input signal $T_{IL} = (t_1^{IL}, t_2^{IL}, ..., t_{n_{IL}}^{IL})$ in IL side, where $t_i^{IL} \in \{0, 1, ..., V_t - 1\}$ represents the tag result from the first step, V_t is the number of tag types. Then T_{IL} will go through tag embedding layers, LSTM-RNN layers and influence the results of CRF tagging.

In order to simulate the scenario of prediction process where the number of high-confidence names found on IL side is less than the number on English side, it is crucial to randomly drop out some high-confidence annotation names in T_{IL} and replace them with *Outside* during the training time.

3 Experiments

3.1 Data and Experimental Setup

To simulate a practical scenario, we evaluate our model on two low-resource ILs: Turkish and Uzbek, using the ground-truth name tagging annotations from the DARPA LORELEI program [5]. Table 1 shows data statistics. The numbers of sentence pairs for training and development represent the high-confidence annotation sets we produced during our experiments. And we exclude all the ground truth data from bitext for training and validation. Since a small proportion of sentences in the ground truth do not have English bitext, the test sets are slightly different in Sec 3.2 and Sec 3.3.

In our experiment, we set learning rate=0.01 and dropout rate=0.5. Dimension of word embedding=300, dimension of hidden layer=100, dimension of character embedding and hidden layer=25, and dimension of tag embedding=25.

3.2 Results of Bitext Name Projection

Bitext name taggers are trained on high-confidence annotation sets. Since most of ground truth sentences also contain parallel data, we can project annotations on bitext of ground truth and directly evaluate the quality of the projection. Here we compare our results with names projected from pure word alignment and also method in Sec 2.1. Table 2 shows the result.

[5] http://www.darpa.mil /program/low-resource-languages-for-emergent-incidents

Category	Turkish	Uzbek
Full sentence pairs for projection	24,193	39,045
Sentence pairs for training	12,276	21,552
Sentence pairs for dev.	755	1,431
Ground truth sentence pairs on bitext	1759	2918
Ground truth names on bitext	1744	2894
Ground truth sentence pairs in total	2,121	3,040
Ground truth names in total	2,178	3,144

Table 1: Data statistics

Dataset	Turkish			Uzbek		
	P	R	F	P	R	F
WA	34.5	33.4	33.9	28.6	29.9	29.2
HA	66.6	38.3	48.7	**66.5**	39.6	49.6
BNT	**67.4**	**49.7**	**57.2**	62.7	**47.8**	**54.3**

Table 2: Performance of projected annotation sets with different projection strategies. *WA* represents projection results purely based on **w**ord **a**lignment with IOB constraint. *HA* represents the **h**igh-confidence **a**nnotation projection. *BNT* represents the annotation projection using **b**itext **n**ame **t**agger.

From the result, it demonstrates that, in the case of low resource languages, annotations with word alignment results perform poorly on both precision and recall rate. So it is hard to improve the projection based on word alignment framework. Even re-ranking strategies with word alignment results is not effective since searching-based method (HA) has significantly outperformed the word alignment results. Also, compared with high-confidence annotations, our final annotation set shows significant better recall rate without much precision loss. Table 3 also indicates that after the second step, there are a huge number of names (not necessarily correct names) been discovered. This indicates in another aspect the significance of the recalling process in the second step. When observing real labeled cases, our model shows stable performances without much influences from the quality of word alignment result. For instance, the bitext name tagger could successfully label *Radyosu'nun* as a I-ORG in Fig 1.

Lang.	High-confidence annotation set			Annotation set after recalling		
	PER	LOC	ORG	PER	LOC	ORG
Turkish	6469	6133	2329	13520	21346	8094
Uzbek	9889	11353	1696	20522	29769	5348

Table 3: Statistics of tag number before and after using bitext name tagger.

Further more, since in the low resource scenario, large size of parallel corpora is not always available, we do experiments on different sizes of training data to evaluate the capability of this framework with less amount of bitexts. The subset sentence pairs for training are randomly selected. Figure 3 shows the result on Turkish and Uzbek. Different from the case where RNN is employed on machine translation, we do not need a huge number of training data because the searching space of prediction is quite small, due to the small amount of tag types rather than the size of a vocabulary. From the curve, we can see that even with only 2000 parallel sentence pairs, our model shows around 50% F-value. Notice that since we can directly employ the word alignment method and also method in Sec 2.1 on the ground truth without training process, the curve of these two methods are flat.

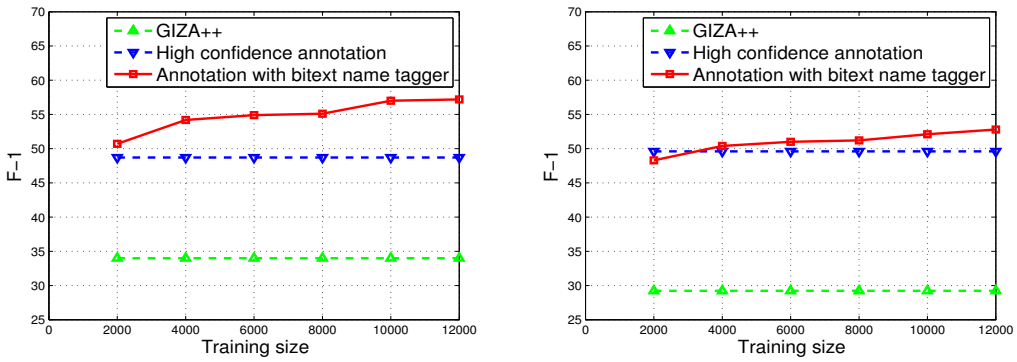

Figure 3: Performances of annotation projection with different size of training data on Turkish(left) and Uzbek(right) bitexts.

Model	Turkish			Uzbek		
	P	R	F	P	R	F
Clean	70.5	66.9	68.7	73.4	68.8	71.0
ExpDriv	45.8	**51.1**	48.3	38.3	41.0	39.6
HA *	62.3	45.3	52.5	59.4	45.2	51.3

BNT + HAI *	**66.4**	50.9	**57.6**	62.2	49.8	**55.3**

Table 4: Performance of IL name taggers. *Clean* represents the performance of LSTM-CRF model trained on human annotation data. *ExpDriv* refers to the baseline **Exp**ectation **driv**en method. *HA* represents LSTM-CRF model trained with **h**igh-confidence **a**nnotation set. *BNT* represents LSTM-CRF model trained with annotation set produced by the **b**itext **n**ame **t**agger. + *PP* represents *BNT* with **p**ost-**p**rocessing strategy. + *HAI* represents *BNT* with **h**igh-confidence **a**nnotations as one of **i**nputs. * indicates consistent improvement compared with results in the line above.

3.3 Results of IL Name Tagging

Since the final goal of annotation projection is to help IL tasks, we train and compare the performances of NER models on IL annotation sets produced with different projection methods. Here we choose the LSTM-CRF model proposed by Lample et al. (2016) to be the model of IL NER system because of its state-of-the-art performance on English NER task[6]. Table 4 shows the results.

From the results, the model trained with annotation set produced by the bitext name tagger outperforms both high-confidence annotations and also the state-of-the-art Expectation-driven learning method for IL name tagging (Zhang et al., 2016). Contrasting results between two different strategies in Sec 2.3, HAI shows consistent improvement across different languages while post-processing strategy fails in Turkish. Table 2 shows that, in Turkish, the precision of annotations from the second step outperforms the first step, which means in this case the assumption of the post-processing strategy is not valid.

4 Related Work

Most of related methods for annotation projection are based on word alignment results. Kim et al. (2010) employed both heuristic method and alignment correction with alignment dictionary of entity mentions. Das and Petrov (2011) designed a label propagation method to automatically induce a tag lexicon for the foreign language to smooth the projected labels. Wang and Manning (2014) project model expectations rather than labels, which facilities transfer of model uncertainty across language boundaries in word alignment projection.

[6]You can download the code of LSTM-CRF tagger from `https://github.com/glample/tagger`

Wang et al. (2013) also proposed a method to joint train word alignment and bilingual name tagging, which involves training process of word alignment. But this joint method is based on two assumptions. First, it requires a readily-trained name tagger in each languages. Even more, both taggers need to have competitive strengths so that they can correct each other. Unfortunately, in the case of low resource languages, no competitive name tagger is available.

One of most recent works linked to annotation projection was proposed by Fang and Cohn (2016) for the task of part of speech tagging (POS). Their work interestingly combined both gold annotations and projected ones by learning a global corrective matrix between gold annotation and projected annotation on IL side. The limitation is that gold annotation set on IL side must exist, which is not always the case especially in an incident language.

5 Conclusion and Future Work

We introduce a weakly-supervised framework for entity annotation projection. Our model takes original English and IL bitexts as inputs and does not heavily depend on word alignment results. Experiment results show that this method can provide significantly better annotations projected from English to IL.

Notice that in the first step of our framework, we do not consider the case where low-resource language does not use the Roman script. Although the method will still work because we also use word alignment results to measure the distance between text sequences, the performance could drop. So in the future work, we should plug in some transliteration techniques and gazetteers to make the system more robust.

Abstract

Much previous research on multiword expressions (MWEs) has focused on the token- and type-level tasks of MWE identification and extraction, respectively. Such studies typically target known prevalent MWE types in a given language. This paper describes the first attempt to learn the MWE inventory of a "surprise" language for which we have no explicit prior knowledge of MWE patterns, certainly no annotated MWE data, and not even a parallel corpus. Our proposed model is trained on a treebank with MWE relations of a source language, and can be applied to the monolingual corpus of the surprise language to identify its MWE construction types.

1 Introduction

Multiword expressions ("MWEs") are word combinations which have idiosyncratic properties relative to their component words (Sag et al., 2002; Baldwin and Kim, 2010), such as *taken aback* or *red tape*. The need for an explicit model of MWEs has been shown to be important in NLP tasks including machine translation (Venkatapathy and Joshi, 2006), parsing (Constant et al., 2012), and keyphrase/index term extraction (Newman et al., 2012). However, existing approaches to MWE identification/extraction typically target specific MWE types that are known to be prevalent in a given language, such as: (a) compound nouns in languages such as English (Copestake, 2003; Ó Séaghdha, 2008), German (Schulte im Walde et al., 2013) and Japanese (Tanaka and Baldwin, 2003); (b) light verb constructions (LVCs) in languages such as English (Butt, 2003), Persian (Karimi-Doostan, 1997) and Italian (Alba-Salas, 2002); and (c) compound verbs in languages such as Japanese (Uchiyama et al., 2005). Note here that the combination of highly-productive MWE types can vary greatly across languages: English is rich with compound nouns and LVCs are also common, but lacks compound verbs; Persian is rich with LVCs and adjective–noun compounds, but has very few compound nouns and compound verbs; and Japanese is rich with LVCs and compound nouns and verbs, but adjective–noun MWEs are rarer. Even for collocation extraction, this knowledge is generally assumed for a given language, in targeting only highly productive constructions such as adjective–noun or verb–noun collocations (Krenn and Evert, 2001; Pecina, 2008).

But what if the language of interest is one where no such prior knowledge exists, e.g. because it is a "surprise" language where rapid deployment of language technologies is required and there is no access to an informant with sufficient linguistic training to be able to inventorise the MWE types in the language (Oard, 2003; Maynard et al., 2003)? Here, there is little expectation of success without an automatic method for determining the inventory and relative frequency of MWEs in a given language. This provides the motivation for this paper: can we develop a method for automatically profiling the MWE inventory of a novel language based simply on a monolingual corpus of that language, and a treebank in a second language such as English?

We carry out this research in the Universal Dependency ("UD") framework (Nivre et al., 2016), using the method of Duong et al. (2015) to induce a delexicalised dependency parser for the surprise language, based on a supervised parsing model for a language such as English where we have a well-developed treebank in the UD. Given the parser output over a monolingual corpus in the surprise language, we then apply one of two methods to extract our MWE profile: (1) a baseline method, where we simply

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 471–481, Osaka, Japan, December 11-17 2016.

extract out delexicalised dependency tuples of relation type `mwe` or `compound` (including the POS tags), aggregate the counts of the pos–relation–pos triples, and extract the most frequent triples; and (2) a supervised reranker over the delexicalised dependency tuples, to better deal with noise in the output of the delexicalised dependency parser.

One additional contribution of this paper is analysis of MWE annotation across different languages in the UD. We find that there are a number of competing styles of annotation, and very different levels of thoroughness in the annotation of MWEs. As part of this, we perform an "oracle" analysis of MWE extraction based on the gold-standard treebank annotations for a given language, and find that the results vary greatly between languages, due to annotation divergences. Using the supervised reranking method, however, and incorporating more and more languages for training (but holding out the surprise language), we find that we are able to "smooth" annotation differences between languages.

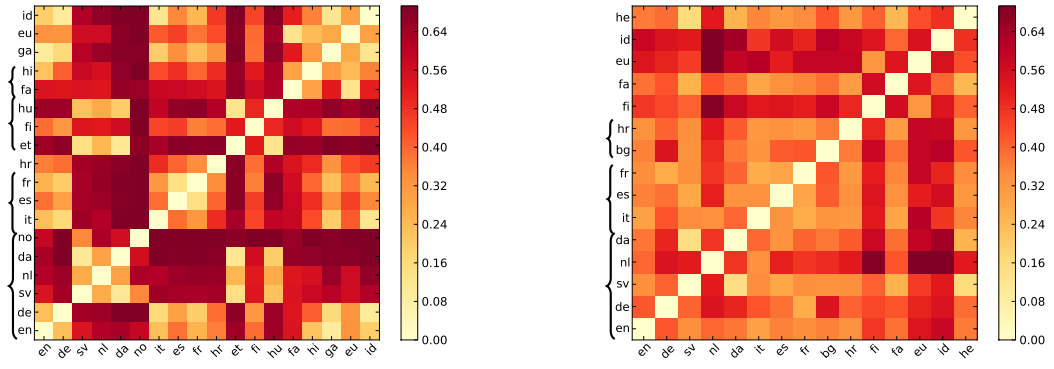
2 Related Work

There is a wealth of research on MWE identification (i.e. distinguishing MWEs from non-idiosyncratic combinations at the token level) and extraction (i.e. determining at the type level which word combinations in a corpus are MWEs). Many of these methods are customised to particular MWE constructions which are known to exist in a given corpus, e.g. noun compounds (Lapata and Lascarides, 2003; Tanaka and Baldwin, 2003), verb particle constructions ("VPCs": Baldwin and Villavicencio (2002; Baldwin (2005)), determinerless prepositional phrases (Baldwin et al., 2004; van der Beek, 2005), or compound verbs (Breen and Baldwin, 2009). There is also a significant body of work on general-purpose MWE extraction, often based on statistical association measures applied to either a monolingual corpus (Evert and Krenn, 2005; Pecina, 2008; Ramisch, 2012) or a parallel corpus (Melamed, 1997; Moirón and Tiedemann, 2006). Even here, however, POS-based constraints are generally applied on the types of MWE that are extracted (e.g. noun–noun or verb–noun bigrams). There are also methods for identifying MWEs in context using supervised models (Diab and Bhutada, 2009; Li and Sporleder, 2010; Schneider et al., 2014), which require exhaustive annotation of MWE token occurrences in a corpus. All of this research differs from our work in that it either assumes knowledge of the type(s) of MWE to extract for a given language, or requires explicitly annotated MWE data in that language.

Closer to home, there has recently been work on general-purpose, unsupervised approaches to MWE extraction, making no assumptions about the types of MWE that exist in a given language (Newman et al., 2012; Brooke et al., 2014). Here, however, the definition of MWE tends to be blurred somewhat to focus on index terms or "formulaic language", i.e. idiomatic expressions with statistically-marked properties in a given corpus — blurred in the sense that many MWEs are not statistically marked, and also that they include formulaic expressions such as *in this paper* that are not formally MWEs.

Also related is recent work on resource development for low-resource languages, such as dependency parsing based on transfer learning from a higher-density language (Naseem et al., 2012; Täckström et al., 2013; Duong et al., 2015). For example, Duong et al. (2015) proposed a neural network-based parser that transfers dependency relations across languages without requiring a parallel corpus. They learn syntactic cross-lingual word embeddings by training the skip-gram model (Mikolov et al., 2013) on a representation of the original text in which the context of each token is represented by its universal POS tags (Petrov et al., 2012). They then incorporate these word embeddings in a transition-based neural network dependency parser (Chen and Manning, 2014).

Our proposed method is the first attempt to learn the MWE profile of a language with no knowledge of the target language except for POS tags (which themselves can be induced automatically, with little or no annotated data: Garrette and Baldridge (2013), Duong et al. (2014)), and no parallel corpus. We train a delexicalised dependency parser based on transfer learning (involving no syntactic annotations for the target language), and train a reranking model based on observed MWEs in only the source language(s).



(a) `compound` (b) `mwe`

Figure 1: Cross-lingual similarity of MWE pattern distributions using JSD

3 Resources

The Universal Dependency Treebank[1] ("UD") is a universal annotation scheme for dependency parsing that is consistent among languages with the goal of cross-lingual learning (Nivre et al., 2016). It is made up of a universal part-of-speech (POS) tag set (Petrov et al., 2012) and universal dependency relation set, and a set of treebanks.

In this paper, we use v1.2 of UD. MWEs are labeled as either `name` (for named entities), `compound` (for binary compound expressions) or `mwe` (for fixed expressions). In this work, we focus specifically on `mwe` and `compound`, as named entity recognition is a specialised subtask of MWE identification with its own dedicated literature (Maynard et al., 2003; Huang et al., 2003; Steinberger and Pouliquen, 2007), and there is every expectation that all languages contain named entities. Although the documentation for UD provides definitions of how to distinguish `mwe` and `compound` in labelling MWEs, there seem to be major inconsistencies in how they have been interpreted for particular languages: some languages do not use these relations at all, while others only annotate a subset of MWE types with these relations.

The languages examined in this paper are as follows, in descending order of prevalence[2] of MWE annotations in UD (as indicated in parentheses):

> Hindi (14.0%), **Indonesian** (9.2%), **Persian** (7.5%), **Croatian** (6.7%), **English** (6.2%), **Swedish** (5.4%), Estonian (4.9%), Irish (4.7%), Finnish (4.4%), Basque (3.7%), Hungarian (2.7%), Dutch (2.2%), Norwegian (1.6%), Danish (1.5%), French (1.5%), Italian (0.8%), Spanish (0.8%), Hebrew (0.7%), Bulgarian (0.6%), German (0.4%)

These were selected based on the fact that they have at least 100 individual occurrences of the `mwe` or `compound` relation. The 5 languages in bold were selected as our test languages, based on the high prevalence of MWE annotations and diversity of MWE patterns.[3] Here and for the remainder of the paper, we define "MWE pattern" to be an ordered tuple of the form $\langle \text{pos}_h, \textsf{rel}, \text{pos}_d \rangle$, where pos_h is the POS of the head, and pos_d is the POS of the dependent in the triple. Based on this definition, English has 56 distinct MWE patterns, Croatian 49, Persian 48, Swedish 45, and Indonesian 26.

4 MWE Patterns

This paper investigates the profile of MWE patterns in a given language, in the form of delexicalised dependency tuples. The most frequent patterns in our 5 target languages with the `compound` relation

[1] `https://universaldependencies.github.io/docs/`

[2] the proportion of MWE tokens

[3] We discarded Hindi despite the high proportion of MWEs because: (1) it only covered `compound` relations, and has no `mwe` relations, and (2) it has a low number of distinct MWE patterns (23), and as such appeared skewed in its annotation.

are: NOUN–NOUN; PROPN–PROPN (i.e. proper noun dependencies, which should be annotated with the `name` relation rather than `compound`, according to the annotation guidelines); and VERB–NOUN, which includes LVCs. There are also other noticeable patterns such as VERB–ADV(erb) and VERB–ADP(osition), corresponding to VPCs (Schulte im Walde, 2004; Baldwin, 2005).

`mwe` patterns are more diverse than `compound` patterns: `compound` patterns mostly involve nouns and verbs, while `mwe` patterns involve a diverse range of POS types, such as ADP–ADP or ADV–ADV, and pairings including CONJ(unctions) or SCONJ (subordinating conjunctions).

We additionally measured the similarity between the MWE pattern probability distribution of the different languages using Jensen–Shannon divergence, as shown in Figure 1 for all languages in UD. To make comparison between related languages easier, we clustered the languages by language family. According to Figure 1, there is no clear indication that languages of the same family have similar MWE patterns, which is something that we might have expected.

These results suggest that although the ultimate goal of the UD project is to have compatible annotations, the MWE annotations are not, at present, consistent. In fact, annotation divergences would appear to be more noticeable than linguistic differences. For example, the Norwegian treebank annotates only VPCs (and not multiword compound nouns, e.g.), and the `mwe` relation is not used at all. That is, the observed differences in MWE patterns certainly reflect differences between languages, but greater than this, they capture differences in the annotation process between different languages.

We also examined the annotation consistency of MWEs between the Train+Dev sets and Test set of each language (based on the provided splits), and observed high consistency (low JSD) between the existing patterns in these sets for the same language. The JSD on `compound` patterns are all below 0.10, except for Spanish (0.23) and French (0.18). Due to the diversity of `mwe` patterns, the JSD is less consistent within each language, with Croatian (0.64) and German (0.44) being notably high, and the rest of the languages below 0.25. This shows that annotation is quite consistent within each language.

Therefore, despite the cross-lingual annotation inconsistency, our corpora appear to be internally consistent enough to train a model over, based on the observed MWEs in a language.

5 Methodology

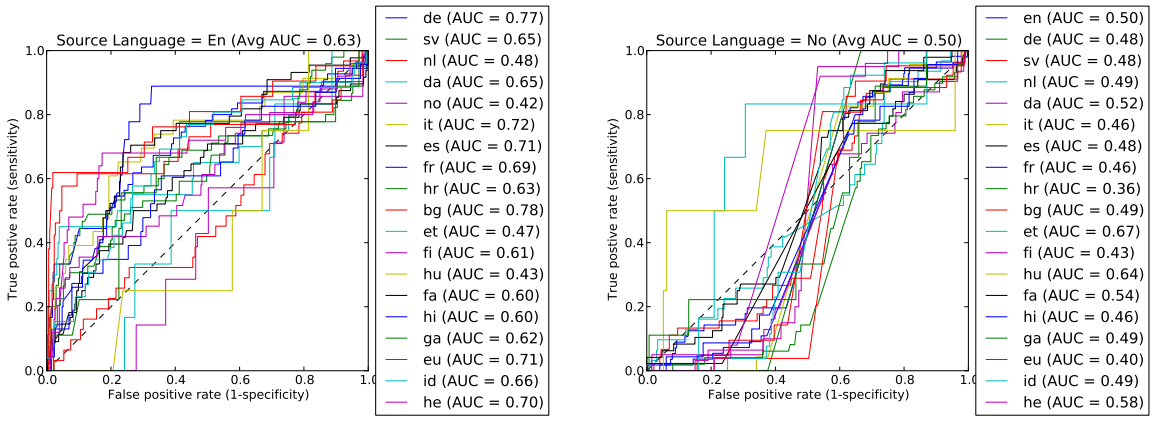
In this work, we measure the likelihood of the triple $\langle \text{pos}_h, \textsf{rel}, \text{pos}_d \rangle$ being an MWE pattern in the target language. The scores are measured according to the respective lexical instances of each triple in the source language, aggregated to compute scores for each triple, and used to train a support vector regression (SVR: Joachims (2006)) model.

The gold-standard labels to train the model are based on the dependency relations: the value is set to 1 if the dependency is `compound` or `mwe`, and 0, otherwise.

We use 8 features in our proposed method: pointwise mutual information (PMI), ϕ-square, the Dice coefficient, student's t test, log-likelihood ratio, pattern fixedness, token/type ratio for a given triple, and token/token ratio across all relations.

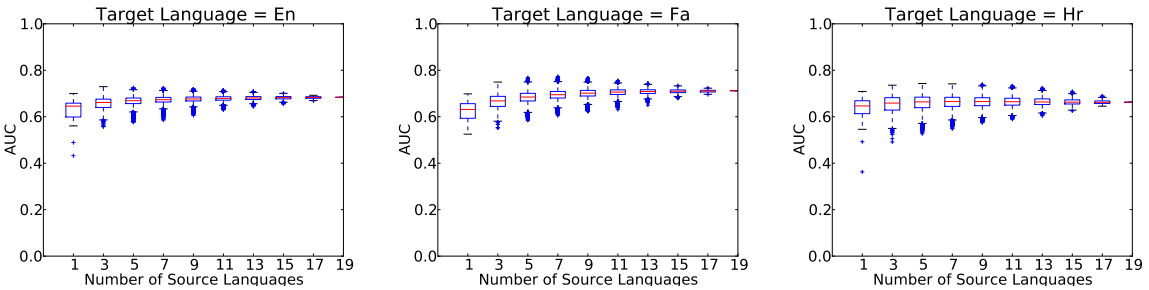
$$
\begin{aligned}
\text{PMI}(x,y) &= \log \frac{p(x,y)}{p(x)p(y)} \\
\phi^2 &= \frac{(n(x,y)n(\bar{x},\bar{y}) - n(x,\bar{y})n(\bar{x},y))^2}{n(x)n(\bar{x})n(\bar{y})n(y)} \\
\text{Dice coefficient} &= \frac{2n(x,y)}{n(x)+n(y)} \\
\text{t}(x,y) &= \frac{\frac{n(x,y)-(n(x)*n(y))}{\text{total words}}}{\sqrt{n(x,y)}}
\end{aligned}
$$

where $n(.)$ is the number of occurrences, and $\bar{x}$ is the number of all instances except x. Pattern fixedness is measured via entropy as $\text{H}(\Pr(D(x,y)))$, where $D(x,y)$ is the difference between the linear position of the head and dependent, binned as follows: $\textit{posdiff} \in \{(-\infty,-2), -2, -1, 1, 2, (2,\infty)\}$.

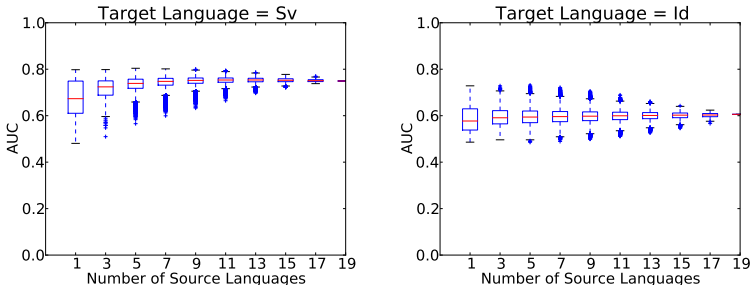


(a) English (b) Norwegian

Figure 2: Selecting a language as a source language



(a) English (b) Persian (c) Croatian



(d) Swedish (e) Indonesian

Figure 3: Distribution of ROC AUC scores when combining source languages

These features are first computed for each lexical instance of a given pattern, and then aggregated to calculate the overall feature values for each triple, using either: (a) the mean (in the case of pattern fixedness); or (b) the median (in the case of the other measures).[4]

After computing the features, we train an SVR model based on the dependency triples in the source language, and then apply the model to rank the triples in the target language. To avoid noisy annotations, we consider only those triples that occur at least twice in each corpus.

We further experiment with a simple ensemble method to combine source languages, in order to smooth over annotation and linguistic differences between languages: we combine the trained rerankers from multiple source languages by calculating the average of the predicted scores from each language.

[4]MWEs components are usually seen in a fixed order and with fixed gap size. We use mean to aggregate the pattern fixedness scores in order to capture any lexical instances which are not used in a fixed order. However, we use the median for the other measures to suppress the impact of outliers. Our preliminary results also confirm that this is the best way to aggregate the scores.

Score	Pattern	Example
0.327	⟨NOUN, ccomp, ADJ⟩	*sure place*
0.306	⟨X, compound, PROPN⟩	*Indo Lanka*
0.301	⟨NOUN, appos, SYM⟩	*$ value*
0.298	⟨ADJ, nmod:npmod, ADV⟩	*little more*
0.295	⟨NOUN, punct, NUM⟩	*5 ”*
0.285	⟨SYM, punct, SYM⟩	*— —*
0.283	⟨AUX, advcl, ADV⟩	*as can*
0.277	⟨NOUN, mwe, SCONJ⟩	*in case*
0.270	⟨SCONJ, mwe, ADP⟩	*due to*
0.268	⟨NOUN, mwe, ADP⟩	*in order*

6 Results

We report on two experiments. First, we train a model using features extracted from the gold-standard treebank in a given source language, and apply it to features extracted from the gold-standard treebank in a target language. We investigate how well our model is able to find the annotated MWE triples when gold-standard dependency relations are provided. This experiment also shows how our model can be used to find new MWE patterns in existing annotated treebanks (missing certain MWE types). Second, we investigate how our model performs in the more realistic scenario of no annotated treebank being available in the target language.

6.1 Experiment I: Learning given the gold standard treebank

In our first experiment, we assume access to gold standard annotations of POS tags and relation edges in both source and target languages, to determine the tractability of the task, assuming perfect parses.

Since the output of our model is a score in the range $[0, 1]$, we evaluate based on the area under the curve (AUC) from a ROC curve. Figure 2 shows the ROC curve for predicting MWEs when English and Norwegian are the source languages. English is among our 5 selected languages — i.e., one of the languages with the highest number of multiword expression patterns — while for Norwegian, the `mwe` relation is not used at all and only `compound:prt` is annotated. According to these results, the average AUC for predicting MWE patterns is 0.63 when English is the source language (averaged across all target languages, excluding English), while it is 0.50 when Norwegian is the source language. This shows that a source language with less annotated patterns makes for a weaker model. The average scores when our 5 selected languages are used as the source language are remarkably similar: English = 0.63, Persian = 0.64, Croatian = 0.64, Indonesian = 0.61 and Swedish = 0.65.

To investigate further, Figure 3 shows how adding more source languages affects the results for MWE pattern extraction over our 5 selected languages. According to these results, using more than one language can increase the AUC, however, using more than 3 languages does not improve the average AUC greatly.

Finally, we show the top-predicted MWE patterns in English in Table 1. We observe errors such as ⟨NOUN, punct, NUM⟩ and ⟨SYM, punct, SYM⟩, because of their idiosyncratic properties across token instances. However, our model also predicts that ⟨NOUN, ccomp, ADJ⟩ is an MWE.

6.2 Experiment II: Learning without gold standard dependency relations

In our second experiment, we evaluate under the more realistic task setting of there being no gold standard treebank in the target language. Instead, we use the cross-lingual parser proposed by Duong et al. (2015) to parse the corpus in the target language (see Section 2). Note that we still use gold-standard POS tags, but this isn't entirely unrealistic given the relative maturity of methods for inducing universal POS taggers (Das and Petrov, 2011; Täckström et al., 2013; Duong et al., 2014).

Obviously, due to the fact that the parser has no access to dependency annotations in the target language, the parser output will be noisy. However, this emulates a true surprise language setup, where we

Language	De	Sv	Da	It	Es	Fr	Hr	Bg	Hu	Fa	Ga	Eu	Id	He
Baseline	**0.816**	0.511	0.481	0.637	0.546	0.656	0.487	0.554	0.406	0.467	0.586	0.497	0.473	0.472
Reranker	0.736	**0.514**	0.428	0.631	**0.610**	**0.684**	0.461	**0.645**	0.470	**0.549**	0.673	0.578	0.513	**0.622**
PMI	0.804	0.512	**0.567**	**0.803**	0.494	0.634	**0.575**	0.471	**0.588**	0.521	**0.687**	**0.595**	**0.756**	0.476
Baseline + gold	0.797	0.750	0.846	0.885	0.879	0.799	0.696	0.917	0.457	0.919	0.799	0.891	0.931	0.788

Table 2: AUC scores when English is used as the source language to transfer dependency links and to train our reranker model. In "Baseline + gold", the trained model is applied to the gold-standard annotation of the target language rather than the parsed corpus.

have no prior knowledge of MWEs or dependency structure in the target language.

In order to evaluate our proposed method and compare it with the gold standard treebank, we change the evaluation method slightly in order to better reflect the expected inconsistencies in the parser output. In terms of gold-standard labeling, we exhaustively consider every edge between all pairs of tokens in each sentence, and consider an edge to be a positive instance if there is an MWE dependency between its token pairs in the gold-standard treebank, and a negative instance otherwise. To evaluate the parser output, which is the baseline in this experiment, we use the generated dependency edges and labels, and evaluate this against the exhaustively-generated gold-standard. To evaluate our system's performance, we use the dependency edges given by the parser and aggregate the reranker's predicted scores at the level of the delexicalised dependency triples, as per the first experiment. Unlike the first experiment, we evaluate using ROC AUC over the token pairs instead of $\langle \text{pos}_h, \mathsf{rel}, \text{pos}_d \rangle$ triples.

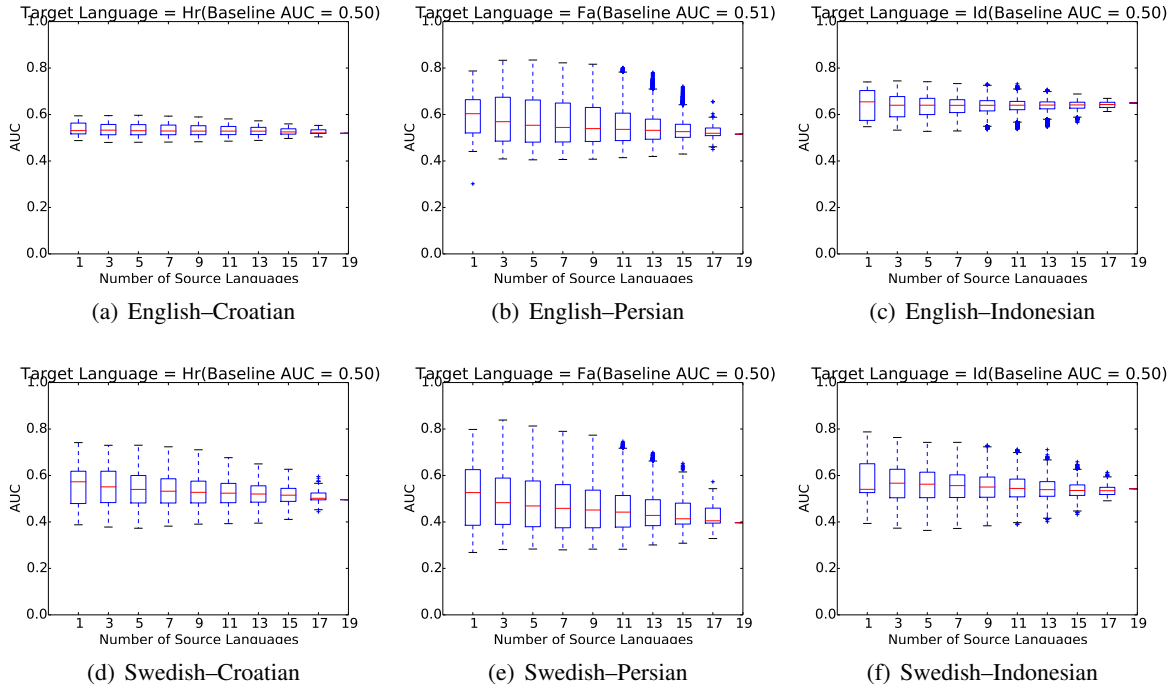
Table 2 shows the AUC scores when English is used as the source language to parse the target language, and English is also used to train our reranking model. Our proposed model ("Reranker") produces above-baseline results for all target languages except German, Danish, Italian and Croatian. We observe a very high percentage (63%) of compounds being predicted as noun–noun compounds in German, which is a large part of the strong results for that language. In order to compare with a collocation extraction methods, we contrast this with a ranking based on the average PMI score for each dependency relation ("PMI"). The results show that for half of the languages simple PMI scores can lead to higher AUC scores, while for the other half, the reranker model (which incorporates PMI scores but is trained on another language), performs better.

The final row in Table 2 is the result of providing the baseline method with gold standard dependency relations (with unknown label, to avoid trivialising the task) and applying the reranker to the gold-standard tuples. Since one source of noise (i.e. the induced parser) is removed in this baseline, we observe much higher scores than the other two approaches, except for Hungarian. For Hungarian, 90% of the annotated MWEs are NUM–NUM compounds, which is the reason that our second baseline performs worse for Hungarian compared to other languages. This result suggests that, unsurprisingly perhaps, the major cause of error in our method is the dependency parser.

Similar to the previous experiment, we also experimented with an ensemble of rerankers. We use English and Swedish as the source language to parse Persian, Croatian and Indonesian. Figure 4 shows how increasing the number of source languages and combining the trained models affects the AUC scores. According to Figure 4, our proposed method on average beats the baseline, when using only one language to train the reranker. However, unlike the previous experiment, combining multiple source languages does not improve the reranker. Additionally, comparing English with Swedish, we observe that the source language used to induce the dependency parser plays an important role.

7 Error Analysis

Finally, we perform error analysis to better understand the performance of the proposed method, focusing on two languages: Persian and Croatian, with 322 and 225 patterns to rank, respectively. We selected these two languages primarily because of the diversity of the MWE annotations in the treebanks (Section 3), and we had access to expert native-speaker annotators. The most frequent annotated patterns in the original treebanks are shown as "Gold standard" in Table 3 (the relation between pos_h and pos_d are either `mwe` or `compound` or both). The dependency parser and reranker are trained on English and



(a) English–Croatian (b) English–Persian (c) English–Indonesian

(d) Swedish–Croatian (e) Swedish–Persian (f) Swedish–Indonesian

Figure 4: Combining source languages given the noisy dependency relations. In (a)–(c), the English treebank is used as the source language for the cross-lingual parser, and in (d)–(f) Swedish is used.

Swedish as the source languages, individually. The top-10 most frequent patterns in the first quartile of the output of the reranker are shown in Table 3. The patterns which match with the gold standard pattern are marked with "†".

When English is the source language, noun compounds are correctly selected as a very frequent pattern in Persian. The pattern of ⟨ADJ, amod, NOUN⟩ is selected as the second most common pattern in Persian, for which almost all token instances are also true MWEs, such as *Islamic republic*, *Islamic revolution*, *right wing* and *fundamental law*.[5] Instances of ⟨NOUN, nmod, NOUN⟩ are more institutionalised, such as *seminar presentation* and *Iftar time*. Persian is rich with LVCs, which shows up in the first column as ⟨NOUN, nsubj, VERB⟩, i.e. misanalysed as verb–subject rather than verb–object pairs, but containing predominantly LVCs. In fact, among the top-20 most frequent token instances of this pattern, 17 are LVCs. As we work our way down the list of dependency triples in Table 3, there are fewer and fewer actual MWE token instances associated with the pattern. For example, the number of MWE instances associated with ⟨ADV, advmod, NOUN⟩ is less than non-MWEs (MWE examples are *before Christ*, and *before revolution*). The primary sources of error were parser errors or the triple being a fragment of a larger MWE. Using Swedish as the source language, we observed a similar trend.

For Croatian, almost all of the tokens associated with the top-2 patterns for both English and Swedish are MWE instances, with the tokens associated with ⟨NOUN, compound, NOUN⟩ based on English corresponding very closely with ⟨NOUN, nmod, NOUN⟩ based on Swedish. As with Persian, as we go down the list, the patterns become more noisy and the MWE tokens sparser, with the exception of ⟨NOUN, compound/nmod, PROPN⟩, for which almost all instances are MWEs (e.g. *president Erdogan*) or part of a larger MWE. Also, the instances of ⟨PROPN, compound, PROPN⟩ are all named entities. None of the token instances associated with ⟨NOUN, nsubj, VERB⟩ and ⟨AUX, aux, VERB⟩ were MWEs.

[5]Note that our model predicts the MWE patterns rather than MWE instances. Therefore, whether an individual MWE is also an MWE in the target language or not, does not affect the final results.

	Source = English	Source = Swedish	Gold standard
Persian	⟨NOUN, compound, NOUN⟩ †	⟨ADP, case, NOUN⟩	⟨NOUN, ∗, VERB⟩
	⟨ADJ, amod, NOUN⟩ †	⟨NOUN, nsubj, VERB⟩ †	⟨ADP, ∗, ADP⟩
	⟨NOUN, nmod, NOUN⟩ †	⟨NOUN, nmod:poss, NOUN⟩ †	⟨ADJ, ∗, VERB⟩

Table 3: Top-ranking Persian and Croatian MWE patterns extracted using English and Swedish as the source language. Those patterns which match the top-ranking gold standard patterns are shown with "†".

8 Conclusion

In this paper, we proposed a method for automatically determining the MWE composition of a novel language, based on delexicalised universal dependency patterns of the form $\langle \text{pos}_h, \textsf{rel}, \text{pos}_d \rangle$. The method is based on determination of MWEs in a source language from a dependency treebank, and training of a model over delexicalised dependency patterns for that language. This is then applied to a target language to rerank patterns, in terms of MWEhood. In our initial experiments, we used gold-standard dependency information for a treebank for the target language, and found the method to be highly successful at ranking dependency patterns. This both validated the method, as well as suggesting the potential for the use of the method in cross-checking the consistency of the UD treebanks. We then applied our method under the more realistic setting of having no gold-standard dependency data for the target language, but instead the output of a dependency parser induced for the target language based only on a POS-tagged monolingual corpus in the target language (and gold-standard data in the source language). We found the method to produce above-baseline results for the majority of languages tested, and that for the false positives associated with higher token frequencies, many of the associated tokens were actually true instances of MWEs (with the wrong dependency relation).

Acknowledgements

We wish to thank Long Duong for help with the transfer-based dependency parsing, Jan Snajder for his kind assistance with the Croatian annotation, and Dan Flickinger, Lars Hellan, Ned Letcher and João Silva for valuable advice in the early stages of development of this work. We would also like to thank the anonymous reviewers for their insightful comments and valuable suggestions. Abstract

In this paper, we propose a novel hybrid deep learning architecture which is highly efficient for sentiment analysis in resource-poor languages. We learn sentiment embedded vectors from the Convolutional Neural Network (CNN). These are augmented to a set of optimized features selected through a multi-objective optimization (MOO) framework. The sentiment augmented optimized vector obtained at the end is used for the training of SVM for sentiment classification.We evaluate our proposed approach for coarse-grained (i.e. sentence level) as well as fine-grained (i.e. aspect level) sentiment analysis on four Hindi datasets covering varying domains. In order to show that our proposed method is generic in nature, we also evaluate it on two benchmark English datasets. Evaluation shows that performance of the proposed method are consistent across all the datasets and often outperform the state-of-art systems. To the best of our knowledge, this is the very first attempt where such a deep learning model is used for sentiment analysis in less-resourced languages such as Hindi.

1 Introduction

Sentiment Analysis (Pang and Lee, 2008) in natural language processing (NLP) deals with the problem of identifying the polarity in a user generated content. With growing social media platforms such as Twitter, Facebook etc., copious amount of data is being generated continuously. According to Domo's Data Never Sleep 2.0[1], the global internet population is about 2.4 billion users. Online platforms such as Twitter alone generate over 300,000 tweets per minute[2]. At the same time more than 26K user reviews are posted on Yelp, an online user review portal. This tremendous amount of semi-structured data poses a great challenge in its efficient processing for any specific purpose. Sentiment analysis for web generated content e.g. tweets and online reviews, is a cumbersome problem mainly due to its unstructured and noisy nature (e.g. *gr8*, *g8* etc. for *great*) and spelling and grammatical mistakes. Considering the challenges as mentioned above, authors have proposed their sentiment analyzers for Twitter data and/or online reviews (Kim and Hovy, 2004; Mohammad et al., 2013a; Gupta et al., 2015). However, most of the works have been done on the resource-rich languages such as English.

India is a multi-lingual country with great linguistic and cultural diversities. There are 22 officially spoken languages. However, there have not been enough research works that address sentiment analysis involving Indian languages, *except* few such as (Balamurali et al., 2012; Bakliwal et al., 2012; Kumar et al., 2015). However, these existing works do not address the fine-grained sentiment analysis at the aspect level. The prime reason behind this is the scarcity of benchmark datasets and other resources/tools in Indian languages. In our work, we focus on sentiment analysis in Hindi, the official language of India and the fourth most spoken language all over in the world. We make use of benchmark datasets released as part of a shared task on sentiment analysis in Indian languages (SAIL) for Twitter (Patra et al., 2015). Recently, we (Akhtar et al., 2016) have created a dataset for aspect based sentiment analysis

(ABSA) (Pontiki et al., 2014) in Hindi. For sentence-level sentiment analysis we annotate these same set of reviews. Here, we evaluate our proposed approach for both coarse-grained (sentence based) and fine-grained (aspect based) sentiment analysis.

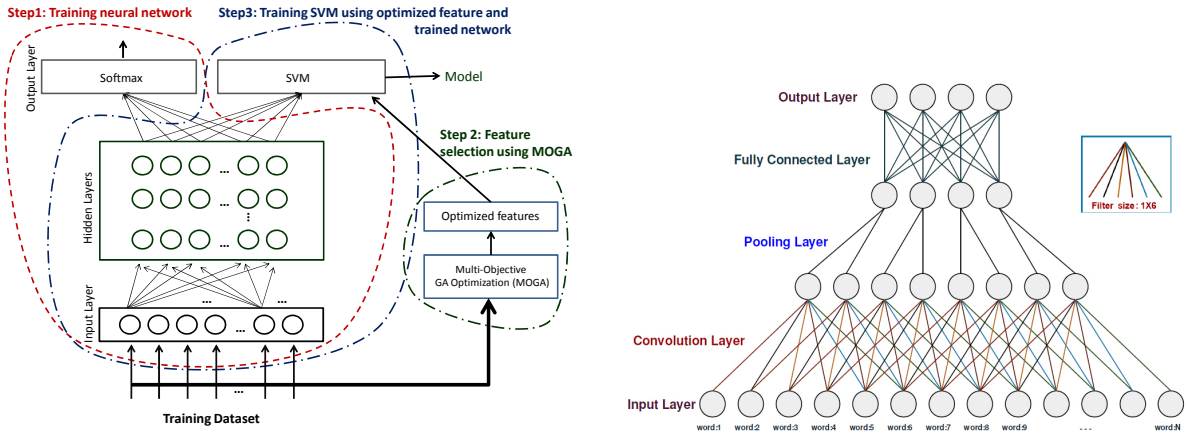
Our proposed method is based on deep learning, which has shown its premise in various NLP problems including sentiment analysis. Authors worldwide have proposed many variants of its architecture (Kim, 2014; dos Santos and Gatti, 2014), which have shown success for solving problems in varying domains. Most of these works employ traditional technique of using softmax as an activation function on top of a typical convolutional neural network (CNN). However, in our work we learn *sentiment embedded vectors* using CNN pipeline and perform final classification using a strong classifier, Support Vector Machine (SVM) (Vapnik, 1995). Replacing softmax layer with some stronger classifier might be useful as shown in very few research, such as computer vision (Tang, 2013) and NLP (Poria et al., 2015).

In this work, we do not use the traditional pipeline of CNN (c.f. Section 2.1) for sentiment classification. Rather, we learn sentiment features through CNN, which we call as '*sentiment-embedded vector*'. Parallely, a multi-objective optimization (MOO) based framework using Genetic Algorithm (GA) (Deb et al., 2002) is employed to derive optimized features for the respective optimization functions. In the final step, we augment the sentiment-embedded vector with the optimized feature set to form '*sentiment augmented optimized vector*'. This vector is used as the feature for sentiment classification using a non-linear SVM. In order to study the impact of external optimized handcrafted features, we build different models of the baseline systems. The existing works which make use of external features in CNN architecture simply append features at the input layer. This method has mainly three drawbacks: **(i)** The information in external features appended at the input layer are not properly reflected in the output due to the processes of convolution and pooling layers. **(ii)** The set of features is not optimized i.e, optimal subset of features is not extracted, instead complete feature set is appended to the word representations at the input layer. **(iii)** Softmax is a weak classifier and has limitation over SVM. We propose to tackle all these problems using our approach, the results of which are encouraging and consistent across datasets of varying domains and languages. Such hybrid model using CNN, SVM and MOGA (c.f. Section 2.3) that performs sentiment classification using sentiment augmented optimized vector is novel, impactful as well as very effective for resource-constrained languages.

We summarize the main contributions of the proposed approach as follows: **i)** a hybrid modified architecture of CNN, that learns sentiment embedded vector instead of traditional pipelined-classification; **ii)** application of MOO for the systematic selection of optimized feature set, to generate sentiment augmented optimized vector; **iii)** replacement of softmax layer to produce more robust hybrid deep learning network by using non-liner SVM based classification at the final step; and **iv)** generic approach, applicable to different languages and domains. We evaluate the approach on the datasets of varying domains, i.e. Twitter (generic as well as sarcastic) and online product reviews (sentence-level and aspect-level), across two different languages *viz.* Hindi and English for sentence-level as well as aspect-level sentiment analysis. Experiments show that the proposed hybrid deep learning architecture is highly efficient for sentiment analysis in multiple domains for Hindi. To the best of our knowledge, this is the very first attempt of using such a hybrid deep learning model for sentiment analysis, especially in less-resource languages. For English, we use the benchmark dataset of SemEval-2015 shared task on sentiment analysis in Twitter (Rosenthal et al., 2015) and SemEval-2014 shared task on aspect based sentiment analysis (Pontiki et al., 2014).

2 Methodology

Logistic regression (LR) (or Softmax regression for multi-class classification) and SVM are two algorithms that often produce comparable results. However, SVM has an edge over LR if the data is not linearly separable, i.e. SVM with non-linear kernel performs better than LR (Pochet and Suykens, 2006). Also, LR focuses on maximizing the likelihood and is prone to over-fitting. However, SVM finds a linear hyperplane by projecting input data into higher dimension and generalizes well. We incorporate this idea in our proposed research by replacing the softmax regression with SVM at the output layer of CNN. The motivation for using CNN architecture are two-fold: (i) The system can learn hidden semantics from a



(a) Proposed methodology

(b) A typical architecture of CNN

Figure 1: (a) Proposed methodology. (b) A typical architecture of CNN.

large unlabeled corpus, and (ii) limited coverage of lexical resources (Hindi SentiWordNet). The proposed approach, *CNN-SVM*$_{W+X}$, operates in three steps (Figure: 1a; red, green & blue dotted lines show the processes of Step 1, 2 and 3, respectively.):

1. Learning sentiment embedded vector using CNN architecture;
2. Generation of sentiment augmented optimized vector using a multi-objective GA (MOGA) based optimization technique; and
3. Training of SVM with non-linear kernel utilizing the network trained in first step and optimized features of Step 2.

In Step 1, we define the network and initialize its weights using Xavier initialization (Glorot and Bengio, 2010). We then train a CNN using a stochastic gradient descent back-propagation algorithm. Parallely, in Step 2, MOO based feature selection technique is employed to identify the most relevant set of features within the framework of SVM. Once the training of CNN is over, i.e. optimal parameters of the network are found, in Step 3 we concatenate the output of top hidden layer and optimized feature set reported by MOGA and feed it to SVM.

CNN performs reasonably well in capturing the relevant lexical and syntactic features on its own. Thus, the first step of the proposed approach ensures that it extracts such features from the training data automatically. The SVM in the proposed approach makes use of the features extracted from CNN along with the optimized features (from MOGA) to define a hyperplane which is more robust as compared to what defined by either CNN or SVM with optimized features alone. The pseudo code of the proposed approach is sketched in Algorithm 1. Statements 1-6 deal with the first step i.e. training of the deep learning network to learn sentiment embedded vectors while statement 7 finds out the optimized feature set. The last step is carried out by statements 8-14.

2.1 Convolutional neural network (CNN)

CNN is a special kind of multi-layer neural network which consists of one or more convolutional and pooling layers, followed by one or more fully-connected layers. The convolutional and pooling layers implicitly extract relevant feature representation from input data, and fed it to the fully connected layers for classification. The size and weights of the convolution filters determine the features to be extracted from the input data. Same convolution filter is floated over the complete input data in order to extract similar features at different spatial locations. Max pool layer is then applied to select the most significant features from the CNN features. Subsequently, after iterating several convolutional and max pooling layers, it is fed to a fully connected layer for classification. In general we use softmax as an activation

function in the fully connected layer. A typical CNN architecture is shown in Figure 1b. Feature map represents the size of the filter while each edge corresponds to a weight of the filter.

2.2 Word representation

A neural network requires word embedding (or, sentence embedding) as an input to the network, i.e. a vector representation of each word or sentence. We use word2vec tool (Mikolov et al., 2013) which efficiently captures the semantic properties of words in the corpus. We train with a corpus of 6.7 million sentences, which were collected from Wikipedia and Twitter sources. This trained model is used for translating a word into its respective vector representation. We set the vector dimension of a word to 200. Each sentence is padded with zero vectors in order to make its length uniform throughout the dataset. Hence, the vector dimension ($Vector_{dim}$) of each sentence (i.e. number of neurons at input layer) counts to 200$\times$max-sentence-length.

2.3 Multi-Objective genetic algorithm (MOGA) based feature selection

We develop a feature selection technique based on multi-objective optimization (MOO) (Deb, 2001). The problem of feature selection can be modeled as follows: Given a set of features F and $M = \langle m_1, m_2, .., m_M \rangle$ objective functions, find a subset F^* of F such that M objectives are optimized simultaneously. For instance, maximization of all objective functions can be mathematically stated as:

$$Objective_M(F^*) = \underset{M, S \epsilon F}{argmax}\{Objective_M(S)\}$$

We use a binary version of genetic algorithm (GA) for determining the best fitting feature set. The basic operations of GA are 'crossover', 'mutation' and 'selection'. First, we randomly initialize N chromosomes of length n, each representing a solution in the population. The length of each chromosome (n) corresponds to the number of features available, i.e. each bit position encodes exactly one feature. The value of 1 in a bit position denotes that the respective feature is used for classifier's training, otherwise the feature is not used. A representation of a chromosome is presented in Figure 2. Selection, crossover

1	1	0	.	.	.	.	0	0	1
F_1	F_2	F_3	.	.	.	.	F_{n-2}	F_{n-1}	F_n

Figure 2: Representation of chromosome in GA based optimization.

and mutation operations are then performed on the chromosomes.

1. **Selection:** At first we select top N solutions w.r.t fitness value. For fitness computation, we construct a SVM based classifier with the selected features, and iterate this process 5 times for 5-fold

cross-validation experiments. In multi-objective optimization we perform non-dominating sorting for the selection. Two solutions, *A* & *B*, are non-dominated to each other if solution *A* is not bad than solution *B* in at least one objective function and vice-verse. In contrast, a solution *A* dominated by *B* if for all objective functions *A* is less optimal than solution *B*. A set of solutions, that are non-dominating to each other but dominates every other solutions in the population forms a non-dominating *front-0*. Similarly, non-dominating *front-1* consists of remaining solutions that are non-dominating to each other but dominate other solutions. Hence, *front-0* solutions dominates *front-1* solutions which in turns dominates *front-2* solutions and so on. Set of solution in *front-0* forms pareto-optimal surface (Rank 1). A pictorial representation of non-dominating solutions are depicted in Fig. 3. We use binary tournament selection, as in non-dominated sorting GA (NSGA)-II (Deb et al., 2000). We use elitism operation, where non-dominated solutions among parent and child generations are propagated to the next generation. MOO provides a set of non-dominated solutions (Deb et al., 2002) on the final Pareto optimal front. Although each of these solutions is equally important from the algorithmic point of view, but user may often require to produce only a single solution. In our case we select the particular solution that yields maximum accuracy.

2. **Crossover:** In crossover, for any two solutions a random split position is chosen. Two new solutions are generated by swapping the information of the chromosomes with each other at the split point.

3. **Mutation:** Similarly, mutation operator is applied to each entry of chromosome, where an entry is randomly replaced by 0 or 1 based on mutation probability.

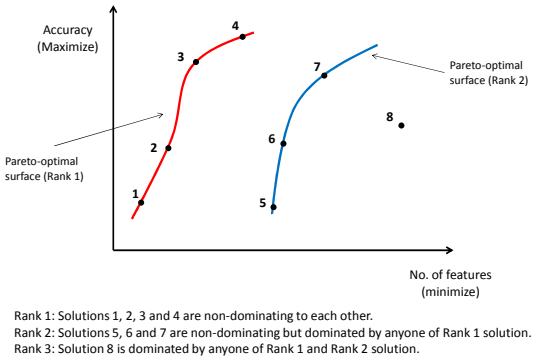

Figure 3: Representation of dominated and non- dominated solutions.

In this work we optimize two objective functions: accuracy (maximize) and number of features (minimize). We set the parameters of MOO as follows: population size=60, number of generations=30, crossover probability=0.8, mutation probability=0.03.

3 Datasets, Experiments and Analysis

3.1 Datasets

For experiments we use the following four datasets for Hindi:

1. **Twitter-Hindi ($Twitter_H$):** We use benchmark dataset released by the organizers of 'SAIL: Sentiment Analysis in Indian Languages' task (Patra et al., 2015).

2. **Online reviews for aspect based sentiment analysis in Hindi ($Review_{A_H}$)[3]:** This dataset is developed by us (Akhtar et al., 2016) for aspect based sentiment analysis (ABSA). It comprises of 5,417 product and service reviews across 12 domains. Reviews are annotated with aspect terms along with

its polarities. We consider four classes, namely *positive*, *negative*, *neutral* and *conflict*. In this work we solve only one problem of ABSA i.e. aspect term sentiment problem.

3. **Online reviews for sentence based sentiment analysis in Hindi ($Review_{S_H}$)[3]:** There is no available benchmark dataset which deals with sentence-level sentiment analysis for online product reviews in Hindi. Therefore, we extract user reviews from $Review_{A_H}$ dataset and annotate these using four classes as mentioned above.

4. **Online movie reviews-Hindi ($Movie_H$)[3]:** We collect user reviews from various news and blog websites, and annotate using four classes.

Detailed statistics of the above datasets are presented in Table 1. For each dataset $Review_{A_H}$, $Review_{S_H}$ and $Movie_H$ we distribute 70%, 20% and 10% of the data as training, test and development, respectively. For generalization, we also evaluate the proposed method on two other benchmark datasets in English *viz.* SemEval 2015 shared task on sentiment analysis in twitter (Rosenthal et al., 2015) and SemEval-2014 shared task on ABSA (Pontiki et al., 2014).

Datasets		**Sentiment**				
		#Pos	**#Neg**	**#Neu**	**#Con**	**Total**
$Twitter_H$	Train	168	559	494	-	1221
	Test	166	251	50	-	467
$Review_{A_H}$	-	1986	569	1914	40	4509
$Review_{S_H}$	-	2290	712	2226	189	5417
$Movie_H$	-	823	530	598	201	2152

Table 1: Dataset statistics. Here, pos: positive, neg:negative, neu:neutral and con:conflict

3.2 Baseline, proposed model and its variants

In order to compare our proposed approach, we define the following baseline models:

- B_{SVM}: This is a SVM based model that incorporates all the available features.

- B_{CNN_W}: It is a simple CNN based model, trained and evaluated using word embedding as features (c.f. Section 2.2).

In addition, we also try to understand the behavior of the proposed model in presence or absence of extra handcrafted features. For a comparative study we define following two models based on CNN architecture:

- CNN-SVM$_W$: This represents our proposed model in the absence of optimized feature set. It is trained and evaluated only with the word embedding features. We extract feature vectors from the top hidden layer and feed it to SVM for training.

- $B_{CNN_{(W+X)}}$: This model is similar to baseline B_{CNN_W}. The only difference is the usage of optimized features as determined by MOO based feature selection technique (in addition to word embedding).

3.3 Feature set

Table 2 shows the set of features that we use for building different models and the optimized feature subset that we obtain through the feature selection technique.

[3]Resource available at http://iitp.ac.in/~ai-nlp-ml/resources.html

Category	Dataset	Feature	Description
Lexical and syntactic features	All	PoS, Word N-grams, Character N-grams	Part-of-Speech tag, Unigram, Bigram and Trigram
Twitter specific features	$Twitter_H$, $Twitter_E$	Hashtags	Number of hashtag(#) tokens in the tweet.
		Emoticons	Binary valued feature denotes the presence or absence of the positive and negative emoticons
		Punctuation	Number of occurrences of contiguous sequence of question marks, exclamation marks etc
		URL and Username	# of url and usernames present in the tweet.
		Average length	Average length of the tokens
Lexicon features	$Review_{A_H}$, $Review_{S_H}$, $Movie_H$	SentiWordNet for Indian Language (Das and Bandyopadhyay, 2010)	# of positive tokens, negative tokens and average score.
	$Review_{A_H}$, $Review_{S_H}$, $Movie_H$, $Review_{A_E}$	Semantic Orientation (Hatzivassiloglou and McKeown, 1997)	Sum of semantic orientation score of each token.
	$Twitter_E$, $Review_{A_E}$	Bing Liu lexicon (Ding et al., 2008)	# of positive tokens and negative tokens.
		MPQA lexicon(Wiebe and Mihalcea, 2006)	Number of positive tokens and negative tokens.
	$Twitter_E$	NRC lexicons (Mohammad et al., 2013b; Mohammad and Turney, 2013)	# of tokens with positive score, negative score and zero score, total emoticons score and total sentiment score.

Dataset	Optimized feature set*
$Twitter_H$	Emoticons, Punctuation, SentiWordNet
$Review_{A_H}$, $Review_{S_H}$	Semantic Orientation
$Movie_H$	Semantic Orientation, SentiWordNet
$Twitter_E$	HashTag, Emoticons, Punctuation, Bing Lui and NRC Lexicon
$Review_{A_E}$	Bing Lui and MPQA Lexicon
*We leave out lexical and syntactic features from the optimized set as these information will be captured by the CNN itself.	

Table 2: Feature set and the optimized features

3.4 Experiments

For experiments we use DL4J[4], a java based package for deep learning implementation, and LibSVM library (Chang and Lin, 2011) for SVM. We use the development set to fine-tune the parameters of CNN. For SVM, we perform grid search to find the optimal parameter settings of RBF kernel. CNN classifier is trained for 50, 100 and 120 epochs with 300 feature maps of size $4 \times Vector_{dim}$. We use stochastic gradient descent and negative log-likelihood as the optimization algorithm and loss function, respectively. In addition, we use L2 regularization and dropout technique (Srivastava et al., 2014) to build a robust system. Results of the proposed method along with the baselines are presented in Table 3a. Our proposed method achieves 62.52% accuracy for $Twitter_H$ which convincingly outperforms SVM based baseline by 13 points, and reports approximately 2 points better accuracy as compared to B_{CNN_W}. Comparison to the participating systems of SAIL shared task shows that we are ahead of the best system as reported in (Se et al., 2015) by almost 7 points. For aspect-level Hindi review dataset, $Review_{A_H}$ the proposed approach reports an accuracy of 65.96% against 54.09% as reported in our previous attempt (Akhtar et al., 2016), which was based only on SVM. Similarly for sentence-level sentiment analysis on $Review_{S_H}$ and $Movie_H$ datasets, our proposed method performs better compared to the other baselines. Since evaluation on $Review_{S_H}$ and $Movie_H$ datasets are performed for the first time, we do not have any existing model for comparison. In Table 3b, we show the class-wise accuracies of *CNN-SVM*$_{(W+X)}$ for the Hindi datasets.

3.4.1 Effect of handcrafted features

Since the twitter-specific features are not very relevant for the product reviews dataset, we only use lexicon-based features for it. In comparison to the baseline B_{CNN_W}, augmenting external features in $B_{CNN_{(W+X)}}$ shows better accuracy. We also observe similar phenomenon for all the other settings. Addition of extra feature helps *CNN-SVM*$_{(W+X)}$ for $Twitter_H$ to achieve accuracy of 62.45% as compared

[4]http://deeplearning4j.org/

to 61.24% without it. Similarly, for $Review_{A_H}$ dataset *CNN-SVM*$_{(W+X)}$'s improvement is close to 5% by just using the sentiment lexicon features. Since word embeddings are good at capturing the semantic information, addition of lexicon based features assist it in finding the sentiment more accurately. It should be noted that augmentation of external features along with the features automatically extracted from CNN at the penultimate layer (sentiment augmented optimized vector) yields better result compared to the model where external features added to the word embeddings at the very input layer. This can be attributed to the fact that information in external features are lost through a series of convolution and max-pooling layers. While we add all features to B_{SVM} in the network, we observe that performance drops. This could be because the network itself captures lexical features on its own, and augmenting features further leads to over-fitting.

Method	**Accuracy**

(b) Class-wise performance

Table 3: Results of baseline models and proposed method for $Twitter_H$, $Review_{A_H}$, $Review_{S_H}$ and $Movie_H$ datasets. Subscript *W+X* represents models with word embedding and optimized feature set while *W* represent models with only word embeddings. B_{SVM} and B_{CNN_W} are the two baseline systems and CNN-SVM$_{(W+X)}$ is the proposed method. CNN-SVM$_W$ represents proposed system without optimized feature set.

3.4.2 Evaluation on other benchmark datasets

In order to show the domain and language adaptability, we evaluate our proposed method i.e. *CNN-SVM*$_{(W+X)}$, on two benchmark datasets in English *viz.* $Twitter_E$ and $Review_{A_E}$. The $Twitter_E$ dataset belongs to SemEval-2015 shared task on sentiment analysis in Twitter (Rosenthal et al., 2015) and comprises of 8,210, 1,654 and 2,392 tweets for training, testing & development, respectively. Tweets in the dataset belong to different genres, i.e. **generic** as well as **sarcastic**. We evaluate the system for both genres in isolation. The second dataset belongs to SemEval-2014 shared task on ABSA (Pontiki et al., 2014). It contains approximately 3,800 user reviews from two domains, *viz.* laptop and restaurant. Table 4 depicts the results on $Twitter_E$ and $Review_{A_E}$ datasets for both the genres and domains, respectively. Results suggest that use of SVM on top of CNN, i.e. *CNN-SVM*$_W$ performs better than the typical CNN system, i.e. B_{CNN_W}. We observe the same phenomenon when optimized feature sets are concatenated with word embeddings in systems $B_{CNN_{(W+X)}}$ and *CNN-SVM*$_{(W+X)}$.

Method	Accuracy			
	$Twitter_E$		$Review_{A_E}$	
	Tweets	Sarcasm	Laptop	Restaurant
B_{SVM}	56.31	58.33	57.18	69.92
B_{CNN_W}	51.61	45.0	64.98	73.46
CNN-SVM$_W$	52.96	50.0	65.29	74.65
$B_{CNN_{(W+X)}}$	56.06	51.67	67.28	74.07
CNN-SVM$_{(W+X)}$	**58.62**	**61.67**	**68.04**	**77.16**

Table 4: Results of baseline models and proposed method for $Twitter_E$ and $Review_{A_E}$ datasets

#	Domain		Sentence	Actual	Predicted
1	$Reviews_H$	D	स्पीकर के आवाज़ की क्वालिटी अच्छी है , लेकिन हम कुछ और तेज़ आवाज़ चाहते थे ।	**Conflict**	**Positive**
		T_l	speekara ke AAvaaZ kee kvaaliTee Achchhee hai , lekin ham kuchh AOra teZ AAvaaZ chaahate the .		
		T_r	The sound quality of the speaker is good, but we expected better sound.		
	$Movie_H$	D	इन फिल्मों में कोई मजबूत कहानी नहीं थी मगर स्टंट के भरोसे फिल्म चल रही थी ।	**Conflict**	**Negative**
		T_l	In philmoN meN koEE majaboot kahaanee naheeN thee magara sTaNT ke bharose philm chal rahee thee .		
		T_r	There was no strong story in the film but has good stunts.		
2	$Twitter_H$	D	गणपति विसर्जन के मौके पर सुरक्षा कड़ी - URL	**Positive**	**Neutral**
		T_l	gaNNapati visarjan ke maoke para surakShaa kaDdee - URL		
		T_r	Tight security on the eve of Ganpati Visargan - URL.		
	$Reviews_H$	D	3जी प्लास्टिक का बना हुआ था जो हाथ से फिसलता था ।	**Negative**	**Neutral**
		T_l	3jee plaasTik kaa banaa huAA thaa jo haath se phisalataa thaa .		
		T_r	It was made up of 3G plastic which was slippery.		
3	$Reviews_H$	D	लेकिन इसमें लगे एएमडी रेडिओन एचडी7670एम ग्राफ़िक्स चिप का प्रदर्शन लाज़वाब है ।	**Positive**	**Neutral**

3.5 Analysis of results

Results suggest that our proposed architecture performs reasonably well for different domains and languages. The traditional CNN architectures are known to be capturing the lexical and structural features very well. We incorporate this idea into our work to learn sentiment embedded vector which helps in the attaining better results as evident from Table 3. The usage of SVM (rather than traditional softmax function) on sentiment embedded vector is able to generate the decision hyperplane more accurately by projecting the CNN features into higher dimension. Further, the (near) optimal set of features produced by MOO based feature selection technique (in addition to CNN features) assists SVM for more accurate prediction using sentiment augmented optimized vector.

We also perform Analysis of Variance (ANNOVA) (Anderson and Scolve, 1978) test which is a measure of statistical significance on the obtained results. We execute our approach 10 times with varying parameter settings. We observed that the variance in mean accuracy between proposed method and state-of-the-art methods is less than 5%. It signifies that improvements over the baselines are statistically significant.

We perform a detailed analysis (quantitative and qualitative) of the outputs to study the effectiveness as well as the shortcomings of the proposed approach.

We observe that 13% and 5.8% mis-classified test instances are correctly predicted by the *CNN-SVM*$_{(W+X)}$ model for Twitter and reviews domain, respectively. Motivations for using CNN architecture are two-fold: i) to learn hidden semantics from a large unlabeled corpus; and ii) handling limited coverage of lexical resources (e.g. Hindi SentiWordNet). In contrast to B_{SVM}, we observe that CNN architecture correctly captures instances such as "@imVkohli: धोनी के 'अतिआत्मविश्वास' के

कारण हारी टीम (@imVkohli: dhonee ke 'AtiAAtmavishvaasa' ke kaaraNN haaree Teema-@imVkohli: Team lost due to over-confidence of Dhoni.)", in which sentiment bearing words: अतिआत्मविश्वास (AtiAAtmavishvaas:Over-confidence) and हारी (haare:lost) were not found in SentiWordNet and in training set as well.

While analysing the outputs for the errors, we observe the following points:

1. Sentiment in a sentence can be either expressed by a explicit use of sentiment word e.g. अच्छा (Achchhaa:good) or by a word which carries implicit sentiment e.g. फीके (pheeke:light). For conflict sentences, explicit use of a positive or negative sentiment word drives the system to predict its output as 'positive' or 'negative'. In the first sentence of Table 5, presence of अच्छी (Achchhee:good) misguides the system to predict its sentiment as 'positive'.

2. Absence of an explicit sentiment marker in a sentence makes it harder for the system to correctly predict the sentiment. For the second sentence in Table 5, the system classifies as 'neutral' as no explicit trigger word is present.

3. The system mis-classifies some of the sentences which have explicit sentiment bearing words, but their corresponding word representations are missing due to their rare occurrences. For example, in the third sentence, word लाज़वाब (laaZvaab:splendid) has a positive sentiment. As its representation is missing from the word embedding output, system incorrectly predicts it as 'neutral'.

4 Conclusion

In this paper, we propose an efficient hybrid deep learning architecture for sentiment analysis in resource-poor languages. We learn sentiment embedded vector using CNN architecture and make a final prediction by replacing softmax function with a stronger classifier, i.e. SVM at the output layer of CNN. Training of SVM is further assisted by the optimized feature set computed by a multi-objective GA based feature selection technique to form sentiment augmented optimized vector. We build various models and evaluate our proposed method on the datasets of varying domains: Twitter (generic & sarcastic) and product/service reviews (aspect-level and sentence-level sentiment analysis). For all datasets we observed that our method consistently reports better accuracy than the various baselines and state-of-the-art systems. We observed that the usage of SVM and optimized feature set in the proposed approach helps it to achieve encouraging performance across the domains and languages compared to the state-of-the-art methods.

In this work, we include only one of the sub-problems of aspect based sentiment analysis i.e. aspect term sentiment classification. In future we would like to solve other sub-problems of ABSA such as aspect term extraction, aspect category detection and its sentiment classification. Aspect term extraction is an sequence labeling task while aspect category detection is a multi-lable classification tasks. We plan to explore recurrent neural networks (RNN) for aspect term extraction and extend our CNN based approach for multi-label classification. Also, since quality of word representation is an important factor in any neural network architecture, we plan to make use of techniques such as distance supervision for enhancing the quality of word representations.

Abstract

In Sanskrit, the phonemes at the word boundaries undergo changes to form new phonemes through a process called as *sandhi*. A fused sentence can be segmented into multiple possible segmentations. We propose a word segmentation approach that predicts the most semantically valid segmentation for a given sentence. We treat the problem as a query expansion problem and use the path-constrained random walks framework to predict the correct segments.

1 Introduction

Word segmentation is an essential step for most of the text processing tasks. In Sanskrit texts, it is very common that the phonemes at the word boundaries undergo changes to form new phonemes, through a process termed *sandhi*. It also makes the word boundary between the words that undergo *sandhi*, indistinguishable. Proximity between phonemes (*saṃhitā*) is the sole criteria for applying *sandhi*, thus phonetic transformation takes place between two consecutive words. This poses a big challenge in identifying individual words in a given sentence, as the same fused form can be segmented into many possible segmentations. Though, there has been considerable advancements in tackling word segmentation challenges faced in other languages including Chinese, Korean and Arabic, a direct application of those approaches is not possible in Sanskrit texts due to the phenomena of *sandhi*. Since the *sandhi* rules are well documented in the tradition, all the syntactically valid segmentations (splits) of a given sentence in Sanskrit can be enumerated. Sanskrit Heritage Reader provides a nice compact interface to show all the valid solutions (Huet and Goyal, 2013). The main challenge is to identify the most relevant solution from all the possible segmentations. The relevance of contextual information in identifying semantically relevant segments is a well-accepted fact (Hellwig, 2009). Mittal (2010), Natarajan and Charniak (2011) have successfully applied statistical methods for *sandhi* splitting in Sanskrit. But, both the approaches relied heavily on word co-occurrence features as their context with minimal usage of the morphological information. We, unlike the previous methods, propose a segmentation approach which effectively combines the morphological features in addition to the word co-occurrence features from a manually tagged corpus of more than 400,000 sentences (Hellwig, 2009). We treat the problem as a query expansion problem that iteratively selects a segment amongst the competing segmentations and then continues to select the next correct segment with the information from extended context. The algorithm terminates when no more candidates remain to be evaluated. We use the scalable "path-constrained random walks (PCRW)" (Lao and Cohen, 2010) framework with linguistically motivated Inductive Logic Programming (ILP) formulations for finding the correct segmentation. Using extensive experiments, we find that our approach outperforms the existing approaches by a significant margin.

2 Challenges in Sandhi Splitting

Processing of Sanskrit text poses challenges of its own due to the *sandhi* phenomena. For example, consider the phonemic change at the boundary for the case of *ramā* + *īśaḥ* → *rameśaḥ*. Here the phonemes *ā* at the end of the previous word and *ī* at the beginning of the subsequent word combine together to

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 494–504, Osaka, Japan, December 11-17 2016.

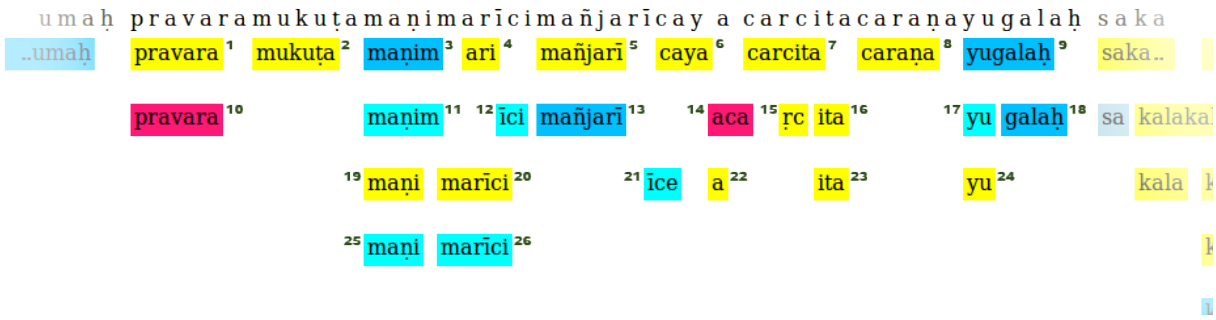

Figure 1: Possible segmentations for the compound "*pravaramukuṭamaimarīcimañjarīcayacarcitacaraṇa-yugalaḥ*" from the Sanskrit Heritage Reader. Each colour specifies a separate morphological class (Goyal and Huet, 2013; Huet and Goyal, 2013).

form the phoneme *e*. Such a transformation does not result in any change in morphological, syntactic or semantic properties of the individual words. However, there are phonetic variations resulting in the words to change their written forms.

As already mentioned, finding a semantically valid segmentation for a given sentence is a challenging task, due to the large number of possible segmentations. For example, consider the sentence, "*tatra sakalārthikalpadrumaḥ pravaramukuṭamaṇimarīcimañjarīcayacarcitacaraṇayugalaḥ sakalakalāpāraṅgato'maraśaktirnāma rājā babhūva*" - [from the text *Pañcatantram (kathāmukham)*] translates to, "There was a king namely Amaraśakthi, who was the wish-granting tree (fulfiller of all the desires) to the whole group of seekers, and the pair of whose feet was covered with a stream of rays originating from the gems in wreaths of eminent noble kings, and who was proficient in all arts". The sentence of 9 words (3 of them being compound words) can be segmented into more than half a million possible syntactically valid segmented sentences[1].

It can also be observed that multiple semantically valid splits are possible for a given string. For example, the phrase *śveto dhāvati* may be decomposed in two different ways. Both, the splits, *śvetaḥ dhāvati* (The white [one, horse] runs) and *śvā itaḥ dhāvati* (The dog runs [towards] here) are valid and give two different interpretations of the same phrase. This re-emphasizes the need for the context of the whole sentence in determining the correct set of candidates. The Sanskrit grammar poses no restriction on words in undergoing sandhi, other than the proximity of the phonemes at word boundaries. Consider the statement *dadarśāvatarantamambarāddhiraṇyagarbhāṅgabhuvaṃ muniṃ hariḥ* (Lord Viṣṇu saw Brahma's son Nārada, descending from the sky). Here, in this statement, the words *ambarāt* (from the sky) and *hiraṇyagarbhāṅgabhuvaṃ* (Nārada, son of Lord Brahma) are not related semantically, barring this they undergo euphonic transformation and fuse together to form *ambarāddhiraṇyagarbhāṅgabhuvaṃ*.

In dealing with segmentation, there are scenarios where the compound words should not be split into the constituents. Exo-centric compound refers to an external entity and the compound should be considered as a whole. Otherwise, the statement in which the compound is used need not result in a meaningful sentence. For example, the word '*daśaratha*' refers to a person and it does not refer to any of its constituents '*daśa*' (ten) or '*ratha*' (chariot). But during the analysis, it is required to use the compound component information, or else there might not be sufficient distributional information about each segment. Compound formation in Sanskrit is highly productive in nature. In the sentence from *Pañcatantram* menioned earlier, the compound,"*pravaramukuṭamaṇimarīcimañjarīcayacarcitacaraṇayugalaḥ*" (The pair of whose feet was covered with a stream of rays originating from the gems in wreaths of eminent noble kings,) is an Exo-centric (*Bahuvrīhi*) compound which consists of 9 constituents. Figure 1 shows the possible segmentation for the mentioned compound. The correct segmentation is the collection of words numbered 1-2-19-20-5-6-7-8-9. In such cases, it may be difficult to obtain distributional information about the compound if we analyse it without decomposing the compound into its components. But, after the analysis, if we do not join the compound components back to the original compound, then it alters the meaning of the sentence.

[1]Using the Sanskrit Heritage Reader available at http://sanskrit.inria.fr/

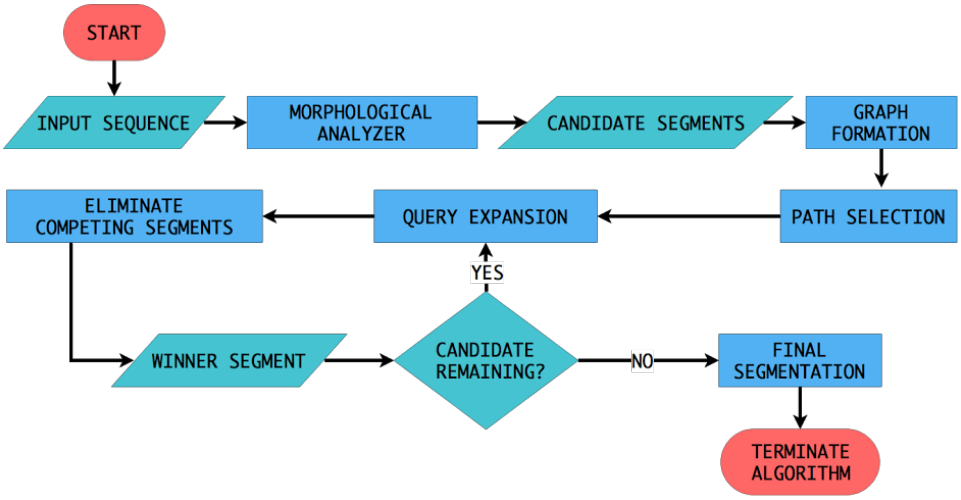

Figure 2: Flowchart for the Proposed Approach

3 Method

We treat the word segmentation problem as a query expansion problem. An input sentence is passed through the Sanskrit Heritage Reader[2]. The Sanskrit Heritage Reader provides all the possible segmentations for the input sentence along with the morphological information for each of the segments, similar to those in Figure 1. The output segments will henceforth be referred to as candidates. We now conceptualise a graph with these candidates as the nodes in the graph, in which we perform path-constrained random walks (PCRW) (Lao and Cohen, 2010) using a set of pre-defined path types. We start with the most promising candidate(s) as our initial query node and perform PCRW to obtain a winner node among the candidates. We add the winner to the extended context and repeat the process until no more candidates remain to be evaluated. We eliminate all the candidates conflicting with the winner node whenever a winner node is selected. The conflicting nodes are eliminated using positional information and *Sandhi rules*. Figure 2 provides the flowchart for the entire process.

3.1 Graph Formation

With the segments from the morphological analyser, we form a weighted multi-digraph $G(V, E, W)$, such that each node in the vertex set V represents a candidate. Every node has three attributes, the word-form, the lemma and the POS tag (morphological information) of the given segment. In this work, POS denotes the morphological information that each word-form possesses based on its usage in the sentences as directly obtained from the Sanskrit Heritage Reader. For nouns, the gender, the plurality and the grammatical case of the word-forms are obtained. For verbs the tense, number and person are the relevant morphological information that we obtain. We now construct multiple edges between all the candidate nodes except those which are conflicting with each other. We decide whether two nodes are conflicting using the position information and *sandhi* analysis. Consider two segments (k, z) and (k', z') in a given sentence. Here k and k' are the starting position (offsets) of these segments relative to the sentence, z and z' are the length of the segments. We say that (k, z) and (k', z') *conflict* if $k \leq k' < k + |z| - 1$ or $k' \leq k < k' + |z'| - 1$ (Huet and Goyal, 2013).

For every non-conflicting pair of nodes, we form edges with varying edge weights where the edge weights are decided by the possible combinations of attribute pairs at these nodes. Since each node has 3 attributes we form a total of 9 directed edges (in E) between every pair. The edge weights (in W) are defined as the co-occurrence probability of the attribute value at the target node given the attribute value at the source node. The probability values can be computed from a suitable corpus.

[2]http://sanskrit.inria.fr/DICO/reader.fr.html

3.2 Language Model

We represent our corpus, from which we obtain the distributional information for our task, as a Graph $G_2(V_2, E_2, W_2)$. We add every unique lemma, POS tag and word-form that occur in the corpus as a vertex in the graph. So, we define V_2, the vertex set as the union of the vocabulary of each of the three attributes. Now we form directed edges (in E_2) between every pair of nodes that co-occur in a sentence in the corpus. We calculate the edge weights (in W_2) using the expression 1.

$$P_{co}(j|i) = \frac{count(j,i)}{count(i)} \tag{1}$$

Here $count(i,j)$ denotes the total number of sentences in the corpus in which the nodes i and j co-occur. $count(i)$ is the count of documents in which node i occurs. For example, in order to compute the edge-weight for an edge from a POS node 'gen.m.sg.' to a lemma node '*hari*', we calculate $P(hari|gen.m.sg.)$, i.e, conditional probability of the lemma '*hari*' co-occurring with any word having the POS tag 'gen.m.sg.' in the same sentence. Similarly, we find edge weights from every possible pair of nodes that co-occur in the given corpus.

3.3 Path Selection using PCRW

With PCRW, the framework supports forming paths of any arbitrary length and also to formulate the constraints for path formations. The constraints we impose for path formation are termed as path types. We define various linguistically motivated path-types as Inductive Logic Programming (ILP) formulations. The path types are defined in Table 1. We form all possible paths in the graph G which satisfy the constraints defined in various path-types. In our formulation of the path types, a single edge path-type is defined as shown in expression 2.

$$Attribute^{constraint}_{node\ id} \xrightarrow{P_{co}} Attribute^{constraint}_{node\ id} \tag{2}$$

$$POS^{Noun}_{i} \xrightarrow{P(j|i)} Lemma^{Verb}_{j} \tag{3}$$

$$Constraint = \{\mathcal{P}(Noun), \mathcal{P}(Verb), \mathcal{P}(Compound), \mathcal{P}(Indeclinable), *\} \tag{4}$$

We define a node-type as $Attribute^{constraint}_{node\ id}$. Here $Attribute_{node\ id}$ denotes the attribute value of the node in G with the id of the node given as the subscript. The superscript is a constraint that specifies the requirements a node in G must satisfy to be in the path of the specified type. Expression 3 is a path-type of length one. Here, the source node in the expression is POS_i, i.e., it expects the POS tag value of node i. The source node in the path must be a noun and the target node must be a verb. In the sentence in Figure 1, the only eligible nodes to be the source node for this path type are nodes numbered 3,13,9 and 18. There are only two nodes which can be the target node which are 10 and 14. Hence, there are eight possible paths of the path-type given in expression 3. Now, consider one of the eight possible paths $nom.sg.f._{13}^{Noun} \xrightarrow{P_{co}(aca|nom.sg.f)} aca_{14}^{Verb}$. We obtain the edge weight as $P_{co}(aca|nom.sg.f)$ from W_2, where 'aca' and '$nom.sg.f$' are two nodes in G_2

Please note that the constraint 'Noun' is defined as the set of all the possible POS tags that a noun word-form can assume. Each POS tag in the Noun set conveys the case, gender and plurality of a word. We similarly define disjoint sets of POS tags for verbs, compounds and indeclinables. The set 'Constraint' is defined in the expression 4, where $\mathcal{P}$ denotes a power set. By defining 'Constraint' as a power set, we can group different POS tags as a single constraint to be used. For example, in $Lemma^{verb}_{i} \longrightarrow Lemma^{Noun-\{nom.sg.m,inst.sg.m.\}}_{j}$, the set $\{nom.sg.m, i.sg.m.\}$ is an element of $\mathcal{P}$, where 'nom' and 'i' signify nominative and instrumental cases respectively. The edge here starts with a verb node and looks for any noun node other than 'nom.sg.m.' and 'i.sg.m.' cases. By design, we do not allow POS tags of noun, verbs or compounds to be combined, as $\mathcal{P}$ does not contain such a combination as its element. We specify '$*$' as a wild-card constraint which allows any POS tag.

Sl. No.	Linguistic Proprety	Path types
1	General Relations	$Lemma_i^* \longrightarrow Lemma_j^*$
2		$POS_i^* \longrightarrow POS_j^*$
3	Compounds	$p(Lemma_i^{compound} \vert Lemma_j^{compound})$
4	Expectancy	$POS_i^{noun} \longrightarrow POS_j^{verb} \longrightarrow Lemma_k^{noun}$
5		$Lemma_i^{noun} \longrightarrow Lemma_j^{verb} \longrightarrow Lemma_k^{noun}$
6	Proximity Nouns	$Word_i^{noun} \longrightarrow Lemma_j^{noun}$, where,$POS_i = POS_j$
7		$Lemma_i^{noun} \longrightarrow Lemma_j^{noun}$, where,$POS_i \neq POS_j$
8	Proximity Verbs	$Lemma_i^{verb-\{absolutive\}} \longrightarrow Lemma_j^{absolutive}$
9		$Lemma_i^{verb-\{gerund\}} \longrightarrow Lemma_j^{gerund}$

Table 1: Path Types for path selection

Path-type starting from node i to node s is defined recursively as follows:

$$PathType_{POS_i}^{Lemma_s} : POS_i^{Noun} \xrightarrow{P(j_1|i)} Lemma_{j_1}^{Verb} \xrightarrow{P(j_2|j_1)} Lemma_{j_2}^{Verb} .... \xrightarrow{P(s|j_k)} Lemma_s^{Verb} \tag{5}$$

$$P(PathType_{POS_i}^{Lemma_s}) = P(j_1|i).P(s|j_k) \prod_{l=2...k} P(j_l|j_{l-1}) \tag{6}$$

In expressions 5 and 6, $P(j|i)$ denotes $P_{co}(Attribute_j|Attribute_i)$. The value of the path from node i to node s is defined as the product of all the weights (from W_2) of the edges in the path. The value so obtained can be thought as a random walk score, where a random walk traverses over graph G_2 starting at node $Attribute_i$ and terminating at $Attribute_s$ with all other nodes in the path as intermediate nodes.

Table 1 defines various path types that we use in our system. Though only a sample of path types is shown, it is implied that path types of other attributes with a similar structure are also formed. In Table 1, we also mention the linguistic properties that motivated us to formulate the path types.

General Relations: The general relations use the '$*$' constraint implying any node can form path of this type. Here we restrict ourselves to the path types which have same attribute types at both the ends of the path (edge). We also use Kneser-Ney smoothing (Kneser and Ney, 1995) for word-form to word-form co-occurrence and lemma to lemma co-occurrence values, though we do not do the same for POS to POS co-occurrence. Smoothing is not provided for POS to POS as we find that all the possible co-occurrences are already captured in the language model.

Compounds: We find bigram probabilities with various compound components since the compounds strictly follow a sequential order in their formation.

Expectancy of a verb: In Sanskrit, there always exists a modifier-modified relation between the words and the verb in the sentence, known as *kāraka* roles or semantic roles. Expectancy plays a vital role in establishing these modifier-modified relations in a sentence. Every verb expects different semantic roles in its sentence usages, which are marked with different syntactic markers in Sanskrit. The path types 4 and 5 try to capture this notion. For example, consider the sentence *rāmaḥ brāhmaṇāya gāṃ dadāti* (Ram gives a cow to the Brahmin). Here the noun words *rāmaḥ* and *brāhmaṇāya* are in different POS tags serving the roles of subject and beneficiary. Though we do not need to know the exact roles, but with the path *rāma⟶dadāti⟶brāhmaṇāya*, we attempt to capture the probability of both the words to co-occur with the verb (both the noun words need not co-occur in the same sentence in the corpus. Refer expression 6), while both being in different POS tags. The path can be an approximation for expectancy.

Proximity - Kulkarni et al. (2015) defined Proximity in Sanskrit as 'the representation of word meanings without any intervention'. But in Sanskrit poetry, this may not be strictly followed as the poet needs to maintain the meter of the verses. Kulkarni et al. (2015) conclude that there is a violation of proximity in case of *viśeṣaṇa-viśeṣya*, i.e., the modifier-modified relation between two nouns, both in case of prose as well as poetry In such situations, morphological markers are one of the ways to identify related words. Paths 6 - 9 attempt to capture this notion. In path 6, we find the co-occurrence probabilities of

two nodes when both appear in the same POS. Path 6 tries to capture the relation of *viśeṣaṇa-viśeṣya* between two nouns. Path 7 exactly finds the inverse where we find the co-occurrence probabilities of two nodes when they are not in the same POS. Path 8 is different from Expectancy path-types as there is no verb in between the nodes.

3.4 Query Expansion with PCRW

In graph G, we form paths of all possible types starting from query node and terminating at any candidate node. No two nodes in a path should be conflicting with each other. For Path types 1, 2 (General relations) and 6 in Table 1, we perform random walks with restarts over graph G to capture the structural properties of the graph. All the three paths are of length 1, i.e. they are edges. Here we relax the criteria for path formation and we form edges with all the possible node pairs in G other than the conflicting nodes. The edge weights are obtained again from W_2. With other path-types, we do not perform random walks over G, but as mentioned the path scores can be seen as random walk traversal over the graph G_2. This effectively helps us to leverage the structural properties of the content graph structure G and the graph G_2, which ideally represents the distributional properties in the language (corpus). We then do a weighted sum of scores from all the paths and the winner node is selected from the combined scores. We eliminate the conflicting nodes with winner nodes and then use the extended context to select the subsequent winner. We choose the initial query node by identifying the longest candidate from the set of candidates. The heuristic is inspired by the maximum matching approach used by Chen and Liu (1992). In case of a tie, we select the candidate with the minimum number of conflicts.

3.5 Supervised Parameter Estimation for Path-Types

Every path type can be considered as a feature and the random walk score at each instance for a pair of (query, source) node is a feature-value. We need to estimate the relative importance of each path type. Our input is a pair of words, the source word and target words. We generate all possible positive instances and down-sample the negative training instances from a training set of 5000 sentences. The label to each instance is a +1 or 0 depending on whether or not the pair of words co-occur in a sentence in the corpus. We use logistic regression with L-BFGS (Andrew and Gao, 2007) optimisation procedure to handle over-fitting. We follow the same optimisation procedure as followed in Lao and Cohen (2010). The authors argue that this approach is superior to the alternative one-weight-per-edge-label approach.

4 Experiments

4.1 Comparison with the Existing Approaches

We compare our system's performance with the existing approaches for *sandhi* splitting by presenting the results of our system on a data-set of 2148 strings, henceforth to be referred to as 'Test 2148', which was used by Natarajan and Charniak (2011) in their work. Table 2 presents the results from 4 different systems. OT2 and OT3 are the best performing variants from Mittal (2010) based on recall and precision respectively. NC4 is the best performing version of the algorithm proposed by Natarajan and Charniak (2011). It is a supervised Bayesian word segmentation approach which employs Gibbs sampling to sample from the posterior distribution of a training set of 25000 split strings. We tested our system on the test data with our pre-trained model and we do not use the training data used in Natarajan and Charniak (2011). Precision is the proportion of correct predictions amongst all the predictions made by the systems. Recall is the proportion of correct predictions which matched with the ground truth to the total number of segments in the ground truth.

Since the dataset does not provide any compound component information, we join the compound components from the prediction by applying the *sandhi* rules in order to obtain the compound before the evaluation. Our approach provides an overall improvement of 28.81% in F-score from the previously best performing system (NC4). A total of 1784 of 2148 (83.05%) were segmented with an F-score of one.

	Test 2148		
System	P	R	F
S	92.38	88.91	90.61
NC4	76.21	64.84	70.07
OT2	63.96	68.74	66.26
OT3	70.52	66.61	68.51

Table 2: Performance evaluation of our proposed system, S with the state of the art, NC4 (Natarajan and Charniak, 2011), OT2 and OT3 (Mittal, 2010).

	DCS 90K			Held-out Dataset		
System	P	R	F	P	R	F
B1	37.02	50.81	42.83	36.89	50.74	42.72
B2	42.25	58.62	49.115	42.04	58.45	48.91
B3	65.13	76.78	70.48	65.07	76.70	70.41
S	74.11	84.92	79.15	73.28	82.73	77.72

Table 3: Performance evaluation of our proposed system, S with the competing baselines B1, B2 and B3 over 100,000 sentences from DCS

4.2 Dataset

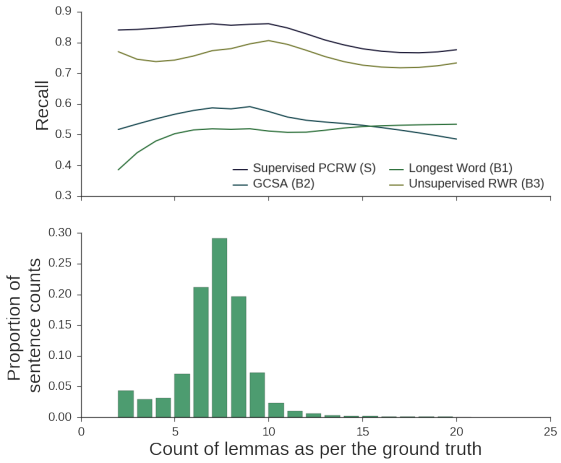
We use the Digital Corpus of Sanskrit (DCS), to build the language models and train our model. The corpus is a digitised collection of ancient works written in both prose and poetry styles with more than 430,000 segmented sentences with 66,000 unique lemmas. The corpus is a rich resource for the task as it contains over 3.2 million segmented tokens which are tagged with lemma and morphological information through expert supervision. We find only about 4067 Out Of Vocabulary (OOV) lemmas in the candidate space for which there was no co-occurrence evidence.

4.3 Baselines

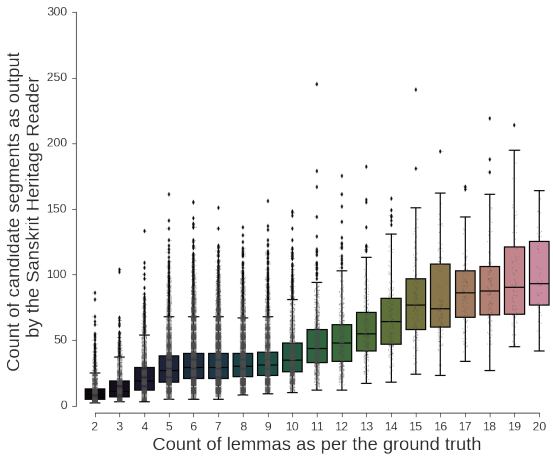
In Section 4.1 we showed the effectiveness of our model over the existing approaches. The systems described in Section 4.1, however, do not handle the context of an entire sentence. Additionally, the systems do not consider the morphological information in their training phases, and hence it will be unfair to use those systems for further analysis. We propose the following methods as our baselines. In all the systems we use the morphological analyser output as the input to predict the correct segmentation.
Longest Word selection (B1) - Inspired by the maximum matching approach from Chen and Liu (1992), we iteratively select the longest word available from the given set of possible segmentations. At each step of the iteration, we eliminate the candidates conflicting with the current winner. This method does not use any morphological information as such.
Greedy candidate selection approach (B2) - Here we consider the morphological analyser output to be a tree, and we perform a greedy selection that maximises the overall likelihood of the selection. In this approach, we combine the co-occurrence probabilities mentioned in paths 1,2 and 6 in Table 1.
Unsupervised RWR - General Relations (B3) - In this approach, we form the graph G for the sentence, similar to as mentioned in Section 3. However, we only use path-types 1,2 and 6 of Table 1. We perform Random Walks with Restarts (RWR) over the graph G and then average the scores from different random walk runs to obtain a winner node.
Supervised PCRW (S) - This is our proposed system, as defined in Section 3.

4.4 Results

We consider 100,000 sentences of varying length (not used for training in Section 3.5) from the DCS corpus. From the 100,000 sentences, 90,000 of the sentences, henceforth to be referred to as "DCS 90K", were used for calculating the co-occurrence values and we keep the remaining 10,000 sentences as held-out data which was not used at any point in our framework. Figure 3b shows the box plot for the number of sentences based on the frequency distribution of lemmas in ground truth against the count of possible candidates as given by the Sanskrit Heritage Reader for all the 100,000 files. From the plot, it is evident that the count of candidates increases manifold with the increase in lemmas. We eliminate all the sentences with exactly one lemma from the dataset which amounts to less than 1% of the total dataset. Table 3 compares the performance of each of the system in terms of precision, recall and F-Score. Our final system S performs the best with an increase of 13.79% and 10.60% in precision and recall respectively from our strong baseline B3 for the DCS 90K dataset. For the held-out dataset, the results remain more or less consistent with those obtained over DCS 90K for all the systems. Our



(a) Recall Vs. GT Frequency distribution



(b) Candidate Vs. GT Frequency distribution

Figure 3: Analysis of systems based on frequency distribution of ground truth (GT) lemmas

system S has an F-Score of 76.58% which is slightly less than the F-score attained on the original dataset, which was 79.15%. Our system could predict all the correct segmentations for as many as 38.64% of the sentences against the 19.57% fully correct predictions of B3.

Variation in Recall based on length of lemmas - The line graphs in the Figure 3a illustrate the recall of each system over the frequency distribution on the 'DCS 90K' based on the number of lemmas per sentence in the ground truth. The x-axis represents the count of lemmas in a sentence, and the y-axis represents average recall. The bar chart represents the proportion of sentences with respect to the count of lemmas in ground truth. The average length of sentences in our dataset is 6.87. It can be observed that our system works better for the sentences of all the lengths.

5 Discussion

A close inspection of the Tables 2 and 3, reveals that for all the systems, precision is higher than recall for the first dataset, and vice-versa in the DCS. On our manual inspection of the dataset, it is found that the DCS being manually tagged, relies on the context to decide whether to decompose a compound into its components. For example the word '*daśaratha*' is a compound word, so is *kṛṣṇārjunanakulasahadevāḥ*. In DCS, '*daśaratha*' being an exo-centric compound, it will not be decomposed into its components. But '*kṛṣṇārjunanakulasahadevāḥ*' is a copulative compound containing names of four different people. DCS decomposes the compound into its components. But, our morphological analyzer decomposes all the compounds into its components as it only considers the syntactic conditions. Unlike the case with first dataset, DCS does not contain segmented word-forms but only segmented lemmas. Hence joining of components is sometimes not possible as grammar cases for the nouns is not available in the system to perform *sandhi*. Due to this issue we find that multiple components which are predicted are treated as separate lemmas. This results in lower precision for the system, especially when 75% of the vocabulary in DCS consists of compounds.

Another intriguing challenge is with the case of compounds where it can be split with different interpretations such that, two possible segmentations result into being the exact negation of each other. Even from the semantic context, it will be difficult to consider whether the negation is required or not. There are a considerable number of sentences in which such issues occur. For example, the string *kurvannāpnoti kilbiṣam* may be decomposed in two different ways '*kurvan āpnoti kilbiṣam*' (While doing, you will accumulate sin) and '*kurvan na āpnoti kilbiṣam*' (While doing, you will not accumulate any sin) Both of them have completely opposite meanings.

6 Related Work

During the last couple of decades, computational analysis of Sanskrit and its grammar has gained considerable attention from the computational linguistics community. Hyman (2008) observes that the Pāṇinian *sūtras* for external *sandhi* can be modeled using a finite state grammar. Huet (2009) developed a tool for segmentation in Sanskrit by building an efficient Finite State Automata (FSA). With efforts from Huet, an automated analyser for exhaustive syntactically valid analysis of a Sanskrit sentence, called as the 'Sanskrit Heritage Reader' is available (Goyal et al., 2012; Goyal and Huet, 2013). However, the system provides all the possible syntactically valid segmentation and it requires human assistance to choose the relevant segmentations so as to form the semantically correct sentence. We use the 'Sanskrit Heritage Reader' in our pipeline to obtain the set of all possible segmentations.

Mittal (2010) has proposed an approach for automated Sanskrit segmentations by relying on the maximum a posteriori estimate from all possible *sandhi* splits for a given string. Natarajan and Charniak (2011) has proposed 'S3 - Statistical Sandhi Splitter', a Bayesian word segmentation approach which can handle *sandhi* formations. Hellwig (2015) proposed a neural network based approach that jointly solves the problem of compound splitting and sandhi resolution. Mochihashi et al. (2009), Johnson et al. (2006) developed non-parametric Bayesian approaches which have been applied on word segmentation tasks. The work uses a Dirichlet process model inspired from the model of Goldwater et al. (2006). Kuncham et al. (2015) have developed a language independent sandhi splitter for agglutinative languages using a strucutred prediction approach.

Word Segmentation challenges for in languages like Arabic, Japanese, Korean and Chinese are extensively studied. Though, in theses languages, identifying the proper word boundary is a challenge, none of these have to deal with the 'Sandhi' as such. In Chinese word segmentation, Xue (2003) presented a character tagging approach. Wang et al. (2014) proposed a method based on dual decomposition (Rush et al., 2010) to combine word-based and character based approaches in an efficient framework. Yao and Huang (2016) proposed a bi-directional RNN with long short-term memory (LSTM) units which makes use of character embeddings. In our approach, we use the PCRW framework proposed by Lao and Cohen (2010). Gao et al. (2013) tackled the problem of query expansion using PCRW for web-log queries. PCRW has been widely used in heterogeneous information networks. The framework has been effectively put to use in Never Ending Language Learning (NELL) (Mitchell et al., 2015; Lao et al., 2011).

7 Conclusion

In this paper we presented an approach to Sanskrit word segmentation using supervised PCRW. We treated the problem as a query expansion problem. In our approach, the input sentence is treated as a graph. The candidate segments form the nodes and there exists an edge between every pair of nodes except the conflicting ones. In Sanskrit, since there is no guarantee of proximity to be maintained between words, we presume that treating the input as a sequence as followed in models like linear-chain Conditional Random Fields (CRF) and Hidden Markov Models might be a serious limitation for the task. Also, with the rich feature space that we employ, inference in CRF Models might be a bottleneck for the model's performance (Doppa et al., 2014). We find that the inclusion of morphological information by means of linguistically motivated ILP path-types greatly increases the performance of the system as much as by 12.30% in F-Score. Our system also outperforms the existing best approach by 28.82% in F-Score. We also showed the effectiveness of our system in a dataset with a collection of both prose and poetry. Our approach is scalable and can be applied to larger datasets as well.

Acknowledgements

The authors would like to thank the anonymous reviewers for their valuable comments and suggestions to improve the quality of the paper. The authors are grateful to Dr. Oliver Hellwig for providing the DCS Corpus and Dr. Gérard Huet for providing the Sanskrit Heritage Engine, to be installed at local systems, and helping with other queries related to Sanskrit Heritage Reader. They are also grateful to Mr. Unnikrishnan T A for his suggestions on the implementation of the framework.

Abstract

In this paper, we first build a manually annotated named entity corpus of Mongolian. Then, we propose three morphological processing methods and study comprehensive features, including syllable features, lexical features, context features, morphological features and semantic features in Mongolian named entity recognition. Moreover, we also evaluate the influence of word cluster features on the system and combine all features together eventually. The experimental result shows that segmenting each suffix into an individual token achieves better results than deleting suffixes or using the suffixes as feature. The system based on segmenting suffixes with all proposed features yields benchmark result of F-measure=84.65 on this corpus.

1 Introduction

Named Entity Recognition (NER) is a natural language processing (NLP) task that consists of finding names in an open domain text and classifying them among several predefined categories such as person, organization and location. It is an important tool in almost all NLP application areas, such as Question Answering, Machine Translation (Chen et al., 2013), Social Media Analysis, Semantic Search or Automatic Summarization.

Since the MUC (Sundheim, 1995) and CoNLL (Sang, 2002) conferences, NER has drawn more and more attention in NLP community. Many NER systems have been developed for English and other language (Ratinov and Roth, 2009; Benajiba et al., 2010; Kravalová and Žabokrtskỳ, 2009). Machine learning based approach have been the predominant in these systems to achieve state-of-the-art results (Radford et al., 2015). As one of them, Conditional Random Fields (CRF) (Lafferty et al., 2001) was proved to an efficient classifier for NER.

Recently, there are more and more concern about how to incorporate more latent sematic features into the NER system (Konkol et al., 2015). Therefore, word cluster IDs function as a non local feature to improve the performance of NER system (Turian et al., 2010; Zirikly and Diab, 2015).

Mongolian is a widely spread language in the world. It is called classical Mongolian in China and called Cyrillic Mongolian in Mongolia and Russia. The classical Mongolian uses Uighur-script, while Cyrillic Mongolian uses Cyrillic-script. In this paper, we address the problem of NER for classical Mongolian.

Compared with other languages, the research on Mongolian NER is still at its initial stage and many issues in Mongolian NER remain unsolved. As far as we know, there has been very little work in the area of NER in Mongolian. Tong (2013) only investigated Mongolian person name recognition. There is still no work publicly reported on recognition of Mongolian location and organization name. Moreover, there are no public available resources and tools for Mongolian NER.

However, proper identification and classification of named entities are very crucial in Mongolian information processing. Therefore, we propose a framework to develop resources and several methods for

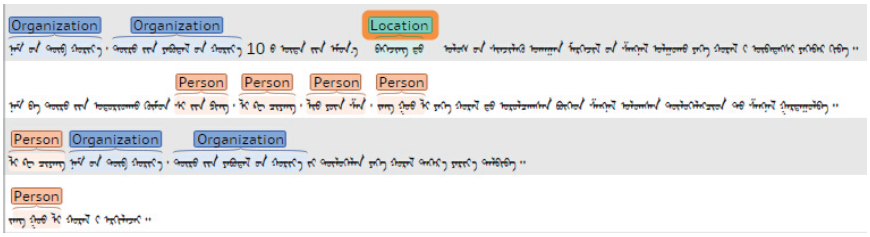

Figure 1: The annotation platform for Mongolian NER.

Mongolian named entity recognition. This paper introduces the work on Mongolian NER that is still in progress.

As one of agglutinative languages, Mongolian has complex morphological structures. We explore different morphological processing methods to alleviate data spareness. Different from the work (Şeker and şen Eryiğit, 2012), we separates Mongolian suffixes from the words and even delete the suffixes. We also propose rich features by exploiting Mongolian orthographic feature, morphological feature, syntactic feature and semantic feature.

The remainder of this paper is organized as follows: Section 2 introduces the construction of Mongolian NER resources; Section 3 presents three morphological processing methods; Section 4 introduces the language independent and language specific features we used; Section 5 describes the results of experiments; Section 6 concludes the paper and summaries some future work.

2 Construction of Mongolian NER resources

2.1 Characteristics of Mongolian

Mongolian writes from top to bottom, and the same letter has different presentation forms decided by position in the word. The NER task of Mongolian was difficult due to the following reasons:

-*Mongolian has large scale vocabulary*: Mongolian has complex morphological structures that each root can be followed by several suffixes to formulate new words. So the larger vocabulary decreased the performance of Mongolian NER system.

-*Absence of capital letters in the orthography*: In English and other Latin language, the proper names always appear with capitalized letter, but there is no concept of capitalization in Mongolian.

-*Multi-category word is very common to named entities*: many common nouns, adjectives and verbs can act as person names or location names, such as an adjective word "" (means "clever") is a very common person name in Mongolian.

-*Subject-Object-Verb word order*: boundaries between named entities are easy to confuse when the subject and object are both proper names.

2.2 Corpus

Nowadays, there is no public annotated corpus about Mongolian named entities. In this paper, we firstly created a new corpus gathered from several Mongolian news web site. We extract mainly content for every web page by analysing the character of each web page html tags. The content of this corpus includes political news, economic news, cultural news and daily news.

This corpus contains 33209 sentences, 59562 named entities and 119M tokens. It annotated manually with person, location and organization by a Mongolian native speaker under the open source platform "Brat" (Stenetorp et al., 2012). The interface of this platform shows in Figure 1. The annotation task cost about three months. At beginning, we discuss almost every sentence to guarantee the quality of annotation. It is time consuming but worth to be done. After twenty days then the annotation become more quick and more unambiguous.

This corpus was converted into BIO2 (Kudo and Matsumoto, 2001) label format. A token is labeled as "B-label" if the token is the beginning of a named entity, and labeled as "I-label" if it is inside a named entity but not the first token within the named entity, others will "O". So there are seven types, that is

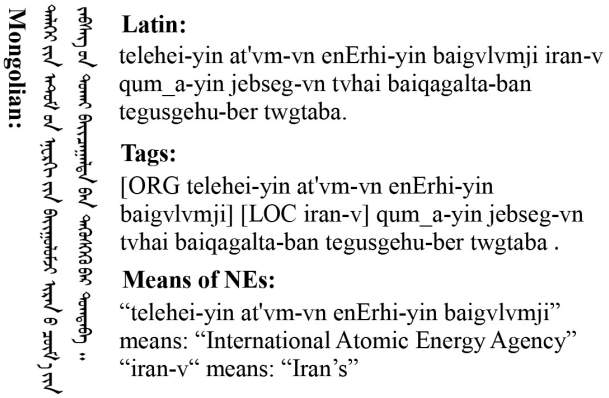

Figure 2: Example of Mongolian NNBS suffixes and named entity tags

"B-PER", "I-PER", "B-LOC", "I-LOC", "B-ORG", "I-ORG" and "O", will be classified by learning algorithm.

The average length of named entities is 2.87 words in our corpus. The person, location and organization entities account for 20.74%, 47.62% and 31.64%, respectively. There are 55% organization entities length are above three words. Mongolian person name always express in one word. However, when transliterating Chinese person into Mongolian, the person name length unchanged. So about 39% person names are three words and 33% person names are only one word.

3 Approach

3.1 Model

CRF is a probabilistic framework that suitable for labeling input sequence data (Lafferty et al., 2001). For an input sequence $X = x_1, x_2...x_n$, CRF model aims to find the best named entity label sequence $Y = y_1, y_2...y_n$ that maximizes the conditional probability $p(y|x)$ among all possible tag sequences. The $p(y|x)$ can be expressed as:

$$p(y|x) = Z(x)^{-1} exp(\sum_t \sum_k \lambda_k f_k(y_{t-1}, y_t, x) \quad (1)$$

where λ_i represents the weight assigned to different features and $Z(x)$ is the normalizing function, it can be defined as:

$$Z(x) = \sum_{y \epsilon Y} exp(\sum_t \sum_k \lambda_k f_k(y_{t-1}, y_t, x) \quad (2)$$

$f_k(y_{t-1}, y_t, x)$ is the binary feature function, such as

$$f_k(y_{t-1}, y_t, x) = 1(y_{t-1} = y', y_t = y, x_t = x) \quad (3)$$

3.2 Morphological processing

For the morphological structure of Mongolian, a Mongolian words can be decomposed into roots, derivational suffixes and inflectional suffixes. As for nouns, the inflectional suffixes contain case suffixes, reflexive suffixes and plural suffixes. All the case suffixes, reflexive suffixes and partly plural suffixes connected to stem through a Narrow Non-Break Space (NNBS) (U+202F, Latin:"-"), so we called them NNBS suffixes. For example, in Figure 2, there are 8 NNBS suffixes in one sentence, and the suffixes appeared inside or beside the named entities.

The NNBS suffixes are used very flexible that each stem can add several NNBS suffixes to change the word form. What's more, the NNBS suffixes in Mongolian can be located unambiguously, while other suffixes segmented may lead to some letters insertion, lost and substitution. Therefore, we proposed three methods to process NNBS suffixes.

RE:Remove all NNBS suffixes in text. After this processing, the sentence in Figure 2 will be "*telehei at'vm enErhi baigvlvmji iran qum_a jebseg tvhai baiqagalta tegusgehu twgtab*."

FE:Take NNBS suffixes as a new feature and replace word with stem. After this processing, sentence length remain unchanged but the feature dimension will add one.

SE:Segment NNBS suffixes as a new token. After then, the sentence will longer, for example, the sentence in Figure 2 will be turned into "*telehei -yin at'vm -vn enErhi -yin baigvlvmji iran -v qum_a -yin jebseg -vn tvhai baiqagalta -ban tegusgehu -ber twgtaba*".

If the suffixes are the last tokens in the entity, we will remove the suffixes from the entity. Because this kind of suffixes only add the syntax function for previous stem. For example, the tag of "iran-v" will change to "*[LOC iran] -v*".

4 Features

Supervised NER is sensitive to the selection of features, we consider the following feature sets for Mongolian. In the following experiment, we fixed all features window at [-1,1], that means take the previous feature, current feature and next feature into consideration, except the contextual feature.

Contextual Feature (CXT): this feature was automatically generated, and mean to combine the current and previous output tokens.

Orthographic Feature (ORT): this feature defined the lexical orthographic nature of the tokens in the text, which means the n-gram of tokens. If the suffixes were split, the n-gram tokens will include suffixes directly.

Syllable Feature (SYN): this feature contained syllable count, first and end syllable of the current token.

Syllable count: we concluded 28 rules about counting Mongolian syllables for the first time, according to Mongolian grammar. In general, too many syllables might not be names.

First and end syllable: some first syllables or end syllables occur frequently in many Mongolian person names.

Look up feature: defined as binary features and matched exactly with the lookup table.

Gazetteers (GAZ): this collected gazetteer consist of 8735 location names and 2731 person names. We extracted location names from Mongolian Chinese dictionary mainly contained Inner Mongolian location names manually. The person names list found in few Mongolian blogging web sites, and mainly contained Mongolian names.

Transliteration table (TRS): this table contained 564 Mongolian borrowed words from Chinese. For example, a very common surname in Chinese "王" ("wang").

Person title and job title list(TIT): this list contained 373 person title entries and 582 job title entries.

Morphological Feature: this feature explored rich morphological structure of Mongolian.

Part-of-speech (POS): we employed a rule and dictionary based POS tagger to produce this features. This top level POS marking set include 15 classes which according with (China Standard, 2011). When SE method applied, the POS feature of NNBS suffixes will be denoted by "F".

NNBS suffixes: used as feature only when the FE method applied. If a word contains NNBS suffixes, the suffixes themselves will be referred as features.

Word Clusters IDs: this feature gained from massive unlabeled corpus after the same SE method preprocessed. The corpus used also crawled from web sites in a more wider range. It contained 337M sentences and its token size and vocabulary showed in Table 1. From Table 1, we found the vocabulary decrease 27% while the token number growth 22%.

Word2vec clusters IDs (W2V): this feature achieved by performing K-means clustering on word2vec vectors in (Mikolov et al., 2013) and directly used the cluster IDs as features. The vectors' dimension in our experiments are 200, the minimum occurrences number of token is 3 and the context window fixed at 8. We retrained word vectors with negative sampling used skip-gram model. A new cluster number assigned to the test token without trained cluster ID.

LDA word classes (LDA): we followed the work in (Chrupala, 2011) to induce LDA to produce different word clusters with the minimum occurrences number of token is 3. If the test tokens are out of

Table 1: Vocabulary decrease after processing by SE method in cluster training corpus (mincount=3)

	Vocabulary	**Tokens number**
Word model	395511	72051575

vocabulary of trained LDA word, we also assigned a new LDA classes number for them.

5 Experiment

In our experiments, we analyzed the impact of various morphological processing and various categories features under an CRF framework with the same parameters. All the experiments carried on 5-fold cross-validation, the proportion of train and test set is 80% , 20%. We evaluated the results by the CoNLL metrics of precision, recall and F-measure.

Precision, means the percentage of corrected named entities (NEs) found by the classifier. It can be expressed as:

$$precsion = \frac{Num(correct\ NEs\ predicted)}{Num(NEs\ predicted)} \tag{4}$$

Recall is the percentage of NEs existing in the corpus and which were found by the system. It can be expressed as:

$$recall = \frac{Num(correct\ NEs\ predicted)}{Num(all\ NEs)} \tag{5}$$

F_1 is the harmonic mean of precision and recall. It can be expressed as:

$$F_1 = \frac{2 * precision * recall}{precision + recall} \tag{6}$$

5.1 Impact of morphological processing

Firstly, we incrementally added features to the three methods mentioned above and each feature window fixed at [-1,1]. The results show in Table 2, the "Baseline" means without any morphological processing. From Table 2 we found that all the three methods can improve the overall performance. When incorporated all features, the SE method achieved the best and improved F-measure by 1.26. Because segmenting by NNBS can decrease the percentage of unknown word in sentences and do help to detect named entities. The features played more effect roles when the suffixes took apart.

Each feature improves the performance based on the former one. The F-measure improvement caused by POS feature is obvious. The contribution of GAZ feature lies in improving both the precision and recall of person names and location names. The TRS feature improves the F-measure because the corpus contains amount of Chinese person and location names. The SYN feature slightly indicates some cues for named entities, the first and end syllable act on prefixes or suffixes. The TIT feature benefits the person names recognition to improve overall F-measure.

Table 3: Results (in F-measure) of different semantic space of LDA word classes and word2vec clusters

Clusters numbers	LDA	Word2vec
50	83.16	83.27
100	83.20	**83.49**
200	**83.26**	83.26
500	83.24	–

Table 4: Results of different LDA word classes and word2vec clusters combination

Clusters IDs combination	F1
LDA200+W2V100	**83.53**
LDA500+W2V200	83.29
LDA100+LDA200	83.13
W2V100+W2V200	83.29
All Cluster IDs	83.24
SE+ORT	82.28

5.2 Impact of word cluster features

Secondly, we evaluate the impact of semantic features, that is, only adding LDA word cluster or word2vec cluster features onto the SE method, Table 3 shows the results. The F-measure varies with cluster number and cluster type, the more word classes does not always mean better performance. The best cluster number is 200 for LDA word cluster and 100 for word2vec cluster. Word2vec clusters outperform the LDA word cluster because that it can induce more context to cluster.

We then combined the best and second performance in Table 3 without other features to produce the best word cluster combination. Table 4 shows the results. In Table 4, SE+ORT means only using context feature with SE method, as baseline system. The F-measure reaches 83.53 when coupled with LDA200 and W2V100. This best F-measure even surpassed the performance of POS and ORT feature combination about F_1 is 83.35 under SE method in the same condition. However, the overall performance reduced when added all type clusters features to the feature set.

5.3 Final system

Finally, we integrate all features including traditional features and word cluster features in SE method, Table 5 shows the final system performance.

In Table 5, AFH represents all the handcraft features, including ORT, POS, GAZ, TRS, SYN and TIT. From Table 5, we find that the same word cluster feature works different when combine with traditional features. With only single word cluster, the effect is weak, but when we use the combination of AFH, LDA100 and LDA200, result reach the best. It outperforms the handcraft features 0.36 in F_1. As the results shown, combining more features does not mean higher performance.

6 Conclusion

In this paper, we built a Mongolian named entity recognition corpus and explored three morphological processing methods with different features combination under the CRF framework. This is the first corpus for Mongolian and we carry on experiment on this corpus. The experimental results show that the proposed methods can alleviate the sparseness of data and improve the performance of Mongolian NER system. In addition, the word cluster features represent the latent semantic of word can also benefit the system. Among the above three methods, treating NNBS suffixes as individual token perform best. It can reach F-measure at 84.65 when combined all features including handcraft features and word cluster features. This work can also provide benchmark system to promote the future Mongolian NER research community.

In the future, we will try our method to other agglutinative languages and expand the work on using word cluster feature. We will also try to use deep neural network to perform to Mongolian NER.

Table 5: Final performance combined all features

Appraising UMLS Coverage for Summarizing Medical Evidence

Elaheh ShafieiBavani, Mohammad Ebrahimi, Raymond Wong, Fang Chen
University of New South Wales, Sydney, Australia

Abstract

When making clinical decisions, practitioners need to rely on the most relevant evidence available. However, accessing a vast body of medical evidence and confronting the issue of information overload, can be challenging and time consuming. This paper proposes an effective summarizer for medical evidence by utilizing both UMLS and WordNet. Given a clinical query and a set of relevant abstracts, we aim to generate a fluent, well-organized, and compact summary that answers the query. Analysis via ROUGE metrics shows that using WordNet as a general-purpose lexicon helps to capture the concepts not covered by the UMLS Metathesaurus, and hence significantly increases the summarization performance. The effectiveness of our proposed approach is demonstrated by conducting a set of experiments over a specialized evidence-based medicine (EBM) corpus - which has been gathered and annotated for the purpose of biomedical text summarization.

1 Introduction

Over the past two decades, clinical guidelines urged practitioners to move towards evidence-based medicine, which is formally defined as *conscientious and judicious use of current best evidence in making decisions about the care of individual patients* (Sackett et al., 1996). Evidence-based medical practice heavily relies on research evidence, rather than intuition, unsystematic clinical experience, or pathologic rationale (Group and Others, 1992). However, searching through and evaluating primary medical literature is extremely time consuming (Sarker et al., 2015). Even targeted searches tend to return a large set of relevant documents, and not summaries or answers to the queries. Hence, the explosive growth of content of medical evidence requires development of techniques to present information to physicians and researchers in an effective way. Automatic text summarization has been introduced as a natural language processing technique to address this problem (Reeve et al., 2007).

Even though the problem of information overload and the advantages of summarization are critical in the biomedical domain, the majority of summarizers are designed to be general-purpose. They usually work with a simple representation of the summary comprising of information that can be directly extracted from the document, such as terms, phrases, or sentences (Mihalcea and Tarau, 2004). However, recent studies (e.g. (Fiszman et al., 2004)) have demonstrated the benefits of summarization based on richer representations that make use of domain-specific knowledge sources. These approaches represent the documents using concepts instead of words, and may also be enriched by using semantic associations among concepts (e.g. synonymy, hypernymy, etc.) (Plaza et al., 2011).

While a query is asked in the field of biomedicine, one of the main challenges is to understand the underlying semantic relatedness of the query and document sentences, and consequently extract the most non-redundant, query-relevant parts from the documents. Documents in biomedicine are very different from documents in other fields, and include very different document types (e.g. patient records, web documents, scientific papers, etc.) (Plaza et al., 2011). Therefore, particular characteristics and the type of

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 513–524, Osaka, Japan, December 11-17 2016.

biomedical documents are required to be exploited by the summarization systems. To this end, promising domain specific NLP techniques have been efficiently employed to release a repository of biomedical vocabularies named the Unified Medical Language System (UMLS[1]) (Bodenreider, 2004). UMLS is a very rich source of information in medical and biological domain. Therefore, most existing biomedical summarizers utilize UMLS as a large lexical and semantic medical ontology. However, UMLS does not provide a full coverage of non-medical concepts, terms, and relations included in general-purpose thesauri such as WordNet[2] (Huang et al., 2009). Moreover, utilizing WordNet to complement the UMLS coverage is challenging due to their different structures, natures, terms, and sizes.

This challenge has motivated us to provide a deeper analysis of biomedical texts by keeping an eye on the biomedical peculiarities. Given a clinical query and a set of relevant medical evidence, our aim is to generate a fluent, well-organized, and compact summary that answers the query. The quality of biomedical summaries is also enhanced by appraising the applicability of both general-purpose (WordNet), and domain-specific (UMLS) knowledge sources for concept discrimination. In details, our approach comprises different components: capturing underlying sentence-to-query and sentence-to-sentence semantic similarities using WordNet and UMLS; ranking and filtering sentences considering their similarity scores to the clinical query; clustering sentences by their relevance to each other; generating new summary sentences through a word graph representation by ensuring their importance and syntactic structure.

The rest of the paper is organized as follows. Section 2 summarizes the background. Utilized data and the preprocessing steps are discussed in Section 3. We demonstrate the proposed approach in Section 4. Section 5 reports the evaluation metrics and the performed experiments. Finally, Section 6 concludes the paper.

2 Background

Text summarization is the process of automatically creating a compressed version of a given text. A summary can either be query-focused (biased to a user query), or generic (conveying the document gist). In traditional query-focused summarization systems, lexical similarity measures are used to select content that are similar to the question. Such approaches also have to ensure that redundant information is minimized. Some recent researches have addressed query-focused text summarization from the question answering perspective (Yu and Cao, 2008), and some others have modeled summarization as a sentence classification problem (Cao et al., 2011). A machine learning classifier trained on a small dataset is employed in another study (Demner-Fushman and Lin, 2007) to select the summary sentences. Another summarization system (Cao et al., 2011) utilizes category of an input question to generate paragraph level summaries. They suggest that the generated summary should be customized with respect to the type of the question. More advanced summarization techniques such as LexRank (Erkan and Radev, 2004) incorporate graph-based methods. LexRank assumes a fully connected and undirected graph for the set of documents to be summarized.

Among the researches performed in the text summarization area, many studies (e.g. (Coumou and Meijman, 2006)) have also explored the obstacles associated with evidence-based medicine practice in the absence of pre-existing systematic reviews. When primary care physicians seek answers to clinical problems, the time required to search, evaluate, and synthesize evidence has been known as a critical factor (Sarker et al., 2016). Literature review and analysis may take a long time (e.g. it takes more than 30 minutes on average for a practitioner to find and extract evidence (Hersh et al., 2002)). Numerous IR approaches have already been proposed to address the search-related needs of practitioners (Hanbury, 2012). However, post-retrieval techniques (e.g. (Sarker et al., 2016)) to perform query-oriented summarization are still scarce. The complicated nature of biomedical texts and the limited amount of suitable annotated data for the task of summarization are the main reasons that raise various difficulties in progress (Athenikos and Han, 2010; Sarker et al., 2016).

To overcome the lack of incorporation of domain-specific information, UMLS came to play, and has proved to be a useful knowledge source for summarization in biomedical domain (Reeve et al., 2007).

[1]Developed by the U.S. National Library of Medicine (available at http://www.nlm.nih.gov/research/umls/)

[2]http://wordnet.princeton.edu

However, a decline is found in the performance of the summarizers which only utilize UMLS as their source of knowledge. The reason is that UMLS is less likely to cover all concepts included in the source text (Plaza et al., 2011). To compensate this deficiency, a question-oriented extractive system for biomedical multi-document summarization (i.e. (Shi et al., 2007)), utilized WordNet as a general-purpose lexicon to capture the concepts not covered by UMLS. They constructed a graph containing ontological concepts (general ones from WordNet, and specific ones from UMLS), name entities, and noun phrases. Our work differs in intent, and explores the utility of graph representation of both domain-independent (WordNet) and domain-specific (UMLS) lexicons for incorporating underlying textual semantic similarities as the main basis of an efficient biomedical summarizer. Next, we discuss the utilized data and the preprocessing steps.

3 Data and Preprocessing

To develop, test, and evaluate our approach, we employed the evidence-based medicine (EBM) corpus[3] gathered and annotated by (Mollá et al., 2015), which is the only available corpus for the task of EBM text summarization. This corpus is sourced from the Clinical Inquiries section of the Journal of Family Practice[4], and consists of 456 clinical queries, with 1396 bottom-line multi-document summaries (i.e. evidence-based answers). The total number of associated single-document evidence-based summaries is 3036, which are generated from 2908 unique articles. Table 1 lists the properties of this corpus. The bottom-line answers are used as the reference (gold) summaries. The question and all the abstracts associated with the bottom-line summary are also considered as the source texts.

total #clinical queries	456

Table 1: Information about the EBM Corpus

The specific nature of the biomedical terminology makes it difficult to automatically process biomedical information (Nadkarni, 2000). One of these difficulties is caused by abbreviations (e.g. the use of *OCP* instead of *oral contraceptive pills*). In our approach, if the abstract includes abbreviations, their expansions are used to replace these shortened forms in the abstract body. If the abstract contains abbreviations and acronyms, but without any definition, the software[5] for abbreviation recognition and definition presented in (Hearst, 2003) is used. To remove the stopwords, we utilized the stopword list included in nltk[6] extended with the PubMed stopwords[7]. We also employed OpenNLP[8] to detect and split the sentences, and Stanford POS tagger (Toutanova et al., 2003) for tokenizing and part of speech tagging of each sentence.

4 The Proposed Approach

4.1 Measuring Semantic Similarity using WordNet and UMLS

Automatic summarization approaches rely on similarity comparison of sentences. For general English text, research on measuring relatedness has relied on WordNet, and for clinical and biomedical vocabularies, they are compiled into UMLS. Quantifying semantic relationships between linguistic terms lies at the core of many NLP applications (Pilehvar and Navigli, 2015). However, hard matching between words has long been an obstacle in identifying the relatedness of two sentences (ShafieiBavani et al., 2016b). We tackle this issue by dealing with concepts instead of terms, and with semantic relations

instead of lexical or syntactical ones. In our approach, the main requirement for computing semantic similarities on WordNet and UMLS is Semantic Signature, which is firstly introduced as a multinomial distribution generated from repeated random walks on WordNet (Pilehvar and Navigli, 2015). We utilize this concept to capture the semantic similarities on both WordNet and UMLS. Note that in our work, a query is treated as a long single sentence.

Semantic Signature on WordNet To construct each semantic signature on WordNet, we make use of WordNet 3.0 (Fellbaum, 1998) repository. We also employ an alignment-based sense disambiguation algorithm presented in (Pilehvar and Navigli, 2015) to disambiguate each word. This algorithm leverages the content of the paired sentence in order to disambiguate each element. Afterwards, an iterative method for calculating Personalized PageRank has been used. The key assumption is that repeated random walks beginning at a sense (node) or a set of senses (seed nodes) in the WordNet network can provide a frequency or multinomial distribution over all the senses in WordNet. A higher probability will then be assigned to senses that are frequently visited from the seeds.

Consider an adjacency matrix *M* for the WordNet network, where edges connect senses according to the relations defined in WordNet (e.g. hypernymy and meronymy). The probability distribution for the starting location of the random walker in the network is denoted by $\vec{w}^{(0)}$. Given the set of senses *S* in a sentence, the probability mass of $\vec{w}^{(0)}$ is uniformly distributed across the senses $s_i \in S$, with the mass for all $s_i \notin S$ set to zero. The PageRank vector is then computed using Equation 1.

$$\vec{w}^{(t)} = (1-\alpha)M\vec{w}^{(t-1)} + \alpha\vec{w}^{(0)} \tag{1}$$

where at each iteration, the random walker may jump to any node $s_i \in S$ with probability $\alpha/|S|$. Following the standard convention, the value of α is set to 0.15. The number of iterations is also set to 30, which is sufficient for the distribution to converge. The resulting probability vector $\vec{w}^{(t)}$ is the semantic signature of the sentence, as it has aggregated its senses similarities over the entire graph. The UKB[9] implementation of Personalized PageRank has been used in this step.

Semantic Signature on UMLS Each semantic signature on UMLS is constructed by performing iterative random walks over the graph representation of version 2015AB of the UMLS Metathesaurus. This algorithm has previously been utilized for query expansion (Martinez et al., 2014). Metathesaurus, Semantic Network and SPECIALIST Lexicon are three major components of UMLS. Our approach focuses on the UMLS Metathesaurus, which contains a wide range of information about the relations between terms in the form of database tables. Among them, MRREL table lists different relations between concepts (i.e. *parent*, *can be qualified by*, and *related and possibly synonymous*). We consider the UMLS concepts as nodes (seeds), and the relations listed in MRREL table as directed edges.

Besides, we employ version 2016 of the MetaMap[10] program to map each sentence to concepts from the UMLS Metathesaurus and semantic types from the UMLS Semantic Network. Using the built-in WSD module, MetaMap allows to disambiguate terms, and returns directly the relevant concept. A broad range of concepts from very generic UMLS semantic types, that have already been considered in capturing WordNet-based semantic similarities, are discarded in this step. These semantic types are defined as *quantitative concept, qualitative concept, temporal concept, functional concept, idea or concept, intellectual product, mental process, spatial concept,* and *language* (Plaza et al., 2011). Thus, only concepts of the rest of semantic types are considered for constructing the semantic signature. Table 2 provides an example of mapping a sentence by MetaMap. Same as WordNet-based semantic signature, the UKB implementation of Personalized PageRank is utilized, but on UMLS.

Let *N* be an adjacency matrix for the UMLS graph with all relations in MRREL. The random walker starts in any of the concepts included in the sentence, and randomly follows one of the relations to another concept. With certain probability, the random walker would restart in any of the concepts, and continue its walk. Finally, the number of visits to each concept in the graph would give an indication of how related that concept is to the sentence terms. The result is a probability distribution over UMLS

1000	Warfarin	Pharmacologic Substance	✔

Table 2: MetaMap mapping for the sentence "*There is no evidence of increased risk for major bleeding as a result of falls in hospitalized patients taking warfarin.*"

concepts. The higher the probability for a concept, the more related it is to the given sentence. The probability distribution for the starting location of the random walker in the network is denoted by $\vec{u}^{(0)}$. Having the set of MetaMap concepts *C* in a sentence, the probability mass of $\vec{u}^{(0)}$ is uniformly distributed across the concepts $c_i \in C$, with the mass for all $c_i \notin C$ set to zero. The PageRank vector is then computed using Equation 2.

$$\vec{u}^{(t)} = (1-\beta)N\vec{u}^{(t-1)} + \beta\vec{u}^{(0)} \tag{2}$$

where at each iteration, the random walker may jump to any node $c_i \in C$ with probability $\beta/|C|$. Following the standard convention, the value of β is set to 0.15. The number of iterations is also set to 30, which is sufficient for the distribution to converge. The resulting probability vector $\vec{u}^{(t)}$ is the semantic signature of the sentence on UMLS, as it has aggregated its concepts similarities over the entire graph.

Semantic Similarities at the Sentence Level For comparing pairs of semantic signatures at the sentence level, we use Weighted Overlap (WO) algorithm proposed by (Pilehvar and Navigli, 2015). This algorithm first sorts the two signatures according to their values and then harmonically weights the overlaps between them. Using the knowledge source N (i.e. WordNet or UMLS), WO calculates the semantic similarity (Sim_N) of two sentence signatures S_{N1} and S_{N2} as:

$$Sim_N(S_{N1}, S_{N2}) = \frac{\sum_{h \in H} (r_h(S_{N1}) + r_h(S_{N2}))^{-1}}{\sum_{i=1}^{|H|} (2i)^{-1}} \tag{3}$$

where *H* denotes the intersection of all senses/concepts with non-zero probability (dimension) in both signatures, and $r_h(S_{Nj})$ denotes the rank of the dimension *h* in the sorted signature S_{Nj}, where rank 1 denotes the highest rank. The denominator is also used as a normalization factor that guarantees a maximum value of one. The minimum value is zero and occurs when there is no overlap between the two signatures, i.e. $|H| = 0$.

To estimate the final semantic similarity score between two sentences, we conducted a set of experiments using the WordNet-based semantic similarities (Sim_W), and/or UMLS-based semantic similarities (Sim_U), and obtained the best result while using both scores with different weights according to Equation 4.

$$Sim_{final}(S_1, S_2) = \mu \times Sim_U(S_{U1}, S_{U2}) + (1-\mu) \times Sim_W(S_{W1}, S_{W2}) \tag{4}$$

where $Sim_U(S_{U1}, S_{U2})$ denotes the semantic similarity score between two sentence signatures on UMLS. The semantic similarity score between two sentence signatures on the WordNet is also shown by $Sim_W(S_{W1}, S_{W2})$. The scaling factor μ was optimized on development data in our experiments and set to 0.6 to reach the best result (Section 5).

4.2 Constructing Similarity Graph

To filter out less query relevant information, sentences are modeled as a Similarity Graph - a weighted undirected graph on which each node represents a sentence and the edge weight carries the similarity

of two sentences (ShafieiBavani et al., 2016b). For more clarity, let $S = \{s_1, s_2, ..., s_n\}$, be a set of sentences, and $(S_{ij})_{i,j=1,...,N}$ be the similarity matrix in which each element indicates the similarity $S_{ij} \geq 0$ between two sentences S_i and S_j (pairwise similarity scores are already achieved in Section 4.1). Hence, the input query and the abstract sentences are considered as nodes on the graph, where we consider two kinds of edge for each node: (1) sentence-to-query similarity edge; (2) sentence-to-sentence similarity edge. The achieved similarity weight for each sentence-to-query and sentence-to-sentence relation is assigned to its corresponding edge in our similarity graph. Considering the combination of sentence-to-query and sentence-to-sentence similarities, our model decides which sentences are relevant to the query, and should be kept for the further clustering step. To this end, we employ a combination model (Chali et al., 2011):

$$C(S_i|Q) = \gamma \times \frac{Sim_{final}(S_i, Q)}{\sum_{S_j \in A} Sim_{final}(S_j, Q)} + (1 - \gamma) \times \sum_{S_k \in A} \frac{Sim_{final}(S_i, S_k)}{\sum_{S_j \in A} Sim_{final}(S_j, S_k)} \times C(S_k|Q) \tag{5}$$

where $C(S_i|Q)$ denotes the score of a sentence S_i given a query Q. A contains all sentences in the abstract set. The weighting parameter $0 \leq \gamma \leq 1$ is used to specify the relative contribution of two similarities: the similarity of a sentence to the query and similarity to the other sentences in the abstract set. Previous experiments (Chali et al., 2011) lead us to choose 0.4 as the best value of γ. The denominators in both terms are for normalization. $Sim_{final}(S_i, S_k)$ is the weight of the edge between two sentence nodes S_i and S_k. Likewise, $Sim_{final}(S_i, Q)$ is the weight of the edge connecting the sentence node S_i to the query node Q. Finally, sentences with $C \geq \delta$ with the best empirical value of 0.5 for δ are picked among the set of sentences. This step results in a subgraph comprising a set of the most query-relevant sentences to be clustered in the next step.

4.3 Clustering Relevant Sentences

In this step, we use Chinese Whispers (CW) which is a graph-based clustering algorithm proposed by (Biemann, 2006). CW is a basic - yet effective - parameter-free algorithm to partition the nodes of graphs in a bottom-up fashion. This algorithm is also a special case of Markov-Chain-Clustering, but time-linear in the number of edges. So, the power of CW lies in its capability of handling very large graphs in reasonable time. First, a distinct class is assigned to each node , and a clustering C containing the singleton clusters c_i is created. Then, a series of iterations is performed to merge the clusters. Specifically, at each iteration the algorithm analyzes each node s in random order and assigns it to the majority class among those associated with its neighbors. In other words, it assigns each node s to the class c that maximizes the sum of the weights of the edges s_i, s_j incident on s_j such that c is the class of s_i (Equation 6).

$$class(s_j) = \underset{c}{argmax} \sum_{\substack{\{s_i, s_j\} \in E(G) \\ s.t. class(s_i) = c}} Sim(s_i, s_j) \tag{6}$$

As soon as an iteration produces no change in the clustering, the algorithm stops and outputs the final clustering. The result of CW is a hard partitioning of the given graph into a number of clusters. Although it is possible to obtain a soft partitioning in CW, we prefer hard partitioning to keep the redundancy low.

4.4 Word Graph-based Summarization of EBM

For each obtained cluster, we build a word graph by iteratively adding sentences to it. This graph is an ordered pair $G = (V, E)$ comprising of a set of vertices (nodes) V, together with a set of directed edges E, which shows the adjacency between corresponding nodes. The graph is first constructed by the first sentence and displays words in a sentence as a sequence of connected nodes. The first word is the start node and the last one is the end node. Words are added to the graph in three steps of the following order: (1) non-stopwords for which no candidate exists in the graph; or for which an unambiguous mapping is possible; (2) non-stopwords for which there are either several possible candidates in the graph; or for which they occur more than once in the sentence; (3) stopwords. As mentioned in Section 3, for the last group, we use the stopword list included in nltk extended with the PubMed stopwords.

Where mapping in the graph is ambiguous (i.e. there are two or more nodes in the graph that refer to the same word/POS pair), we follow the instructions stated by (Filippova, 2010): the immediate context (the preceding and following words in the sentence, and the neighbouring nodes in the graph) or the frequency (i.e. the node which has words mapped to it) is used to select the candidate node. A new node is created only if there are no suitable candidates to be mapped to, in the graph. Conducting this step not only removes the redundancy, but also makes use of redundant parts to indicate the salient path (Figure 1 (a)). Edge weights are calculated using the weighting function defined in Equation 7 (Filippova, 2010).

$$W(e_{i,j}) = \frac{(freq(i) + freq(j))/\sum_{s \in S} diff(s,i,j)^{-1}}{freq(i) \times freq(j)} \tag{7}$$

where $freq(i)$ is the number of words mapped to the node i. The function $diff(s,i,j)$ refers to the distance between the offset positions of words i and j in sentence s.

Utilizing Synonymy To reduce the redundancy caused by existing synonym words in the sentences, we use the synsets in WordNet to identify synonym representative candidate if available. For example, consider n different sentences containing words *biliary*, *bilious*, *tumor*, *tumour*, and *neoplasm*. The first two words, and the latter three ones are synonyms of each other. Assume each sentence contains one of these possible combinations (i.e. biliary tumor, biliary neoplasm, biliary tumour, bilious tumor, bilious neoplasm, bilious tumour). Without an appropriate synonym mapping based on a notion of synonymy, several synonym nodes will be added to the word graph as separate nodes. We consider their frequency to pick one of them as the representative of its synonyms from the other sentences. The weight of the obtained node is computed by summing the frequency scores from the other nodes (Figure 1 (b)).

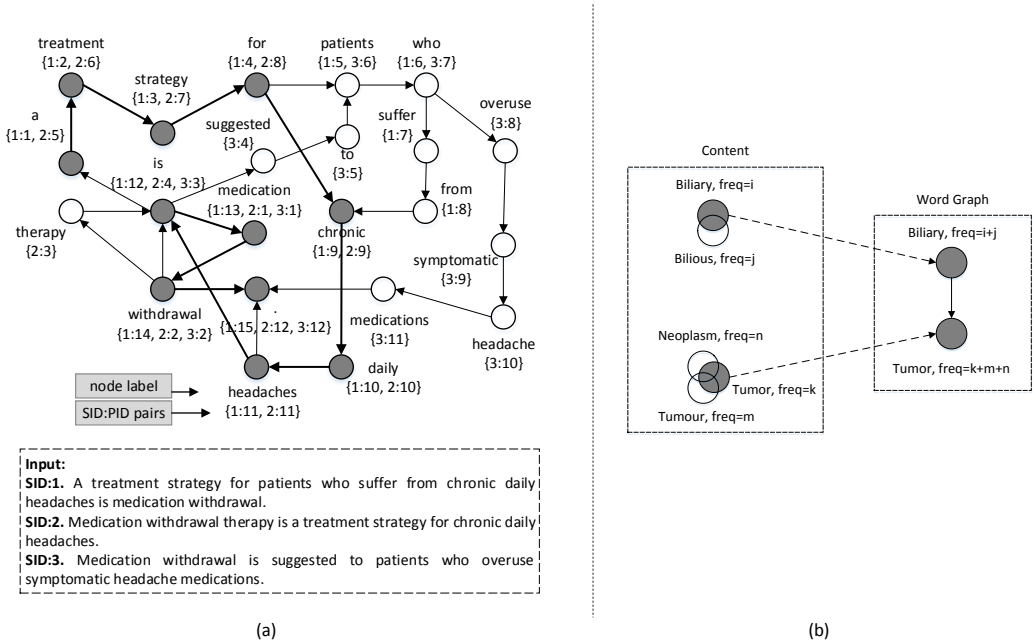

Figure 1: (a) An example of the Constructed Word Graph. Thick edges indicate salient paths. (b) An example of Biomedical Synonym Mapping

Ensuring Information Richness To re-rank the summary candidates based on the information richness, important key-phrases have been exploited using the TextRank algorithm (Mihalcea and Tarau, 2004). Hence, a word recommends other co-occurring words, and the strength of the recommendation is recursively computed based on the importance of the words making the recommendation. The score of a key-phrase *k* is computed by summing the salience of the words it contains, normalized with its $length + 1$ to favor longer n-grams. The paths are then re-ranked based on their key-phrases and the score of a summary candidate c is given by Equation 8.

$$Score_{Key}(c) = \frac{\sum_{i,j \in path(c)} W(e_{i,j})}{length(c) \times \sum_{k \in c} (\frac{\sum_{w \in k} TextRank(W)}{length(k)+1})} \quad (8)$$

The heuristic algorithm discussed in (Boudin and Morin, 2013) is then used to find the k-shortest paths ($k = 50$ throughout our experiments) from start to end node in the graph. Paths shorter than eight words or do not contain a verb are filtered before re-ranking. The remaining paths are re-ranked and the path that has the lightest average edge weight is eventually considered as the richest summary sentence.

Ensuring Syntactic Structure Since our word graph generates new summary sentences, we need to ensure the grammatical structure of these newly constructed sentences. So, we build a part-of-speech based language model (POS-LM) to re-rank the paths in our word graph (ShafieiBavani et al., 2016a). The POS-LM assigns a score to each generated summary in terms of grammatical structure, and helps in identifying the most grammatical sentence among the k-richest sentences. It estimates the probability of string of m POS tags by $p(t_1^m) \propto \prod_{i-1}^{m} p(t_i|t_{i-n+1}^{i-1})$ (Monz, 2011), where *n* is order of the language model, and t_i^j refers to the sub-sequence of tags from position *i* to *j*.

To build a POS-LM, we make use of Stanford POS tagger to annotate a large part (∼100 M-words) of the BioMed Central full-text corpus for text mining research[11]. Then, we remove all words from the pairs of words/POS in the POS annotated corpus. Finally, the SRILM toolkit (Stolcke and others, 2002) is employed to collect n-gram statistics. The candidate sentences also need to be annotated with POS tags, and the score of each summary is estimated by the 7-gram language modeling, based on its sequence of POS tags. To re-rank the obtained paths, POS-LM gives the perplexity score ($Score_{LM}$), which is the geometric average of $1/probability$ of each sentence, normalized by the number of words. So, $Score_{LM}$ for each sequence of POS in the k-richest sentences is computed by Equation 9.

$$Score_{LM}(c) = 10^{\frac{\log prob(c)}{|word|}} \quad (9)$$

where $prob(c)$ is the probability of summary candidate C including $|word|$ number of words, computed by the 7-gram POS-LM. A unity-based normalization is then used to bring the values of $Score_{Key}(c)$ in Equation 8, and the score of POS-LM into the range [0, 1]. The score of each summary is finally given by Equation 10.

$$Score_{final}(c) = \eta \times Score_{Key}(c) + (1 - \eta) \times Score_{LM}(c) \quad (10)$$

The scaling factor η was optimized on development data in our experiments and set to 0.4 (Section 5). Hence, the most grammatical candidate among the candidates that contain the most important phrases, has been selected as the summary for each cluster. All automatic summaries were generated by selecting sentences until the summary is 30% of the original document size (Plaza et al., 2011). This choice of the summary size is based on the well-accepted heuristic that a summary should be between 15% and 35% of the size of the source text. Considering this convention, we pick a number of three summary sentences (based on their sentence-to-query similarity scores) to answer the corresponding clinical query.

5 Experiments

In our work, the generated summaries are assessed automatically through version 2.0 [12] of ROUGE (Lin, 2004) over the released EBM corpus by (Mollá et al., 2015). ROUGE measures the summary quality by counting the overlapping units between system-generated summaries and human-written reference/gold summaries. We used ROUGE F-measure for unigram, bigrams, and SU4 (skip-bigram with maximum gap length 4) to evaluate the generated summaries. The bottom-line answers in the EBM corpus have also been used as the reference summaries.

To investigate the effectiveness of our approach, we compare our summarizer with *FastSum* (Schilder and Kondadadi, 2008), and a research prototype *LexRank* (Erkan and Radev, 2004). FastSum is a fast query-focused multi-document summarization system based only on word frequency features of topics,

[11] http://old.biomedcentral.com/about/datamining
[12] http://kavita-ganesan.com/content/rouge-2.0

documents, and clusters. Each sentence is ranked based on a linear function of scores using a variety of frequency measures. A support vector machine regression is also used to learn weights of the features. Comparing our approach with FastSum would let us evaluate the superiority of our approach over the word frequency-based approaches on the task of query-focused multi-document summarization. LexRank is a topic-oriented generic summarizer that focuses on multi-document extractive text summarization, and extracts the information in the text that is related to the user specified topic. This prototype outperformed both centroid-based methods and other systems participating in DUC in most of the cases (Erkan and Radev, 2004). Comparison with LexRank will allow us to evaluate whether semantic information provides benefits over merely lexical information in graph-based summarization approaches. Table 3 shows an example of a summary generated by human (Gold), our proposed approach (Proposed), and LexRank.

Question: Are major bleeding events from falls more likely in patients on warfarin?
Gold Summary: There is no evidence of increased risk for major bleeding as a result of falls in hospitalized patients taking warfarin. [*PubMed IDs: 7668955, 15638939*]
Proposed Summary One study found no difference in major bleeding complications between patients taking anticoagulation therapy with not taking. Criteria for taking warfarin were not reported. Prescribing warfarin for patients judged less likely to fall.
LexRank Summary No major hemorrhagic complications were seen following 131 falls in the anticoagulation group (93 patients) and 269 falls in the group not on anticoagulation (175 patients). The study was limited because most falls were from a seated position or partially controlled by an attendant. Major hemorrhage was defined as bruising or cuts requiring immediate attention from a physician.

Table 3: An example of Gold summary, Proposed summary, and LexRank summary

Three different baselines for sentence selection have also been used, each aiming to construct a different type of summary according to the type of information in various parts of the source. In details, we pick the first and last third sentences of each set of abstracts related to a clinical query, so called (*first part*, and *last part*). We also consider all sentences included in the abstracts related to a clinical query as *whole part*. Afterwards, included sentences of each of these three parts are considered as the input bag of sentences for the following baselines:

- Head Baseline: This baseline is used in a variety of summarization applications, specifically in the news summarization area. In our work, this baseline generates summaries by unintentionally selecting three sentences from the *first part*.
- Random Baseline: Randomly selects three sentences from the *whole part*.
- Tail Baseline: The last sentences in the medical abstracts usually provide conclusions. Hence, this has been used as a baseline for summarization of biomedical texts (Demner-Fushman and Lin, 2007). In our work, this baseline generates summaries by selecting three sentences at random from the *last part*.

The average performance of the baseline systems and the proposed approach in terms of ROUGE scores are provided in Table 4.

System	ROUGE-1	ROUGE-2	ROUGE-SU4
Head Baseline	0.2710	0.1723	0.1593
Random Baseline	0.2623	0.1801	0.1509
Tail Baseline	0.2866	0.1834	0.1607
FastSum	0.3382	0.2081	0.188
LexRank	0.3407	0.2069	0.1938
Proposed	**0.3985**	**0.2450**	**0.2259**

Table 4: Average scores by ROUGE metrics over the EBM corpus

The statistics point out the effectiveness of our summarizer over the compared systems on all evaluation metrics. Besides, considering the results obtained by *Tail Baseline*, it has been realized that the last part of each abstract is more likely to be included in the summary.

Standard Deviation of ROUGE Scores Since Table 4 demonstrates the average results, an important research question that immediately arises is how much the ROUGE scores differ across the abstracts. Hence, the standard deviation of different ROUGE scores for the summaries generated by the proposed approach are shown in Table 5.

Metric	ROUGE-1	ROUGE-2	ROUGE-SU4
Standard Deviation	0.02104	0.03250	0.03079

Table 5: Standard deviation of ROUGE scores for the summaries generated by the proposed approach

Exploring Scaling Factors In our work, two free parameters are defined: (1) μ for measuring semantic similarities using WordNet and UMLS; (2) η for final re-ranking score of each generated summary sentence. We randomly selected 30% of the EBM corpus as our development set to tune these parameters. Figure 2 shows the results obtained by ROUGE-1 F-Measure, using different values for μ and η. The best results are obtained using $\mu = 0.6$, and $\eta = 0.4$. Performance deteriorates when the UMLS portion in measuring semantic similarities is less or more than 0.6. On the other hand, when contribution of *TextRank* score is whatever except 0.4, the performance gradually decreases. The lowest performance is obtained when *TextRank* score is ignored in re-ranking the generated summary sentences, and also when the UMLS semantic signature occupies 0.9 of whole 1.0 value of final semantic similarity measure. This demonstrates the importance of using both WordNet and UMLS to capture the semantic similarities.

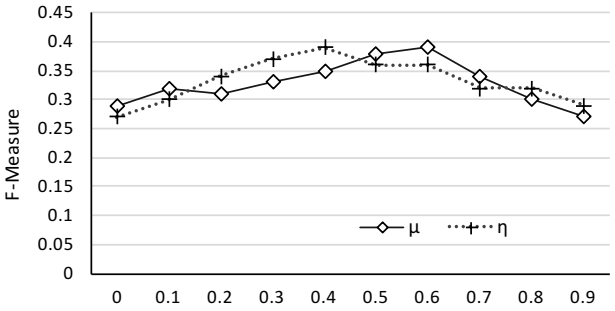

Figure 2: Exploring scaling factors μ and η on the development set

6 Conclusions

We have presented an effective approach for summarizing biomedical texts. Given a clinical query, our approach generates a well-organized, informative summary from a set of related biomedical abstracts through: (1) repetitive random walks on WordNet and UMLS to capture semantic similarities between sentences and the input query; (2) filtering out less query-relevant sentences; (3) clustering the remaining relevant sentences; (4) summarizing the clusters through a word graph-based approach, which considers the important key-phrases along with the syntactic structure of the generated summaries. Based on an automatic evaluation (via ROUGE metrics) using an evidence-based medicine corpus, our approach outperforms the two competitive systems. It has also been found that the last part of each abstract is more likely to be included in the summary. We have tackled the main issue faced by state-of-the-art biomedical summarizers (i.e. decline in summarization efficiency due to the poor UMLS coverage of general concepts in the documents to be summarized) (Plaza et al., 2011). This issue is addressed by using WordNet to represent the layman knowledge, and UMLS to represent the professional knowledge. We believe that this approach can bridge the knowledge and language gaps in biomedical summarizers.
