METEOR (Denkowski and Lavie, 2011). Figure 2 lists the definitions of these metrics. In these definitions, LCS stands for Longest Common Subsequence, Kronecker $\delta[a]$ which is 1 if $(a = true)$ else zero, and $\text{ID}_1^n = \langle 1, \cdots, n \rangle$ which is the identity permutation over $[1..n]$. Next we present an alternative view of permutations.

3 Factorization and order complexity

In factorization we seek to decompose a permutation to reveal a tree of its atomic ordering patterns. Figure 3 shows the factorization process applied to $\pi = \langle 2, 4, 5, 6, 1, 3 \rangle$. It starts out by representing π as a tree with root decorated with π itself (Figure 3a). In every step we seek the *minimal number* of adjacent *sub-permutations*. For $\langle 2, 4, 5, 6, 1, 3 \rangle$ this minimal number is four, namely $\{2\}$, $\{4, 5, 6\}$, $\{1\}$ and $\{3\}$. The first step leads to Figure 3b, where the sub-permutations are represented as subtrees with roots decorated with operators (permutations) over their child nodes. Applying factorization recursively to $\langle 4, 5, 6 \rangle$ leads to choices in binarization because both $\{4, 5\}$ and $\{5, 6\}$ are sub-permutations (Figures 3c and 3d). Next we summarize the formal results underlying factorization.

Primal permutations[3] are permutations that do not properly contain sub-permutations. Example common primal permutations are $\langle 1, 2 \rangle$, $\langle 2, 1 \rangle$ and $\langle 2, 4, 1, 3 \rangle$. Primal permutations signify the *atomic reorderings*. The following result shows they are also the *building blocks* of all permutations.

Factorization (Albert and Atkinson, 2005) Every permutation π can be written[4] as $\sigma[\pi_1, \cdots, \pi_m]$, where σ is *primal and unique*, and each π_j is a sub-permutation of π. If $m \geq 4$ then $\pi_1, \cdots, \pi_m$ are *unique*.

The uniqueness of σ and $\pi_1, \cdots, \pi_m$ for $m \geq 4$ is crucial for efficiency (Section 5). We call m the **arity** of π, written $\mathbf{a}(\pi)$ (or simply $\mathbf{a}$). For example, $\langle 4, 2, 3, 1 \rangle$ has arity 2: $\sigma = \langle 2, 1 \rangle$, $\pi_1 = \langle 4, 2, 3 \rangle$ and $\pi_2 = \langle 1 \rangle$. Applying Albert & Atkinson's result recursively factorizes π into PETs, see (Gildea et al., 2006) and Section 5 for efficient algorithms.

Permutation complexity is the class of metrics over PETs. This class includes *ground metrics* over primal permutations (operators), and higher-order metrics over PETs for other factorizable permutations. In a trivial sense, useful here, the existing baseline metrics can be seen as operating over weaker kinds of factorization which leave (parts of) π unfactorized.

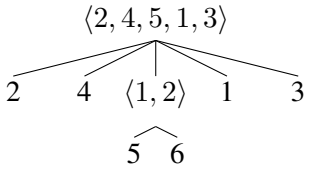

Figure 4: Weak factorization

Weak factorization A permutation π is a *weak factorization (WF)* of itself, represented as a single node with operator equivalent to π. The process applies recursively factorizing an operator in a given weak factorization τ into any number of sub-permutations (not necessarily minimal). Weak factorization may terminate at any point.

Intuitively, we would like permutation complexity metrics to be sensitive to factorization into primal permutations. This can be achieved by imposing a partial order over the different weak factorizations

[3] Also known as simple or non-decomposable permutations.

[4] The notation $\sigma[\pi_1 \cdots \pi_m]$ stands for a sequence of sub-permutations $\pi_1 \cdots \pi_m$ which is permuted by σ.

of the same permutation, assigning minimal complexity to PET factorizations. Next we formalize the notion of *tight metrics* implementing this intuition.

4 Permutation complexity: Tight metrics

A complexity metric $C(\cdot)$ is a function from weak factorizations to non-negative reals.

Tight/Semi-tight metrics A complexity metric $C(\cdot)$ is **tight** for a non-primal permutation π iff for every two weak factorizations $\tau_x \neq \tau_y$ of π holds: if τ_x factorizes into τ_y then $C(\tau_x) > C(\tau_y)$. A **semi-tight** metric fulfills the weaker requirement $C(\tau_x) \geq C(\tau_y)$ for all cases except when τ_x is the flattest weak factorization (single node) and $C(\tau_y)$ is a PET, where it strictly requires $C(\tau_x) > C(\tau_y)$.

A metric $C(\cdot)$ is tight iff it is tight for all π. It is semi-tight if it is semi-tight for at least one π and tight otherwise.

Let wf be a weak factorization and let $\mathcal{O}_{wf}$ be the multi-set of (non-leaf) node operators (permutations). We now narrow our attention to functions $F(\cdot)$ over the multi-set $\mathcal{O}_{wf}$, i.e., $C(wf) = F(\mathcal{O}_{wf})$. This means that we are disregarding the bracketing structure of wf. In Section 5 we incorporate bracketings by extending this framework to forests.

What should metric $F(\mathcal{O}_{wf})$ fulfill to be tight? We will parameterize $F(\cdot)$ with a ground metric $C_o(\cdot)$ over node operators, i.e., $F_{C_o}(\cdot)$. The idea here is that higher-order metrics over PETs can better delegate local operator complexity to a dedicated ground metric defined directly over operators, particularly primal permutations.

An operator complexity function $C_o(op)$ monotone non-decreasing[5] in operator length $|op|$ implements the idea that longer primal permutations are more complex,[6] cf. (Brignall, 2010) Theorem 2.2.:

> *Every primal permutation of length $n \geq 2$ contains another primal permutation of length $(n-1)$ or $(n-2)$ (Schmerl and Trotter, 1993).*

For example, $\langle 2,4,1,5,3\rangle$ contains $\langle 2,4,1,3\rangle$, and the latter contains $\langle 2,1\rangle$.[7]

Now we look at functions $F_{C_o}(\cdot)$ that are *monotone increasing* in the arithmetic average of $C_o(\cdot)$: $\textsc{Avg}_{C_o}(wf) = \frac{1}{|\mathcal{O}_{wf}|} \times \sum_{op \in \mathcal{O}_{wf}} C_o(op)$. For semi-tightness $\textsc{Max}_{C_o}(wf)$ is suitable. The following theorem says that a metric is tight if it assigns lower complexity to a permutation factorizing into a PET with shorter average primal permutation length.

Theorem 1 A metric $C(\cdot)$ is tight (semi-tight) if for some $C_o(\cdot)$, monotone non-decreasing in *operator length*, metric $C(\cdot)$ is monotone increasing (respectively non-decreasing) in $\textsc{Avg}_{C_o}(\cdot)$.

Proof Assume τ_0 factorizes to τ_j in a number of steps $j \geq 1$. In every step τ_{i-1} to τ_i, one operator op in τ_{i-1} of length $|op| > 2$ factorizes into $\sigma[op_1, \cdots, op_m]$, where $m \geq 2$. By the nature of factorization, $|\sigma| = m$ and $\sum_{i=1}^{m} |op_i| = |op|$. Let $\mathcal{O}^-$ stand for multi-set $\mathcal{O}$ excluding op. The average length of operators in τ_i is $\frac{1}{|\mathcal{O}_{\tau_i}|} \times (\sum_{p \in \mathcal{O}_{\tau_i}} |p|)$; it can be rewritten into $\frac{1}{m+|\mathcal{O}_{\tau_{i-1}}|} \times (m + |op| + \sum_{p \in \mathcal{O}^-_{\tau_{i-1}}} |p|)$ and again into $\frac{1}{m+|\mathcal{O}_{\tau_{i-1}}|} \times (m + \sum_{p \in \mathcal{O}_{\tau_{i-1}}} |p|)$. The desired inequality $\frac{m+\sum_{p \in \mathcal{O}_{\tau_{i-1}}} |p|}{m+|\mathcal{O}_{\tau_{i-1}}|} < \frac{\sum_{p \in \mathcal{O}_{\tau_{i-1}}} |p|}{|\mathcal{O}_{\tau_{i-1}}|}$ holds under the condition that $\sum_{p \in \tau_{i-1}} |p| > |\mathcal{O}_{\tau_{i-1}}|$, i.e., the average length of operators in a weak factorization is greater than the number of non-leaf nodes. The latter is a tautology because the branching factor of any node is always two or more. Tightness (semi-tightness) follows if $C(\cdot)$ is monotone increasing (respectively monotone non-decreasing) in $\textsc{Avg}_{C_o}(\cdot)$ when C_o is monotone non-decreasing in operator length. □

In other words, a metric assigning lower complexity to more factorizable permutations (by average operator length) is tight, i.e., *it allows comparing permutations by the smallest complexity assigned to them within this framework.* In Figure 3, a tight metric $C(\cdot)$ assigns $C(3a) > C(3b) > C(x)$ for

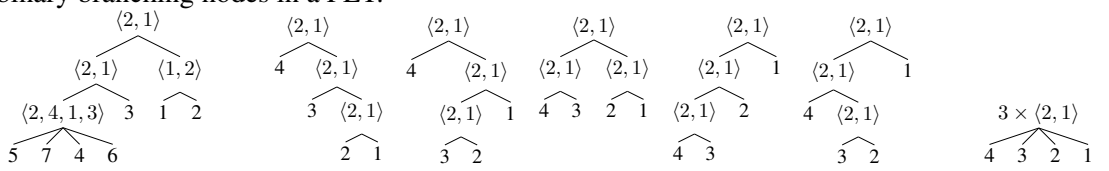
[5] $C_o(op)$ could be *monotone increasing*, but the weaker requirement is sufficient. Practically, we could parameterize $C_o(op)$ in operator-clusters and train it on data.

[6] A further practical requirement is $C_o(op) = 0$ iff $op = \langle 1,2\rangle$. But this is not necessary for tightness.

[7] By definition a primal permutation cannot be a sub-permutation of another primal permutation.

$x \in \{3c, 3d\}$. A semi-tight metric assigns complexity scores such that either $C(3a) \geq C(3b) > C(x)$ or $C(3a) > C(3b) \geq C(x)$ for $x \in \{3c, 3d\}$.

An example tight metric is the number of nodes in a PET; the more nodes the shorter the average length of primal operators. Beside maximum operator length, another semi-tight metric is the number of non-binary branching nodes in a PET.



(a) PET $\langle 5, 7, 4, 6, 3, 1, 2\rangle$. (b) Five different PETs for $\pi = \langle 4, 3, 2, 1\rangle$. (c) Flattened PET

Figure 5: In 5a and 5b PETs for different permutations. In 5c a flattened PET for the five in 5b.

5 From permutation trees to forests

For many computational purposes, a single *canonical PET* is sufficient, cf. (Gildea et al., 2006). A single PET can be computed in linear-time, cf. (Uno and Yagiura, 2000; Zhang and Gildea, 2007). Crucial for efficiency is the *uniqueness* of the sub-permutations for factorizations of arity $\mathbf{a} \geq 4$ (see Albert and Atkinson's result – Section 3), i.e., there is a single choice for a set of *split points* between adjacent sub-permutations. For arity $\mathbf{a} = 2$, there are at most $(n-1)$ choices for a single split point, if $|\pi| = n$. This is also crucial for our Permutation Forest algorithm defined next.

Some permutations factorize into multiple alternative PETs (see Figure 5b). The alternative PETs of π can be packed into an $O(n^2)$ permutation forest (PEF).

Flattened PET In a PET, chains of binary operators, either all inverted or all monotone, can be flattened leading to a *special kind* of packed representation. For example, the monotone operators in the PETs in Figures 3c and 3d can be flattened into the representation in Figure 3b. Therefore, we distinguish this from regular factorization by writing the encapsulated chain explicitly as in $3 \times \langle 2, 1\rangle$ in Figure 5c. This notation means that all binarizations of this order are allowed under that node. Various metrics defined in the next section are computed without the need to unpack this representation (e.g., the number of possible binarizations), which leads to algorithms over PEFs in $O(n)$. In the sequel we refer to function FLAT(PET) which "flattens" PET in this fashion.

A **permutation forest** (akin to a parse forest) $\mathcal{F}$ for π (over $[1..n]$) is a data structure consisting of a subset of $\{[[i, j, \mathcal{I}_i^j]] \mid 0 \leq i \leq j \leq n\}$, where $\mathcal{I}_i^j$ is a (possibly empty) set of *inferences* for π_{i+1}^j. If π_{i+1}^j is a sub-permutation and it has arity $\mathbf{a} \leq (j - (i+1))$, then each inference consists of a $\mathbf{a}$-tuple $[p, l_1, \ldots, l_{\mathbf{a}-1}]$, where the **operator** p is the permutation of the $\mathbf{a}$ sub-permutations ("children" of π_{i+1}^j), and for each $1 \leq x \leq (\mathbf{a}-1)$, l_x is a "split point" which is given by the index of the last integer in the x^{th} sub-permutation in π.

Function PEF$(i, j, \pi, \mathcal{F})$;
`# Args: sub-perm. π over [i..j] and forest F`
Output: Parse-Forest $\mathcal{F}(\pi)$ for π;

begin
1. if $([[i, j, \star]] \in \mathcal{F})$ then return $\mathcal{F}$; `#memoization`
2. $\mathbf{a} := \mathbf{a}(\pi)$;
3. if $\mathbf{a} = 1$ return $\mathcal{F} := \mathcal{F} \cup \{[[i, j, \emptyset]]\}$;
4. For each set of split points $\{l_1, \ldots, l_{\mathbf{a}-1}\}$ do
5. $\quad p := \text{RANKLISTOF}(\pi_1^{l_1}, \pi_{(l_1+1)}^{l_2}, \ldots, \pi_{(l_{\mathbf{a}-1}+1)}^{n})$;
6. $\quad \mathcal{I}_i^j := \mathcal{I}_i^j \cup [p, l_1, \ldots, l_{\mathbf{a}-1}]$;
7. $\quad$ For each $\pi_v \in \{\pi_1^{l_1}, \pi_{(l_1+1)}^{l_2}, \ldots, \pi_{(l_{\mathbf{a}-1}+1)}^{n}\}$ do
8. $\quad\quad \mathcal{F} := \mathcal{F} \cup PermForest(\pi_v)$;
9. $\mathcal{F} := \mathcal{F} \cup \{[[i, j, \mathcal{I}_i^j]]\}$;
10. Return $\mathcal{F}$;
end;

Figure 6: Pseudo-code of permutation-forest factorization algorithm. Function $\mathbf{a}(\pi)$ returns the arity of π. Function RANKLISTOF$(r_1, \ldots, r_m)$ employs *Counting Sort* (Cormen et al., 2001) to sort the sub-permutations $r_1, \ldots, r_m$ as integer ranges in $O(n)$, and returns a permutation p over $[1..m]$ signifying their order. The top-level call is PEF$(\pi, 0, n, \emptyset)$. We will use PEF(π) thereby overloading PEF$(\cdot)$.

Let us exemplify the inferences on $\pi = \langle 4,3,2,1\rangle$ (see Figure 5b) which factorizes into pairs of sub-permutations ($\mathbf{a} = 2$): a split point can be at positions with index $l_1 \in \{1,2,3\}$. Each of these split points (factorizations) of π is represented as an *inference* for the *same root node* which covers the whole of π (placed in entry $[0,4]$); an inference here consists of the permutation $\langle 2,1\rangle$ (swapping the two ranges covered by the children sub-permutations) together with $\mathbf{a}-1$ indexes $l_1,\ldots,l_{\mathbf{a}-1}$ signifying the split points of π into sub-permutations: since $\mathbf{a} = 2$ for π, then a single index $l_1 \in \{1,2,3\}$ is stored with every inference. For the factorization $((4,3),(2,1))$ the index $l_1 = 2$ signifying that the second position is a split point into $\langle 4,3\rangle$ (stored in entry $[0,2]$) and $\langle 2,1\rangle$ (stored in entry $[2,4]$). For the other factorizations of π similar inferences are stored in the permutation forest.

Figure 6 shows a simple top-down factorization algorithm which starts out by computing the arity $\mathbf{a}$ using function $\mathbf{a}(\pi)$. If $\mathbf{a} = 1$, a single leaf node is stored with an empty set of inferences. If $\mathbf{a} > 1$ then the algorithm computes all possible factorizations of π into $\mathbf{a}$ sub-permutations (a sequence of $\mathbf{a}-1$ split points) and stores their inferences together as $\mathcal{I}_i^J$ associated with a node in entry $[[i,j,\mathcal{I}_i^j]]$. Subsequently, the algorithm applies recursively to each sub-permutation.

The Albert and Atkinson uniqueness results for $\mathbf{a} \geq 4$ implies that the number of sets of split points is exactly one. For $\mathbf{a} = 2$ there are at most $n-1$ such sets. This means that line 4 in Figure 6 is at most linear in n. Similarly for $\mathbf{a} \geq 4$ line 7 does at most $(n-1)$ recursive calls, and for $\mathbf{a} = 2$ only two. In total, this algorithm has time complexity $O(n^3)$.

6 Evaluation metrics by factorization

So far we presented the Permutation Complexity class of metrics and defined tightness. In this section we present example tight and semi-tight metrics.

The (semi-)tight metrics presented next are linear-time in permutation length. Each of these metrics concentrates on one aspect of PETs/PEFs: factorization extent ($|\textsc{Pet}|$), bracketing freedom ($\#\textsc{Pets}$), and maximum arity ($\textsc{Max}_{|\mathbf{Op}|}$). These example metrics are summarized in Figure 7.

$$
\begin{aligned}
|\textsc{Pet}|(\pi) &= \frac{\textsc{Count}_{node}(PET(\pi))-1}{n-2} \\
\#\textsc{Pets}(\pi) &= \frac{\textsc{Count}_{pet}(\textsc{Pef}(\pi))-1}{\textsc{Count}_{pet}(\textsc{Pef}(\textsc{Id}^n))-1} \\
\textsc{Max}_{|\mathrm{Op}|}(\pi) &= 1 - \frac{MaxOp(PET(\pi))-2}{n-2}
\end{aligned}
$$

Figure 7: Summary of metrics: $\textsc{Count}_{node}$ is number of nodes in $PET(\pi)$; $MaxOp(PET)$ is maximum operator length in PET; $\textsc{Count}_{pet}(PEF)$ returns count of PETs in PEF.

$|\textbf{PET}|(\pi)$ is the ratio of number of nodes in a PET of π to the number of nodes in PET for $\textsc{Id}^n$. This is a *tight metric cf. Section 4.*

$\#\textbf{PETs}(\pi)$ is the ratio of number of different PETs that π factorizes into to this number for a fully monotone permutation. This metric is semi-tight: consider a flattened PET together with a complexity function based on average operator length – taking into account that flattened nodes receive operator length expressed as monotone decreasing in the Catalan number.

$\textbf{MAX}_{|\mathbf{Op}|}(\pi)$ is one minus the normalized maximum operator length in a PET of π (normalized by the range of lengths, i.e., $[2..n]$).

Having defined tight and semi-tight metrics, next we will evaluate these metrics against a gold standard: human judgements in MT.

7 Experimental setting

Data We use human rankings of translations from WMT13 (Bojar et al., 2013) for ten language pairs with a diverse set of MT systems.

Meta-evaluation We conduct **system level** meta-evaluation by following the method used in (Macháček and Bojar, 2013). All MT systems were first ranked by the ratio of the times they were judged to be better than some other system. All the metrics that we tested compute system level scores for the same systems and then we rank systems by that score (per each metric). The rankings that are

produced by all metrics are compared with human judgment using Spearman rank correlation coefficient. When there are no ties, Spearman correlation can be expressed by $\rho = 1 - \frac{6 \sum d_i^2}{n(n^2-1)}$, where $d_i = y_i - x_i$ represents a distance in ranks given by humans and the metric for system i.

Statistical significance We use bootstrap re-sampling with 1000 samples for computing statistical significance. We apply the t-test and we consider a difference significant if $p < 0.05$.

Table 3: Pairs-wise comparison over 10 language pairs. In the triple $N/B/D$: N is number of language pairs where the new metric significantly outperforms the baseline, B is baseline outperforms new metric and D is the number of language pairs where the difference is insignificant (draw). Bold show the cases where $N > B$.

Evaluating reordering All the tested metrics are defined on the sentence level. Since words in the reference or system translations might not be aligned, we introduce a brevity penalty for the ordering component as in (Isozaki et al., 2010).[8] After scaling sentence-level reordering score $ordering(\pi)$ by a brevity-penalty $BP(|\pi|, |ref|)$, we interpolate the result with a reordering-free (bag-of-words) lexical score $F1(ref, sys)$, i.e.,[9] $SenScore(ref, sys) = \alpha \times F1(ref, sys) + (1 - \alpha) \times BP(|\pi|, |ref|) \times ordering(\pi)$, where π is the permutation represent-

[8]This is the same as in BLEU with the small difference that instead of taking the length of system and reference translation as its parameters, it takes the length of the system permutation and the length of the reference.

[9]$F1 = 2 \times \frac{precision \times recall}{precision + recall}$, where $precision(ref, sys) = \frac{|ref \cap sys|}{|sys|}$ and $recall(ref, sys) = \frac{|ref \cap sys|}{|ref|}$, assuming each of ref and sys is represented as a bag of words.

ing the word alignment between sys and ref. The interpolation parameter was fixed $\alpha = 0.5$, weighing both lexical and reordering metrics equally, to avoid introducing preference for one over the other, but in principle this could be tuned on human rankings.

We score a system $\mathcal{S}$ by aggregating $SenScore$ weighted by reference length over reference-system pairs in the system's corpus $\mathcal{C}_\mathcal{S}$ and normalize: $Score(\mathcal{S}) = \frac{\sum_{(ref,sys)\in\mathcal{C}_\mathcal{S}} |ref| \times SenScore(ref,sys)}{\sum_{(ref,sys)\in\mathcal{C}_\mathcal{S}} |ref|}$.

Word alignments We align system and reference translations directly using the METEOR aligner (Denkowski and Lavie, 2011), which implements beam search over all possible monolingual alignments that could be built with exact, stem, WordNet and paraphrase match, where each matching mode is weighted depending on language pair.[10]

All metrics in our experiments are interpolated in the same manner with lexical component and brevity penalty, and are fed with the same input permutations.

Results The scores for translation into-English are in Table 2. Table 1 shows the results for the out-of-English direction. We also include BLEU-Moses straight from WMT13 tables for an impression regarding a known full metric. The present tight/semi-tight metrics outperform the baselines on six language pairs (English into Czech/ Russian/ Spanish/ German, and out of Russian and German). But the baselines prevail on four (English into French, and out of Czech, French and Spanish). We hypothesize that English-French shows local reordering where hierarchical factorization has small effect. The results for French- and Spanish-English might be explained similarly. For English-Russian and English-Czech, #PETs (bracketing freedom) is superior, likely because Russian and Czech allow freer order than English which is difficult for MT systems to capture. English-Russian shows low correlations for all metrics (including BLEU), suggesting that either all systems participating are judged of lower quality, or that human judgements are less consistent. For Czech-English, FUZZY, which outperforms all metrics, concentrates on monotone patterns suggesting that Czech-English MT systems in WMT13 differ mainly in how well they obtain correct phrases/blocks in their translations rather than long-distance ordering.

Comparison between ten metrics over ten language pairs is difficult. Hence, we present a pair-wise comparison between the metrics. Table 3 shows for each new metric $\mathcal{N}$ and baseline $\mathcal{B}$ a ratio $N/B/D$ where N is the number of language-pairs where statistically significant improvement by $\mathcal{N}$ over $\mathcal{B}$ is found, B is the reverse situation and D is the number of draws (insignificant difference).

Table 3 shows clearly that the tight metric |PET| performs more often than not better than each of the baselines. Semi-tight metric $\text{MAX}_{|\text{Op}|}$ concerns factorizability and performs as well as FUZZY outperforming the other baselines. Semi-tight metric #PETs concerns bracketing freedom and performs worse than many baselines, suggesting that for most language pairs bracketing freedom, which does not always favor more factorization, is not sufficient. Furthermore, tight and semi-tight metrics |PET| and $\text{MAX}_{|\text{Op}|}$ outperform the *not* semi-tight metrics suggesting that the improvement comes from (semi-)tightness rather than arbitrary functions over trees.

Our results exemplify that factorizing word order mismatch might have higher chance of correlating with human evaluation than the baselines. The tight and semi-tight metrics tested here are simple instantiations that illustrate the general class. More effective variants do more justice to the complexity of primal permutations. Furthermore, different metrics cover different dimensions of complexity. The results show that the importance of a dimension depends on the language pair.

8 Conclusions

The factorized representations of permutations as PETs and PEFs bring together two ingredients (1) grouping words into blocks, and (2) factorization into primal permutations. In this paper we propose a class of metrics, Permutation Complexity, define and show tightness for a sub-class, extend PETs to PEFs and explore example (semi-)tight evaluation metrics exploiting both the hierarchical and primality dimensions. Experiments with WMT13 data show that tight or semi-tight metrics compare favorably

[10]We also make METEOR minimize the number of unaligned words using "-t maxcov".

to the baselines in correlation with human evaluation. Our results can be seen as novel evidence suggesting that tightness might constitute a guiding principle for word order evaluation. The metrics presented in this work only exemplify the range of possible metrics based on the same intuition. In future work we aim at further ordering of the space of metrics, exploring a variety of new complexity metrics, and testing their value on various (evaluation) tasks.

Abstract

Conventional attention-based Neural Machine Translation (NMT) conducts dynamic alignment in generating the target sentence. By repeatedly reading the representation of source sentence, which keeps fixed after generated by the encoder (Bahdanau et al., 2015), the attention mechanism has greatly enhanced state-of-the-art NMT. In this paper, we propose a new attention mechanism, called INTERACTIVE ATTENTION, which models the interaction between the decoder and the representation of source sentence during translation by both reading and writing operations. INTERACTIVE ATTENTION can keep track of the interaction history and therefore improve the translation performance. Experiments on NIST Chinese-English translation task show that INTERACTIVE ATTENTION can achieve significant improvements over both the previous attention-based NMT baseline and some state-of-the-art variants of attention-based NMT (i.e., coverage models (Tu et al., 2016)). And neural machine translator with our INTERACTIVE ATTENTION can outperform the open source attention-based NMT system Groundhog by 4.22 BLEU points and the open source phrase-based system Moses by 3.94 BLEU points averagely on multiple test sets.

1 Introduction

Neural Machine Translation (NMT) has made promising progress in recent years (Sutskever et al., 2014; Bahdanau et al., 2015; Luong et al., 2015a; Jean et al., 2015; Luong et al., 2015b; Tang et al., 2016; Wang et al., 2016; Li et al., 2016; Tu et al., 2016; Shen et al., 2016; Zhou et al., 2016), in which attention model plays an increasingly important role. Attention-based NMT represents the source sentence as a sequence of vectors after a RNN or bi-directional RNN (Schuster and Paliwal, 1997), and then simultaneously conducts dynamic alignment with a gating neural network and generation of the target sentence with another RNN. Usually NMT with attention model is more efficient than its attention-free counterpart: it can achieve comparable results with far less parameters and training instances (Jean et al., 2015). This superiority in efficiency comes mainly from the mechanism of dynamic alignment, which avoids the need to represent the entire source sentence with a fixed-length vector (Sutskever et al., 2014).

However, conventional attention model is conducted on the representation of source sentence (fixed after generated) only with reading operation (Bahdanau et al., 2015; Luong et al., 2015a). This may let the decoder tend to ignore past attention information, and lead to over-translation and under-translation (Tu et al., 2016). To address this problem, Tu et al. (2016) proposed to maintain tag vectors in source representation to keep track of the attention history, which encourages the attention-based NMT system to consider more untranslated source words. Inspired by neural turing machines (Graves et al., 2014), we propose INTERACTIVE ATTENTION model from the perspective of memory reading-writing, which provides a conceptually simpler and practically more effective mechanism for attention-based NMT. The NMT with INTERACTIVE ATTENTION is called NMT$_{|\mathsf{A}}$, which can keep track of the interaction history with the representation of source sentence by both reading and writing operations during translation.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2174–2185, Osaka, Japan, December 11-17 2016.

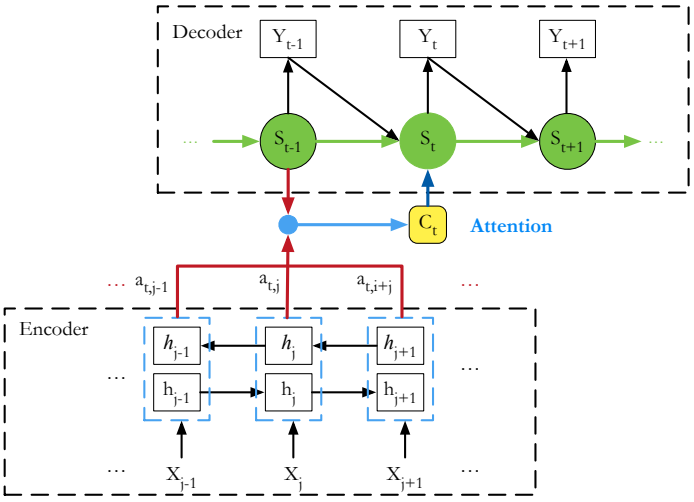

Figure 1: Illustration for attention-based NMT.

This interactive mechanism may be helpful for the decoder to automatically distinguish which parts have been translated and which parts are under-translated.

We test the efficacy of NMT_{IA} on NIST Chinese-English translation task. Experiment results show that NMT_{IA} can significantly outperform both the conventional attention-based NMT baseline (Bahdanau et al., 2015) and coverage models (Tu et al., 2016). And neural machine translator with our INTERACTIVE ATTENTION can outperform the open source attention-based NMT system Groundhog by 4.22 BLEU points and the open source phrase-based system Moses by 3.94 BLEU points.

RoadMap: In the remainder of this paper, we will start with a brief overview of attention-based neural machine translation in Section 2. Then in Section 3, we will detail the INTERACTIVE ATTENTION-based NMT (NMT_{IA}). In Section 4, we report our empirical study of NMT_{IA} on a Chinese-English translation task, followed by Section 5 and 6 for related work and conclusion.

2 Background

Our work is built upon the attention-based NMT (Bahdanau et al., 2015), which takes a sequence of vector representations of the source sentence generated by a RNN or bi-directional RNN as input, and then jointly learns to align and translate by reading the vector representations during translation with a RNN decoder. Therefore, we take an overview of the attention-based NMT in this section before detail the NMT_{IA} in next section.

2.1 Attention-based Neural Machine Translation

Figure 1 shows the framework of attention-based NMT. Formally, given an input source sequence $\mathbf{x}=\{x_1, x_2, \cdots, x_N\}$ and the previously generated target sequence $\mathbf{y}_{<\mathbf{t}}=\{y_1, y_2, \cdots, y_{t-1}\}$, the probability of the next target word y_t is

$$p(y_t|\mathbf{y}_{<\mathbf{t}}, \mathbf{x}) = softmax(f(\mathbf{c}_t, y_{t-1}, \mathbf{s}_t)) \quad (1)$$

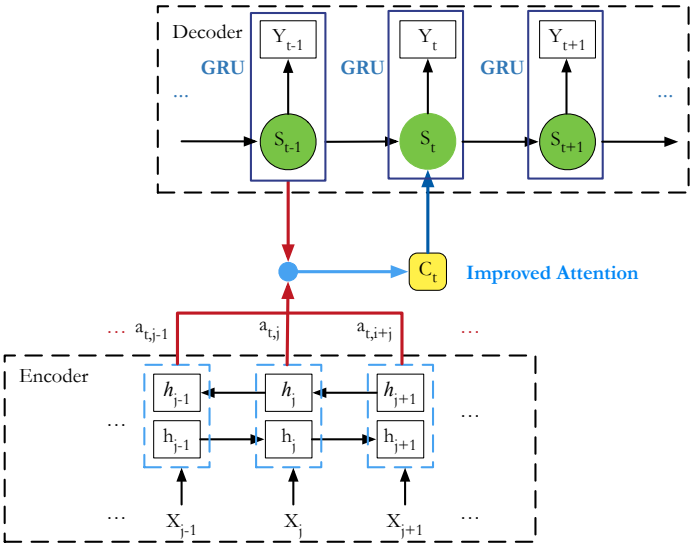

Figure 2: Illustration for improved attention model of NMT.

where $f(\cdot)$ is a non-linear function, and $\mathbf{s}_t$ is the state of decoder RNN at time step t which is calculated as

$$\mathbf{s}_t = g(\mathbf{s}_{t-1}, y_{t-1}, \mathbf{c}_t) \tag{2}$$

where $g(\cdot)$ can be any activation function, here we adopt a more sophisticated dynamic operator as in Gated Recurrent Unit (GRU) (Cho et al., 2014). In the remainder of the paper, we will also use GRU to stand for the operator. And $\mathbf{c}_t$ is a distinct source representation for time t, calculated as a weighted sum of the source annotations:

$$\mathbf{c}_t = \sum_{j=1}^{N} a_{t,j}\mathbf{h}_j \tag{3}$$

Formally, $\mathbf{h}_j = [\overrightarrow{\mathbf{h}_j}^T, \overleftarrow{\mathbf{h}_j}^T]^T$ is the annotation of x_j, which is computed by a bi-directional RNN (Schuster and Paliwal, 1997) with GRU and contains information about the whole input sequence with a strong focus on the parts surrounding x_j. And its weight $a_{t,j}$ is computed by

$$a_{t,j} = \frac{exp(e_{t,j})}{\sum_{k=1}^{N} exp(e_{t,k})} \tag{4}$$

where $e_{t,j} = \mathbf{v}_a^T tanh(\mathbf{W}_a\mathbf{s}_{t-1} + \mathbf{U}_a\mathbf{h}_j)$ scores how well $\mathbf{s}_{t-1}$ and $\mathbf{h}_j$ match. This is called automatic alignment (Bahdanau et al., 2015) or attention model (Luong et al., 2015a), but it is essentially reading with content-based addressing defined in (Graves et al., 2014). With the attention model, it releases the need to summarize the entire sentence with a single fixed-length vector (Sutskever et al., 2014; Cho et al., 2014). Instead, it lets the decoding network focus on one particular segment in source sentence at one moment, and therefore better resolution.

2.2 Improved Attention Model

The alignment model $a_{t,j}$ scores how well the output at position t matches the inputs around position j based on $\mathbf{s}_{t-1}$ and $\mathbf{h}_j$. Intuitively, it should be beneficial to directly exploit the information of y_{t-1} when

reading from the representation of source sentence, which is not implemented in the original attention-based NMT (Bahdanau et al., 2015). As illustrated in Figure 2, we add this implementation into the attention model, inspired by the latest implementation of attention-based NMT[1]. This kind of attention model can find a more effective alignment path by using both previous hidden state $\mathbf{s}_{t-1}$ and the previous context word y_{t-1}. Then, the calculation of $e(t,j)$ becomes

$$e_{t,j} = \mathbf{v}_a^T tanh(\mathbf{W}_a \tilde{s}_{t-1} + \mathbf{U}_a \mathbf{h}_j) \tag{5}$$

where $\tilde{\mathbf{s}}_{t-1} = \mathbf{GRU}(\mathbf{s}_{t-1}, \mathbf{e}_{y_{t-1}})$ is an intermediate state tailored for reading from the representation of source sentence with the information of y_{t-1} (its word embedding being $\mathbf{e}_{y_{t-1}}$) added. And the calculation of update-state $\mathbf{s_t}$ becomes

$$\mathbf{s}_t = \mathbf{GRU}(\tilde{\mathbf{s}}_{t-1}, \mathbf{c}_t) \tag{6}$$

3 Interactive Attention

In this section, we will elaborate on the proposed INTERACTIVE ATTENTION-based NMT, called NMT$_{\mathsf{IA}}$. Figure 3 shows the framework of NMT$_{\mathsf{IA}}$ with two rounds of interactive read-write operations (indicated by the yellow and red arrows respectively), which adopts the same prediction model (Eq. 1) with improved attention-based NMT. With annotations $\mathbf{H} = \{\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_N\}$ of the source sentence $\mathbf{x} = \{x_1, x_2, \cdots, x_N\}$, we take $\mathbf{H}$ as a memory, which contains N cells with the jth cell being $\mathbf{h}_j$. As illustrated in Figure 3, INTERACTIVE ATTENTION in NMT$_{\mathsf{IA}}$ contains two key parts at each time step t: 1) attentive reading from $\mathbf{H}$, and 2) attentive writing to $\mathbf{H}$. Since the content in $\mathbf{H}$ changes with time, we will add time stamp on $\mathbf{H}$ (hence $\mathbf{H}^{(t)}$) and its cells (hence $\mathbf{h}_j^{(t)}$).

At time t, the state $\mathbf{s}_{t-1}$ first meets the prediction y_{t-1} to form an "intermediate" state $\tilde{\mathbf{s}}_{t-1}$, which can be calculated as follows

$$\tilde{\mathbf{s}}_{t-1} = \mathbf{GRU}(\mathbf{s}_{t-1}, \mathbf{e}_{y_{t-1}}) \tag{7}$$

where $\mathbf{e}_{y_{t-1}}$ is the word-embedding associated with the previous prediction word y_{t-1}. This "intermediate" state $\tilde{\mathbf{s}}_{t-1}$ is used to read the source memory $\mathbf{H}^{(t-1)}$

$$\mathbf{c}_t = \mathbf{Read}(\tilde{\mathbf{s}}_{t-1}, \mathbf{H}^{(t-1)}) \tag{8}$$

After that, $\tilde{\mathbf{s}}_{t-1}$ is combined with $\mathbf{c}_t$ to update the new state

$$\mathbf{s}_t = \mathbf{GRU}(\tilde{\mathbf{s}}_{t-1}, \mathbf{c}_t) \tag{9}$$

Finally, the new state $\mathbf{s}_t$ is used to update the source memory by writing to it to finish the interaction in a round of state-update

$$\mathbf{H}^{(t)} = \mathbf{Write}(\mathbf{s}_t, \mathbf{H}^{(t-1)}) \tag{10}$$

The details of $\mathbf{Read}$ and $\mathbf{Write}$ in Eq. 8 and 10 will be described later in next section.

From the whole framework of NMT$_{\mathsf{IA}}$, we can see that the new attention mechanism can timely update the representation of source sentence along with the update-chain of the decoder RNN state. This may let the decoder keep track of the attention history during translation. Clearly, INTERACTIVE ATTENTION can subsume the coverage models in (Tu et al., 2016) as special cases while conceptually simpler. Moreover, with the attentive writing, INTERACTIVE ATTENTION potentially can modify and add more on the source representation than just history of attention, and is therefore a more powerful model for machine translation, as empirically verified in Section 4.

[1] https://github.com/nyu-dl/dl4mt-tutorial/tree/master/session2

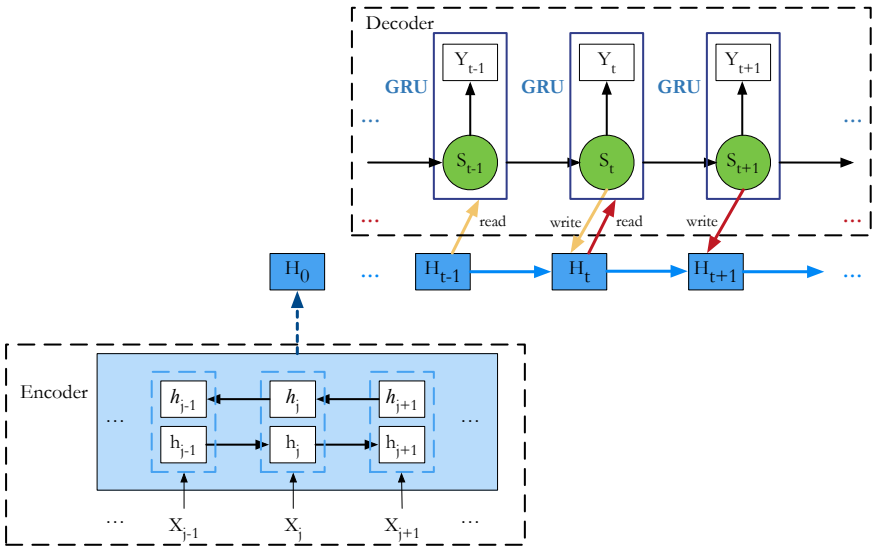

Figure 3: Illustration for the NMT$_{|A}$. The yellow and red arrows indicate two rounds of interactive read-write operations.

3.1 Read and Write of Interactive Attention

Attentive Read Formally, $\mathbf{H}^{(t')} \in \mathbb{R}^{n \times m}$ is the memory in time t' after the decoder RNN state update, where n is the number of memory cells and m is the dimension of vector in each cell. Before the state $\mathbf{s}$ update at time t, the output of reading $\mathbf{c}_t$ is given by

$$\mathbf{c}_t = \sum_{j=1}^{n} \mathbf{w}_t^R(j)\mathbf{h}_j^{(t-1)} \tag{11}$$

where $\mathbf{w}_t^R \in \mathbb{R}^n$ specifies the normalized weights assigned to the cells in $\mathbf{H}^{(t-1)}$. We can use content-based addressing to determine $\mathbf{w}_t^R$ as described in (Graves et al., 2014) or (quite similarly) use the reading mechanism such as the attention model in Section 2. In this paper, we adopt the latter one.[2]

Attentive Write Inspired by the writing operation of neural turing machines (Graves et al., 2014), we define two types of operation on writing to the memory: FORGET and UPDATE. FORGET is similar to the forget gate in GRU, which determines the content to be removed from memory cells. More specifically, the vector $\mathbf{F}_t \in \mathbb{R}^m$ specifies the values to be forgotten or removed on each dimension in memory cells, which is then assigned to each cell through normalized weights $\mathbf{w}_t^W$. Formally, the memory ("intermediate") after FORGET operation is given by

$$\tilde{\mathbf{h}}_i^{(t)} = \mathbf{h}_i^{(t-1)}(1 - \mathbf{w}_t^W(i) \cdot \mathbf{F}_t), \qquad i = 1, 2, \cdots, n \tag{12}$$

where

- $\mathbf{F}_t = \sigma(\mathbf{W}_F, s_t)$ is parameterized with $\mathbf{W}_F \in \mathbb{R}^{m \times m}$, and σ stands for the $Sigmoid$ activation function;
- $\mathbf{w}_t^W \in \mathbb{R}^n$ specifies the normalized weights assigned to the cells in $\mathbf{H}^{(t)}$, and $\mathbf{w}_t^W(i)$ specifies the weight associated with the ith cell in the same parametric form as $\mathbf{w}_t^R$.

[2] Wang et al. (2016) verified the former one for the read operation on the external memory.

UPDATE is similar to the update gate in GRU, deciding how much current information should be written to the memory as the added content

$$\mathbf{h}_i^{(t)} = \tilde{\mathbf{h}}_i^{(t)} + \mathbf{w}_t^W(i) \cdot \mathbf{U}_t, \qquad i = 1, 2, \cdots, n \tag{13}$$

where $\mathbf{U}_t = \sigma(\mathbf{W}_U, \mathbf{s}_t)$ is parameterized with $\mathbf{W}_U \in \mathbb{R}^{m \times m}$, and $\mathbf{U}_t \in \mathbb{R}^m$. In our experiments, the weights for reading (i.e., $\mathbf{w}_t^R$) and writing (i.e., $\mathbf{w}_t^W$) at time t are shared when conducting interaction with the source memory.

3.2 Optimization

The parameters to be optimized include the embedding of words on source and target languages, the parameters for the encoder, the decoder and other operations of NMT$_{|\mathsf{A}}$. The optimization is conducted via the standard back-propagation (BP) aiming to maximize the likelihood of the target sequence. In practice, we use the standard stochastic gradient descent (SGD) and mini-batch with learning rate controlled by AdaDelta (Zeiler, 2012).

4 Experiments

We report our empirical study of NMT$_{|\mathsf{A}}$ on Chinese-to-English translation task in this section. The experiments are designed to answer the following questions:

- Can NMT$_{|\mathsf{A}}$ achieve significant improvements over the conventional attention-based NMT?
- Can NMT$_{|\mathsf{A}}$ outperform the attention-based NMT with coverage model (Tu et al., 2016)?

4.1 Data and Metric

Our training data consist of 1.25M sentence pairs extracted from LDC corpora[3], with 27.9M Chinese words and 34.5M English words respectively. We choose NIST 2002 (MT02) dataset as our development set, which is used to monitor the training process and decide the early stop condition. And the NIST 2003 (MT03), 2004 (MT04), 2005 (MT05), 2006 (MT06) datasets are used as our test sets. The numbers of sentences in NIST MT02, MT03, MT04, MT05 and MT06 are 878, 919, 1788, 1082, and 1664 respectively. We use the case-insensitive 4-gram NIST BLEU[4] as our evaluation metric, with statistical significance test (*sign-test* (Collins et al., 2005)) between the proposed models and the baselines.

4.2 Training Details

In training the neural networks, we limit the source and target vocabulary to the most frequent 30K words for both Chinese and English, covering approximately 97.7% and 99.3% of two corpus respectively. All the out-of-vocabulary words are mapped to a special token UNK. We initialize the recurrent weight matrices as random orthogonal matrices. All the bias vectors are initialized to zero. For other parameters, we initialize them by sampling each element from the Gaussian distribution of mean 0 and variance 0.01^2. The parameters are updated by SGD and mini-batch (size 80) with learning rate controlled by AdaDelta (Zeiler, 2012) ($\epsilon = 1e^{-6}$ and $\rho = 0.95$). We train the NMT systems with the sentences of length up to 50 words in training data, and set the dimension of word embedding to 620 and the size of the hidden layer to 1000, following the settings in (Bahdanau et al., 2015). We also use dropout for our baseline NMT systems and NMT$_{|\mathsf{A}}$ to avoid over-fitting (Hinton et al., 2012). In our experiments, dropout was applied on the output layer with dropout rate setting to 0.5.

Inspired by the effort on easing the training of very deep architectures (Hinton and Salakhutdinov, 2006), we use a simple pre-training strategy to train our NMT$_{|\mathsf{A}}$. First we train a regular attention-based NMT model (Bahdanau et al., 2015). Then we use the trained NMT model to initialize the parameters of NMT$_{|\mathsf{A}}$ except for those related to the operations of INTERACTIVE ATTENTION. After that, we fine-tune all the parameters of NMT$_{|\mathsf{A}}$.

[3]The corpora include LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06.

[4]ftp://jaguar.ncsl.nist.gov/mt/resources/mteval-v11b.pl

SYSTEMS	MT03	MT04	MT05	MT06	AVERAGE
Moses	31.61	33.48	30.75	31.07	31.73
Groundhog	30.96	33.09	30.61	31.12	31.45
RNNsearch*	33.42	36.04	33.60	32.24	33.83
NMT$_{\mathsf{IA}}$	35.09*	37.73*	35.53*	34.32*	35.67

Table 1: BLEU-4 scores (%) of the phrase-based SMT system (Moses), NMT baselines: Groundhog and RNNsearch* (our implementation of improved attention model as described in Section 2.2), and our INTERACTIVE ATTENTION model (NMT$_{\mathsf{IA}}$). The "*" indicates that the results are significantly ($p<0.01$) better than those of all the baseline systems.

4.3 Comparison Systems

We compare our NMT$_{\mathsf{IA}}$ with four systems:

- **Moses** (Koehn et al., 2007): an open source phrase-based translation system[5] with default configuration. The word alignments are obtained with GIZA++ (Och and Ney, 2003) on the training corpora in both directions, using the "grow-diag-final-and" balance strategy (Koehn et al., 2003). The 4-gram language model with modified Kneser-Ney smoothing is trained on the target portion of training data with the SRILM toolkit (Stolcke and others, 2002),
- **Groundhog**: an open source NMT system[6] implemented with the conventional attention model (Bahdanau et al., 2015).
- **RNNsearch***: our in-house implementation of NMT system with the improved conventional attention model as described in Section 2.2.
- **Coverage Model**: state-of-the-art variants of attention-based NMT model (Tu et al., 2016) which improve the attention mechanism through modeling a soft coverage on the source representation by maintain a coverage vector to keep track of the attention history during translation.

4.4 Main Results

The main results of different models are given in Table 1. Before proceeding to more detailed comparisons, we first observe that

- RNNsearch* outperforms Groundhog, which is implemented with the conventional attention model as described in Section 2.1, by 2.38 BLEU points averagely on four test sets;
- RNNsearch* only exploit sentences of length up to 50 words with 30K vocabulary, but can achieve averagely 2.10 BLEU points higher than the open source phrase-based system Moses, which is trained with full training data.

Clearly from Table 1, NMT$_{\mathsf{IA}}$ can achieve significant improvements over RNNsearch* by 1.84 BLEU points averagely on four test sets. We conjecture it is because our INTERACTIVE ATTENTION mechanism can keep track of the interaction history between the decoder and the representation of source sentence during translation, which may be helpful for the decoder to automatically distinguish which parts have been translated and which parts are under-translated.

4.5 INTERACTIVE ATTENTION Vs. Coverage Model

Tu et al. (2016) proposed two coverage models to let the NMT system to consider more about untranslated source words. Basically, they maintain a coverage vector for each hidden state for source to keep track of the attention history and feed the coverage vector to the attention model to help adjust future attention.

[5]http://www.statmt.org/moses/

[6]https://github.com/lisa-groundhog/GroundHog

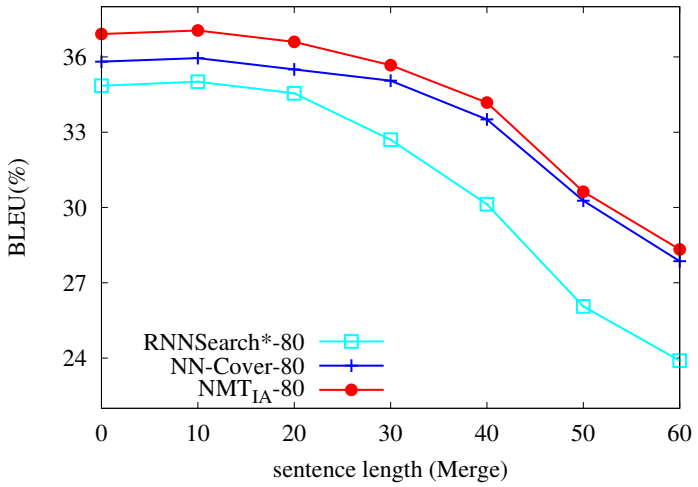

Figure 4: The BLEU-4 scores (%) of generated translations on the merged four test sets with respect to the lengths of source sentences. The numbers on X-axis of the figure stand for sentences *longer than* the corresponding length, e.g., 40 for source sentences with > 40 words.

SYSTEMS	MT03	MT04	MT05	MT06	AVERAGE
RNNsearch*-80	33.34	37.10	33.38	33.70	34.38
NN-Cover-80	33.69	38.05	35.01	34.83	35.40
NMT$_{|A}$-80	35.69*+	39.24*+	35.74*+	35.10*	36.44

Table 2: BLEU-4 scores (%) of the conventional attention-based model (RNNsearch*-80), the neural network based coverage model (NN-Cover-80) (Tu et al., 2016) and our INTERACTIVE ATTENTION model (NMT$_{|A}$-80). "-80" means the models are trained with the sentences of length up to 80 words, which is consistent with the setting in (Tu et al., 2016). The "*" and "+" denote that the results are significantly ($p<0.01$) better than those of RNNsearch*-80 and NN-Cover-80 respectively.

Although we do not maintain a coverage vector, our INTERACTIVE ATTENTION can potentially do similar things, therefore subsuming coverage models as special cases. We hence compare our INTERACTIVE ATTENTION model with the coverage model in (Tu et al., 2016). There are two coverage models proposed in (Tu et al., 2016), including linguistic coverage model and neural network based coverage model (NN-Cover). Since the neural network based coverage model generally yields better results, we mainly compare with the neural network based coverage model. Although the coverage models are originally implemented on Groundhog in (Tu et al., 2016), they can be easily adapted to the "RNNsearch*". Following the setting in (Tu et al., 2016), we conduct the comparison with the training sentences of length up to 80 words. Clearly from Table 2, our NMT$_{|A}$-80 outperforms the NN-Cover-80 by +1.04 BLEU scores averagely on four test sets.

A more detailed comparison between conventional attention model (RNNsearch*-80), neural network based coverage model (NN-Cover-80) (Tu et al., 2016) and NMT$_{|A}$-80 suggests that our NMT$_{|A}$-80 is quite consistent on outperforming the conventional attention model and the coverage model. Figure 4 shows the BLEU scores of generated translations on the test sets with respect to the length of the source sentences. In particular, we test the BLEU scores on sentences longer than $\{0, 10, 20, 30, 40, 50, 60\}$ in the merged test set of MT03, MT04, MT05 and MT06. Clearly, on sentences with different length, NMT$_{|A}$-80 always yields consistently higher BLEU scores than the conventional attention-based NMT and the enhanced version with the neural network based coverage model. We conjecture that with the attentive writing (described in Section 3.1), INTERACTIVE ATTENTION potentially can modify and add more on the source representation than just history of attention, and is therefore a more powerful model for machine translation.

We also provide some actual translation examples (see Appendix) to show that our INTERACTIVE ATTENTION can get better performance then baselines, especially on solving under-translation problem. We think the interactive mechanism of NMT_{IA} is helpful for the decoder to automatically distinguish which parts have been translated and which parts are under-translated.

5 Related Work

Our work is related to recent works that focus on improving attention models (Luong et al., 2015a; Cohn et al., 2016; Feng et al., 2016). Luong et al. (2015a) proposed to use global and local attention models to improve translation performance. They use a global one to attend to all source words and a local one to look at a subset of source words at a time. Cohn et al. (2016) extended the attention-based NMT to include structural biases from word-based alignment models, which achieved improvements across several language pairs. Feng et al. (2016) added implicit distortion and fertility models to attention-based NMT to achieve translation improvements. These works are different with our INTERACTIVE ATTENTION approach, as we use a rather generic attentive reading while at the same time performing attentive writing.

Our work is inspired by recent efforts on attaching an external memory to neural networks, such as neural turing machines (Graves et al., 2014), memory networks (Weston et al., 2014; Meng et al., 2015) and exploiting an external memory (Tang et al., 2016; Wang et al., 2016) during translation. Tang et al. (2016) exploited a phrase memory for NMT, which stores phrase pairs in symbolic form. They let the decoder utilize a mixture of word-generating and phrase-generating component, to generate a sequence of multiple words all at once. Wang et al. (2016) extended the NMT decoder by maintaining an external memory, which is operated by reading and writing operations of neural turing machines (Graves et al., 2014), while keeping a read-only copy of the original source annotations along side the "read-write" memory. These powerful extensions have been verified on Chinese-English translation tasks. Our INTERACTIVE ATTENTION is different from previous works. We take the annotations of source sentence as a memory instead of using an external memory, and we design a mechanism to directly read from and write to it during translation. Therefore, the original source annotations are not accessible in later steps. More specially, our model inherited the notation and some simple operations for writing from (Graves et al., 2014), while NMT_{IA} extends it to "unbounded" memory for representing the source. In addition, although the read-write operations in INTERACTIVE ATTENTION are not exactly the same with those in (Graves et al., 2014; Wang et al., 2016), our model can also achieve good performance.

6 Conclusion

We propose a simple yet effective INTERACTIVE ATTENTION approach, which models the interaction between the decoder and the representation of source sentence during translation by using reading and writing operations. Our empirical study on Chinese-English translation shows that INTERACTIVE ATTENTION can significantly improve the performance of NMT.

Get Semantic With Me! The Usefulness of Different Feature Types for Short-Answer Grading

Ulrike Padó
Hochschule für Technik Stuttgart
Schellingstr. 24
70174 Stuttgart
ulrike.pado@hft-stuttgart.de

Abstract

Automated short-answer grading is key to help close the automation loop for large-scale, computerised testing in education. A wide range of features on different levels of linguistic processing has been proposed so far. We investigate the relative importance of the different types of features across a range of standard corpora (both from a language skill and content assessment context, in English and in German). We find that features on the lexical, text similarity and dependency level often suffice to approximate full-model performance. Features derived from semantic processing particularly benefit the linguistically more varied answers in content assessment corpora.

1 Introduction

Computerised testing is becoming ubiquitous in the educational domain, and automated and semi-automated grading of tests is in high demand to relieve the workload of teachers (especially in the context of Massive Open On-line Courses or repeated testing for continuous feedback during the academic year). NLP is a key technology to close or at last narrow the automation loop for grading of free-text answers and essays. We focus on the automated grading of *short-answer questions* (i.e., assessment questions that require a free-text answer up to two or three sentences in length). For this task, the training data consists of a question, at least one reference answer and several student answers. Systems then predict answer accuracy as a binary *correct-incorrect* decision or as a more fine-grained multi-class problem (or even a regression task predicting points). In contrast to the related essay grading task, correct student answers stay closer to the reference answer than good essays might to an example essay.

As is often the case in young research areas, an important contribution was made by the Semeval-2013 shared task (Dzikovska et al., 2013), which introduced standard evaluation benchmarks. Two large data sets are now available with performance standards for system comparison.

On the shared task data, researchers have experimented with various features based on linguistic processing, from syntactic information (used by a majority of entries in SemEval-2013, Dzikovska et al. (2013)) to deep semantic representations (Ott et al., 2013) or Textual Entailment (TE) systems (Zesch et al., 2013). Others, staying closer to the surface level, have recently experimented with sophisticated measures of textual similarity (Jimenez et al., 2013; Sultan et al., 2016) or inferring informative answer patterns (Ramachandran et al., 2015). However, similar to other NLP tasks (like, for example, TE), one of the biggest challenges remains beating the lexical baseline: At SemEval-2013, the baseline consisting of textual similarity measures comparing reference and student answer frequently was not outperformed.

Given the large feature space proposed so far and the lack of consensus about where to find the most useful features, we ask whether there are any regularities in the predictiveness of features across corpora. Is there a hierarchy of features that are always, sometimes or never useful across different corpora and languages? Are features from deep linguistic processing informative over and above the lexical baseline, or are they subsumed by the more shallow features? And, finally, do the optimal feature sets differ with corpus characteristics like language or elicitation task?

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2186–2195, Osaka, Japan, December 11-17 2016.

We will investigate these questions as follows: Section 2.1 defines our task and hypotheses. Section 2.2 introduces the corpora and 3 describes the features. Section 4 specifies our implementation of the experiments. We first validate our feature set against literature results in Section 5, then look at feature predictiveness individually in Section 6 and in combination in Section 7. Section 8 concludes.

2 Background: Task and Data

We look for highly predictive features for the short-answer grading task that generalise over different corpora. We also ask how much information can be drawn from more abstract features from deeper levels of linguistic processing that is not covered by the strong NGram and text similarity baselines.

2.1 Task and Hypotheses

We investigate these questions by looking at unseen-question 2-way classification of short answers. In this task, the test data contains only questions (and the corresponding answers) not seen during training, but from a similar domain as the training data. We choose this task because it makes no assumptions about pre-existing student answers for each question, which maps well to small-scale testing in many educational settings. The task is binary classification of answers as *correct* or *incorrect*.

We select data from the spectrum of available short-answer corpora (see, e.g., the excellent overview article by Burrows et al. (2015)) according to two criteria: Language and elicitation task. There are two predominant tasks: On the one hand, there are corpora that assess content mastery in specific knowledge domains. These corpora contain answers by mostly highly proficient speakers. On the other hand, there are learner corpora assessing language students' reading comprehension by asking questions about the content of a text. Answers to these questions are characterised by learner mistakes and the heavy influence of *lifting* answers from the reading text, with the result of overall less variation within answers. In order to vary language, we use one German and one English corpus for each mode (see 2.2 below).

We hypothesise that the higher levels of answer variation in content-assessment corpora as opposed to the language-skill corpora will necessitate features from deeper processing levels to uncover parallels between student and reference answer. We do not expect corpus language to have a big effect, except perhaps in the usefulness of pre-processing like lemmatisation for inflection-rich German.

2.2 Data

We use the corpora listed in Table 1. The SciEntsBank (SEB) and Beetle corpora are the SemEval-2013 corpora (Dzikovska et al., 2013), which we consider as one data set. Both contain content assessment questions from science instruction, in English. CSSAG is a set of German content assessment questions about programming in Java; the data set used here is an extension of the corpus described in Padó and Kiefer (2015), following the same design principles. CREG (Meurers et al., 2011b) and CREE (Meurers et al., 2011a) are language-skill corpora. Learners of German and English, respectively, read texts and answered questions about their content.

	#Questions/ #Answers	#Q/#A (Test Set)	Task	Language
SEB (Dzikovska et al., 2013)	135/4969	16/733	Content	English
Beetle (Dzikovska et al., 2013)	47/3941	9/819		
CSSAG (Padó and Kiefer, 2015)	31/1926	NA		German
CREG (Meurers et al., 2011b)	85/543	NA	Language	
CREE (Meurers et al., 2011a)	61/566	NA		English

Table 1: Corpus sizes and characteristics

For Beetle and SEB, ample test sets exist which we use in Section 5 to validate our full models before delving into feature analysis. For the smaller corpora, there are no separate test sets[1] and the data sets

[1]There is a designated test set for CREE, but it repeats some questions from the training set, so it is not appropriate for the unseen question task. We therefore combined development and test data for CREE.

were considered too small to create them. Following Hahn and Meurers (2012), we present results for leave-one-question-out cross-validation, where we hold out each question in turn and train models on the remaining data.

All corpora contain the question texts, at least one reference answer per question and the student answers with a human-assigned correctness judgment. All corpora have explicit *correct/incorrect* annotation, except for CSSAG. CSSAG answers are scored in half-point steps up to a maximum number of points per question (usually 1 or 2). We convert CSSAG scores into binary labels by mapping all answers with more than 50% of points to *correct* and all other answers to *incorrect*.

3 Features

We compute established literature features on five different levels of linguistic processing. In the order of processing complexity, these are NGram features, text similarity features, dependency features, abstract semantic representations in the LRS formalism (Richter and Sailer, 2004) and entailment votes from a TE system, which we treat as a black box.

In the unknown question setting, all features are computed in relation to the reference answer given for each question (the question is also considered for some features, see below). Features usually code the overlap between units (NGrams, dependency relations, etc.) in the reference and student answer. We use the reference answer as the basis, so the features express the percentage of reference answer units shared between student and reference answer. The higher the percentage, the more completely does the student answer cover the reference. If the percentage is lower, the student answer is probably incomplete. The inverse percentage can of course also be computed; where the corresponding features performed well, we include them also. Wherever there is more than one reference answer, we use the maximum overlap of all the answer options, assuming that graders will evaluate student answers according to the most similar reference answer.

Table 2 gives an overview over the feature set. In more detail, the features are:

NGram features measure the overlap in uni-, bi- and trigrams between reference and student answer. NGrams are computed on both tokens and lemmas (to raise coverage).

Similarity measures compare reference and student answer on the text level. We use Greedy String Tiling (GST, Wise (1996)), a string-based algorithm popular in plagiarism detection that deals well with insertions, deletions and re-arrangement of the text.[2] We also use the classical Cosine measure as a vector-based approach and compute the Levenshtein edit distance between the texts. The measures are run on lemmatised text before (with stop words, WSW) and after stop word filtering (SWF). Stop word filtering includes removal of words in the question (*question word demotion*, Mohler et al. (2011)). The rationale is that students should be graded on the new information they provide over and above the concepts mentioned in the question. We chose not to use similarity measures that need external resources (such as WordNet or large corpora), since they may not be equally appropriate for the different corpus domains and show inconsistent performance.

Dependency features code the overlap between the student and reference answer dependency relations in terms of lemmatised triples of governor, dependency type and dependent.

Semantics features are derived by the parsing and alignment component in CoSeC (Hahn and Meurers, 2012). It constructs LRS (Lexical Resource Semantics, Richter and Sailer (2004)) analyses of the texts and attempts to align the components. We then compute the overlap in aligned components between reference and student answers as well as the question and student answer. The motivation for the latter measure is similar to question-word demotion in that high overlap between question and answer may point to question copying with little additional content.

TE decisions are computed using the Excitement Open Platform[3] (EOP, Magnini et al. (2014)). Dzikovska et al. (2013) propose constructing the Text from question and student answer and using

[2] Minimum string length is four characters.

[3] `http://hltfbk.github.io/Excitement-Open-Platform/`

the reference answer as the Hypothesis that may or may not be entailed by the Text. For us, this led to many false-positive entailment judgments by the TE system, most likely because the longer the Text, the easier it becomes to construct relations between Text and Hypothesis. We therefore use only the student answer as the Text. Our features are the entailment decision itself and the confidence score returned by the system. If there are multiple reference answers, the student answer may well entail one, but not the others. Therefore, we record any Entailment decision and its confidence score over any Non-Entailment decision, and in the case of only Non-Entailment decisions, record the lowest confidence score to capture the judgment closest to Entailment. This means that a high score size correlates with a positive decision and a low score with a negative decision.[4]

Feature Group	Feature Names
NGram	Unigram(Token,Lemma), Bigram(Token,Lemma), Trigram(Token,Lemma)
Similarity	GST(WSW,SWF), Cosine(WSW,SWF), Levenshtein(WSW,SWF)
Dependency	SRDependency, RSDependency
Semantics	LRS-QS, LRS-RS, LRS-SR
TE	TEDecision, TEConfidence

Table 2: Overview of the feature set

4 Method

We pre-processed the corpora with the DKPro pipeline (Eckart de Castilho and Gurevych, 2014), using the OpenNLP segmenter[5], the TreeTagger for POS tags and lemmas (Schmid, 1995) and the MaltParser (Nivre, 2003) for dependency parses. All tools (including the LRS parser and the EOP TE system) are used as-is without additional evaluation and tuning on our data.

Since our goal is to gain insight into the contribution of the different feature groups, we consider only one learning algorithm and do not investigate ensemble learning (although this is a common and promising approach in the literature (Dzikovska et al., 2013)). For our small data sets, overfitting is a concern. We therefore use decision trees, namely the J48 implementation in the Weka machine learning toolkit (Hall et al., 2009), which addresses overfitting by a pruning step built into the algorithm.

We report unweighted average F1 scores for comparability with Dzikovska et al. (2013), and, for the full models, accuracy for comparison to Hahn and Meurers (2012) and Meurers et al. (2011a). Tests for significance of differences between results are carried out by stratified shuffling (Yeh, 2000). The independent observations needed for this approach are the sets of answers belonging to one question.

5 Full Models and Literature Benchmarks

As the first step, we compare the performance of the decision tree algorithm and the whole feature set to the literature benchmarks for the data sets. We show that the model and features we chose achieve realistic performance to ensure that our analyses below are meaningful.

In addition to the benchmarks, we report the frequency baseline (always assign the more frequent class) and a lexical baseline (a decision tree trained with just the UnigramToken feature)[6].

For the binary grading task, the human upper bound for accuracy (measured as agreement between the raters) is in the high eighties. For the CREE and CREG corpora, grader agreement is reported as 88% (Bailey and Meurers, 2008) and 87% (Ott et al., 2012), respectively.

Table 3 lists the unweighted average F1 scores and accuracies for the different data sets. The SEB and Beetle figures are for the held-out test sets; for the other data sets, we report leave-one-question-out cross-validation results. All models outperform the frequency baseline.

[4]We use the MaxEntClassification algorithm with settings Base+WN+TP+TPPos+TS for English and settings Base+GNPos+DBPos+TP+TPPos+TS for German.

[5]`https://opennlp.apache.org/`

[6]Note that this baseline differs from the lexical baseline used in the SemEval-2013 evaluation, where a combination of similarity measures was used. The SemEval-2013 lexical baseline is the same for SEB and F=78.8 for Beetle.

	SEB		Beetle		CSSAG		CREG		CREE	
	F	Acc	F	Acc	F	Acc	F	Acc	F	Acc
Frequency Bsl	37.1*	59.0	36.7*	58.0*	38.4*	62.4*	37.4*	52.7*	44.4*	59.5*
UnigramToken Bsl	61.8*	64.0	69.8	72.9	67.4	72.0	78.6	78.6	66.5	81.3
Full model	52.8	61.5	68.1	70.8	66.6	69.3	81.5	82	70.2	80.4
Literature	62.9	–	66.6	–	–	–	–	86.3	–	88.4

Table 3: Performance of the full feature set in comparison to baselines and literature results. * indicates a significant difference between baseline and full model.

Four of the five models do not significantly differ from the UnigramToken baseline, although two numerically outperform it. This is a familiar picture from the SemEval-2013 competition and underscores the difficulty of the task.

A notable anomaly is the SEB model, which significantly underperforms on F-score and numerically underperforms on accuracy against both baselines. The leave-one-question-out cross-validation result for this model on the training set is comparable to the Beetle test set result at an F-score of 66.0 and accuracy of 67.7. We hypothesise that the training and test set for the SEB data differ substantially.

The SEB model performance of course also does not reach the literature result (although the cross-validation result of F=66.6 is comparable), while the Beetle model even numerically outperforms the literature benchmark (we compare to the median participant performance at SemEval-2013, Dzikovska et al. (2013)). For CSSAG, no prior literature results exist. The CREG result is roughly similar to the best model to date reported in Hahn and Meurers (2012). The literature result for CREE (Meurers et al., 2011a) is not completely comparable, as it was computed on the held-out test set that does not satisfy the unseen question task. Therefore, it is not surprising that our model does somewhat worse on a purely unseen question evaluation.

Overall, with the exception of the SEB model, we have been able to verify that out feature set and learner are able to approximate state-of-the-art results. We still include the SEB data set in our analyses below since the leave-one-question-out cross-validation result is much more consistent with the other models and we hypothesise a mismatch of test and training data.

6 Performance of Individual Features

For our analysis of feature impact, we first look at the performance of each feature individually. We train a decision tree with just that feature and report unweighted average F1 scores. We present only features that outperform the frequency baseline by at least 10 points F-score. The cells in Table 4 show the difference in F-score between the single-feature and full-model performance. Features that perform numerically close to the full model (within 15 percent of the F-score) are bold-faced.

We first discuss the table from the point of view of the different feature groups. As expected, the **NGram features** are strong and approximate full-model performance consistently. The higher-order NGrams drop off against the Unigrams since they are sparser. The lemmatised NGram features were introduced to potentially overcome this problem, but they consistently do less well than the token-level features. Analysis shows that lemmatisation yields higher overlap percentages between reference and student answer, but this figure now correlates less with answer accuracy. Apparently, there are important differences between reference and student answer on the token level that are lost through lemmatisation.

The **similarity measures** are also strong across the board. Among the measures we tested, Greedy String Tiling is the best predictor of response accuracy. Further, our results support the suggestion by Okoye et al. (2013) that stop words should not be removed, but we can qualify this recommendation: For measures like Greedy String Tiling and Levenshtein that explicitly operate on word sequences, stop word removal hurts performance. For the Cosine measure, on the other hand, removal is generally beneficial because it removes spurious overlap. Levenshtein edit distance is the least predictive of the similarity measures. This fits well with the analysis in Heilmann and Madnani (2013), who also see uneven performance of the model containing their edit-distance feature.

Feature Group	Feature	SEB	Beetle	CSSAG	CREG	CREE
NGrams	UnigramToken	**-4.3**	**-1.8**	**0.8**	**-2.9**	**-3.7**

	TEConfidence	-12.9	-13.3	**-4.6**	**-10.7**	**2.2**
	Full model	66.0	72.6	66.6	81.5	70.2

Table 4: Performance of individual features across all data sets ($F_{feature} - F_{full\ model}$ for all $F_{feature}$ at least 10 points F-score above the Frequency baseline).

The **dependency** features are also informative for all corpora (except for CREE). Here and in the semantic features, we again find that the RS normalisation works better than the SR normalisation, that is, specifying how much of the reference answer is covered by the student answer predicts overall accuracy better than looking at how much of the student answer is present in the reference answer. This is because the latter direction does not accurately model incomplete student answers.

The **semantic representations** are highly predictive, but only for Beetle and CSSAG, although they are within 20% F-score for SEB. The overlap between question and student answer (QS) is probably informative for Beetle because of questions that ask about specific components in an electric circuit which have to be mentioned in a correct answer. This observation calls into question the usefulness of question word demotion in all situations. Specifically in Beetle, question word demotion can be counterproductive. Take, for example, the question *Why do you think those terminals and the negative battery terminal are in the same state?* with one reference answer *Terminals 1, 2 and 3 are connected to the negative battery terminal*, and its demoted version *1, 2 3 connected to*, which matches correct answers as well as incorrect answers which speak about a connection to the positive battery terminal.

The **TE** confidence feature works well for CSSAG and outperforms the full model for CREE by two points F-score. Performance for SEB and Beetle is within 20% F-score of the full model performance. Recall that the construction of the confidence value guarantees a correlation of high confidence with an Entailment decision and lower confidence with a Non-Entailment decision, so the feature carries most of the information of the nominal TEDecision feature in addition to the graded confidence.

In sum, all features are useful, but not in all cases. As expected, there are workhorse features like NGrams and similarity that strongly predict response accuracy across the board. We find that this general applicability extends to dependency features, as well. The more abstract semantic and TE features are useful in specific cases.

To further analyse these performance patterns, we now turn to an analysis from the point of view of the corpus types. We hypothesised in Section 2.1 that there would be little influence of language, but a noticeable difference between the corpora collected with different elicitation tasks.

First of all, there is indeed no discernible difference between the German and English corpora. Even NGram lemmatisation, while helpful for CSSAG and CREG, also approximates the full models for Beetle and CREE quite well and the best token-level NGram features always outperform the lemmatised features.

We do however see a clear difference between the content assessment and language-skill assessment corpora. The language-skill corpora (CREG and CREE) profit comparatively little from the deeper processing of the dependency and LRS features; NGram and text similarity features are however very strong predictors of response accuracy. This can be explained by the typical answers in these corpora: Since students' language proficiency is limited, they often lift all or part of their answers directly from the reading. The target answers are adapted from the same texts and therefore lexically similar. Lexical and string overlap are therefore sufficient to distinguish between a correct and an incorrect answer. Then why are the TE features so strikingly successful for these corpora? This can be explained by the fact that, for CREG, and especially for CREE, the reference answers are slightly re-formulated from the reading texts by the instructor, a highly proficient speaker of the target language (frequent changes include tense and contractions, but also paraphrasing, often with POS changes for the words involved). The generalisation strategies in the TE system help find the underlying semantic similarity that is obscured on the token level.

For the content assessment corpora, in addition to the NGram and similarity features, features from deeper levels of processing are always useful. (The TE confidence is within 20% F-score for SEB and Beetle, as are the "missing" semantic and dependency features.) The deeper processing levels apparently help uncover paraphrasing by (mostly) language-proficient test-takers.

From the analysis of individual feature performance, we thus find that the NGram and similarity surface features, as well as the dependency features, are predictive for every corpus, but the features from deeper processing are useful especially for the content assessment corpora.

7 Feature Groups and Combined Performance

The discussion in Section 6 showed a clear performance pattern for the different feature groups. One possible next step would be to combine all the features that are highly predictive of response accuracy into one model. However, the features are highly inter-correlated, so their joint performance does not necessarily exceed any single performance. Recall that for CREE, the TEConfidence feature alone outperforms the full model by two points F-score. To quantify the amount of inter-correlation, an average 67% of the variation in the UnigramToken feature can be explained by a linear combination of the other feature groups (*excluding* the NGram features) across the corpora. This explains the high UnigramToken baseline - the other features strongly co-vary with the NGram features and contribute relatively little additional information.

In order to find the most predictive feature combinations, we choose an extrinsically-motivated model-building strategy. We propose adding features in the order of processing effort necessary to produce them, with the motivation that any information that can be gained by simple means should not be duplicated by more costly methods. Starting from the NGram feature set, we incrementally add more features and monitor the performance to find the cut-off point at which the complete model performance has been approximated (or even out-performed).

Table 5 shows the results. Note that the NGram feature group as a whole often outperforms the UnigramToken baseline, since the higher-order NGram features in the feature group contribute additional information. Adding the TE features in the final step results in the full model performance. The intermediary results in bold face represent substantial increases in model performance. Underlined results numerically outperform the full model.

As expected after our discussion of feature patterns in Section 6, we find that for all corpora, subsets of the feature groups suffice to approximate full model performance. In four out of five cases, we even optimise performance by using fewer features.

There are few surprises in the feature groups that contribute substantially to model performance: Again, we see a strong reliance on the NGram and similarity features. For three out of the five corpora, the full model performance can be reached or exceeded just by these two feature groups. Adding dependency features further improves four out of five models (although the CSSAG improvement is negligibly small).

Feature Group	SEB	Beetle	CSSAG	CREG	CREE
UnigramToken Bsl	61.7	70.9	67.4	78.6	66.5
NGrams	**62.1**	**72.6**	**66.5**	**80.5**	**60.9**
+ Similarity	**62.6**	72.6	**69.4**	**82.5**	**67.4**
+ Dependency	**64.7**	70.9	69.5	**83.5**	**69.8**
+ Semantics	64.7	**73.4**	66.4	83.4	**70.7**
+ TE (full model)	**66.0**	72.6	66.6	81.5	70.2

Table 5: Performance in F-score when adding feature groups in order of processing effort. Boldfaced figures indicate a substantial contribution to model performance, underlined figures exceed full model performance.

SEB, Beetle and CREE profit from features from deep processing (semantics and TE). This matches our analysis above that the more varied language in content assessment corpora (and the highly-proficient paraphrasing that creates the reference answers from the reading text for CREE) can be successfully addressed by more abstract features from deeper levels of linguistic analysis.

For the individual corpora, there is a clear correspondence between feature groups with highly predictive features in Table 4 and useful feature groups in Table 5. Any feature group containing a feature that approximates full model performance within about four points F-score proves useful in incremental model construction. Interesting exceptions to this rule are CSSAG and CREE, where the semantic and TE features (CSSAG) or just the TE features (CREE) are individually predictive within four points F-score of the full model, but do not improve combined model performance. Since these features are added last, the information they contain appears to be already covered by the combination of the other feature groups. However, the best incremental CREE model still does not outperform the model only using TEConfidence (F=72.4). The CREG and SEB models profit from adding feature groups that alone are not extremely predictive (CREG: similarity and dependency features, SEB: similarity, dependency and TE features). These feature groups clearly add relevant new information given the backbone of NGram features.

In sum, we again find that the NGram and text similarity features are very predictive of response accuracy for all corpora. This is mirrored in the literature in the SemEval-2013 performance of the CU model (Okoye et al., 2013) that focuses on these feature types, or the strong results recently presented by Sultan et al. (2016), who use lexical overlap and vector-based text similarity features. Dependency features are also worth computing, as they further improve performance for four out of five models. Features from deeper linguistic processing levels are useful if the student answers differ from the reference answer by proficient paraphrasing (as opposed to insertions, deletions and re-orderings). This is the case whenever proficient speakers answer content assessment questions (or adapt the reference answer, as for the language skill assessment in CREE).

8 Conclusions

The goal of this paper was to identify highly predictive features for the short-answer grading task. We used five corpora from the content and language-skill assessment domains to ensure that our findings would generalise and verified that our full feature set approximates literature results.

The analyses found generally applicable features in the realm of shallow (Unigram) to medium (text similarity and dependency) linguistic analysis. Features on deeper processing levels were found to co-vary substantially with the shallow features. This explains why the lexical baseline is hard to break. Deeper features (semantic representations and TE) are however useful to model the higher levels of linguistic variation in our content-assessment corpora (as opposed to the language-skill corpora). There was no language-specific pattern to feature predictiveness.

These results serve as a starting point for future research into automated short-answer grading. Depending on the corpus type at hand, our feature recommendations can be used to quickly build a well-motivated basis model to expand by further deep or shallow features, according to corpus type.

Abstract

Violence is a serious problems for cities like Chicago and has been exacerbated by the use of social media by gang-involved youths for taunting rival gangs. We present a corpus of tweets from a young and powerful female gang member and her communicators, which we have annotated with discourse intention, using a deep read to understand how and what triggered conversations to escalate into aggression. We use this corpus to develop a part-of-speech tagger and phrase table for the variant of English that is used, as well as a classifier for identifying tweets that express grieving and aggression.

1 Introduction

The USA has the highest rate of firearm related deaths compared to other industrialized countries. Violence is particularly prevalent in cities like Chicago, which has seen a 40% increase in firearm violence in 2015; someone is shot every 2-3 hours in the city. The Chicago Police Department claims that gang violence is exacerbated by taunting between gang members on social media. Recent studies have shown that the new "digital street" is likely to have consequences for one's lived experiences (Moule et al., 2013; Patton et al., 2013; Pyrooz et al., 2015). Gangs that are highly organized have an increased likelihood of engaging in online behaviors that may include harassing others via the web (Moule et al., 2013).

In this paper, we work with a dataset of tweets posted by a young and particularly powerful female Chicago gang member, Gakirah Barnes, and people with whom she communicated. We use the dataset to develop a system that can automatically classify tweets as expressing either *loss*, grieving the death of friends or family who were shot, or *aggression*, threatening to harm others often in retribution for a loss. Tweets that don't fall into either category are classified as *other*. The ultimate goal of our work is to alert community outreach groups when aggressive tweets are identified so that they can intervene to alleviate a potentially violent situation. We are also interested in enabling interventions when youths are traumatized before grief turns to retribution. Our team includes social workers who labeled the data with discourse tags representing the intention behind the tweet, and computer scientists who developed the classification system in close consultation with the social workers.

The language used in the tweets is quite different from Standard American English and also from language used in Twitter by other populations. Sample tweets are shown in Figure 1, illustrating the many factors that characterize the form of these tweets: the use of dialectal (African American Vernacular English or AAVE) grammar and vocabulary (Rickford, 1999; Green, 2002), gang-related slang, non-standard orthography, emojis, and abbreviated expressions. Individual words do not always mean what

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2196–2206, Osaka, Japan, December 11-17 2016.

Tweet	Label	Youth Interpretation
If We see a opp Fuck it We Gne smoke em 😈	Aggression (Threat)	he mean like if he see opp he go kill him opp mean like the people he dont like
Dnt get caught on Dat 800 block lame ass Lil niggas Betta take Dat Shyt on stony spot	Aggression (Insult)	he saying them lil nigga better not get caught on the 800 block or they go kill them so he tell them if they wanna live they better stay on stony
Young niggas still getting shot babies still dying 🙏	Loss	he mean like teen keep die and babys and kid keep die

Figure 1: Tweets and a Chicago youth's interpretation of them.

they do in Standard American English. A Chicago youth from the neighborhood helped us interpret the tweets. His interpretations of the sample tweets are shown on the right in Figure 1.

Given this non-standard language, natural language tools that are widely used in the NLP community cannot be used for our task. Out-of-vocabulary words and abbreviated informal expressions mean that part-of-speech taggers are not accurate. Some words carry different meanings than in most other contexts (e.g., *smoke* in the first tweet of Figure 1 means 'kill') and thus even online slang dictionaries such as Wiktionary do not have accurate definitions for words in this context. In fact, 56.9% of the words in our corpus which are not in WordNet (Beckwith et al., 1991) have incorrect definitions in Wiktionary. The intuitions of the computer scientists on the team about the meaning of tweets was often incorrect and thus, interaction with the social workers was critical.

Our approach to classifying tweets features three key contributions:

- A new corpus that is annotated with discourse intention based on a deep read of the corpus, as well as POS tags.[1]
- NLP resources for the sub-language used by Chicago gang members, specifically a POS tagger and a glossary.
- A system to identify the emotion conveyed by tweets, using the Dictionary of Affect in Language.

We developed a part-of-speech (POS) tagger for the gang sublanguage and applied machine translation alignment to produce a phrase table that maps the vocabulary they use to Standard English. Features for the emotion classifier included the POS tags produced by our tagger as well as the Dictionary of Affect in Language's (DAL) quantitative scores representing the affect of words. (Whissell, 2009). In order to access the correct word in the DAL for each Twitter word, we used the glossary we derived to find the standard English terms corresponding to slang. Our supervised classifier is able to recognize *loss* tweets with 62.3% f-measure and *aggression* tweets with 63.6% f-measure, improving over the baseline by 13.7 points (aggression) and 5.8 points (loss).

In the following sections, we describe our annotated corpus, the sublanguage tools we developed and the classifier.

2 Related Work

Wijeratne et al. (2015) engineered a general surveillance platform that uses commonly available sentiment analysis tools as a component, but does not process the language of social media posts based on the specific language and culture of street gangs with an aim towards detecting aggression. Others have analyzed urban gangs' social media presence using spatialized network data (Radil et al., 2010) and automated the analysis of graffiti style features (Piergallini et al., 2014) to predict gang affiliation. Research has also studied the psychological impact of crime on urban populations by analyzing social media, finding that crime exposure over a year can result in negative emotion and anxiety (Valdes et al.,

[1]The dataset is available at http://dx.doi.org/10.7916/D84F1R07 .

2015). Yet others are analyzing news reports to build a database of gun violence incidents (Pavlick and Callison-Burch, 2016).

There has been work on POS tagging for Twitter (Derczynski et al., 2013; Owoputi et al., 2013), including for other languages (Rehbein, 2013). We discuss (Owoputi et al., 2013) in detail in Section 4.1 The most closely related work is (Jørgensen et al., 2016), which studies African American Vernacular English in three genres (movie scripts, lyrics, tweets). They use a very large unlabeled corpus. In contrast, we use a small labeled corpus and investigate domain adaptation using additional data. Given the short amount of time since the publication of (Jørgensen et al., 2016), we have not been able to obtain their data or system to compare to ours, which we intend to do in the future.

Other research has used statistical approaches to automatically characterize dialect variation in Twitter across cities and to show how the geographical distribution of lexical variation changes over time (Eisenstein, 2015). There has been quite a bit of work examining other kinds of phenomena on Twitter; researchers have developed systems to analyze accommodation (Danescu-Niculescu-Mizil et al., 2011), sentiment analysis (e.g., (Agarwal et al., 2011; Rosenthal et al., 2015)) and clues to geolocation (Dredze et al., 2016).

3 Our Corpus

3.1 Data Collection, Corpus, and Qualitative Analysis

To create our corpus, we analyzed publicially available Twitter communication from Gakirah Barnes, who became a gang member in Chicago at age 13 and was killed at age 17, as well as tweets from people who communicated with her. Barnes changed her Twitter handle to @TyquanAssassin in memory of her friend Tyquan Tyler, who was killed in 2012. She subsequently swore to avenge Tyler's death and became a known gang leader with 9 killings to her name before she was in turn shot and killed at age 17. We focus on Gakirah because she was highly active on Twitter, posting over 27,000 tweets from December, 2011 until her death on April 11, 2014. Her typical content ranged from discussing friends and intimate relationships to threats and taunts towards rival gangs and grieving the loss of friends killed due to gang or police violence. To start, we used Radian6[2], a social media tracking service, to capture several thousand tweets by, mentions of, and replies to @TyquanAssassin. We then applied a deep read to 718 of these tweets sent during a 34-day period starting on March 15th, 2014, two weeks before another of Gakirah's friends, Raason "Lil B" Shaw, was killed by the Chicago police (March 29th, 2014) and ending one week after Gakirah's death (Thursday, April 17th, 2014). A deep read is a type of textual analysis in which annotators use outside knowledge such as context to interpret textual data. They identify and describe subtle details of the tweet such as moments of escalation. (Patton et al., 2016) We selected this time period because it represents two violent events and the conditions for retaliation are feasible. Figure 1 shows three tweets from this period. We subsequently included 102 tweets from January 14th to January 20th of the same year in the analysis in order to create a test set.

Modeling a social work approach to conducting research, we created an interdisciplinary research team comprised of a social work researcher and computer scientists (Ford, 2014). The social workers developed the annotation categories based on work with two 18 year old African American men, from a Chicago neighborhood with high rates of violence, who we hired as research assistants. They were asked to interpret the 718 tweets from the 34-day period described above. The research assistants were provided an Excel spread sheet with Gakirah Twitter data which listed the author of the tweet, the content (excluding images), the URL to the specific Twitter page and the date and time with which the tweet was posted. They provided their initial reactions about the tweets including: their first impressions, general tone, emotion and explanation of language. They also interpreted emojis that were connected to text when they were able to access the URL for a specific tweet.

Next, the social work team used the Chicago youth interpretations to ensure they had an accurate understanding of the culture, context, and language embedded in the tweets. They then analyzed communications from Gakirah Barnes and other Twitter users in her network. The deep read analysis we developed was based on a coding process that related external events to expressed events. As part of the

[2]http://radian6.com

coding process, the social work team developed a codebook to reflect categories found in the data using a random sample of 50 Twitter communications from Gakirah and others in her Twitter network. The research team then used the codebook to code all 820 tweets. Given the context of the case study, (i.e. gang violence, aggression, and trauma), initial codes identified content in posts that were perceived as threatening or violent. We then focused on posts identified through our coding process and interpretations from youth research assistants as threatening or violent, and asked "why was this communicated?" To achieve this goal, we developed a 6 step process to understand how and what triggered conversations to escalate into aggression, a process we have termed the *Digital Urban Violence Analysis Approach*. These six steps include analyzing: a triggering event; the context about the author; the tweet content; information derived from the conversational network; the linguistic form and tone of the tweet; and finally, the next event or turning point. During this process we acquired a deeper understanding of the context surrounding the variation in Twitter communication. For example, we learned that aggressive and threatening communication was often times preceded by posts that reflected loss or grief. A total of 26 codes were developed through open coding which provided an explanation for why a threatening or violent post was communicated on Twitter. Critical to this process was the coding meetings or "member checking" where the social work team came together with the computer scientists to discuss the validity of codes. Chicago youth called in to discuss how they interpreted posts, the social work team described how they developed codes and identified emerging themes and the computer scientists often asked specifically about the qualitative coding process to better understand why certain text was coded as aggression or threat. A fuller description of the methodology can be found in (Patton et al., 2016).

Based on the coding meetings, we then engaged in a second round of coding, or selective coding, which was used to further examine why a category existed and to collapse the 26 codes further. We noticed that the majority of our codes fit into three broad categories: 1) aggression, 2) grief and 3) other. The collapsed aggression code contained examples of insults, threats, bragging, hypervigilance and challenges with authority. The collapsed grief code included examples of distress, sadness, loneliness and death. The "other" codes contained examples of general conversations between users, discussions about women, and tweets that represented happiness. The January data (the test set) was coded by two annotators; inter-annotator agreement on the test set is $\kappa = 0.62$, which is moderate agreement.

3.2 Data Used in Computational Experiments

The dataset used for our NLP experiments contains the 820 tweets from Gakirah and people with whom she communicated as just described. This data is partitioned into a training set of 616 tweets, a development set of 102 tweets, and a test set of 102 tweets. The training and development set come from March and April of 2014, and the test set consists of tweets from January of the same year.

We manually annotated this data set for part of speech (POS) tags. One annotator tagged the dev and train sets and another annotated the dev and test sets. Inter-annotator agreement was $\kappa = 0.80$ on the dev set. There is a large amount of domain specific language which our annotators frequently were unfamiliar with as well as many tweets with a variety of words used in a manner different from Standard English. One such example is the use of the word *ass* which at times can be used as an adverb, adjective, or noun, whereas in Standard English *ass* is almost always used exclusively as a noun. An example can be found in the second tweet in Figure 1, *lame ass Lil niggas*.[3] The first annotator interpreted *ass* as an intensifying modifier to the adjective *lame* and tagged it is an adverb, while the second annotator read it as the second in a string of three adjectives modifying *niggas*. Additionally, the noun phrase *stony spot* in the same tweet is read by the first annotator as a common noun phrase (an adjective modifying a noun) whereas the second annotator interpreted it as the name of a location and as such tagged both as proper nouns. These discrepancies and others like them lead to a difficult task, involving reconciling problems that do not exist in newswire data; for example, confusion between common and proper nouns account for 20% of the inter-annotator disagreement. Experiments to train a system to automatically produce

[3]Note that this is not the "Ass Camouflage Construction" (ACC) discussed by Collins et al. (2008) and others, in which a phrase of type *your ass* acts as a pronoun. Instead, this is an instance of the following unnamed construction: "An [AAVE] construction distinct from the ACC, one not common to standard colloquial English, involves the combination of adjectives or nouns with the nouns *ass* and *behind* to form complex adjectives only usable pre-nominally" (Collins et al., 2008, p.32).

POS annotation are described in Section 4.1.

For the classification experiments, we used the collapsed categories of *aggression* and *loss*. Tweets that do not have an aggression or loss label are grouped into a miscellaneous *other* group. We experimented with using the full data containing all three labels and a subset of the data containing only aggression and loss annotations; we describe these experiments in Section 5.

4 NLP Analysis for the Language of Twitter Posts

4.1 Part-of-Speech Tagging

Part of speech (POS) tagging is used as a source of features in many NLP classification tasks. Our data, being fairly different from most Standard English corpora, necessitated the creation of a tagger specific to this domain: the Stanford POS tagger trained on newswire achieves an accuracy of only 34.8% on our dev set (Table 1), and even the CMU Tweet-specific POS tagger (Owoputi et al., 2013) achieves only 81.5% (as compared to 91.5% on the CMU test set). We therefore hand-annotated our corpus with POS tags (see Section 3.2). We used the CMU tokenization scheme and tagset with minor changes. We tokenized the raw data using the CMU "twokenizer" for tweets, and then we performed a second tokenization step that splits all unicode emojis into individual emoji symbols separated by spaces. As our corpus had more acronyms and other miscellaneous words which CMU tags uniformly as "G" for garbage, we use the context of the word in the sentence to give it an appropriate tag (such as "N"). Furthermore, our data also includes many emojis as well as emoticons. CMU's tagset only had an "E" tag for emoticons but not for emojis; we tag all emojis with "E" as well. As such, our final tagset included all 25 tags of CMU tagset, with the exception of the "G" tag, resulting in 24 tags in the tagset. These differences caused an unfair decrease in accuracy for the CMU tagger which we want to use as a baseline in fair comparison; therefore, for evaluation of the CMU tagger we created a separate evaluation corpus on which to test CMU wherein all emojis were replaced with the emoticon ":)" and all "G" tags were not counted. Our own tagger was trained and tested on the unmodified data with all emojis preserved. A similar transformation was also necessary in converting the output from the Stanford Tagger due to the PTB tagset differing from the CMU tagset. The transformation is fairly straightforward as PTB tags have more detail than CMU tags. Additionally, because there are some CMU tags specific to Twitter language such as the "#" tag for hashtags or the "L" tag for words with contractions such as *I'm*, all such tags were not included in the accuracy rating for Stanford.

For features, we use word unigram and bigram features, the predicted tags from the previous two words ("Tags In Window"), character n-grams for the target word, and miscellaneous binary character features such as whether or not there was punctuation, capitalization, etc. in the word in question. Furthermore, our tagger also leverages Brown Clusters created by CMU for the task of POS tagging tweets.

Tagger	Oct27 Test	Dev Set	Test Set
Stanford	52.2%	34.8%	26.0%
CMU	**91.5**%	81.5%	78.0%
Our Tagger	90.3%	**89.8**%	**81.5**%

Table 1: POS Tagger Accuracy Results

We train our tagger on the entirety of the Oct27 CMU dataset containing around 1800 tweets as well as our manually annotated gang tweets training data (616 tweets – see Section 3.2). In order to leverage the similarity to standard tweets we made use of domain adaptation (Daumé III, 2007). We also tried an even simpler method: by adding an additional feature corresponding to the domain of the sentence in the training data as well as the domain of the sentence to be tagged, the classifier is able to effectively give a weighting to the value added by each of the domains when tagging the other. This simple method of domain adaptation performed slightly better than the Daumé method for this tagging task. In Table 2 we can see that the CMU data without domain adapatation adds 0.8%, and our simple domain adaptation adds another 0.9%.

The results on the CMU test set, our dev set, and our test set are shown in Table 1. The differences between our tagger and the CMU tagger on the dev and test sets are statistically significant ($p < 0.0001$, McNemar's test). There is a large difference between the dev and test set accuracy among all taggers,

Tagger	Dev Set
Our Tagger	**89.8**%
- Misc Char Features	89.7%
- Word Bigrams	89.5%
- Word Unigrams	89.1%
- Domain Adaptation	88.9%
- CMU data	88.1%
- Tags In Window	88.7%
- CMU Brown Clusters	88.0%
- Char n-grams	86.9%

Table 2: POS tagger feature ablation study: we show accuracy results when each listed feature is removed

due presumably to the difference in annotators. Accuracy for all three taggers is higher on the CMU test set than on the Gang dev and test sets as well. This is likely in part due to the very specific nature of the language in our tweets.

Table 2 shows an ablation study in which we remove one feature at a time. A lower result means that this feature contributes more. Surprisingly, the single most important feature is the character n-grams, followed by the CMU Brown Clusters. Because of the similarity of much of the vocabulary used, the Brown Clusters produce a reasonable increase in accuracy similar to the increase reported for CMU's tweet tagger. The CMU Brown Clusters had a hit rate of 93% for words in our corpus, excluding URLs, hashtags, user handles and emojis. The high hit rate, coupled with the fact that these clusters were derived from Twitter data, likely contributed to the value.

4.2 Extracting a Glossary

Another challenging NLP task involved the creation of a glossary for the gang tweets. Our method involved using the machine translation software Moses (Koehn et al., 2007). We glossed about 400 of the tweets from our corpus into Standard American English, and used MGIZA++ to extract an alignment. (We did not succeed in creating a phrase table, presumably because the corpus was too small.) From the alignments that Moses generated, we created a simplified phrasebook, mapping one gang tweet word to one or more English words. This approach was most effective in translating the many acronyms and abbreviations that exist in gang tweets.

5 Predicting Aggression in Twitter Posts

We experiment with three supervised classification systems to predict which tweets are aggressive or demonstrate loss. Two of our systems are Support Vector Machines (SVM) (Cortese and Vapnik, 1995); these experiments include ternary classification on the full dataset (TCF) and binary classification on the aggression-loss subset (BCS). Our TCF experiments include two binary classifiers, which classify tweets as aggression versus other and loss versus other; all tweets not classified as aggression or loss are labeled other. We also implemented an additional model, in an attempt to improve performance on the full dataset. This system is a cascading classifier (CC), which uses two SVM models. One model is trained to identify one class containing all aggression and loss tweets and a second class containing all other tweets using a binary classifier on the full dataset. This enables automatic generation of an aggression/loss subset. The tweets selected by the first SVM are then passed to a second model. This second model is the same model as the BCS for Loss and Aggression.

We compute features for these classifiers from our Twitter data, including unigrams, predicted POS tags, and emotion scores. For unigram features, Twitter handles are mapped to a common token, and URLs are handled similarly. Emojis behave as regular words for all features.

5.1 Emotion Features

Our approach to identifying aggression and loss in tweets depends on identifying the emotion expressed. We use the Dictionary of Affect in Language (DAL) in order to obtain the emotional content of individual words. The DAL is a lexicon that maps over 8000 English words to a three dimensional score. The three dimensions of this score are pleasantness; activation, which is a measure of a word's intensity; and imagery, which is a measure of the ease with which a word can be visualized. Our system extends the DAL with WordNet in order to identify the emotional content of Standard English words in our data that do not occur in the DAL following Rosenthal and McKeown (2013). For each word that is not found in the DAL and is found in WordNet, the synonyms from the first (most common) synset are searched against the DAL. We assume that the emotion of a synonym will be similar to that of the original word. Thus, if there is a match between the synonyms and the DAL, the emotion score of the synonym is used for the original word.

💯	HUNDRED POINTS SYMBOL
🙏	PERSON WITH FOLDED HANDS
😂	FACE WITH TEARS OF JOY
😈	SMILING FACE WITH HORNS
💸	MONEY WITH WINGS

Figure 2: The five most common emojis in our dataset and their unabbreviated descriptions.

A more difficult task is to apply the DAL to the nonstandard English and Twitter-specific elements of the tweets. We assume each token that is not found in the DAL or WordNet is not a Standard English word. We considered various lexicons for "translating" these tokens to standard English. One such lexicon is the phrasebook automatically generated through machine translation (Section 4.2). We also attempted to translate the tweets by using a larger knowledge base, Wiktionary. With Wiktionary, we considered the definition of a word to be its translation. Wiktionary contains an entry for about half (47.7%) of the nonstandard words in the tweets; however, due to the obscure nature of most of these words, only 45.1% of these definitions are correct. In comparison, the MT-generated phrasebook manages to identify a comparable number (43.6%) of the nonstandard words to Wikipedia. Additionally, the phrasebook is much more accurate on the words that it manages to translate than Wiktionary - 83.2% of the translations from the phrasebook are accurate. We thus use the MT-phrasebook we derived from the training data instead of Wiktionary as a translation lexicon in our final system.

We use a similar technique to obtain an emotion score for the emojis found in many of the tweets. Emojis are Unicode symbols that depict faces, animals, objects, and many other entities (Figure 2). They have recently become very popular in online communication, replacing the older "emoticon" (a facial expression depicted by punctuation, for example :)). Emojis are often used to contribute to or clarify the emotion of the words they accompany. Additionally, a significant number (12.6%) of non-stopword tokens in our data are emojis. Since emojis play a significant role in the overall emotional content of a tweet, it is imperative that we include the emotional content of these emojis when scoring the tweets for their overall emotion. We attempt to solve this problem by using an additional lexicon for emojis, which maps these symbols to a representative English word or phrase. Our Emoji Lexicon uses abbreviated versions of the Unicode "names," or informative glosses, that describe the symbol in words. Thus, similar to the process we use to translate nonstandard words and slang, we utilize this lexicon to obtain a English "translation" of each emoji we come across.

We obtained an emotion score for each tweet using these techniques. We preprocess the data, removing the stopwords and Twitter specific features that do not add emotional content, such as URLs and Twitter handles. For each nonstandard token, we search a translation lexicon (either the MT-generated phrasebook or the Emoji Lexicon) to obtain a Standard English translation. Once a translation is obtained for a nonstandard element, it is applied to the DAL system described above to obtain an emotion score. For words whose emotion scores are found directly in the DAL or through WordNet, the translation process is skipped. Once the three-dimensional emotion score of each individual word is identified, the scores are combined to represent the overall emotion of the tweet. A number of different methods of combining the emotion scores were tested; however, the best results were obtained by using, for each

Experiment	Label	Precision	Recall	F-measure
TCF	**Aggression**	0.525	0.600	0.560
	Baseline (unigrams)	0.462	0.514	0.486
TCF	**Loss**	0.500	0.625	0.556
	Baseline (unigrams)	0.500	0.688	0.578
TCF	Average of **Aggression** and **Loss**	0.513	0.613	0.558
TCF	**Aggression** or **Loss**	0.588	0.800	0.678
CC	**Aggression**	0.471	0.923	0.623
CC	**Loss**	0.483	0.933	0.636
CC	Average of **Aggression** and **Loss**	0.477	0.928	0.630
BCS	**Aggression**	0.868	0.943	0.904
	Baseline (unigrams)	0.906	0.829	0.866
BCS	**Loss**	0.750	0.938	0.833
	Baseline (unigrams)	0.813	0.813	0.813

Table 3: Experimental Results on the test set. TCF is a Ternary Classification on the Full dataset (the three classes being **Aggression**, **Loss**, and neither). We provide separate results for our two classes of interest, as well as the macro-average for the two classes. We also give results for a binary task in which we collapse **Aggression** and **Loss** into one class ("**TCF Aggression** or **Loss**"). CC is the Cascading Classifier whose first step is an identification of **Aggression** or **Loss** (the system in line labeled "**TCF Aggression** or **Loss**"), and whose second step is a binary classification on the positively identified data points from the first step using the BCS system. We again provide separate results for our two classes of interest and the macro-average. BCS is Binary Classification on the aggression-loss Subset of the training data.

dimension, the minimum and maximum scores across all words in the tweet.

5.2 Results

We experimented with different approaches to classifying our data according to the aggression, loss, and other categories. In addition to SVMs, we experimented with a number of ML approaches, but we found SVMs to work best for this task. The results are shown in Table 3, as well as the f-scores of baseline unigram models for each experiment.[4] The results are better on the aggression-loss subset (BCS) than on the full dataset (TCF). However, the aggression-loss subset does not represent real-world data, as all tweets that are not labeled loss or aggression were removed prior to the experiment. The Cascading Classifier (CC) was thus implemented in an attempt to achieve better results on a realistic dataset. The CC performs better than the unigram baselines and the TCF models on both the aggression and loss categories, with both improvements statistically significant (using randomization) at $p = 0.023$ for aggression and $p = 0.039$ for loss. For our task, the high recall of our system is beneficial; it ensures that all the tweets that could potentially escalate to violence are recommended to the user, so that they can decide whether or not to intervene.

We also report results on the development set and demonstrate the contributions made by the POS tags and emotion scores as features over the baseline with respect to the dev set (Table 4). Note that the POS tags were separated into two features: a unigram POS language model, and a bigram model. We only show results for those single features in combination with unigrams that improve over the baseline. The last line for each experiment/label pair represents the final feature set that was used by each experiment on the test set.

All of our features have an impact on our classifiers. Emotion scores are useful for classification on the aggression/loss subset of the data and for classification of the aggression label of the full dataset. POS tags are useful for almost all experiments with the exception of classification of the aggression label on

[4]The "other" category had a precision of 0.706, a recall of 0.462, and a 0.558% f-measure with the TCF classifier.

Experiment	Label	Features	F-measure
TCF	**Aggression**	unigrams (baseline)	0.609
		unigrams, bigrams	0.674
		unigrams, POS-unigrams	0.674
		unigrams, emotion score	0.659
		unigrams, bigrams, POS-unigrams, emotion score	0.741
TCF	**Loss**	unigrams (baseline)	0.756
		unigrams, POS-bigrams	0.818
TCF	**Aggression + Loss**	unigrams (baseline)	0.727
		unigrams, bigrams	0.738
		unigrams, POS-bigrams	0.812
		unigrams, bigrams, POS-bigrams	0.821
BCS	**Aggression**	unigrams (baseline)	0.866
		unigrams, bigrams	0.884
		unigrams, emotion score	0.914
		unigrams, bigrams, emotion score	0.926
BCS	**Loss**	unigrams (baseline)	0.708
		unigrams, POS-unigrams	0.766
		unigrams, emotion score	0.723
		unigrams, POS-unigrams, emotion score	0.800

Table 4: Results on the development set and a breakdown of impact of the feature sets. The first line given for each experiment and label is the unigram baseline, and the last line is the full feature set.

the subset and of the loss label on the full dataset. Since the subset models were used as part of the CC, the features for these models are also important to our cascading classifiers.

6 Conclusion

We have presented a new corpus of tweets written by young African Americans associated with gangs in Chicago. The tweets present a challenge to natural language processing since they exhibit many features that differentiate them from Standard American English and from a representative collection of English language tweets, and since they carry complex meaning in context. We have discussed a methodology which involves a close reading of tweets in conjunction with informants, and which leads to an annotation scheme for the tweets which interprets them in the social and communicative context. We have shown that we can use POS tagging at a reasonable level if we annotate a small corpus with POS tags. We have then used this POS tagger in conjunction with a glossary to develop a system that can tag tweets as expressing two categories from the annotation scheme, namely loss and aggression, with F-measures above 60% on our test set for both categories.

The work we describe in this paper is only a first step towards our goal of creating a tool that can alert social workers to the need to intervene, with the ultimate goal of reducing gang-related violence. In future work, we will extend our corpus to include more authors, more time periods, and greater geographical variation. We also intend to further investigate how close the relationship between expressions of aggression on Twitter and real world aggression is.

{cscchen, csztwang, csylei, cswjli}@comp.polyu.edu.hk

Abstract

Nowadays, social media has become a popular platform for companies to understand their customers. It provides valuable opportunities to gain new insights into how a person's opinion about a product is influenced by his friends. Though various approaches have been proposed to study the opinion formation problem, they all formulate opinions as the derived sentiment values either discrete or continuous without considering the semantic information. In this paper, we propose a Content-based Social Influence Model to study the implicit mechanism underlying the change of opinions. We then apply the learned model to predict users' future opinions. The advantage of the proposed model is the ability to handle the semantic information and to learn two influence components including the opinion influence of the content information and the social relation factors. In the experiments conducted on Twitter datasets, our model significantly outperforms other popular opinion formation models.

1 Introduction

Social media services, such as Twitter, Facebook, etc. provide fast and effective platforms for people to receive messages from their neighbors/friends and express their own opinions. The online communication can gradually influence one's opinions (Anagnostopoulos et al., 2008). In fact, according to a marketing survey[1], 71% of the consumers said they are more likely to make a purchase based on social media referrals. Naturally, social media offers a great chance for companies to conduct marketing by influencing the opinions of their potential customers. In order to achieve that, exploring and understanding the intrinsic mechanism of opinion formation is of great importance.

Informational influence is a primary process for forming opinions on products in social media (Das et al., 2014). It describes the following scenario: when users lack the necessary information, they will seek for the opinions of their neighbors to update their beliefs. Taking the informational influence as premise, several models are proposed with different assumptions of how a person updates her/his own opinions according to the neighbors' opinions (Clifford and Sudbury, 1973; DeGroot, 1974; Hegselmann and Krause, 2002). In these models, opinions are pre-defined as statuses through discrete categories including positive, negative and neutral opinion (Hegselmann and Krause, 2002; Galam, 2002; De et al., 2014) or continuous scales of opinion strengths (Clifford and Sudbury, 1973; DeGroot, 1974; Yildiz et al., 2011; Chazelle, 2012). However, on most social media platforms, people exchange their views by posting and replying through textual messages. The summarized opinion status simplifies the opinion formation process, and ignores the effects of semantic information hidden in the exchanged content information. Even if two messages have the same opinion category, different semantic information of the contents may result in different effects on others' opinions. We take two postings of the product "Samsung Galaxy" as examples:

(1): *"I can't post gifs on this stupid Galaxy S6."*

(2): *"Just lost my new Galaxy S6 and very sad."*

(1) expresses complaints about a problem in the usage of the product, which may lead other users to an unfavorable impression on the product. However, (2) expresses the personal sad mood for the loss and

[1] http://www.socialmediatoday.com/content/30-statistics-how-social-media-influence-purchasing-decisions-infographic

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2207–2216, Osaka, Japan, December 11-17 2016.

no bad effect on "Samsung Galaxy" is transmitted through this message. The two examples show that the summarized opinion representations are not able to differentiate the opinion influences of different expressions on other users. Therefore, it is necessary to deeply explore the user-generated content in social communication, especially to understand the actual opinion influence derived from the messages during the communication.

The problem becomes discovering the underlying relevance between a person's opinion and the received content information. The intuitive solution is to employ the co-occurrence patterns of one's opinion and her/his neighboring messages. However, as the data grows, the patterns of co-occurrences can be sparse and ineffective for prediction. Vector representations of words and phrases have been successfully applied in many Natural Language Processing tasks (Bengio et al., 2003; Le and Mikolov, 2014). Through encoding the semantic information, word embedding makes it possible to overcome the curse of dimensionality.

Therefore, we propose a Content-based Social Influence Model (CIM) based on the neural network framework which encodes the content information with word embeddings. We represent each opinion word as a dense vector in the continuous space. We then compose the opinion word vectors of one's previous message and her/his neighboring messages to form the social opinion context vector and feed the vector to a softmax layer for opinion prediction. To construct the social opinion context vector, we incorporate two social relation factors, stubbornness and interpersonal influence. Stubbornness represents the degree a user insists on her/his previous opinion and interpersonal influence represents the influence one receives from neighbors. Also, the social relation factors are polarity-related which can be either positive or negative.

Different from previous opinion formation models which only learn the opinion influence of social relationships, our proposed model learns two opinion influence components, i.e., the opinion word embeddings and the social relation factors. The learned word vectors reflect the opinion influence of different opinion words during the discussion on a specific issue, and the social relation factors including stubbornness and interpersonal influence. Integrating these two components together, our model has the capability to describe the opinion formation process more accurately. In the experiments conducted on three Twitter datasets, our proposed model performs better than other state-of-art opinion influence models. Besides, we also study the expression of users with different influence powers. The analysis could be as a reference for companies to understand the different effects of different wordings and furthermore manage their social accounts better.

The rest of paper is organized as follows. We first review the related work in Section 2. Section 3 formulates the problem and describes the framework of our proposed model. Then, the experiments and evaluation are given in Section 4. Finally, we conclude and mention potential future works in Section 5.

2 Related Work

2.1 Opinion Influence Modeling

Opinion formation is a problem firstly studied by the researchers in the sociology and statistics areas. One notable work is proposed by DeGroot (DeGroot, 1974), which takes opinions as continuous values and assumes that one updates her/his opinions by averaging neighboring opinions. Hegselmann et al., (Hegselmann and Krause, 2002) propose the Flocking model with another assumption. They assume that people are influenced by others depending on how close their opinions are. Different from these two studies which represent opinions with continuous values, voter model represents opinion as discrete category (Clifford and Sudbury, 1973). In this model, a person selects only one of her/his neighbors uniformly at random, and takes the current opinion of the neighbor as her/his own opinion. A modification is termed as the Majority voter model (Krapivsky and Redner, 2003), where the user adopts the majority opinion in his/her neighborhood. Apart from the neighboring influence, another social relation factor stubbornness is considered in opinion prediction models. It represents the degree that one insists on her/his own opinion. The DeGroot model, Flocking model and the Voter model are extended with the idea of stubbornness (Acemoglu and Ozdaglar, 2011; Yildiz et al., 2013). Recently, De et al., (De et al., 2014) propose an asynchronous linear model (AsLM) based on the DeGroot model, which first

introduces the negative influence and proves the effectiveness of the proposed model on the social media dataset. However, existing models fail to consider the effects of content information on the opinion formation problem. Our work is the first try to integrate semantic information into opinion behavior modeling.

2.2 Neural Network in NLP Tasks

Recently, neural network has received great achievements in Natural Language Processing tasks, such as language modeling (Bengio et al., 2003), machine translation (Cho et al., 2014) and sentiment classification (Tang et al., 2014). One of the most useful neural network techniques for NLP is the word embedding, which learns vector representations of words (Bengio et al., 2003; Collobert and Weston, 2008; Mikolov et al., 2013). The neural language model proposed by Bengio et al., (Bengio et al., 2003) uses the concatenation of several previous words (context) as the input of the feed-forward neural network, and then the encoded context vector is used to predict the next word (target word). Following the word embedding techniques, several models are extended to achieve the phrase-level and sentence-level representations by composing all vectors of words in the phrase or sentence together. The basic composition method is using weighted average of all word vectors (Zanzotto et al., 2010; Mikolov et al., 2013). In (Mikolov et al., 2013), they use a simple data-driven approach, where phrases are formed based on the unigram and bigram counts of the words. Furthermore, considering the syntactic structure of the phrases or sentences, a method combining the words by their orders in the syntactic tree is proposed (Socher et al., 2011).

The proposed content-based social influence model bears similarities with the neural language model. In the opinion formation tasks, we regard the neighboring opinions and one's previous opinion as the "contexts", and the "target" is one's future opinion category. The model has a more complex framework since the social relation factors including stubbornness and interpersonal influence are considered with the word embeddings.

3 Approach

3.1 Problem Definition

Formally, we denote the network of users who are interested in the same issue as $G = (V, E)$, where each vertex $u \in V$ represents a user, and each edge $e \in E$ represents a following friendship between two users. The number of users is N. The neighbor set for each user $u \in V$ is denoted by $F_u = \{v|(u, v) \in E\}$, whose size is $n(u)$.

Additionally, the opinion expression behavior of a user is formulated as a triple $< p, o, t >$ which represents that a user u posts a tweet p with the opinion category o at the timestamp t. There are three values of +1, 0, -1 for opinion category o indicating the "positive", "negative" and "neutral" sentiment respectively. Given a user u, his opinion behaviors are represented as a sequence of triples: $\{< p_u(1), o_u(1), t_u(1) >, \cdots, < p_u(i), o_u(i), t_u(i)) >, \cdots, < p_u(m(u)), o_u(m(u)), t_u(m(u)) >\}$

Furthermore, given the above definitions, we define the neighboring opinion set for each user u at each timestamp $t_u(i)$ as $C_u(i) = \{p_{F_u^1}(t_1), \cdots, p_{F_u^v}(t_v), \cdots, p_{F_u^{n(u)}}(t_{n(u)})\}$, where $t_u(i-1) < t_v < t_u(i)$ for each neighbor $v \in F_u$. It includes all the information u receives from his neighbors in F_u since previous posting time $t_u(i-1)$. Considering opinion words are the most representative parts to reflect one's opinion, we only keep the opinion words within each tweet. For brevity, we rewrite the neighboring opinion set as $C_u(i) = \{C_u^1(i), \cdots, C_u^v(i), \cdots, C_u^{n(u)}(i)\}$, where $C_u^v(i) = \{C_{u,1}^v(i), \cdots, C_{u,|C_u^v(i)|}^v(i)\}$ contains all opinion words in the tweet $p_{F_u^v}(t_v)$. If there does not exist a posting from a neighbor v during the time period, $C_u^v(i)$ is an empty set. Also, we represent the tweet $p_u(i)$ with the opinion words set $S_u(i) = \{S_{u,1}(i), \cdots, S_{u,|S_u(i)|}(i)\}$.

The problem can be defined as: given the neighboring opinion information received in previous timestamp $C_u(i)$ and previous personal opinion $S_u(i-1)$, our objective is to predict the future opinion category $o_u(i)$ at the timestamp $t_u(i)$.

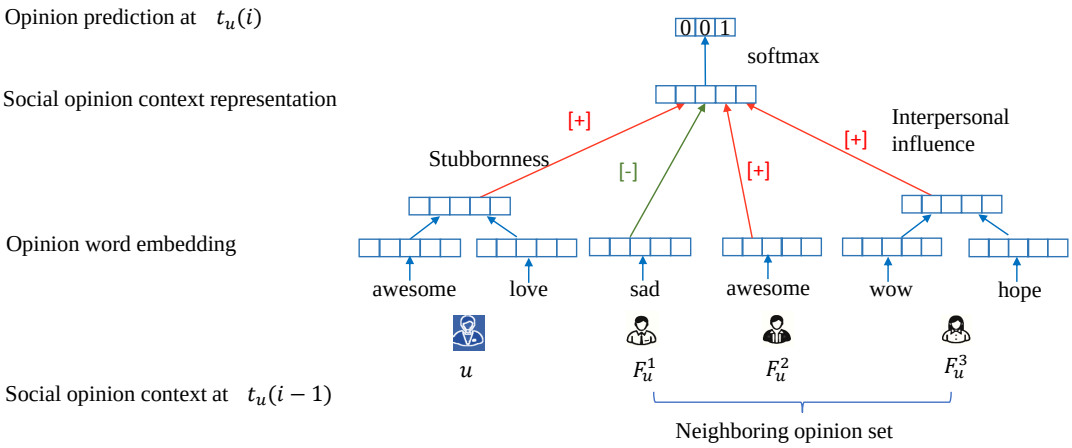

Figure 1: The graphical representation of the CIM on the opinion prediction

3.2 Framework

In this paper, we propose a novel influence model based on representation learning to solve the opinion prediction problem. Different from the existing models which learn the social relation factors including stubbornness and interpersonal influence for each user individually, our model proposes an unified framework by learning the opinion influence of the content information and the influence among social relationships together. We represent each opinion word as a dense vector, and present the composition method for the formation of social opinion context vector by concerning the polarity-related social relation factors (Section 3.2.1). Afterwards, the social opinion context vector is then used to predict one's opinion category (Section 3.2.2). Finally, we present how to learn the proposed model (Section 3.2.3). The graphical description for our proposed model is in Figure 1.

3.2.1 Social Opinion Context Composition with Polarity-related Influence

In this work, we represent each opinion word w as a low-dimensional continuous and real-valued vector $\Phi(w)$, with the dimension d. To obtain the representation of the opinions from u's vth friend, we sum the vectors of all opinion words in the set $C_u^v(i)$, and represent it as $\Phi(C_u^v(i))$. Given all neighboring opinion representations, the social opinion context vector $c_u(i)$ could be obtained by combining them together. Traditional composition methods form the phrase vector by combining word vectors with the weights obtained from the data, or applying the matrix transformation to the concatenation of word vectors (Le and Mikolov, 2014). In this work, we propose a composition method utilizing two social relation factors that have been commonly considered in previous influence models (Das et al., 2014; De et al., 2014). The social relation factors are used to describe the influence among users on the network. The stubbornness factor describes how much a person insists on her/his previous opinion, and the interpersonal influence represents the strength a neighbor has to change one's opinion. Because the interpersonal influence has the linear property (De et al., 2014), our method averages all the word vectors in the neighboring opinion set $C_u(i)$ and one's own previous opinion set $S_u(i-1)$ with the social relation factors. Formally, it is denoted as follows:

$$c_u(i) = \sum_{v=1}^{n(u)} tanh(\alpha_{uv})\Phi(C_u^v(i)) + tanh(\alpha_{u0})\Phi(S_u(i-1)) \tag{1}$$

where $\Phi(S_u(i-1)) = \sum_k^{|S_u(i-1)|} \Phi(S_{u,k}(i-1))$. α_{uv} represents the interpersonal influence on user u's opinion from the vth neighbor, and α_{u0} represents u's stubbornness. The two social relation factors are limited between -1 and 1 by using tangent function in Eq (2), which allows both positive and negative influence.

$$tanh(\alpha_{uv}) = \frac{e^{\alpha_{uv}} - e^{-\alpha_{uv}}}{e^{\alpha_{uv}} + e^{-\alpha_{uv}}} \tag{2}$$

The idea of polarity-related influence was firstly proposed by (De et al., 2014), and was proved quite effectively for opinion prediction on social network. The positive influence happens when a user trusts her/his friend, s/he will accept the opinion of her/his friend and express the same one. The negative influence implies that a user gets influenced by her/his friend, but to the opposite direction.

3.2.2 Opinion Prediction

Finally, social opinion context vector could be taken as the features to predict the future opinion category in the output layer. The output layer of our approach is expressed by the following equations.

$$P(o_u(i)|c_u(i)) = softmax(Vc_u(i) + b) \tag{3}$$

The softmax function represents the probability of current vector belonging to the jth class.

$$\sigma(z)_j = \frac{e^{z_j}}{\sum_{k=1}^{K} e^{z_k}} \tag{4}$$

where $V \in \mathbb{R}^{K \times d}$, and $b \in \mathbb{R}^K$. K is the number of opinion categories, and it is set 3 in our model.

3.2.3 Learning

The model is parameterized by the social relation factors α, the word representation $\Phi(w)$ for each opinion word, and the output parameters V, b. The objective function we need to maximize is the log-likelihood of all opinion behavior sequences defined in Eq (5).

$$\mathcal{L}(O) = \sum_{u=1}^{N} \sum_{i=1}^{m(u)} \log P(o_u(i)|C_u(i), S_u(i-1)) \tag{5}$$

We learn the model using the stochastic gradient decent (SGD) algorithm. The dimensionality of the word embedding d is set as 30. During the training phrase, we normalize the gradients if the norm exceeds 1 (Pascanu et al., 2013). The training phrase stops when the training error has a decrease less than 1 or reaches the maximum iteration length of 100. The model is implemented by Theano library (Bastien et al., 2012).

4 Experiment

4.1 Data Collection

We select three well-known electronic products widely discussed on Twitter for the purpose of performance evaluation. They are "Samsung Galaxy", "Xbox" and "PlayStation". For each product, we collect all the tweets containing the product name, such as "Samsung Galaxy", published from 1st March, 2014 to 30th November, 2014 by using the Twitter streaming API[2]. We remove the inactive users with less than 30 tweets and the over active users with more than 1000 tweets. We also collect the following relationships among the users, and further construct the user network for each individual product.

Table 1 summarizes the statistics of the datasets. The "# of users" and the "# of avg friends" describe the size of the network. During each communication round, not all of a user's friends provide the suggestions, and the friends who actually post tweets and influence the user's future opinion are the active friends. Each communication round starts after a user posts a tweet, and ends when the user updates her/his opinion with a new tweet. Therefore, we define the average number of active friends by "# of avg active friends". The active level is denoted as $("\#ofavgactivefriends")/("\#ofavgfriends")$. It implies the interests of the users on the discussion of a product. From the statistics, we observe that the products "Samsung Galaxy" and "Xbox" are actively discussed by the users with the 39%, 37% active level respectively. However, the communication on the topic "PlayStation" is not as frequent as the communication on the other two topics.

[2]https://dev.twitter.com/streaming/overview

Table 1: Network statistics.

Topic	Samsung Galaxy	Xbox	PlayStation
# of users	8921	4358	5158
# of avg friends	14.42	9.58	11.83
# of avg active friends	5.65	3.58	3.33
active level	**0.39**	**0.37**	**0.28**

4.2 Opinion Processing

Many approaches has been proposed to analyze the sentiment from the text (Hu and Liu, 2004; Pang and Lee, 2008; Mukherjee et al., 2012). However, all these methods fail to explore the reason why people express or change their opinions. In our work, we take the sentiment of tweets as premise and discover the social influence during the communication. The Vader method recently proposed by (Hutto and Gilbert, 2014) has been proved better than typical state-of-art benchmarks on analyzing the sentiment of tweets with 96% accuracy on the Twitter dataset. With the constructed twitter-specific sentiment lexicon, Vader method considers the grammatical and syntactical rules to access the sentiment scores of tweets. We utilize the Vader method to score the sentiment of each tweet and to tag the sentiment category. The tweet with positive sentiment score is tagged as positive, the one with negative score is tagged as negative, and the one with zero score is tagged as neutral.

Additionally, we obtain all the opinion words with the following rules. For each tweet, all the opinions words included in the twitter-specific sentiment lexicon (Hutto and Gilbert, 2014) are extracted. If an opinion word follows a negation word, we retain the phrase "not"+"opinion word" instead of the original opinion word. For example, the opinion word extracted from the tweet "I don't like the Samsung Galaxy S6." is the phrase "not like". For the tweets only stating the facts without expressing an opinion, we use the word symbol "NeuW" to represent them. To alleviate the word sparsity, we only keep the opinion words that occur more than 50 times in the whole dataset and replace the infrequent opinion words with the corresponding symbols. The positive opinion words are replaced with the symbol "PosW", and the negative opinion words are replaced with the symbol "NegW". Finally, the numbers of the remaining opinion words for the topic "Samsung Galaxy", "Xbox", and "PlayStation" are 880, 1146 and 505, respectively.

4.3 Experimental Set-up

We compare the proposed model CIM with four baseline models, i.e., the DeGroot model, the Flocking model, the Voter model and the AsLM model. These models have different assumptions for the opinion formation process. To be fair, all baseline models incorporate the factor of personal stubbornness. It means that all models take the influence from one's previous opinion into account. For the DeGroot model (Acemoglu and Ozdaglar, 2011), the Flocking model (Hegselmann and Krause, 2002) and the AsLM model (De et al., 2014), each tweet is represented as a continuous sentiment score. For the Voter model with the assumption of the majority adoption (Krapivsky and Redner, 2003), each tweet is summarized by its opinion category. To further verify the effectiveness of the content information, we develop another influence model Content_SVM which is implemented with LIBSVM (Chang and Lin, 2011). The model trains SVM classifiers individually for each user by taking all the neighboring opinion words and the opinion words in one's previous tweet as features. To be consistent with the linear influence assumption, the linear kernel is used in SVM training process. The parameters of each model are set for their best performances experimentally.

We split the data into the training dataset and test dataset according to the posting time. The training dataset is constructed by using the data before the $m(u)-1$ timestamp for each user u. With the influence model learned from the training set, we predict the last opinion for each user.

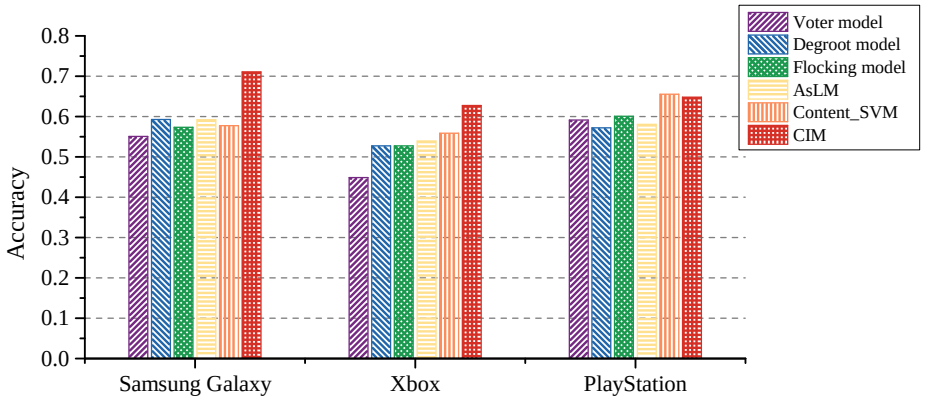

Figure 2: Performances on opinion prediction

4.4 Opinion Prediction Performances

We first evaluate the prediction accuracy for all the models. The results are displayed in Figure 2.

$$Accuracy = \frac{the\ number\ of\ correctly\ predicted\ users}{the\ number\ of\ all\ users}$$

The content-based models (Content_SVM and CIM) almost outperform the baseline methods in all three topics, which verifies that employing the detailed content information is more effective than only using the opinion statuses for opinion behavior prediction.

Meanwhile, CIM performs consistently much better than all baseline methods on the topics of "Samsung Galaxy", and "Xbox". Compared with other methods which only learns the social relation factors from opinion behaviors for each user individually, CIM encodes the semantic information into the dense vectors of the opinion words through learning from the opinion behaviors of all users. The good performance of CIM demonstrates its better ability to capture two types of opinion influence components including opinion influence of the opinion words and social relation factors together. However, CIM has a slightly lower accuracy compared with the best competitor on the topic "PlayStation". It can be attributed to the lower active level of users on the PlayStation than those on the other two topics. The insufficient communication histories over the network make it difficult to learn the actual influence of opinion words for opinion prediction, and may even harm the results.

4.5 The Effect on Opinion Category

For a more detailed analysis, we further evaluate the ability of CIM on predicting different opinion categories. We present the distributions of three opinion categories in both the training dataset and the test dataset in Table 2. The F1 score which considers both precision and recall, is used as the measurement on each opinion category. The experimental results are included in Table 3.

On the topics of "Samsung Galaxy" and "Xbox" with the active communication environment, CIM still has a significant improvement concerned with the evaluation metrics on all the three opinion categories. Specifically, the improvements compared with the best competitors on the positive opinion prediction and the negative opinion prediction are 17.7%, 21.5% for the topic "Samsung Galaxy" and 11.5%, 20.3% for the topic "Xbox" respectively. Compared with predicting the neutral opinions, forecasting the positive and negative opinions is more useful for companies to understand the customer needs and the brand reflection.

On the topic "PlayStation" with the relatively inactive communication, best performances of different evaluation metrics are obtained by different models. CIM performs well on the prediction of the positive and neutral opinions but poorly on the prediction of negative opinions. It reveals that the weakness of CIM is mainly on learning the negative opinion formation process when the communication is insufficient. We also note that the Voter model which performs poorly on the other two topics has better results on the "PlayStation" topic. Different from influence models based on the interpersonal influence,

Table 2: Opinion category statistics.

Topic	Samsung Galaxy		Xbox		PlayStation	
	Training set	Test set	Training set	Test set	Training set	Test set
% of negative opinion	11.05	14.61	16.33	6.81	11.99	19.73
% of positive opinion	19.96	19.95	41.56	26.88	25.03	19.28
% of neutral opinion	65.43	65.41	42.11	66.31	62.98	60.99

Table 3: Performances on three opinion categories.

Topic	Samsung Galaxy			Xbox			PlayStation		
	F1_Pos	F1_Neg	F1_Neu	F1_Pos	F1_Neg	F1_Neu	F1_Pos	F1_Neg	F1_Neu
Degroot	0.4950	0.1932	0.6913	0.5185	0.1935	0.6035	0.2531	0.1405	0.7064
Flocking	0.4449	0.2677	0.6780	0.4469	0.2069	0.6240	0.3513	**0.3711**	0.7125
AsLM	0.5812	0.2139	0.7028	0.5597	0.2298	0.6293	0.3210	0.2025	0.7338
Voter	0.4826	0.1762	0.6246	0.4637	0.1694	0.4709	**0.5655**	0.2688	0.6782
Content_SVM	0.4918	0.1436	0.6732	0.5972	0.2004	0.6106	0.5616	0.3410	0.7458
CIM	**0.6842**	**0.3253**	**0.7787**	**0.6658**	**0.2765**	**0.6677**	0.5568	0.1521	**0.7518**

the Voter model assumes that one will accept the mainstream view of her/his neighbors as the future opinion. The results indicate that when neighboring messages are insufficient, the group influence of all neighbors dominates. It motivates us to utilize the group influence with the interpersonal influence together for benefiting the opinion behavior prediction in the insufficient communication situation.

4.6 Analysis of Wording for Influential Users

With the learned model, the companies could get the insights into how to become an influential voice on the social media by improving their wordings. We analyze different expressions used by users with different social opinion influence degrees in the network. Based on the learned interpersonal influences, we calculate the influence strengths of Twitter users by averaging their outgoing influence strengths on their followers. Based on the influence strengths, we divide users into three groups. The users with influence strengths more than 0.5 are categorized as the positively influential users. The users with influence strengths less than -0.5 represent the negatively influential users. The remaining are regarded as the ordinary users with little influence.

We then extract the high frequent words from the users in different influence groups. The results show that the positively influential users more likely utilize the words describing the facts, e.g., ”security”, ”special” and impress”. However, the tweets posted by strong negative influential users are more emotional with the words like ”Woo”, ”Wow” or the emoticons ”o_o”. The analysis indicates that the detailed information about the products tends to make positive effects, while heavily emotional expressions may annoy people and influence them in the opposite direction.

5 Conclusions

In this paper, we propose to characterize the users' tweets with detailed opinion content instead of discrete opinion categories or continuous scores. To the best of our knowledge, this is the first attempt to incorporate the content information into opinion behavior modeling. Existing models only learn the social relation factors from the pre-defined opinion sequences. Differently, our proposed model based on the feed-forward neural network framework is capable of learning the opinion word representations which encodes the actual influence of the opinions words, and learn the two social relation factors from the opinion behaviors of all users. The experiments conducted on the Twitter dataset demonstrate the effectiveness of our proposed model on the opinion prediction. We also examine the expressions of users with different influence degrees, which could provide useful information for companies to manage their accounts. Based on the current work, we will further combine more influencing factors including the personal interests and group influence in the future model.

Abstract

We propose a non-parametric Bayesian model for learning and weighting symbolically-defined constraints to populate a log-linear model. The model jointly infers a vector of binary constraint values for each candidate output and likely definitions for these constraints, combining observations of the output classes with a (potentially infinite) grammar over potential constraint definitions. We present results on a small morphophonological system, English regular plurals, as a test case. The inferred constraints, based on a grammar of articulatory features, perform as well as theoretically-defined constraints on both observed and novel forms of English regular plurals. The learned constraint values and definitions also closely resemble standard constraints defined within phonological theory.

1 Introduction

Constraint-based models of language, often in the form of "maximum entropy" or "log-linear" models, are prominent in many applications and theoretical analyses in computational linguistics and psycholinguistics, including in text segmentation (Beeferman et al., 1999; Poon et al., 2009), machine translation (Och and Ney, 2002), syntactic alternation choice (Bresnan et al., 2007), and phonology (Goldwater and Johnson, 2003). Building successful models – and learning about human behavior from them – relies on the ability to identify relevant constraints, and this can be a difficult problem.

In this paper, we propose a system for learning both the values of and symbolic definitions for such constraints. We present a framework that combines observed data about linguistic outcomes with a flexible probabilistic context-free grammar of constraint structure to jointly infer (binary) feature values for multiple constraints and likely symbolic definitions for those constraints. We ground the model in a morphophonological setting, using the model to infer what phonological constraints affect the output form of regular English plurals, although it can be applied to other problems for which a constraint grammar can be defined.

The inference procedure moves beyond existing methods for learning *extensional* definitions of constraint values (Griffiths and Ghahramani, 2005; Görür et al., 2006; Doyle et al., 2014) from observational data to incorporate top-down information about likely *intensional* constraint definitions, improving both the applicability of the constraints and the theoretical basis for their values. We show that learning the constraints through this model performs as well as using pre-specified phonologically-standard constraints in explaining both observed and novel regular plural morphophonology. In addition, the structure of the learned constraints is similar to standard phonological constraints, showing that the model can be useful in both applications and theory-building.

2 Constraint-based models and the phonological test case

Our core problem is how to learn appropriate identities and weights for log-linear features in linguistic applications. In general, we assume some set of input types $\{x_i\}$, with $n_{i\cdot}$ instances of each type observed. The input type x_i is observed to produce n_{ij} instances of each outcome type y_j, and, as we are using a log-linear model, we assume that the number of observed input-output pairs (x_i, y_j) is proportional to the exponential of the weighted sum of the constraint values v_{ijk} over all constraints k. At least

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2217–2226, Osaka, Japan, December 11-17 2016.

some subset of these constraints k are unknown, and our goal is to learn the number of and values for these unknown constraints, as well as weights for both the known and unknown features.

Furthermore, we assume that the values of the unknown constraints are based on definitions that are generated from a symbolic grammar. This allows the model to inject theory- or observation-based structure into the learning process, improving the plausibility of the constraint values and allowing the researcher to identify likely definitions for the constraints to apply to unobserved inputs. At present, we limit ourselves to the case where the unknown constraints are binary and depend only on the outcome type y_j, a simplified case that is particularly relevant to phonological constraint acquisition. We discuss avenues for relaxing the binarity limitation in Section 7.

Gaps in log-linear phonological modeling We consider phonological theory as a test case because it has a well-established constraint-based framework, Optimality Theory (OT; Prince and Smolensky (1993)). But there is a gap in learning methods for OT-style phonology. Multiple methods have been proposed within OT for learning constraint weights or orderings (Tesar and Smolensky, 2000; Boersma and Hayes, 2001; Goldwater and Johnson, 2003) when the constraint definitions are known. None of these can learn constraint definitions, though three general tracks of research have pushed toward this goal. One track builds phonetically-grounded constraints based on the difficulty of producing or understanding the sound sequences (Hayes, 1999), but cannot produce constraints that lack such grounded motivations (Hayes, 1995). A second track learns constraints within a phonotactic problem, looking solely at attested output forms (Hayes and Wilson, 2008; Berent et al., 2012), but the phonotactic learning problem does not take input forms into account, and searches over a finite constraint set (instead of an infinite grammar). A third track uses data-driven learning to infer constraints (Doyle et al., 2014), but this method only learns which words violate a given constraint, and not a symbolic or intensional definition to apply it to novel words.

We propose a model to fill the gaps between these research tracks, by inferring constraints: 1) in the absence of articulatory motivation, 2) in the presence of input forms, and 3) with explicit, symbolic constraint definitions. The model uses a simple (but infinite) grammar of constraints to jointly learn a matrix of constraint violations, likely definitions for the constraints, and relative weights on the constraints that adequately explain the observed phonological forms.

Phonological constraints and log-linearity Traditional versions of OT do not employ log-linearity, so we work with the MaxEnt OT (MEOT; Goldwater and Johnson (2003)) framework, an extension that connects constraint-based phonology to the general class of log-linear models. (Traditional, non-log-linear, OT is approximated as the difference between weights on the MEOT constraints grow.) Some existing work on phonotactic and phonological constraint learning (Hayes and Wilson, 2008; Doyle et al., 2014) has been based in such a log-linear framework.

As with all OT frameworks, the core structure supposes that phonological forms are produced by starting with an input form, generating a set of output candidates, determining what constraints each candidate input-output pair violates, and selecting an output form based on the number and strength of the candidates' constraint violations. There are two types of constraints: those that depend on both the input and output ("faithfulness"), and those that depend only on the output ("markedness"). Each constraint has an associated weight, which is always non-positive; no constraint violations can make an output form more likely to be chosen. MEOT is a log-linear model, so summing the weights of all violated constraints provides each candidate's linear predictor, which is logit-transformed to a probability.

In terms of the general framework from the start of this section, faithfulness constraints are known, while the markedness constraints and weights for both constraint types are unknown.[1] In addition, we assume that the definitions for the markedness constraints are generated by a PCFG over phonological features of the sounds of the output candidates. Our specific grammar is discussed in Sect. 5.2.

[1]We limit ourselves to the learning of markedness constraints in this paper, as faithfulness constraints appear to be less arbitrary than markedness constraints (McCarthy, 2008), and may be representable as part of the output candidate generation process (Riggle, 2009).

3 Model structure

We represent the constraints as two matrices: F, the observed faithfulness constraints, which depend on both input and output forms; and M, the unobserved markedness constraints, which depend only on the output form. Each cell of F and M tells the number of violations of a constraint by a given input-output mapping. F_{ijk} is the number of violations of faithfulness constraint k by input-output pair type (x_i, y_j); M_{jl} is the number of violations of markedness constraint l by output candidate y_j. For each input x_i, some subset of the output forms $\{y_j\}$ are possible; this subset will be denoted $\mathcal{Y}(x_i)$. The weight vector w provides weights for both F and M, and is unobserved.

M is a non-parametric binary matrix with a known number of rows (candidates) but an unknown number of columns (constraints). Each column $M_{\cdot l}$ of the matrix M, which we will refer to as a "violation profile", is a binary vector of length J, the number of output candidates, specifying whether the candidate y_j violates this constraint. w is a vector of real numbers; within OT, weights are strictly negative, so we draw from $-\exp(\eta_w)$.

Previous work on constraint learning (Doyle et al., 2014) generated M through an Indian Buffet Process (Griffiths and Ghahramani, 2005), with the number of constraints L generated by a Poisson prior (with parameter α) and the violation profiles generated by a rich-get-richer scheme. In the present work, we retain the Poisson prior over L, but we want the violation profiles to be derived from symbolic constraint definitions d instead. The definitions are built from the underlying grammar G and specify whether each candidate y_j violates d. Within our model, we assume that a candidate y_j can be an exception to the definition d (switching a one to zero or vice versa in M_{jl}), and the number of exceptions is drawn from a exponential prior (Rational Rules framework; Goodman et al. (2008)). Thus, given a constraint definition d_l, the probability of it producing a violation profile $M_{\cdot l}$ is given by

$$p(M_{\cdot l}|d) \propto \exp(-bQ(M_{\cdot l}; y_\cdot, d_l)) \tag{1}$$

where $Q(M_{\cdot l}; y_\cdot, d_l)$ is the number of exceptions in $M_{\cdot l}$ given candidates $\{y_j\}$ and definition d_l, and b is the exception parameter, with larger b penalizing exceptions more strongly. As neither the true violation matrix M nor the true constraint definitions d are observed, we estimate the probability of a violation profile $M_{\cdot l}$ by marginalizing over possible constraint definitions (see Sect. 4.1).

The probability of whole observed corpus Y is the product of the probabilities across all observed input-output pairs:

$$p(Y|M, F, W) \propto \prod_i \frac{\left(\exp\left(\sum_{jk} w_{Fk} F_{ijk} + \sum_{jl} w_{Ml} M_{jl}\right)\right)^{n_{ij}}}{\left(\sum_{y_z \in \mathcal{Y}(x_i)} \exp\left(\sum_k w_{Fk} F_{izk} + \sum_l w_{Ml} M_{zl}\right)\right)^{n_{i\cdot}}} \tag{2}$$

In summary: F is observed, $w \sim -\exp(\eta_w)$, $L \sim \text{Poiss}(\alpha)$, $M_{\cdot l} \sim \exp(-bQ(M_{\cdot l}; y_\cdot, d_l))$, and $d_l \sim \text{PCFG}(G)$. We infer likely constraint matrices and weights M and w from their joint posterior distribution, which is proportional to the product of the probabilities of the data (Eqn. 2), constraints M, and weights w:

$$p(M, w|Y, F, \alpha, b, \eta_w, G) \propto p(Y|M, F, w)p(M|b, G)p(w|\eta_w) \tag{3}$$

4 Model Inference

For the model to find appropriate constraint structures, we use Markov Chain Monte Carlo (MCMC) inference over the space of constraint definitions d, markedness matrices M, and weight vectors w.

4.1 Inference over d

Inference on M requires knowledge of the prior over violation profiles (i.e., columns of M), but this is a sum over the infinite set of constraint definitions. To estimate this, we use importance sampling over constraint definitions d. For a given profile m, we start by drawing a constraint definition d from the PCFG, then Metropolis-Hastings sample through the space of constraint definitions, with three possible

move types of equal probability: subtree replacement, incision, and excision. In terms of the constraint definitions in Sect. 5.2, replacement changes a feature value, a phoneme, or a phoneme sequence; excision removes a feature, phoneme or phoneme sequence; and insertion adds a feature, phoneme, or phoneme sequence.

Subtree replacement The first move, subtree replacement, comes from Goodman et al. (2008). Subtree replacement chooses a non-terminal node uniformly randomly in the tree, and re-draws all of its children according to the PCFG probabilities. If a subtree replacement is to be made, the jump probability of moving from tree T to T' by redrawing the subtree S_X at node X is:

$$J_R(T';T) = \frac{1}{N_R} \cdot \prod_{r \in S'_X} p(r), \tag{4}$$

where N_R is the number of non-terminal nodes in T, S'_X is the new subtree with root X, and r ranges over the rules triggered by S'_X.

Node excision The second move is node excision, which promotes a subtree one level up in the tree, eliminating its parent node and sibling subtree. It selects a node X uniformly randomly from the set of nodes that can be excised (nodes with at least one grandchild Z that is also a valid child of X under the CFG). If no excisable nodes exist in the tree, the model attempts a different move type (replacement or insertion) instead. Excision removes a node Y – the child of X and parent of Z – from the tree, as well as the current sibling of Z (with its subtree). If an excision is to be made, the jump probability of choosing to excise between X and Z in tree T to yield tree T' is:

$$J_E(T';T) = \frac{1}{N_E} \cdot \frac{1}{N_{E;X}}, \tag{5}$$

where N_E is the number of nodes in T that have at least one excisable grandchild, and $N_{E;X}$ is the number of excisable grandchildren of X in T.

Node insertion The third move, node insertion, reverses node excision. A new node is inserted between a parent and child node, and the child node gets a new sibling subtree. Node selection for insertion works similarly to excision; a node is drawn uniformly randomly from the set of insertable nodes, those that have at least one child that could also be its grandchild. As with excision, if no insertable nodes exist, a different move type is attempted. Once an insertable node X is chosen, the model chooses a child node Z uniformly among its children that could be a grandchild of X. That node becomes a grandchild of X, and the model draws a new node Y from the PCFG, such that Y is a valid child of X, parent of Z, and sibling of the remaining child node of X (call this A). Finally, Z draws a new sibling B in its new lower position, according to the PCFG. Given that an insertion is to be made to the tree T, the probability of that insertion being node Y between X and Z is:[2]

$$J_I(T';T) = \frac{1}{N_I} \cdot \frac{1}{N_{I;X}} \cdot \frac{p(X \to AY)}{p(X \to A*)} \cdot \frac{p(Y \to ZB)}{p(Y \to (Z * \mid * Z))} \cdot \prod_{r \in S_B} p(r), \tag{6}$$

where N_I is the number of nodes in T that have at least one insertable child, and $N_{I;X}$ is the number of insertable children of X in T. The third fraction is the probability of choosing Y as the new child in T', and the fourth fraction is the probability of choosing B as the new sibling of Z, as well as whether Z is the left- or right-hand child of Y. The final term is the probability of the subtree S_B.

Acceptance probability Using the jump probabilities between trees given by the above equations, we can calculate the acceptance probability of a possible Metropolis move from T to T'. This is the product of the ratio of the forward and backward jump probabilities and the ratio of the trees given the current violation profile m:

[2]This equation assumes that Z is the right-hand child of X and the left-hand child of Y. If Z is the left-hand child of X or the right-hand child of Y or both, the probability is calculated similarly, but the third or fourth fraction changes to reflect the actual structure.

$$\frac{p(m|T')p(T')J(T;T')}{p(m|T)p(T)J(T';T)}. \tag{7}$$

The Metropolis method samples constraint definitions $\{d^{(1)}, \cdots, d^{(n)}\}$ from the posterior distribution $p(d|M_{\cdot l})$. These samples are used to estimate the probability of the violation profile m given the constraint grammar G by taking the harmonic mean of $p(M_{\cdot l}|d^{(t)})$ over all samples (Newton and Raftery, 1994).[3] This provides a prior for the columns of the matrix; coupled with the Poisson prior on the number of columns, we have a phonologically-motivated prior over matrices with an indefinite number of columns.

4.2 Inference over M

Inference on M uses five possible sampling moves, all of which rely on the estimates of $p(M_{\cdot l}|G)$ obtained above. Three of the sampling moves are equivalent to previous work with non-parametric binary constraint matrices (Görür et al., 2006; Doyle et al., 2014): columns may be removed or added, and each cell M_{jl} is Gibbs sampled, potentially changing whether candidate y_j violates constraint l.

We introduce two new moves – splitting or combining columns – to more efficiently move between constraint definitions. These can shift violations that explain the data well but are exceptions within their current column into a column where they fit better. Without them, moving violations between columns requires first removing them via Gibbs sampling, which may be very unlikely due to the loss in data likelihood from the loss of critical constraint violations.

A proposed split and its acceptance probability are drawn as follows. The likelihood of a violation M_{jl} being an exception within its profile $M_{\cdot l}$ is estimated from the proportion of samples from $p(d|M_{\cdot l})$ that mark the violation as exceptional. The set of violations V to be moved is drawn as a sequence of independent Bernoulli draws based on each violation's likelihood of being an exception. The exception likelihood is smoothed using a Beta-binomial distribution with parameter β, by taking the maximum a posteriori estimate of the likelihood:

$$p(m_{jl} \in V) = \frac{N_E + \beta - 1}{N_E + N_N + 2\beta - 2} \tag{8}$$

The number of Metropolis samples in which M_{jl} was an exceptional violation is N_E and a non-exceptional violation is N_N. Higher β increases the overall smoothing, and the effect of the smoothing decreases as more Metropolis samples are drawn. We set $\beta = 100$, as we expect substantial noise due to the size of the sample space.

4.3 Inference over w

After each matrix sample, we apply Metropolis-Hastings sampling on w. Our proposal distribution is $-\Gamma({w_k}^2/\eta_M, \eta_M/-w_k)$, which the current weight w_k as its mean. We set $\eta_M = 1$ as a default.

5 Experiment

5.1 English regular plural morphophonology

We test this model on the English regular plural system, which has one underlying form (/z/) with three attested output realizations: [z], [s], or [əz] (as in *hugs, huts*, and *hushes*, respectively). Two markedness constraints drive this alternation in the standard phonological analysis, which can be written in terms of the phonetic feature sequences they penalize: [-VOI][+VOI] and [+STR][+STR]. The former penalizes outputs where consecutive consonants do not agree in voicing, and the latter penalizes outputs where consecutive consonants are both strident (s,z,sh,ch). These are coupled with three faithfulness constraints, which penalize removing, adding, or changing a phoneme (MAX, DEP, and IDENT in OT terminology).

For this experiment, we consider four candidate outputs for each input: the bare singular form, plus forms with each of the three attested allomorphs of the regular plural suffix. The candidates for plural

[3] Harmonic mean estimation can be noisy and take a large number of iterations to converge (Neal, 1994), so we tested a range of violation profiles and found consistent convergence to the expected constraint definitions and profile probabilities within a few thousand samples.

hug (underlying /hʌgz/), for instance, are [hʌg], [hʌgz], [hʌgs], or [hʌgəz]. In general, the [əz] candidate wins only when the singular ends in a strident, the [s] candidate wins only when the singular ends in a voiceless non-strident, and the [z] candidate wins the rest of the time. The training set consists of the plural forms of 26 nouns, each understood by at least 89% of 18-month-old English learners (Dale and Fenson, 1996).[4] The model is given 100 examples of each plural, always using the standard pluralization.

5.2 The constraint grammar

Potential constraint definitions are sequences of phonological feature bundles. There are 23 phonological features, each capturing different characteristics of a sound; for instance, the phoneme [s] has phonological features including [+consonantal, +strident, –voiced], while the similar phoneme [z] has features including [+consonantal, +strident, +voiced]. A feature bundle within a constraint definition matches all phonemes with all of the bundle's features. Thus a definition [+consonantal, +strident][+consonantal, +voiced] matches the strings sz and zz, but not zs. Phoneme-to-feature mappings are based on Riggle (2012).[5] To make sure that model's success is not based on the grammar generating only definitions relevant to the English plural problem, we include Kleene stars, matching zero or more consecutive occurrences of a feature bundle. While some other phonological constraint definitions, such as vowel harmony, require Kleene stars, the English plural does not.

Note that the constraints are not necessarily binary when defined as sequences of feature bundles; a candidate can contain multiple sequences that violate a constraint. But because we are considering the effect of adding a suffix to a stem word, we can subtract the stem's violations from each candidate. Since all the candidates from a given input share the singular form as a stem, the same number of violations are subtracted from all of them, and the candidate probabilities within the log-linear model are unchanged.

5.3 Model parameters and implementation

We ran the model for 200 iterations in three trial runs, with deterministic annealing on the first 100. For estimating $p(M_{.l})$, 1000 burn-in samples were taken and discarded, and 250 additional samples (every second sample out of 500 to reduce autocorrelation) of d are averaged. For violation profiles $M_{.l}$ that reoccured, each time $p(M_{.l})$ was re-calculated, half as many additional samples were drawn (125, 62, ..., to a minimum of 25) and incorporated into the average. The parameters α and η_w are set to 1 and b is set to 10, to encourage fewer constraints and parity between violations and definitions. These fit the standard phonological assumption of phonologically-motivated and parsimonious constraints.

6 Results

We tested the model's performance in four ways: how well the learned structures explain observed plurals, how well they predict novel plurals, how accurately they reflect the standard violation profiles, and how interpretable the constraint definitions are. In all cases, we compared against a baseline of the standard phonological constraints that phonological theory suggests. This baseline M was derived from the two standard English markedness constraints, [+STR][+STR] and [-VOI][+VOI], with no exceptions. Baseline weights were sampled as in Sect. 4.3, with M held constant.

Explaining observed plurals The first test is to show that the model can learn a phonological system for the observed plurals. The model satisfies this goal if it predicts the observed forms at least as well as the baseline model. We calculate both the mean and MAP values of the data likelihood (Eq. 2) over the final 100 iterations of each of the three model runs, and report the across-run means in Table 1. t-tests found no significant differences between the learned and baseline performance on the training data.

Predicting novel plurals The second test of the model is whether its learned constraints extend to newly-encountered words. This is a crucial feature for human acquisition; children quickly learn to generalize morphophonological systems. It also represents an important model improvement, as Doyle

[4]Training words: *baby, ball, balloon, banana, bath, bird, blanket, book, car, chair, daddy, diaper, door, drink, eye, hug, key, kiss, kitty, mommy, nap, nose, phone, shoe, spoon, toothbrush*

[5]There is one deviation from Riggle's system: we do not specify voicing on sonorants, because sonorants do not have voiceless versions and do not trigger [-VOI][+VOI] violations.

	MAP LL	Mean LL	Min. Cand. Prob.	Mean Cand. Prob.
Model	-2.94	-7.91	.986	.995
Baseline	-5.16	-10.6	.974	.991

Table 1: Comparing the performance of the learned constraints to the baseline of the standard phonological constraint definitions. On the left, training data log-likelihoods on the left, based on values from the final 100 iterations for the three model runs. On the right, test set probability masses for the correct plural forms. The learned constraints perform as well as the phonologically standard constraints.

et al. (2014)'s constraint learning model was incapable of making such predictions due to its strictly-extensional constraints. For the test set, we used the 25 most frequent countable nouns in the Corpus of Contemporary American English (COCA; Davies (2008)) that take regular plurals, none of which were in the training set.[6] Five of these nouns end with phonemes that did not occur word-finally in the observed data, requiring the model to have made phonological generalizations from the training data.

To assess the predictive power of the learned constraints, we obtained constraint definitions by using the $p(d|m)$ Metropolis sampler to generate a distribution over definitions for each violation profile. Violation profiles $M_{\cdot l}$ are taken from the final iteration of each model run. For a new candidate y, the probability $m_{y;l}$ that y violates constraint l was estimated using constraints d drawn from the $p(d|M_{\cdot l})$ Metropolis sampler. $m_{y;l}$ was then used as the constraint value for the log-linear predictor. Both the model and baseline constraints correctly put the highest probabilities on the correct plural forms, as shown in Table 1. All correct plural forms received at least 98% of the probability mass under the model constraints, and there was no significant difference between the model and baseline predictions.

Violation profile accuracy The previous test showed that the constraint definitions effectively extend to unobserved forms. Now we want to examine their correspondence with phonological theory. First, we want to see if the right number of constraints was learned. Two of the model runs had two markedness constraints throughout the final 100 iterations, like the baseline. The third model run used four markedness constraints over its final 100 iterations, but the extra markedness constraints supplied violations that matched two of the faithfulness constraints (DEP and IDENT). Those faithfulness constraints' weights dropped to near zero in this run, though, meaning that all learning and baseline runs had five active constraints. In the runs with two markedness constraints, we tested how their violation profiles and definitions mapped to the baseline constraints.[7] Over the final 100 iterations, the learned violation profiles agree with their corresponding baseline violation profiles on an average of 98.9% of all candidates, showing that both constraint sets have similar phonological meanings.

Similarities in constraint definitions We compared the likely constraint definitions, as estimated by the Metropolis sampler for $p(d|m)$, for the learned and baseline violation profiles to their phonologically standard counterparts. Table 2 shows the most likely constraint definitions for each violation profile, given either the baseline violation profiles (based on the standard constraint definitions) and the two-constraint runs of the model. On three of the four learned constraints, the model agrees with the inferred definition given the baseline violations. Reasons for the deviations from the phonologically standard definitions are discussed in Sect. 7.

Experiment summary We performed four tests of the constraint learner. The model learned a set of constraints and weights that could explain observed data and effectively generalize to unobserved forms. In addition, we find that the constraint definitions it learns correspond with the definitions that come from a baseline set of constraints, although additional information is needed to identify the exact same constraints as the baseline set.

[6]These words are: *time, year, way, day, thing, world, school, state, family, student, group, country, problem, hand, part, place, case, week, company, system, program, question, government, number, night*

[7]The remaining analyses are limited to the two-constraint learning runs; the four-constraint solution represents convergence failure to a local optimum with joint probability (Eq. 3) well below the two-constraint solutions because of its lower probability M. Better exploration of the constraint space would move this run toward the two-constraint solution.

Standard	Baseline	Model Run 1	Model Run 2
[+STR][+STR]	[+STR][-SYL]	[+STR][-SYL]	[+STR][-SYL]
[-VOI][+VOI]	[-VOI][+VOI]	[-VOI][+VOI]	[-VOI,-STR][-SG,-HI]*[-NAS,+VOI]
Key: voi=voicing, str=strident, sg=spread glottis, hi=high, nas=nasal, syl=syllabic			

Table 2: The phonological standard definitions and the most likely constraint definitions inferred in the baseline and model runs. Baseline/model d likelihoods based on 10000 samples from $p(d|m)$.

7 Discussion

Definitional ambiguity Although the constraints extend seamlessly to new data and their violation profiles mostly match, Table 2 showed the constraint definitions don't quite match the standard definitions. This is because multiple definitions can have identical violation profiles, as there are many phonological features; for instance, based on the first constraint's violation profile, the model has learned to penalize sz and zz sequences, but not səz. Phonological theory says that this constraint's definition is [+STR][+STR], but given the available data, any feature that is negative for [z] and [s] but positive for [ə] (or vice versa) will produce the same violation pattern, and the model has no reason to prefer one to the other.[8]

The complex definition of the second constraint in the second model run arises similarly. Small differences (8% of violations) between the model and baseline violation profiles lead the model to infer this more complicated definition, which penalizes stems ending in voiceless non-stridents getting either the [əz] suffix (with [ə] matching the [-SG,-HI] bundle and [z] matching [-NAS,+VOI]) or the [z] suffix (with the Kleene star vacuously satisfied). Such stems should get the [s] suffix, so this constraint definition is consistent with the observed data, and overreaching by handling two constraints' function: penalizing [z] like the [-VOI][+VOI] constraint would, but also penalizing [əz], which is covered by the faithfulness constraint DEP.

Such definitional ambiguity can be reduced through simultaneous learning of multiple phonological phenomena. The [+STR][-SYL] definition could be ruled out by observing the faithful manifestation of s-initial onset clusters in English, as in *stop* or *spin*; the Kleene-star definition could be ruled out by faithful realizations of non-harmonious *kid* or *peg*. Such learning would also be more realistic, as learners generally observe and learn a range of phonological phenomena simultaneously.

Relaxing binarity One important remaining step is to allow for non-binary constraints in the model, which could be introduced in multiple ways. One possibility is to mimic non-binary constraints through multiple, overlapping binary constraints (Frank and Satta, 1998), though this would require changes to the current PCFG. Another possibility is to treat the existing binary matrix as an indicator of whether a constraint is violated and add a second matrix, with positive integer values, corresponding to the number of violations of that constraint. Griffiths and Ghahramani (2011) use a similar design to overcome the binary nature of an Indian Buffet Process for object recognition.

Theory testing Our model also represents a way to investigate the plausibility of different theoretical statements of a constraint, casting constraint selection through the lens of model comparison. In addition, if the underlying constraint grammar is varied, this model could be used to investigate the plausibility and effectiveness different potential grammars.

8 Conclusion

We presented a model for learning binary, symbolically-defined constraints in a log-linear model from a combination of observational data and an infinite grammar over constraint definitions. We tested this model on a morphophonological problem and showed that it accurately inferred the values of the constraints, and found appropriate constraint definitions (though with some issues of definitional ambiguity).

[8] In fact, $p(d|m)$ is approximately equal for a range of constraint definitions that include [+STR][-SYL], [+STR][+STR], [+STR][-LABIAL], and others.

Abstract

This paper explores the role of tense information in Chinese causal analysis. Both tasks of causal type classification and causal directionality identification are experimented to show the significant improvement gained from tense features. To automatically extract the tense features, a Chinese tense predictor is proposed. Based on large amount of parallel data, our semi-supervised approach improves the dependency-based convolutional neural network (DCNN) models for Chinese tense labelling and thus the causal analysis.

1 Introduction

Causal analysis plays a crucial role in the applications such as event extraction (Hashimoto et al., 2012; 2014), causality inference (Tanaka et al., 2012), question-answering (Oh et al., 2013), and motivation identification (Nguyen et al., 2015). Compared to English, the topic of causal analysis in Chinese is rarely touched. In this work, we explore the role of tense information in Chinese causal analysis. As pointed by Mirza (2014), the causal relation and temporal information is correlated. In a causal relation, the cause intuitively precedes its effect. In other words, the tense information could be useful features in the tasks of causal analysis.

Two tasks of causal analysis are investigated in this study: causal type classification and causal directionality identification. The Chinese discourse relation corpus, Chinese Discourse Treebank (CDTB) (Li et al., 2014), is adopted as our dataset. In CDTB, six types of causality relations, **Purpose**, **Background**, **Hypothetical**, **Inference**, **Condition**, and **Cause-Result**, are defined.

A discourse relation connects two arguments. In the case of causality, one of the two arguments (e.g., *arg*1) presents a situation, and it is causally affected by the other argument (e.g., *arg*2). For example, the first part of the sentence (S1) shows a reason, and the second part, which is underlined, is its effect.

(S1) 由於產能不足，國內自給率不到四成，大部分要仰賴進口。 (Because of insufficient capacity, the domestic self-sufficiency rate is less than 40, most rely on imports.)

The direction of *arg*1 and *arg*2 is reversible. Like (S1), the reason is described in the former argument in most cases, and the effect is presented in the latter argument. However, (S2) shows a counter-example that presents the effect in the former part. To exactly extract the cause and the effect in natural language, causal directionality identification is required.

(S2) 西藏銀行部門積極調整信貸結構，以確保農牧業生產等重點產業的投入，加大對工業，能源，交通，通信等建設的正常資金供應量。(Tibet banking sector actively adjust credit structure in order to ensure the input of agricultural production and other key industries, and increase the industrial, energy, transportation, communications, construction of the normal supply of funds.)

There is no tense annotation in the CDTB. For this reason, we select all the samples of causality re-

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2227–2237, Osaka, Japan, December 11-17 2016.

lation from CDTB, and manually label the tense for each argument as ground-truth for the two tasks. To automatically extract the tense features, a Chinese tense predictor is required. The grammatical tense in English explicitly denotes the temporal information for a given text. In Chinese, however, the temporal information is communicated with aspect particles such as 了 (le) and 着 (zhe) and temporal adverbials such as 現在 ("now") and 明天 ("tomorrow") (Xue et al., 2008; Ge et al., 2015). In other words, it is more challenging to determine the tense in Chinese text. Thus, we propose a semi-supervised algorithm that learns to label tense information in Chinese text. With UM-Corpus, a large English-Chinese parallel corpus aligned at sentence-level (Tian et al., 2014), we generate a pseudo-labelled Chinese tense corpus by deriving the tense information from their English counterpart. Dependency-based convolutional neural network (DCNN) is trained to predict Chinese tense. We incorporate the semi-supervised Chinese tense predictor in the tasks of causal type classification and causal directionality identification. The experimental results are compared with the supervised approach and the ideal situation where human-labelled information is available.

The contribution of this paper is three-fold: (1) we transfer the tense information from English sentence to its Chinese counterpart based on sentence-aligned English-Chinese parallel corpus, (2) we train Chinese tense predictor with DCNN and use it to label tense markers on a Chinese sentence, and (3) we apply the tense information to identify causal type and causal directionality of a sentence. The rest of this paper is organized as follows. Section 2 surveys the related work. Section 3 describes the experimental materials. Section 4 shows our approach to Chinese tense labelling. Section 5 illustrates the use of tense information in causal type and causal directionality identification. Section 6 concludes this paper.

2 Related Work

Causal analysis attracts much attention in AI community for years. A variety of issues have been explored. One of the hottest topic is event analysis, where causal information plays a crucial role (Do et al., 2011; Riaz and Girju, 2013; 2014; Mirza and Tonelli, 2014; Kives et al., 2015). Other applications include generation of event causality hypotheses (Hashimoto et al., 2015), motivation identification (Nguyen et al., 2015), causality detection and extraction (Hashimoto et al., 2012; Mihaila and Ananiadou, 2013), causal inference (Tanaka et al., 2012), question answering (Oh et al., 2013), and future scenario generation (Hashimoto et al., 2014). The correlation between temporality and causality is studied by Mirza (2014) and Mirza and Tonelli (2014).

Unlike English, no grammatical tense is available in Chinese. Various approaches are explored to address the topic of Chinese tense prediction. Liu et al. (2011) propose an unsupervised method for Chinese tense labelling by learning from a Chinese-English parallel corpus. Zhang and Xue (2014) deal with Chinese tense inference by training a supervised model with various linguistic features on a Chinese tense corpus (Xue and Zhang, 2014). Following the unsupervised method by Liu et al. (2011), we develop a semi-supervised model that benefits from a large amount of data labelled by an accurate English tense predictor.

Neural networks such as recurrent neural network (RNN) and convolutional neural network (CNN) are very popular in NLP community. Kim (2014) releases a sentence classifier with convolutional neural network (CNN), where a sentence is represented as a sequence of word vectors (Mikolov et al., 2013). Based on Kim's work, Ma et al. (2015) propose the dependency-based CNN (DCNN) by adding the structure information features to the sentence representation. In this work, we employ DCNN for Chinese tense classification under supervised, unsupervised, and semi-supervised learning.

3 Linguistic Resources

Three types of corpora are used in this work. Section 3.1 describes the corpus for Chinese causal analysis. Section 3.2 and Section 3.3 introduce the corpora for developing our Chinese tense predictor.

3.1 Chinese Causality Corpus

There are few resources for Chinese causal analysis. In this work, we extract instances labelled with causality relation in the Chinese Discourse Treebank (CDTB) (Li et al., 2014) as the basis of our causality dataset. Similar to the English discourse corpus, e.g., Penn Discourse Treebank (PDTB) (Prasad

et al., 2008), CDTB is a Chinese corpus annotated with discourse information. A type of discourse relation is given to a pair of text spans (arguments). For instances of the explicit discourse relation, the connectives (discourse markers) are also annotated.

CDTB does not provide the information of causal directionality. Here we manually label the directionality for each instance extracted from CDTB. Table 1 summarizes the six types of the causality relation. The distributions of explicit/implicit and directionality are shown. Cause-Result, which appears more than 50%, is the majority. Most cases are implicit except Hypothetical and Condition. In terms of directionality, 73.1% of instances are in the direction of Reason-Effect. Furthermore, all the instances of Hypothetical, Inference, and Condition are Reason-Effect. In contrast, 78% of Purpose instances are Effect-Reason. In general, Chinese speakers tend to express the reason before the effect. We release the annotated tense corpus as a resource for NLP community.[1]

Causal Type	Number of Instances	Explicit or Implicit	Number of Instances	%	Directionality	Number of Instances	%
Purpose	332	Explicit	162	48.8%	Reason-Effect	73	22.0%
		Implicit	170	51.2%	Effect-Reason	259	78.0%
Background	127	Explicit	4	3.1%	Reason-Effect	98	77.2%
		Implicit	123	96.9%	Effect-Reason	29	22.8%
Hypothetical	69	Explicit	55	79.7%	Reason-Effect	69	100.0%
		Implicit	14	20.3%	Effect-Reason	0	0.0%
Inference	38	Explicit	3	7.9%	Reason-Effect	38	100.0%
		Implicit	35	92.1%	Effect-Reason	0	0.0%
Condition	71	Explicit	37	52.1%	Reason-Effect	71	100.0%
		Implicit	34	47.9%	Effect-Reason	0	0.0%
Cause-Result	677	Explicit	200	29.5%	Reason-Effect	612	90.4%
		Implicit	477	70.5%	Effect-Reason	65	9.6%
Total	1,314	Explicit	461	35.1%	Reason-Effect	961	73.1%
		Implicit	853	64.9%	Effect-Reason	353	26.9%

Table 1: Statistics of the causality relations in Chinese causality corpus.

3.2 Chinese Tense Corpus

Human-annotated and machine-generated Chinese tense corpora will be used to learn Chinese tense predictor. The human-annotated Chinese tense corpus was developed by Xue and Zhang (2014). Based on a word-aligned Chinese-English parallel treebank, tense, modality, eventually, and event types are manually annotated. Due to the copyright issue, only a subset of data is available for us. For every event, one of the seven tenses is labelled: “Past”, “Present”, “Future”, “Relative Past”, “Relative Present”, “Relative Future”, and “None”. We convert all the relative tenses to absolute ones. Finally, total 3,358 instances are extracted. Figure 1 shows the distribution of the human-annotated dataset used in the experiments.

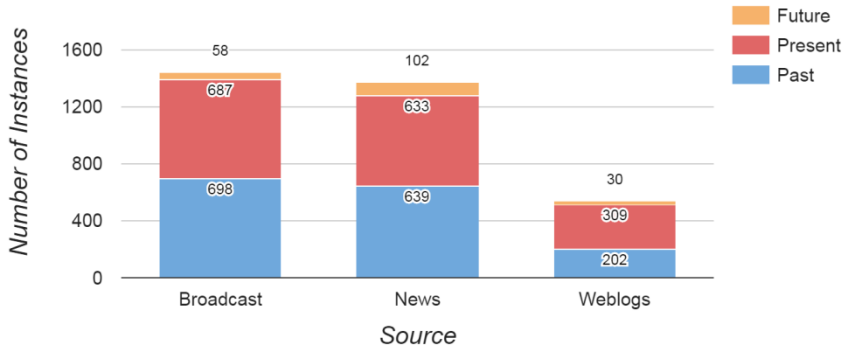

Figure 1: Distribution of instances extracted from the human-labelled Chinese tense corpus.

[1] http://nlg.csie.ntu.edu.tw/nlpresource/chinese_causality

3.3 English-Chinese Parallel Corpus

In contrast to the human-annotated Chinese tense corpus, a large English-Chinese parallel corpus, UM-Corpus (Tian et al., 2014), is adopted to label Chinese sentences with tense information. In UM-Corpus, text from eight domains are collected and aligned at sentence-level. A total of 2,215,000 sentences are released. How to develop the machine-generated Chinese tense corpus will be described in Section 4.2.

4 Chinese Tense Labelling

Because grammatical tense is inherent in an English sentence, tense prediction is relatively easier. A large amount of pseudo-labelled data can be generated by tense mapping between English-Chinese parallel sentences. Section 4.1 shows a rule-based tense predictor to determine the tense in the English side. Section 4.2 specifies how to transfer the tense information to its Chinese counterpart by bilingual verb alignment. Section 4.3 proposes a dependency-based convolutional neural network (DCNN) to predict Chinese tense.

4.1 Rule-based English Tense Predictor

Based on the definition of the Stanford typed dependencies[2], we develop a rule-based English tense predictor. For each of the 18 combinations among tenses, voices, and aspects, Table 2 presents the rules in the tense determination. Figure 2 illustrates the dependency tree of the sentence "He was being punished", where the verb "punished" is tagged as VBN (past participle verb), and its dependents contain aux(was/VBD) and auxpass(being/VBG). According to the rules in Table 2, the tense of this sentence is past, the voice is passive, and the aspect is progressive.

Tense	Voice/Aspect	Verb POS	Dep. Auxiliary Verb	Sample
Present	Active/Simple	VB, VBP, VPZ		I write.
	Active/Progressive	VBG	aux(am/VBP)	I am writing.
	Active/Perfect	VBN	aux(have/VBP)	I have written.
	Passive/Simple	VBN	auxpass(is/VBZ)	He is punished.
	Passive/Progressive	VBN	aux(is/VBZ), auxpass(being/VBG)	He is being punished.
	Passive/Perfect	VBN	aux(has/VBZ), auxpass(been/VBN)	He has been punished.
Past	Active/Simple	VBD		I wrote.
	Active/Progressive	VBG	aux(was)-VBD	I was writing.
	Active/Perfect	VBN	aux(had)-VBD	I had written.
	Passive/Simple	VBN	auxpass(was/VBD)	He was punished.
	Passive/Progressive	VBN	aux(was/VBD), auxpass(being/VBG)	He was being punished.
	Passive/Perfect	VBN	aux(had/VBD), auxpass(been/VBN)	He had been punished.
Future	Active/Simple	VB	aux(will/MD)	I will write.
	Active/Progressive	VBG	aux(will/MD), aux(be/VB)	I will be writing.
	Active/Perfect	VBN	aux(will/MD), aux(have/VB)	I will have written.
	Passive/Simple	VBN	aux(will/MD), auxpass(be/VB).	He will be punished.
	Passive/Progressive	VBN	aux(will/MD), aux(be/VB), auxpass(being/VBG)	He will be being punished.
	Passive/Perfect	VBN	aux(will/MD), aux(have/VB) auxpass(been/VBN)	He will have been punished

Table 2: Rules for English tense prediction with the information of POS tagging and dependency parsing.

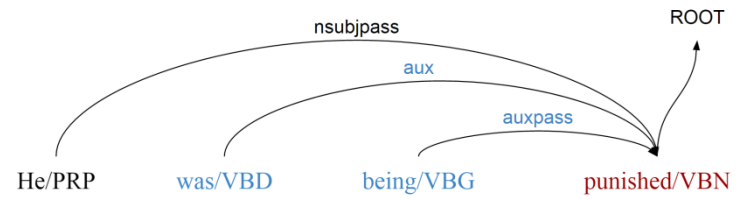

Figure 2: Dependency tree of the sentence "He was being punished".

[2] http://nlp.stanford.edu/software/dependencies_manual.pdf

We evaluate the performance of the English tense predictor on the dataset from the NTHU Academic Writing Database[3]. In this dataset, 1,171 English sentences are carefully annotated with linguistic information such as tense, voice, aspect, and argumentative zone. Our rule-based tense predictor achieves an accuracy of 91.98%. Error analysis shows that most wrongly labelled instances are due to the errors of POS tagging and dependency parsing. (S3) shows an example. The verb (VB) "image" is wrongly labelled as a noun (NN) by the Stanford tagger. Our rule-based English tense predictor is released as a tool[4].

(S3) "When combined with multiphoton excitation, both schemes can image thick samples with three-dimensional optical sectioning and much improved resolution."

4.2 Machine-generated Chinese Tense Corpus

As described in Section 3, total 2,215,000 English-Chinese parallel sentences are released in UM-Corpus. We perform Chinese word segmentation, POS tagging, and dependency parsing for the Chinese sentences with Stanford CoreNLP (Manning et al., 2014). UM-Corpus is aligned at sentence level, but a sentence may contain multiple verbs. For a sentence with multiple verbs, we employ the alignment tool GIZA++[5] to align English verbs with their Chinese counterparts (Och and Ney, 2003). However, not all cases are perfectly aligned. In the example shown in Figure 3, the English verb "go" is wrongly aligned with two Chinese tokens 那回 ("that time") and 去 ("go") because the Chinese word segmenter does not correctly separate 那 ("the") and 回 ("back"). To reduce the noise, we remove all the instances that fail to align. As a result, we obtain 615,521 Chinese instances with tense information as the pseudo-labelled corpus.

Table 3 shows the statistics of this corpus. On the one hand, instances of the *present* tense, which occupy 63.75%, are the majority. On the other hand, only 6.7% of the instances are with the *future* tense. Among all domains, the odd distribution of Law is observable. About 49.09% of the instances in the Law domain are in *future* tense because most legal provisions are made to regulate what will happen in the future. Microblog is the smallest domain, i.e., only 954 instances are found.

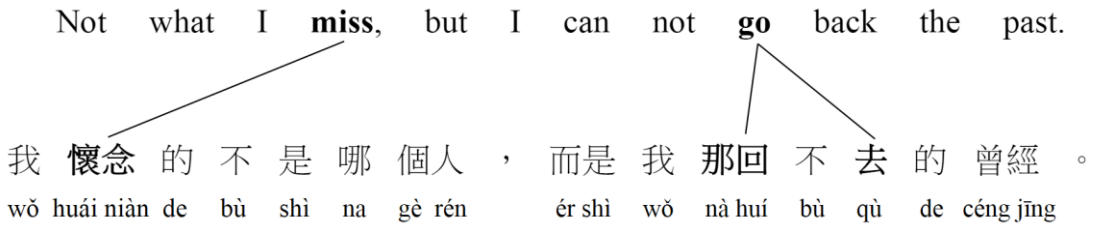

Figure 3: An imperfectly aligned case where the English verb "go" is aligned with two Chinese tokens due to word segmentation error.

4.3 DCNN-Based Chinese Tense Predictor

Tense labelling for a given sentence is a task of sentence classification. In this work, we employ the dependency-based convolutional neural network (DCNN) as the classifier (Ma et al., 2015). Based on the sentence classifier with CNN (Kim, 2014), the DCNN gains improvement by incorporating the information of linguistic structure. In addition to a sequence of word vectors like the skip-gram (Mikolov et al., 2013), the outcome of dependency parsing such as ancestor paths and siblings are added to the sentence representation. In this work, the skip-gram is trained on the Tagged Chinese Gigaword (CGW) corpus 2.0 (Graff et al., 2005; Huang, 2009), and a Chinese word is represented as a vector with a dimension of 400.

Table 3: Distribution of the machine-labelled Chinese tense corpus.

4.3.1 Unsupervised Learning for Chinese Tense Labelling

In the setting of unsupervised learning, we train the DCNN classifier on the machine-generated Chinese tense corpus, and test on the human-annotated Chinese tense corpus. The support vector machine (SVM) with RBF kernel and the random forest (RF) classifiers are also trained as baseline models. The hyperparamters of both classifiers are adjusted with grid search. The McNemar test is applied for significance testing at p=0.05. Table 4 shows the results in accuracies in the order of domain size. In general, the more the data, the better the performance. All the three models trained on the tiny Microblog dataset are superior to those trained on Law, the relatively larger dataset, because of the odd distribution of the Law domain. The DCNN significantly outperforms the other two models in most domains except for Microblog and Subtitles. DCNN with the data from all domains achieves the highest accuracy of 68.62% in the unsupervised approach. The performances of SVM and RF with all data are slightly decreased. That confirms the selection of pseudo data is crucial for traditional classifiers (Liu et al., 2011). In contrast, the DCNN model is not affected by this issue. That shows the high discriminative ability of the neural network model.

Domains	Number of Instances	DCNN	SVM	RF
Microblog	954	48.62%	50.14%	49.45%
Law	30,054	43.28%	41.06%	40.75%

4.3.2 (Semi-)Supervised Learning for Chinese Tense Labelling

This section evaluates our model under supervised and semi-supervised learning. Five-fold cross validation is performed on the 3,358 genuine instances. For each fold, one fifth of 3,358 genuine instances (human-annotated) are used for testing, and four-fifth of 3,358 genuine instances and various amounts of pseudo-labelled (machine-generated) data are used for training. Table 5 compares the accuracies of

Settings	# Genuine Data	# Pseudo Data	DCNN	SVM	RF
Supervised	3,358	0	66.77%	64.79%	65.92%
Unsupervised	0	615,521	68.62%	62.20%	61.57%
Semi-Supervised	3,358	10,000	68.00%	66.10%	62.85%
	3,358	20,000	68.59%	66.33%	61.99%
	3,358	100,000	67.97%	66.60%	63.80%
	3,358	300,000	68.56%	66.42%	64.13%
	3,358	615,521	**69.64%**	65.86%	63.83%

Table 5: Comparison of supervised, unsupervised, and semi-supervised learning for Chinese tense labelling.

supervised, unsupervised, and semi-supervised training. Our model gains improvement by adding the genuine instances to large pseudo-labelled corpus. Compared to supervised training, adding the pseudo-labelled data increases the performance of DCNN up to 69.64%. SVM is also improved under semi-supervised training. RF is a counter-example that performs best under supervised training, but still does not compete with DCNN.

5 Causal Analysis

The DCNN-based Chinese tense predictor is used to label the tense features to the instances in the causal corpus. Sections 5.1 and 5.2 confirm if the two tasks of causal analysis gain improvement from tense information. This work focuses on the correlation between tense information and causal analysis in Chinese text. The bag-of-word SVM classifiers with or without tense features are experimented to verify if the tense information improves the two tasks of causal analysis. The tense features consist of six binary values: *arg*1-*is-past*, *arg*1-*is-present*, *arg*1-*is-future*, *arg*2-*is-past*, *arg*2-*is-present*, and *arg*2-*is-future*. Three sources of tense features are compared: labelled by the supervised model (M_{super}), labelled by the semi-supervised model (M_{semi}), and labelled by human (M_h). Refer to Section 4.3.2, the supervised model is the DCNN-based Chinese tense predictor trained on 3,358 genuine data. The semi-supervised model is the DCNN-based Chinese tense predictor trained on the combination of 3,358 genuine and 615,521 pseudo data. The model with human-labelled tense, M_h, is an ideal model since human-labelled information is unavailable in real applications. Five-fold cross validation is performed. The hyperparameters are adjusted for the SVM (RBF) classifier with grid search. The McNemar test is applied for significance testing at p=0.05.

5.1 Causal Type Classification

In the task of causal type classification, the model predicts one of the six causal types for a given argument pair. The performances measured in accuracy and macro F-score are given in Table 6. Compared to the model with only Word feature (M_w), tense information indeed improves the performance of this task. M_h is significantly superior to M_w at p=0.05. Furthermore, it is surprising that M_{semi} competes with M_h.

Model	M_w		M_{super}		M_{semi}		M_h	
	Accuracy	F-Score	Accuracy	F-Score	Accuracy	F-Score	Accuracy	F-Score
Explicit	75.48%	44.74%	76.35%	44.93%	76.57%	46.48%	**77.00%**	**46.63%**
Implicit	59.78%	30.84%	60.60%	29.09%	**62.36%**	**32.48%**	62.25%	29.71%
Overall	65.28%	35.71%	66.11%	34.64%	67.33%	**37.38%**	**67.41%**	35.64%

Table 6: Experimental results of causal type classification.

The confusion matrices of M_h and M_{semi} are shown in Tables 7 and 8, respectively. M_h tends to predict an instance to Cause-Result, the largest type of the six. In contrast, M_{semi} is fairer that more instances are classified to minor types.

(S4) is an example which is correctly classified to Cause-Result by M_{semi}, but wrongly classified to Background by M_h. The part of effect is underlined, while the rest is the part of reason. This instance shows the grey zone between Cause-Result and Background. By definition, Cause-Result holds on a stronger factually cause-effect relation.

Types	Purpose	Background	Hypothetical	Inference	Condition	Cause-Result
Purpose	66.57%	0.00%	0.30%	0.00%	1.51%	31.63%
Background	6.30%	19.69%	0.00%	0.79%	0.00%	73.23%
Hypothetical	13.04%	0.00%	49.28%	0.00%	1.45%	36.23%
Inference	10.53%	7.89%	0.00%	5.26%	5.26%	71.05%
Condition	21.13%	1.41%	1.41%	0.00%	21.13%	54.93%
Cause-Result	6.20%	4.73%	0.74%	0.44%	0.89%	87.00%

Table 7: Confusion matrix of the model with human-labelled tense features.

Types	Purpose	Background	Hypothetical	Inference	Condition	Cause-Result
Purpose	72.29%	0.60%	0.30%	0.00%	1.20%	25.60%
Background	6.30%	31.50%	0.00%	0.79%	1.57%	59.84%

Inference	10.53%	15.79%	0.00%	5.26%	5.26%	63.16%
Condition	28.17%	1.41%	1.41%	0.00%	22.54%	46.48%
Cause-Result	9.45%	6.20%	1.33%	0.44%	0.74%	81.83%

Table 8: Confusion matrix of the model with the tense features labelled by our semi-supervised tense predictor.

(S4) 僅中國陸上三大天然氣最富集的四川盆地，近四十多年來，已累計生產一千六百三十三億立方米天然氣。基本上解決了成都、重慶等一批大中城市的民用燃料，並形成以天然氣為原料的中國最大的維尼龍生產線四川維尼龍廠。 (Sichuan Basin, the only place with the three major natural gas resources in China, nearly forty years, has produced a total of 163.3 billion cubic meters of natural gas. This basically provided domestic fuel for Chengdu, Chongqing and other cities, and found the Sichuan Vinylon plant, China's largest production line of Vinalon using natural gas as raw materials)

5.2 Causal Directionality Identification

In the task of causal directionality identification, the binary classifier predicts one of the two direction (i.e., Reason-Effect and Effect-Reason) for a given argument pair. Refer to Table 1, 73.1% of instances in the direction of Reason-Effect, and no instances in the direction of Effect-Reason are found in the Hypothetical, Inference, and Condition types. Thus, only the performances of Purpose, Background, and Cause-Result are reported in Table 9. The results are consistent with the task of causal type classification. The ideal model M_h achieves the best performance and significantly outperforms M_w (p=0.05), and M_{semi} is second.

Model	M_w		M_{super}		M_{semi}		M_h	
	Accuracy	F-Score	Accuracy	F-Score	Accuracy	F-Score	Accuracy	F-Score
Purpose	87.04%	78.31%	88.25%	81.23%	88.85%	82.19%	91.26%	86.04%
Background	77.16%	43.55%	77.16%	43.55%	77.16%	43.55%	78.74%	50.39%
Cause-Result	90.84%	54.52%	90.84%	53.29%	90.84%	55.68%	91.13%	59.18%
Overall	88.18%	60.52%	88.53%	60.35%	88.71%	62.06%	89.76%	66.03%

Table 9: Experimental results of causal directionality identification.

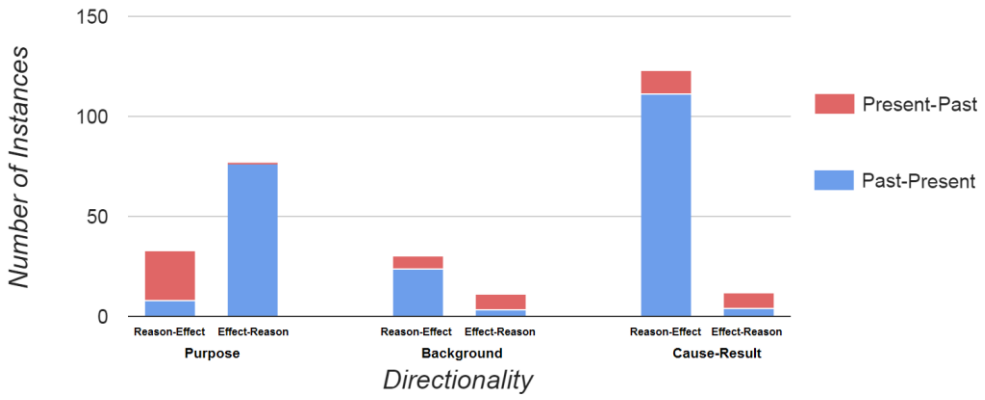

Figure 4: Relationship between causal directionality and chronology.

Figure 4 presents the relationship between causal directionality and chronology. Due to the sparseness of the tense of future, only the two transitions, Past to Present (forward) and Present to Past (reverse), are shown. The direction of Reason-Effect is the majority in the types of Background and Cause-Result, where the reason and the effect of most instances happen in the order of chronology. The type of Purpose is different. As the instance of Purpose shown in (S5), where the part of effect is underlined, while the rest is the part of reason. In the case of Purpose, the reason usually happens after the effect because the reason is the goal, and the effect is the manner to achieve to goal. The statistics reflects the special natural of the Purpose type.

(S5)香港特別行政區行政長官董建華今日（星期二）與四萬名信眾出席佛教界慶祝香港回歸祈福大會，為香港的繁榮安定及世界和平祝禱。(Today (Tuesday), Hong Kong Chief Executive Tung Chee-hwa and forty thousand faithful attended the Buddhist blessing event to celebrate the return of Hong Kong, for the prosperity and stability of Hong Kong and the world peace.)

6 Conclusion

This work investigates the role of tense information in Chinese causal analysis. We annotate the tense information on CDTB, and propose an approach that learns from parallel data for Chinese tense labelling. Our semi-supervised approach improves the performance of the DCNN and SVM models. The best model achieves an accuracy of 69.64% in Chinese tense labelling, while its outcome is useful information for the tasks of causal analysis.

Experimental results confirm the causal analysis tasks gain improvement from the tense features. Furthermore, we observe the high discriminative ability of the neural network model when the pseudo-labelled data are added to training set. Linguistics phenomena about causality and chronology are discussed with the evidence of data. We release the annotated tense corpus and a high performance rule-based English tense predictor for NLP community.

Abstract

Latent Dirichlet Allocation (LDA) and its variants have been widely used to discover latent topics in textual documents. However, some of topics generated by LDA may be noisy with irrelevant words scattering across these topics. We name this kind of words as topic-indiscriminate words, which tend to make topics more ambiguous and less interpretable by humans. In our work, we propose a new topic model named TWLDA, which assigns low weights to words with low topic discriminating power (ability). Our experimental results show that the proposed approach, which effectively reduces the number of topic-indiscriminate words in discovered topics, improves the effectiveness of LDA.

1 Introduction

Latent Dirichlet Allocation (LDA) (Blei et al., 2003) and its variants are generative statistical topic models providing a powerful framework for finding topics in text documents. In generative process, each document is a mixture of several topics, and the generation of each word belongs to one of the document's topics (Heinrich, 2009).

Mimno et al. have found that LDA often produces topics that are not interpretable or meaningful (Mimno et al., 2011). According to our observation, most of topics (especially those considered uninterpretable) contain some words which are common in the corpus. For example, words like 'science', 'academic' or 'abstract' in a corpus about scientific publications will appear in most of topics. To explain this kind of words more clearly, we prepare another example showed in Table 1(a). The table shows the top 5 words for 5 topics generated by standard LDA from a corpus of reviews about smart phones. Word 'phone' can be easily recognized as a common word in the corpus about phones, and we can find that all the topics contain this word. For words which are likely to scatter across many topics are difficult to discriminate different topics, we denote this kind of words, such as 'phone', as **topic-indiscriminate words**. We use the term **topic discriminating power** to denote the ability of a word discriminating different topics. Topic-indiscriminate words have low topic discriminating power.

Table 1: An example about a result of standard LDA

(a) Result of standard LDA

Topic	Word
1	sound, headphones, **phone**, bass, card
2	screen, iphone, **phone**, display, ear
3	picture, **phone**, photo, video, gb
4	memory, sd, gb, **phone**, battery
5	android, **phone**, nexus, Samsung, google

(b) Document frequency (DF) of words

Word	DF	Word	DF
phone	2041	screen	1900
memory	1553	picture	1451
sound	1221	sd	928
android	915	iphone	837
headphones	428	card	389

These topic-indiscriminate words tend to bring some irrelevant words into topics, which make these topics less interpretable. We explain the cause of this negative effect using the following example. Subjectively, in Table 1(a), we can see that Topics 1, 2, 3, 4, 5 can be easily interpreted to topics about sound, screens, pictures, memory cards and Android systems respectively. Words such as 'card' in Topic 1, 'ear' in Topic 2 and 'battery' in Topic 4 seem to be irrelevant to other words in their topics, which make these topic hard to be understood. We consider that these words are brought into topics by topic-indiscriminate words. Figure 1 shows the word co-occurrence relationship about words in Topic 1. Each node represents a word, while two words are linked together if they co-occur in the same document. We can find that word 'card' only co-occur with 'phone' and never co-occur with other words. According to (Heinrich, 2005), if two words co-occur in the same document, these two words are more likely to be assigned at the same topic in LDA. Plausibly, word 'card' is assigned to Topic 1 because of the co-occurrence with word 'phone'. Hence, it is reasonable for us to consider that topic-indiscriminate words will result in worse performance of LDA.

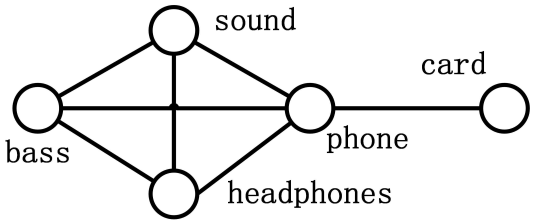

Figure 1: Graph about word co-occurrence

Wilson et al. claim that LDA should take weights of words in documents into consideration (Wilson and Chew, 2010). They consider that words which scatter across more documents are less important and should be given lower weights. We call this kind of word as document-indiscriminate words in our paper. Generally, stop words (e.g. 'the', 'of' and 'is') or common words are document-indiscriminate words, for the reason that these words appear in most of documents. Topic-indiscriminate words are a bit different from document-indiscriminate words, which is illustrated in the following example. Table 1(b) shows us top 10 most frequent words in the corpus of Table 1(a). We can find that words 'screen' and 'memory', which are kernel words for Topics 2 and 4, have high document frequency. On the other hand, they just appear in Topics 2 and 4 respectively. Therefore, they are document-indiscriminate words instead of topic-indiscriminate words, i.e. words with high topic discriminating power. In Wilson's approach, word 'screen' and 'memory' will be assigned lower weights to decrease their rankings in Topics 2 and 4. This will make topics less interpretable, as these words are important for people to understand topics. Hence, Wilson's approach has low ability to find out topic-indiscriminate words accurately, although it does well in finding document-indiscriminate words.

In this paper, we explore the topic discriminating power of LDA, and propose a new LDA model called Term Weighting LDA (TWLDA), which provides a way to measure this power according to supervised term weighting schemes. With our model, topic-indiscriminate words will be given lower weights and have less negative effect on the results of LDA. The reason why we apply supervised term weighting schemes to measure topic discriminating power is that they have been used to measure the discriminating power of words among categories in text categorization tasks (Lan et al., 2009). Words which concentrate on one topic can better discriminate that topic, and the topic discriminating power of these words are stronger. Hence, topic-indiscriminate words, whose topic discriminating power are weak, will be considered less important and be given lower weights in our proposed model. In summary, we conclude our contributions as follows: (a) We explore the topic discriminating power of words in LDA, and find that these words will make the generated topics less interpretable; (b) To solve the problem caused by topic-indiscriminate words, we propose a new model called TWLDA, which can measure the topic discriminating power of words and assign low weights to topic-indiscriminate words in order to reduce the negative effect caused by these words; (c) We explore our proposed TWLDA with different term weighting schemes, and find that supervised schemes, especially entropy-based supervised

schemes, have better performance than others; (d) We also conduct several experiments to demonstrate the effectiveness of TWLDA with different evaluation metrics.

2 Related Work

2.1 Latent Dirichlet Allocation

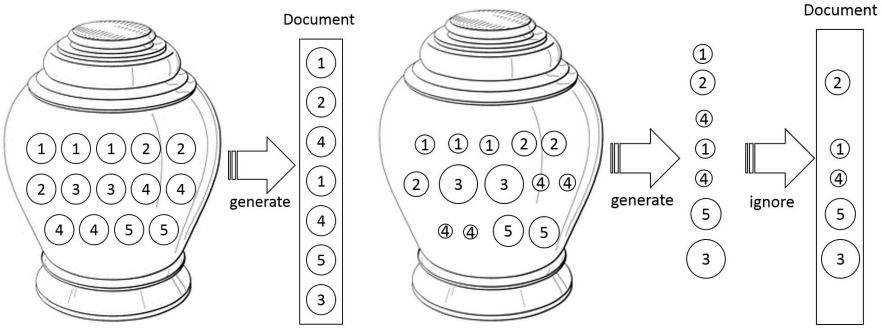
Latent Dirichlet Allocation (Blei et al., 2003) is a generative topic model. It assumes that the words in a document are drawn from a set of latent variables called topics which are distributions over words in the vocabulary.

However, some of the generated topics may mix unrelated or loosely-related words (Mimno et al., 2011). To tackle this problem, some knowledge-based topic models have been proposed in (Andrzejewski et al., 2009; Chen et al., 2013; Chen et al., 2014). These models use expert domain knowledge to guide LDA. For example, DF-LDA (Andrzejewski et al., 2009) takes domain knowledge in the form of must-links and cannot-links given by users. A must-links means that two words should be assigned to the same topic while a cannot-links means that two words should not. Besides, there are several models utilizing seed words provided by users (Burns et al., 2012; Jagarlamudi et al., 2012; Mukherjee and Liu, 2012). In some recent works, for example, GKLDA model (Chen et al., 2013) utilizes the general knowledge such as lexical knowledge to boost the performance.

2.2 Term Weighting Schemes and its Usage in LDA

Term weighting schemes are widely used to measure the importance of words in documents. They can be classified into supervised schemes and unsupervised schemes (Lan et al., 2009). The supervised schemes exploit category information of training documents while unsupervised schemes do not. There are many unsupervised schemes widely used in Information Retrieval (IR) tasks, such as tf, $tf \cdot idf$ (Sparck Jones, 1972) and some variants (Leopold and Kindermann, 2002; Paik, 2013). However, these schemes ignore the categories labels of each document. On the contrast, supervised schemes use the documents labeled with category information. Some supervised schemes are proposed recently, e.g., $iqf \cdot qf \cdot icf$ (Quan et al., 2011), rf (Lan et al., 2009) and some variants (Ko, 2012). Wang et al. propose some entropy-based term weighting schemes such as bdc which are based on the entropy of terms in categories (Wang et al., 2015). Wang et al. declare that bdc outperforms the state-of-the-art schemes, e.g. $tf \cdot idf$, $iqf \cdot qf \cdot icf$ and rf, in text categorization tasks.

Wilson et al. propose a model called WLDA, which applies term weighting schemes to weight terms in LDA. In their model, term weighting schemes are applied to measure the document discriminating power of words. Words which scatter across more documents are given relatively low weights. However, topic-indiscriminate words may not scatter across almost all the documents. Instead, they scatter across most of topics. Hence, the model proposed by Wilson et al. cannot give topic-indiscriminate words relatively low weights. To overcome this problem, we propose a new LDA model, which can give topic-indiscriminate words relatively low weights.



(a) Traditional generating process (b) Our proposed generating process

Figure 2: Word generating process

3 Generative Process Considering Weights of Words

Some of topics generated by LDA may be uninterpretable which contain irrelevant words. According to our observation, these words tend to scatter across many topics. We denote these words as **topic-indiscriminate words** due to the fact that they cannot discriminate different topics. We use the term **topic discriminating power** to denote the ability of words discriminating topics. Topics of LDA will be less interpretable if they mix with these topic-indiscriminate words. Hence, these words have much negative effect on the results of LDA.

To eliminate or alleviate the negative effect caused by topic-indiscriminate words, a possible way is to reduce the number of them occurring in documents. If the number of topic-indiscriminate words occurring in documents is discounted, the negative effect of these words to the results of LDA will also be alleviated (Heinrich, 2005). Inspired by this way, we propose a new generative process, which take weights of words into consideration. If a word gets a lower weight, the number of this word will be discounted more strongly in documents. Therefore, words with lower weights will have less negative effect on the results of LDA.

To explain our generative process, we describe the procedure of generating words from one topic in Figure 2. The urn represents the word distribution of a topic. Each ball has a mark number, which corresponds to a word in the vocabulary. The number of the balls is proportional to the number of words in the topic, while the size of balls represents its weights. In traditional LDA, each ball is considered having the same size (shown in Figure 2 (a)). In our proposed process, the sizes of balls are varied according to their weights (shown in Figure 2 (b)). The process of generating a word from a topic is as follows. Firstly, a ball is selected from the urn with the same process as traditional model. Secondly, we conduct a random choice to decide whether to put this ball into the document or not. Balls with large size are more likely to be put into the document. As the example shown in Figure 2 (b), balls '1' and '4' are smaller and are less likely to be put into the document.

4 Term Weighting LDA

According to the proposed generative process, we propose a new topic model called Term Weighting LDA (TWLDA). Section 3 has shown that words with lower weights generally have weaker negative effect on results of LDA. Since topic-indiscriminate words negatively affect the results of LDA, we expect to find out a way to give these words relatively low weights. In our work, we use supervised term weighting schemes to calculate weights of words. Supervised term weighting schemes are widely applied to measure the the importance of words in different categories in text categorization (Wang et al., 2015). We regard the topics as categories in documents. Topic-indiscriminate words, which scatter across many topics, will be considered unimportant and get relatively low weights by supervised schemes. However, the topics of words are unknown in the beginning. In order to obtain topics of words, an additional step is conducted before we calculate weights of words. In this step, we execute a topic model. This topic model can be standard LDA or other topic models, such as PLSI (Hofmann, 1999) and so on, which can find out the topics of words in documents. In summary, the proposed TWLDA consists of four main processes, which are shown as follows:

- Step 1: $\overrightarrow{\varphi'} \longleftarrow TopicModel()$
- Step 2: $\overrightarrow{\sigma} \longleftarrow Calculate(\overrightarrow{\varphi'})$
- Step 3: Discounting the number of words
- Step 4: Executing *xLDA* with the discounted values

In Step 1, a topic model is executed. Then a topic-word distribution $\overrightarrow{\varphi'}$ is generated by a this topic model.

In Step 2, according to the $\overrightarrow{\varphi'}$, we apply a supervised term weighting scheme to calculate weights of words $\overrightarrow{\sigma}$. Since supervised schemes have the ability to measure the topic discriminating power of words, in principle, all the supervised term weighting schemes can be applied here.

Step 3 is to discount the number of words by their weights. The number of words is diminished proportionally according to weights of words. Hence, the total discounted number of words in document m under topic k is calculated as follows:

$$n_m'^{(k)} = \sum_{t=1}^{t=V} \sigma_t n_{mkt} \tag{1}$$

where σ_t denotes the weight of word t, which is ranging from 0 to 1. n_{mkt} is the number of word t belonging to topic k in document m. Similarly, the total discounted number of word t under topic k is calculated as follows:

$$n_k'^{(t)} = \sum_{m=1}^{m=M} \sigma_t n_{mkt} \tag{2}$$

Step 4 is to execute the standard LDA or its variants, denoted as xLDA, using the discounted values calculated in Equations 1 and 2. Generally, xLDA can be standard LDA or its variants, such as GKLDA (Chen et al., 2013). The main procedures are the same as xLDA. We take standard LDA for example. In Gibbs Sampling process (Chatterji and Pachter, 2004), conditional probability of word t in document m under topic k is calculated using the following formula:

$$p(z_i = k|\overrightarrow{z}_{k,\neg i}, \overrightarrow{w}, \overrightarrow{\alpha}, \overrightarrow{\beta}) = \frac{n_{m,\neg i}'^{(k)} + \alpha_k}{\sum_{k=1}^{k=K}(n_{m,\neg i}'^{(k)} + \alpha_t)} \frac{n_{k,\neg i}'^{(t)} + \beta_k}{\sum_{t=1}^{t=V}(n_{k,\neg i}'^{(t)} + \beta_t)} \tag{3}$$

where $\overrightarrow{\alpha}$ and $\overrightarrow{\beta}$ are hyperparameters of the model. Equation 3 is mostly the same as the formula in the Gibbs Sampling process of traditional LDA (Geman and Geman, 1984). The difference is that those counting variables are replaced with the discounted values, such as $n_{m,\neg i}'^{(k)}$ and $n_{k,\neg i}'^{(t)}$, calculated in Step 3. Equation 3 shows that word t will have less probability to be assigned in topic k if the weight of word t is lower. As a result, words with lower weights will get lower ranking in topics. Hence, the negative effect on results of LDA caused by topic-indiscriminate words will be alleviated if their weights are relatively low. By replacing with the discounted values, other variants of LDA can also be executed in Step 4.

5 Experiment

In this section, we conduct experiments to verify the effectiveness of TWLDA. In the first experiment, we apply the following supervised term weighting schemes in TWLDA: $iqf \cdot qf \cdot icf$ and bdc. We also use unsupervised term weighting schemes $tf \cdot idf$ for comparison. Besides, we will compare the performance of TWLDA with standard LDA and WLDA, which is proposed in (Wilson and Chew, 2010). In our second experiments, we test the performance of TWLDA, WLDA and standard LDA if we do not delete stop words in the pre-processing step.

5.1 Datasets and Pre-processing

Datasets: We use two datasets in our experiments. 'dataset1' consists of online reviews from Amazon. There are totally 39,554 reviews mixed together. 'dataset2' has been used in (Chen et al., 2013), which consists of 8,958 reviews about camera and phone. We obtain it in the website [1].

Pre-processing: Reviews in 'dataset1' are preprocessed as follow. Firstly, words are converted into lower case, and the words with upper or lower case are treated as the same words. Secondly, all punctuations in documents are eliminated and only those alphabetic and numeric characters can be retained. Thirdly, we perform stemming and remove the stop words. In this work, we only use nouns,

[1] https://github.com/czyuan/GKLDA

adjective, verb and adverb. Besides, we do not preprocess $dataset2$ for it has been pre-processed in (Chen et al., 2013).

Parameter Setting: The iteration of TWLDA is set to 2500, which consists of 1000 iterations for the topic model in Step 1 and 1500 iterations for xLDA in Step 4 in Section 4. We set the iterations of preceding LDA model to 1000 due to the reason that most of topic models will converge within 1000 iterations in both two datasets which are used in our experiments. For the reason that small changes of α and β will not affect the results much (Jo and Oh, 2011; Titov and McDonald, 2008), we set $\alpha = 1$ and $\beta = 0.1$ as the setting in (Chen et al., 2013). The value of topic number K is fixed to 20.

5.2 Evaluation Metrics

In this section, we use two ways to evaluate the performance of our proposed model, one is quantitative evaluation and the other is qualitative evaluation. In quantitative evaluation, we use the Topic Coherence (Mimno et al., 2011) and $Precision@n$ as our evaluation metric. Topical Coherence (Mimno et al., 2011) is a metric commonly used to evaluate the performance of LDA, since it shows a well consistence with the judgement of human beings. In (Arora et al., 2012; Brody and Elhadad, 2010; Chen et al., 2014), Topical Coherence is used to compare the performance of different topic models. The better performance of topic model will get higher score in Topic Coherence. We also use $Precision@n$ (or $p@n$), a commonly used metric in information retrieval (Mukherjee and Liu, 2012; Zhao et al., 2010), for evaluation. Top words are more important in topic models, and we set *n* to 5, 10, 15 and 20. We ask two judges to label top 20 words in topics. Each topic is labeled as *correct* if it had more than half of its words related to each other; otherwise *incorrect*. Then, we asked these two judges to label each word of the top 20 words in topics which are labeled good. Since judges already had the conception of each topic in mind, each word was labeled *correct* if it consisted with the concept of the topic; otherwise *incorrect*. We use $p@n$ in two experiments shows in Section 5.3 and Section 5.4. Cohen's Kappa score for word labeling is showed in Table 2, which indicates high agreements between two judges with all the scores larger than 0.8 according to scale in (Landis and Koch, 1977).

Table 2: Cohen's Kappa for agreements of judges

	Topic Labeling	**Word Labeling**			
		p@5	p@10	p@15	p@20
Dataset1	0.858	0.806	0.830	0.879	0.859
Dataset2	0.832	0.842	0.875	0.892	0.872

Table 3: The number of correct topics

	dataset1	dataset2
bdc-TWLDA	15	14
WLDA	9	12
tf-idf-TWLDA	10	12
standard LDA	9	10
iqf-TWLDA	13	13

5.3 Comparison of Exiting LDA & TWLDA with Different Term Weighting Schemes

Different term weighting schemes in TWLDA can result in different performance. In our experiment, we firstly compare the performance of TWLDA using different state-of-the-art supervised term weighting schemes, such as $iqf \cdot qf \cdot icf$ and bdc. We also use $tf \cdot idf$ for comparision. We denote TWLDA using these schemes as tf-idf-TWLDA, iqf-TWLDA and bdc-TWLDA. Furthermore, we compare TWLDA with standard LDA and WLDA.

Quantitative Evaluation: For the reason that the process of Gibbs Sampling is random, we will get different results each time we run the model. We executed each model for 10 times, and calculate the average Topic Coherence value in each iteration. The results of the standard LDA using different term weighting schemes are shown in Figure 3. Figure 4 shows the average $precision@n$ of all good topics over two datasets, while Table 5.2 shows the number of correct topics. We find that:

- From the Topic Coherence results results, bdc-TWLDA and iqf-TWLDA outperform standard LDA and WLDA in both two datasets. bdc-TWLDA, which is an entropy-based scheme, performs the best. On the contrary, the results of TWLDA get worse when it apply tf-idf.

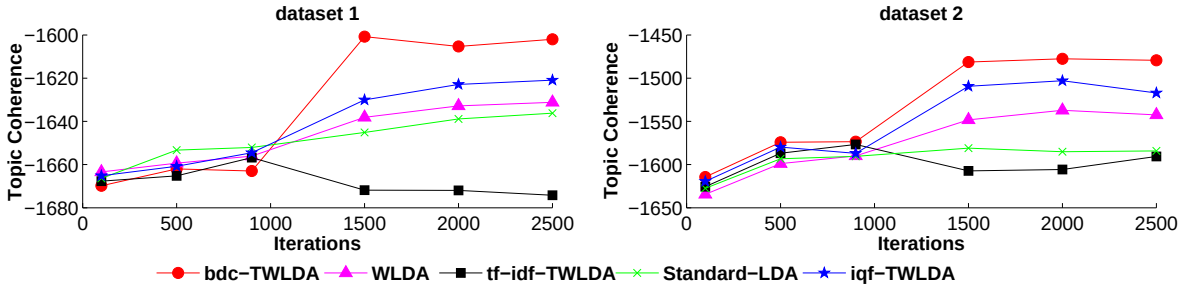


Figure 3: Comparison of TWLDA (xLDA is standard LDA) with different term weighting schemes on Topic Coherence Evaluation

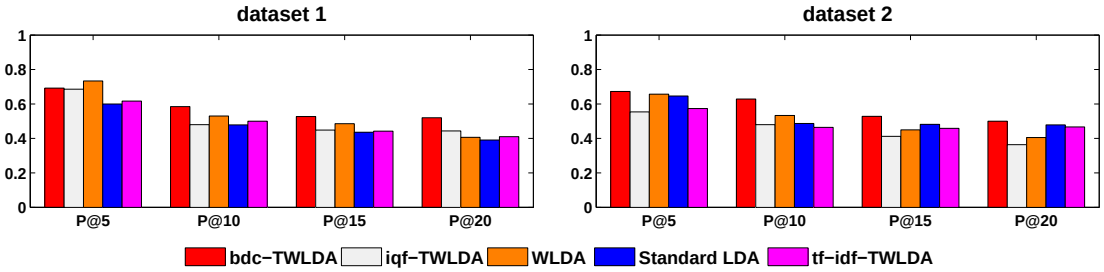

Figure 4: Average Precision@n (P@n) of coherent topics from two datasets

- From the $Precision@n$ results in Figure 4 and correct topic number in Table 5.2, bdc-TWLDA performs best and improve standard LDA by more than 10%. bdc-TWLDA generates most correct topics in both datasets, while iqf-TWLDA ranks second. Although iqf-TWLDA performs worse than WLDA in dataset2 in $Precision@n$ score, it performs better than WLDA in dataset1.

- In general, entropy-based term weighting scheme bdc performs best in both datasets. It corresponds to the experimental result of Wang et al. which shows that the bdc performs better than $iqf \cdot qf \cdot icf$. Supervised scheme $iqf \cdot qf \cdot icf$ also performs better than standard LDA at most of cases. However, tf-idf-LDA gets the worst results in both datasets.

Qualitative Results: Table 4 shows the qualitative results of LDA and bdc-TWLDA in two datasets. We choose the top 5 words of each topic generated respectively by LDA and bdc-TWLDA. We ask two judges to mark those 'bad' topics which are un-interpretable by human into red color. Although the labeling of topics may be subjective, we tried our best to have the consensus between two human judges. As the results shown in Table 4, standard LDA has 11 un-interpretable topics, while there are only 6 interpretable topics in the result of bdc-TWLDA. Furthermore, there are topic-indiscriminate words scattering across several topics, such as 'phone', 'time' and 'word'. In the results of dataset2, there are 10 uninterpretable topics in standard LDA and only 6 topics in bdc-TWLDA. We do not present the results of dataset2 for the limitation of space in our paper. We also do not show the results of WLDA here, which have 11 and 9 un-interpretable topics in dataset1 and dataset2 respectively. Overall, we can see that TWLDA shows higher performance than the standard LDA.

5.4 Performance of TWLDA without Eliminating Stop Words

To demonstrate that our approach also has good performance even though we do not eliminate stop words in the preprocessing step, we execute bdc-TWLDA, WLDA and standard LDA in the following situation: eliminating stop words and retain stop words. In this experiment, we only use dataset1, since dataset2 has been pre-processed and all the stop words have been deleted. We asked two judges to label correct topics (the labeling criteria are introduced in Section 5.2). The Cohen's Kappa value of these two judges are 0.891, which indicates they achieve high agreements. Figure 5 shows the number of correct topics in

Table 4: Quality comparison between standard LDA and bdc-TWLDA

different models when they eliminate and retain stop words. The number of correct topic in all the three models experiences a fall if they retain stop words, especially standard LDA which decreases from 9 to 2. We can also find that bdc-TWLDA still has high performance when it retain stop words.

Table 5: The number of correct topics in different models

Models	Eliminate stop words	Retain stop words	percentage of decrease
bdc-TWLDA	15	13	13%
WLDA	9	5	44%
Standard LDA	9	2	78%

5.5 Experimental Results Discussion

Our experiments show that the performance of TWLDA depends on the term weighting schemes we choose. The reason is that the capacities of different schemes measuring topic discriminating power are different. Entropy-based schemes like bdc perform the best. In information theory, words which are scattered in most of topics have larger entropy. The entropy of a word can well indicate those topic-indiscriminate words. We get the conclusion that entropy-based term weighting schemes are effective in TWLDA. In the experiments, supervised term weighting schemes outperform unsupervised term weighting schemes in TWLDA. Both bdc and $iqf \cdot qf \cdot icf$ perform better than the standard LDA, while $tf \cdot idf$ perform worse than standard LDA. The reason is that unsupervised term weighting schemes can just measure the document discriminating power of words, other than topic discriminating power.

6 Conclusions

In this paper, we firstly explore topic discriminating power of words in LDA. We observe that topics perform worse if they contain words with low topic discriminating power. These topic-indiscriminate words have negative effects on the results of LDA. In order to solve these problems, we proposed a new model called TWLDA. TWLDA can apply different supervised term weighting schemes to give topic discriminating words relatively low weights in LDA or variants of LDA. The results show that TWLDA has a significant performance while applying supervised term weighting schemes like *bdc*. The number of topic-indiscriminate words is reduced in topics generated by TWLDA with *bdc*.

Abstract

Deep learning techniques are increasingly popular in the textual entailment task, overcoming the fragility of traditional discrete models with hard alignments and logics. In particular, the recently proposed attention models (Rocktäschel et al., 2015; Wang and Jiang, 2015) achieves state-of-the-art accuracy by computing soft word alignments between the premise and hypothesis sentences. However, there remains a major limitation: this line of work completely ignores syntax and recursion, which is helpful in many traditional efforts. We show that it is beneficial to extend the attention model to tree nodes between premise and hypothesis. More importantly, this subtree-level attention reveals information about entailment relation. We study the recursive composition of this subtree-level entailment relation, which can be viewed as a soft version of the Natural Logic framework (MacCartney and Manning, 2009). Experiments show that our structured attention and entailment composition model can correctly identify and infer entailment relations from the bottom up, and bring significant improvements in accuracy.

1 Introduction

Automatically recognizing sentence entailment relations between a pair of sentences has long been believed to be an ideal testbed for discrete approaches using alignments and rigid logic inferences (Zanzotto et al., 2009; MacCartney and Manning, 2009; Wang and Manning, 2010; Watanabe et al., 2012; Tian et al., 2014; Filice et al., 2015). All of these methods are based on sparse features, making them brittle for unseen phrases and sentences.

Recent advances in deep learning reveal another promising direction to solve this problem. Instead of discrete features and logics, continuous representation of the sentence is more robust to unseen features without sacrificing performance (Bowman et al., 2015). In particular, the attention model based on LSTM can successfully identify the word-by-word correspondences between the two sentences that lead to entailment or contradiction, which makes the entailment relation inference more focused on local information and less vulnerable to misleading information from other parts of the sentence (Rocktäschel et al., 2015; Wang and Jiang, 2015).

However, conventional neural attention models for entailment recognition problem treat sentences as sequences, ignoring the fact that sentences are formed from the bottom up with syntactic tree structures, which inherently associate with the semantic meanings. Thus, using the tree structure of the sentences will be beneficial in inducing the entailment relations between parts of the two sentences, and then further improving the sentence-level entailment relation classification (Watanabe et al., 2012).

Furthermore, as MacCartney and Manning (2009) point out, the entailment relation between sentences is modular, and can be modeled as the composition of subtree-level entailment relations. These subtree-level entailment relations are induced by comparing subtrees between the two sentences, which are by nature a perfect match to be modeled by the attention model over trees.

In this paper we propose a recursive neural network model that calculates the attentions following the tree structures, which helps determine entailment relations between parts of the sentences. We model the entailment relation with a continuous representation.The relation representations of non-leaf nodes are recursively computed by composing their children's relations. This approach can be viewed as a *soft* version of Natural Logic (MacCartney and Manning, 2009) for neural models, and can make the recognized entailment relation easier to interpret.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2248–2258, Osaka, Japan, December 11-17 2016.

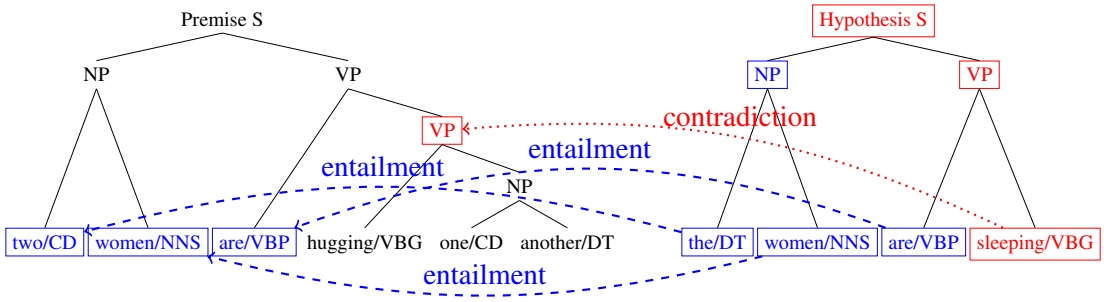

Figure 1: Exemplary trees for the premise sentence "two women are hugging one another" and the hypothesis sentence "the women are sleeping". The syntactic labels (NP, VP, CD, etc.) are not used in the model. The dashed and dotted lines show the lowest level of alignments from the hypothesis tree nodes to the premise tree nodes. The blue dashed lines mark the entailment relations, and the red dotted line marks the contradiction relation. In the hypothesis tree, tree nodes in blue squares are identified to be entailment from the premise, and nodes in red squared are identified to contradicts the premise. By composing these relations from the bottom up, we reach a conclusion that the sentence-level entailment relation is contradiction. Please also refer to Figure 5 for real examples taken from our experiments.

We make the following contributions:

1. We adapt the sequence attention model to the tree structure. This attention model directly works on meaning representations of nodes in the syntactic trees, and provides a more precise guidance for subtree-level entailment relation inference. (Section 2.2)

2. We propose a continuous representation for entailment relation that is specially designed for entailment composition over trees. This entailment relation representation is recursively composed to induce the overall entailment relation, and is easy to interpreted. (Section 2.3)

3. Inspired by the forward and reverse alignment technique in machine translation, we propose dual-attention that considers both the premise-to-hypothesis and hypothesis-to-premise directions, which makes the attention more robust to confusing alignments. (Section 2.4)

4. Experiments show that our model brings significant performance boost based on a Tree-LSTM model. Our dual-attention can provide superior guidance for the entailment relation inference (Figure 4). The entailment composition follows the intuition of Nature Logic and can provide a vivid illustration of how the final entailment conclusion is formed from bottom up (Figure 5). (Section 4)

2 Structured Attentions & Entailment Composition

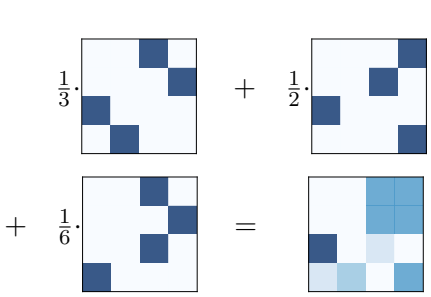
Here we first give an overview and formalization of our model, and then describe its components.

2.1 Formalization

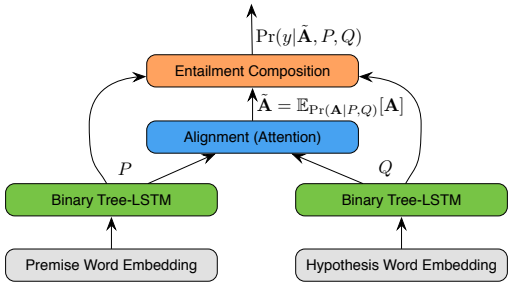
We assume both the premise tree and the hypothesis tree are binarized.

We use the premise tree and hypothesis tree in Figure 1 to demonstrate the process of our approach. The premise sentence is "two women are hugging one another", and the hypothesis sentence is "the women are sleeping".

Following the traditional approaches (MacCartney and Manning, 2009; Watanabe et al., 2012), we first find the alignments from hypothesis tree nodes to premise tree nodes (i.e., the dashed or dotted curves in Figure 1). Then we explore inducing the sentence-level entailment relations by 1) first computing the entailment relation at each node of the hypothesis tree based on the alignments, and then 2) composing the entailment relations at the internal hypothesis nodes from bottom up to the root in a recursive way. Our model resembles the work of Natural Logic (MacCartney and Manning, 2009) in the spirit that the entailment relation is inferred *modularly*, and composed *recursively*.



(a) Expected alignment over 3 alignments with probability distribution of $(\frac{1}{3}, \frac{1}{2}, \frac{1}{6})$. Each alignment is a matrix of $\{0,1\}^{4\times4}$, and the expected alignment is a matrix of $\mathbb{R}^{4\times4}$.



(b) Architecture of our neural network. Layers with the same color share the same parameters. The alignment module calculates the expected alignment $\tilde{\mathbf{A}}$. The Entailment Composition module infers the final entailment y.

Figure 2: Expected alignments calculation (a) and overview of the network architecture (b).

We formalize this entailment task as a structured prediction problem similar to Mnih et al. (2014), Ba et al. (2015), and Xu et al. (2015). The inputs are two trees: premise tree P, and hypothesis tree Q. The goal is to predict a label $y \in \{\text{contradiction}, \text{neutral}, \text{entailment}\}$. Note that although the output label y is not structured, we can still consider the problem as a structured prediction problem, because: 1) the input is a pair of trees; and 2) the internal alignments are structured.

More formally, we aim to minimize the negative log likelihood of the gold label given the two trees. The objective can be written in the online fashion as:

$$\ell = -\log \Pr(y|P,Q) = -\log \sum_{\mathbf{A}} \Pr(y, \mathbf{A}|P,Q)$$

$$= -\log \sum_{\mathbf{A}} \Pr(\mathbf{A}|P,Q) \cdot \Pr(y|\mathbf{A},P,Q) = -\log \mathbb{E}_{\Pr(\mathbf{A}|P,Q)}[\Pr(y|\mathbf{A},P,Q)],$$

where the structured latent variable $\mathbf{A} \in \{0,1\}^{|Q|\times|P|}$ represents an alignment. $|\cdot|$ is the number of nodes in the tree. $\mathbf{A}_{ij} = 1$ if and only if node i in Q is aligned to node j in P, otherwise $\mathbf{A}_{ij} = 0$.

However, enumerating over all possible alignments $\mathbf{A}$ takes exponential time, we need to efficiently approximate the above log expectation.

Fortunately, as Xu et al. (2015) point out, as long as the calculation $\Pr(y|\mathbf{A},P,Q)$ only consists of linear calculation, simple nonlinearities like $\tanh$, and softmax, we can have following simplification via first-order Taylor approximation:

$$\ell = -\log \mathbb{E}_{\Pr(\mathbf{A}|P,Q)}[\Pr(y|\mathbf{A},P,Q)] \approx -\log \Pr(y|\mathbb{E}_{\Pr(\mathbf{A}|P,Q)}[\mathbf{A}],P,Q)],$$

which means instead of enumerating over all alignments and calculating the label probability for each alignment, we can use the label probability for the expected alignment as an approximation:[1]

$$\tilde{\mathbf{A}} \triangleq \mathbb{E}_{\Pr(\mathbf{A}|P,Q)}[\mathbf{A}] \quad \in \mathbb{R}^{|Q|\times|P|} \tag{1}$$

Figure 2a shows an example of expected alignment calculation. The objective is simplified to

$$\ell \approx -\log \Pr(y|\tilde{\mathbf{A}},P,Q). \tag{2}$$

With this observation, we split our calculation into two steps as the top two modules in Figure 2b. First in the Alignment module, we calculate the expected alignments $\tilde{\mathbf{A}}$ using Equation 1 (Section 2.2). Then we calculate the node-wise entailment relation, propagate and compose the relation from bottom up to find out the final entailment relation (Equation 2) in the Entailment Composition module (Section 2.3). Both of these two modules rely on the composition of tree node meaning representations (Section 3).

2.2 Attention over Tree Nodes

First we calculate the expected alignments $\tilde{\mathbf{A}}$ between the hypothesis Q and the premise P (Equation 1):

$$\tilde{\mathbf{A}} = \mathbb{E}_{\Pr(\mathbf{A}|P,Q)}[\mathbf{A}].$$

[1]We use bold letter, $\mathbf{A}$, for binary alignments, and tilde version, $\tilde{\mathbf{A}}$, for the expected alignments in the real number space.

To simplify the calculation, we further approximate the global (binary) alignment $\mathbf{A}$ to be consisted of the alignment $\mathbf{A}_i \in \{0,1\}^{1\times|P|}$ of each tree node $i \in Q$ independently. $\mathbf{A}_i$ is the ith row of $\mathbf{A}$:

$$\mathbf{A} = [\mathbf{A}_1^T; \mathbf{A}_2^T; \ldots; \mathbf{A}_{|Q|}^T]^T,$$

$$\Pr(\mathbf{A}|P,Q) = \prod_i^{|Q|} \Pr(\mathbf{A}_i|P,Q).$$

$\Pr(\mathbf{A}_{i,j} = 1|P,Q)$ is the probability of the node $i \in Q$ being aligned to node $j \in P$, which is defined as:

$$\Pr(\mathbf{A}_{i,j} = 1|P,Q) \triangleq \frac{\exp(T_{2k,1}([\mathbf{h}_i;\mathbf{h}_j]))}{\sum_k \exp(T_{2k,1}([\mathbf{h}_i;\mathbf{h}_k]))}. \quad (3)$$

$\mathbf{h}_i, \mathbf{h}_j \in \mathbb{R}^k$ are vectors representing the semantic meanings of node i, j, respectively, whose calculation will be described in Section 3. $T_{2k,1}$ is an affine transformation from $\mathbb{R}^{2k}$ to $\mathbb{R}$. This formulation essentially is equivalent to the widely used attention calculation in neural networks (Bahdanau et al., 2014), i.e., for each node $i \in Q$, we find the relevant nodes $j \in P$ and use the softmax of the relevances as a probability distribution. In the rest of the paper, we use "expected alignment" and "attention" interchangeably.

The expected alignment of node i being aligned to node j, by definition, is:

$$\tilde{\mathbf{A}}_{i,j} = \Pr(\mathbf{A}_{i,j} = 1|P,Q) \cdot 1 = \Pr(\mathbf{A}_{i,j} = 1|P,Q).$$

2.3 Entailment Composition

Now we can calculate the entailment relation at each tree node and propagate the entailment relation following the hypothesis tree from bottom up, assuming the expected alignment is given (Equation 2):

$$\ell \approx -\log \Pr(y|\tilde{\mathbf{A}}, P, Q).$$

Let vector $\mathbf{e}_i \in \mathbb{R}^r$ denote the entailment relation in a latent relation space at hypothesis tree node $i \in Q$. At the root of the hypothesis tree. We can induce the final entailment relation from entailment relation vector $\mathbf{e}_{\text{root}}$. We use a simple $\tanh$ layer to project the entailment relation to the 3 relations defined in the task, and use a softmax layer to calculate the probability for each relation:

$$\Pr(y|\tilde{\mathbf{A}}, P, Q) = \text{softmax}(\tanh(T_{r,3}(\mathbf{e}_{\text{root}}))).$$

At each hypothesis node i, $\mathbf{e}_i$ is calculated recursively given the meaning representation at this tree node $\mathbf{h}_i$, the meaning representation of every node in the premise tree $\mathbf{h}_j, j \in P$, and the entailment from i's children, $\mathbf{e}_{i,1}, \mathbf{e}_{i,2}$:

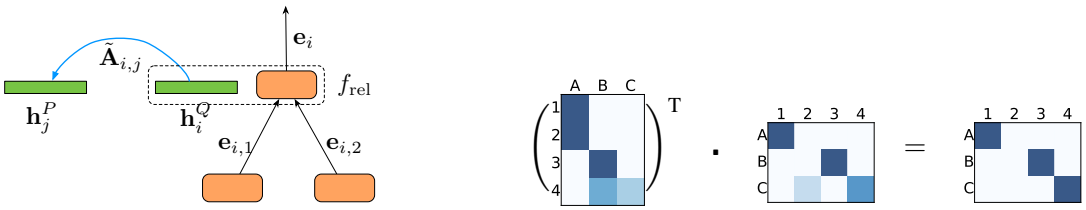
$$\mathbf{e}_i = f_{\text{rel}}([\mathbf{h}_i; \sum_{j\in P} \tilde{\mathbf{A}}_{i,j}\mathbf{h}_j], \mathbf{e}_{i,1}, \mathbf{e}_{i,2}) \quad (4)$$

Figure 3a illustrates the calculation of the entailment composition. We will discuss f_{rel} in Section 3.

2.4 Dual-attention Over Tree Nodes

We can further improve our alignment approximation in Section 2.2, which does not consider any structural information of current tree, nor any alignment information from the premise tree.

We can take a closer look at our conceptual example in Figure 1. Note that the alignments have, to some extent, a symmetric property: if a premise node j is most relevant to a hypothesis node i, then the hypothesis node i should also be most relevant to premise node j. For example, in Figure 1, the premise phrase "hugging one another" contradicts the hypothesis word "sleeping". In the perspective of the premise tree, the hypothesis word "sleeping" contradicts by the known claim "hugging one another". This suggests us to calculate the alignments from both side, and eliminate the unlikely alignment if it only exists in one side. This technique is similar to the widely used forward and reversed alignment technique in the machine translation area.



(a) Entailment composition at hypothesis tree node i. The composition is based on the meaning representation of current node $\mathbf{h}_i^Q$, the expected alignment for node i, $\tilde{\mathbf{A}}_i$, expected meaning representation of aligned premise tree node $\sum_{j \in P} \tilde{\mathbf{A}}_{i,j} h_j^P$, and known entailment relations from children nodes $\mathbf{e}_{i,1}, \mathbf{e}_{i,2}$.

(b) An example of dual-attention eliminating uncertainty in the alignment. In the left attention matrix, word "4" can be aligned to either "B" or "C". In the middle attention matrix, word "C" can be aligned to either "2" or "4". The element-wise product eliminates these uncertainty and results in the right attention matrix.

Figure 3: Entailment composition (a) and dual-attention calculation (b).

In detail, we calculate the expected alignments $\tilde{\mathbf{A}}$ from hypothesis to premise, and also the expected alignments $\tilde{\mathbf{A}}^R$ from premise to hypothesis, and use their element-wise product

$$\tilde{\mathbf{A}}^* = \tilde{\mathbf{A}} \cdot \tilde{\mathbf{A}}^R$$

as the attention to feed into the Entailment Composition module.[2] This element-wise product is a mimic of the intersection of two alignments in machine translation. Figure 3b shows an example.

In addition to our dual-attention, Cohn et al. (2016) also explore to use the structural information to improve the alignment. However, their approach requires introducing some extra terms in the objective function, and is not straightforward to integrate into our model. We leave adding more structural constraints to further improve the attention as an open problem to explore in the future.

3 Review: Recursive Tree Meaning Representations

Here we describe the final building block of our neural model.

In Section 2.2, we did not mention the calculation of the meaning representation $\mathbf{h}_i$ for node i in Equation 3, which represents the semantic meaning of the subtree rooted at node i. In general, $\mathbf{h}_i$ should be calculated recursively from the meaning representations $\mathbf{h}_{i,1}$, $\mathbf{h}_{i,2}$ of its two children if node i is an internal node, otherwise $\mathbf{h}_i$ should be calculated based on the word $\mathbf{x} \in \mathbb{R}^d$ in the leaf.

$$\mathbf{h}_i = f_{\text{MR}}(\mathbf{x}_i, \mathbf{h}_{i,1}, \mathbf{h}_{i,2}). \tag{5}$$

Similar is Equation 4, where the relation $\mathbf{e}_i$ is recursively calculated from the relation of its two children, as well as the meaning $\mathbf{h}_i$ comparing with the meaning of the premise tree:

$$\mathbf{e}_i = f_{\text{rel}}([\mathbf{h}_i; \sum_{j \in P} \tilde{\mathbf{A}}_{i,j} \mathbf{h}_j], \mathbf{e}_{i,1}, \mathbf{e}_{i,2}). \tag{6}$$

Note the resemblance between these two equations, which indicates that we can handle them similarly with the same form of composition function $f(\cdot)$.

We have various choices for composition function f. For example, we can use simple RNN functions as in Socher et al. (2013). Alternatively, we can use a convolutional layer to extract features from $\mathbf{x}_i, \mathbf{h}_{i,1}, \mathbf{h}_{i,2}$ and use pooling as aggregation to form $\mathbf{h}_i$. In this paper we choose Tree-LSTM model (Tai et al., 2015). Our model is independent to this composition function and any high-quality composition function is sufficient for us to infer the meaning representations and entailments.

Here we use Equation 5 as an example. Equation 6 can be handled similarly. Similar to the classical LSTM model (Hochreiter and Schmidhuber, 1997), in the binary Tree-LSTM model of Tai et al. (2015), each tree node has a state represented by a pair of vectors: the output vector $\mathbf{h} \in \mathbb{R}^{1 \times k}$, and the memory cell $\mathbf{c} \in \mathbb{R}^{1 \times k}$, where k is the length of the Tree-LSTM output representation. We use $\mathbf{h}$ as the meaning

[2] We need to normalize $\tilde{\mathbf{A}}^*$ at each row to make each row a probability distribution.

Method	k	$\|\theta\|_M$	Train	Test
LSTM sent. embedding (Bowman et al., 2015)	100	221k	84.8	77.6

Table 1: Comparison between our structured model with other existing methods. Column k specifies the length of the meaning representations. $|\theta|_M$ is the number of parameters without the word embeddings.

representation of the tree node in the attention model. The LSTM transition calculates the state $(\mathbf{h}_i, \mathbf{c}_i)$ of node i with leaf word $\mathbf{x}_i \in \mathbb{R}^d$, and two children with states $(\mathbf{h}_{i,1}, \mathbf{c}_{i,1})$ and $(\mathbf{h}_{i,2}, \mathbf{c}_{i,2})$ respectively.

We can abuse the mathematics a little bit, and write the transition at an LSTM unit as a function:

$$[\mathbf{h}_i; \mathbf{c}_i] = \mathrm{LSTM}(\mathbf{x}_i, [\mathbf{h}_{i,1}; \mathbf{c}_{i,1}], [\mathbf{h}_{i,2}; \mathbf{c}_{i,2}])$$

In practice, we use the above $\mathrm{LSTM}(\cdot,\cdot,\cdot)$ function as $f_{\text{MR}}(\cdot,\cdot,\cdot)$, and $f_{\text{rel}}(\cdot,\cdot,\cdot)$. But we only expose the output $\mathbf{h}_i$ to the above layers, and keep the memory $\mathbf{c}_i$ visible only to the $\mathrm{LSTM}(\cdot,\cdot,\cdot)$ function.

Following Zaremba et al. (2014), function $\mathrm{LSTM}(\cdot,\cdot,\cdot)$ is summarized by Equations 7-9:

$$\begin{pmatrix} \mathbf{i}_i \\ \mathbf{f}_{i,1} \\ \mathbf{f}_{i,2} \\ \mathbf{o}_i \\ \mathbf{u}_i \end{pmatrix} = \begin{pmatrix} \sigma \\ \sigma \\ \sigma \\ \sigma \\ \tanh \end{pmatrix} T_{d+2k,k} \begin{pmatrix} \mathbf{x}_i \\ \mathbf{h}_{i,1} \\ \mathbf{h}_{i,2} \end{pmatrix} \tag{7}$$

$$\mathbf{c}_i = \mathbf{i}_i \odot \mathbf{u}_i + \mathbf{f}_{i,1} \odot \mathbf{c}_{i,1} + \mathbf{f}_{i,2} \odot \mathbf{c}_{i,2}, \tag{8}$$

$$\mathbf{h}_i = \mathbf{o}_i \odot \tanh(\mathbf{c}_i), \tag{9}$$

where $\mathbf{i}_i$, $\mathbf{f}_{i,1}$, $\mathbf{f}_{i,2}$, $\mathbf{o}_i$ represent the input gate, two forget gates for two children nodes, and the output gate respectively. $T_{d+2k,k}$ is an affine transformation from $\mathbb{R}^{d+2k}$ to $\mathbb{R}^k$.

4 Empirical Evaluations

We evaluate the performances of our structured attention model and structured entailment model on the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015). The SNLI dataset contains ~ 570k sentence pairs. We use the binarized trees in SNLI dataset in our experiments.

4.1 Experiment Settings

Network Architecture

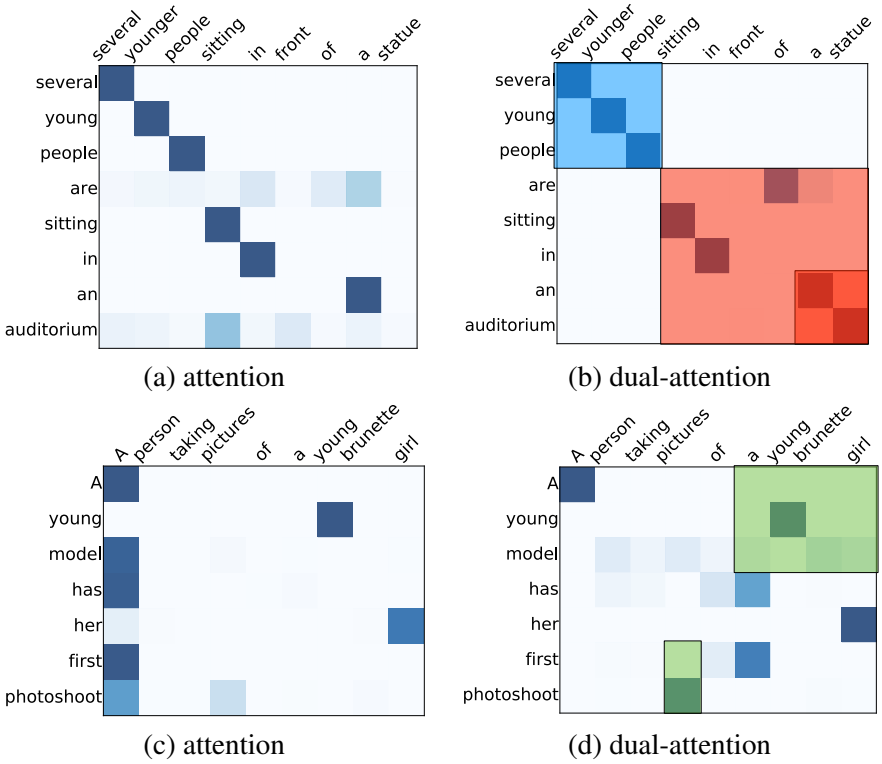
The general structure of our model is illustrated in Figure 2b. We omitted a dropout layer between the word embedding layers and the tree LSTM layers in Figure 2b. We use cross-entropy as the training objective.[3]

Parameter Initialization & Hyper-parameters

We use GloVe (Pennington et al., 2014) to initialize the word embedding layer. In the training we do not change the embeddings, except for the OOV words in the training set. For the parameters of the rest layers, we use a uniform distribution between -0.05 and 0.05 as initialization.

Our model is trained in an end-to-end manner with adam (Kingma and Ba, 2014) as the optimizer. We set the learning rate to 0.001, β_1 to 0.9, and β_2 to 0.999. We use minibatch of size 32 in the training. The dropout rate is 0.2. The length for the Tree-LSTM meaning representation $k = 150$. The length of the entailment relation vector $r = 150$.

[3]Our code is released at `https://github.com/kaayy/structured-attention`.



(a) attention (b) dual-attention

(c) attention (d) dual-attention

Figure 4: Attention matrices for exemplary sentence pairs. Note that, for brevity we *only show* the attentions between each word pair, and skip the attentions of tree nodes. Some important tree node alignments calculated by our model are highlighted using the colored boxes, where the colors of the boxes represent the entailment relations (see Figure 5). (a) (b) Premise: several younger people sitting in front of a statue. Hypothesis: several young people sitting in an auditorium. Dual-attention fixes the misaligned word "auditorium". (c) (d) Premise: A person taking pictures of a young brunette girl. Hypothesis: A young model has her first photoshoot. Dual-attention fixes the uncertain alignments for "photoshoot" and "model".

4.2 Quantitative Evaluation

We present a comparison of structured model with existing methods of LSTM-based sentence embedding (Bowman et al., 2015), LSTM with attention (Rocktäschel et al., 2015), Binary Tree-LSTM sentence embedding (our implementation of Tai et al. (2015)), mLSTM (Wang and Jiang, 2015), and LSTM-network (Cheng et al., 2016) in Table 1.

We first try Binary-Tree LSTM with a composition function f_{rel} of a recurrent network with attention as in Rocktäschel et al. (2015), which achieves an accuracy of 81.8. We find the training of this RNN is difficult due to the vanishing gradient problem.

Using Binary-Tree LSTM for entailment relation composition instead of the simple RNN brings $\sim$4.6 improvement. We observe that the vanishing gradient problem is greatly alleviated. Dual-attention further improves the tree node alignment, achieving another 0.8 improvement.

Our structured entailment composition model outperforms the similar mLSTM model, which essentially also uses an LSTM layer to propagate the "matching" information, but sequentially. With the help of dual-attention, our model outperforms mLSTM with a 1.1 point margin.

4.3 Qualitative Evaluation

Due to space constraints, here we highlight two examples in Figure 4 for both standard attention and dual-attention, and Figure 5 for entailment composition. To pick the most representative examples from the dataset needs careful consideration. Ideally random selection is most convincing. However, due to

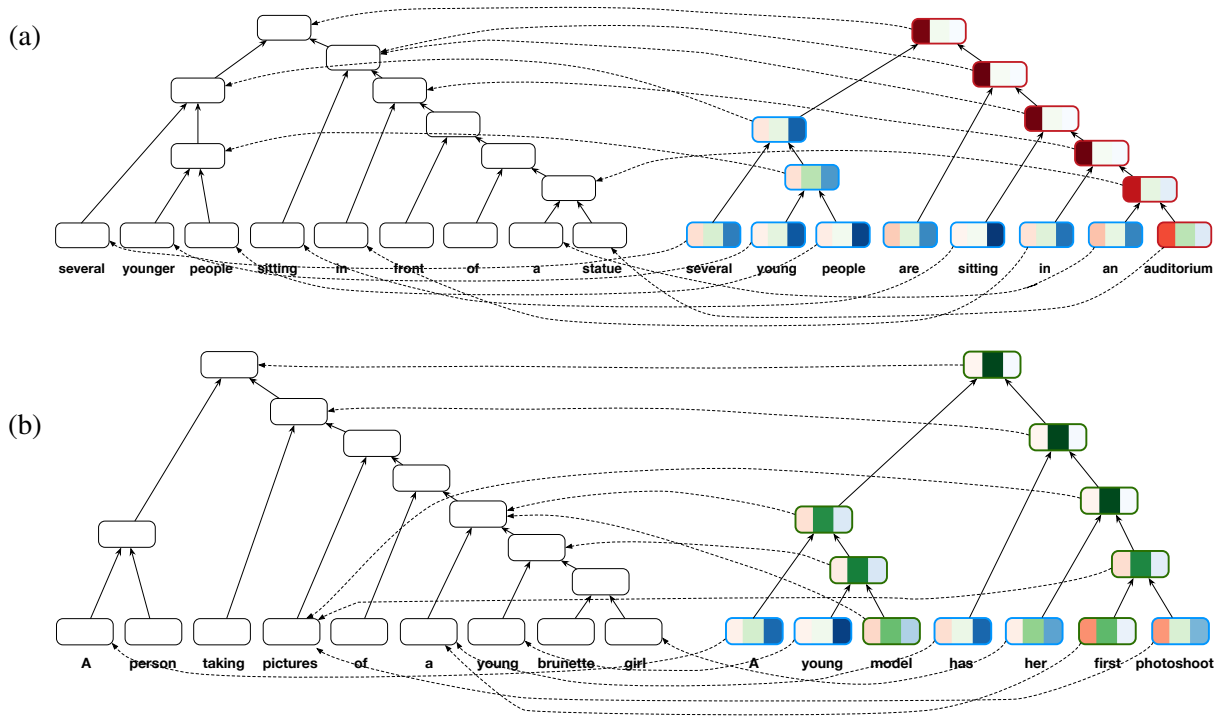


Figure 5: Examples illustrating entailment relation composition. (a) for Figure 4 (b); (b) for Figure 4 (d). For each hypothesis tree node, the dashed line shows to its most confident alignment. The three color stripes in each node indicate the confidences of the corresponding entailment relation estimation: red for contradiction, green for neutral, and blue for entailment. The colors of the node borders show the dominant estimation. Note: there is no strong alignment for hypothesis word "are" in (a).

the fact that most correctly classified examples in the datasets are trivial sentence pairs with only word insertion, deletion, or replacement, and many incorrectly classified examples in the datasets involves common knowledge, (e.g., "waiting in front of a red light" entails "waiting for green light", or "splashing through the ocean" contradicts "is in Kansas",) it is time-consuming to find meaningful insights from randomly selected examples. Here we manually choose two examples from the test set of the SNLI corpus, with consideration of both generality and non-triviality. They both involve complex syntactic structures and compositions of several relations. In addition, some examples that need more subtle linguistic insights are discussed in Section 4.4.

Our first example is shown in Figure 4 (a) and (b), with premise "several younger people sitting in front of a statue", and hypothesis "several young people sitting in an auditorium". Figure 4 (a) and (b) only show the word-level attention for brevity. In this example, note the hypothesis word "auditorium", which has no explicit correspondence in the premise sentence, but indeed has an implicit correspondence "statue" that indicates the conflict relation. The standard attention model aligns "auditorium" to "sitting" since they more frequently co-occur, leading to an incorrect relation of "entailment" (not shown in Figure 5). The dual-attention model correctly finds the alignment between "auditorium" and "statue" since "sitting" is more likely to be aligned to the same word in the premise. The colored boxes in Figure 4 (b) show some important tree node alignment calculated by our model. The colors represent the entailment relation based on the alignment, as shown in Figure 5 (a).

In Figure 5 (a), each tree node is filled with three color stripes, whose darknesses show the confidences of the corresponding entailment relations. For this example, the contradiction relation from "statue" and "auditorium" flips every tree node from bottom up and finally make the final result contradiction, similar to our concept example in Figure 1.

Another example with premise "a person taking pictures of a young brunette girl", and hypothesis "a

young model has her first photoshoot". The word-level attentions are shown in Figure 4 (c) (d). The standard attention is uncertain about two words: 1) word "model" has several meanings, making it hard to find the right alignment, but in the perspective of from premise to hypothesis, it is easier since a girl is more likely to be a model. 2) Similar is for hypothesis word "photoshoot", which can either be aligned to "a" or "pictures" but since "a" is aligned to other words, dual-attention aligns "photoshoot" to "pictures".

In Figure 5 (b), we can see that there are two parts in the hypothesis indicates that the relation should be neutral: 1) "a young brunette girl" is not necessarily a "a young model"; and 2) the "pictures" taken are not necessarily "her first photoshoot".

4.4 Discussion

Although many attention-based models, including our model, achieve superior results in the Stanford Natural Language Inference dataset, we still need to circumvent some problems to apply these neural models to more general textual entailment problems.

Despite those sentence pairs that require more common knowledge to find the entailment relations as we mentioned in Section 4.3, we are more interested in sentences that are difficult because they involve non-trivial linguistic properties.

Consider the following two pairs of sentences that are difficult for current attention and composition based models:

1.
   - Premise: The boy loves the girl.
   - Hypothesis: The girl loves the boy.

   Here the only difference between the two sentences is the order/structure of the words. To handle this problem the attention-based models should take the reordering into consideration when composing entailment relations.

2.
   - Premise: A stuffed animal on the couch.
   - Hypothesis: An animal on the couch.

   In this example, almost every hypothesis word occurs in the premise sentence, but it is difficult to infer that "a stuffed animal" is not "an animal". While in most cases the monotonicity of entailment suggests that a word deletion in the premise sentence either leads to entailment, e.g., "a cute animal" entails "an animal", or a reverse entailment, e.g., "some animal" reverse entails "animal" (See MacCartney and Manning (2009) for more details), but for words like "stuffed" it is quite different: their monotonicity directions depend on the nouns being modified, e.g., "a stuffed animal" does not entails "an animal", but "a stuffed toy" entails "a toy". This observation suggests that we might need to consider phrases like "stuffed animal" as a whole instead of treating the two words separately and then composing the entailment relations.

In addition, training of the neural models rely on large training corpora, which makes it difficult to directly apply neural models on traditional RTE datasets, e.g., the Pascal RTE dataset (Dagan et al., 2006) and the FraCaS dataset (Cooper et al., 1996), which are usually small and contain many named entities that are hard for neural models to identify.

5 Conclusion

We have presented an approach to model the composition of the entailment relation following the tree structure for the sentence entailment task. We adapted the attention model for tree structures. Experiments show that our model bring significant improvements in accuracy, and is easy to interpret.

Acknowledgments

We thank the anonymous reviewers for helpful comments. We are also grateful to James Cross, Dezhong Deng, and Lemao Liu for suggestions. This project was supported in part by NSF IIS-1656051, DARPA FA8750-13-2-0041 (DEFT), and a Google Faculty Research Award.

Abstract

We have released plWordNet 3.0, a very large wordnet for Polish. In addition to what is expected in wordnets – richly interrelated synsets – it contains sentiment and emotion annotations, a large set of multi-word expressions, and a mapping onto WordNet 3.1. Part of the release is enWordNet 1.0, a substantially enlarged copy of WordNet 3.1, with material added to allow for a more complete mapping. The paper discusses the design principles of plWordNet, its content, its statistical portrait, a comparison with similar resources, and a partial list of applications.

1 Introduction

WordNet (Fellbaum, 1998), developed at Princeton University and available on an open licence since the early 1990s, has proven useful in thousands of applications to English texts. It is not flawless, but it strikes a most reasonable balance between the formalisation of the descriptions of lexical meaning and the wide coverage required for practical applications. Wordnets for other languages have been built upon the WordNet blueprint, but almost none of them come close to WordNet's size and coverage. That limits their influence on language technology for those languages. It is therefore unclear whether the success of the "WordNet phenomenon" is not somehow restricted to English. It must also be noted that most of those wordnets have been translated, one way or another, from Princeton WordNet, mainly in order to reduce the workload and cost. This construction method does not quite take into consideration the peculiarities of the given language's lexical semantic systems, inasmuch as the lexical material and the network of relations strongly depend on the solutions specific to English.

The goal of the plWordNet team was to build a wordnet which provides a faithful and comprehensive description of the system of Polish lexical semantics. That is to say, its structure should represent accurately the lexico-semantic relations between lexical meanings in Polish, and be motivated only by observations derived from Polish language data. We were determined to avoid any form of translation from wordnets for other language, and even any kind of structure transfer. That was meant to keep our wordnet's structure free from the idiosyncrasies of the lexical systems of other languages. We also aimed to have a resource with good coverage with respect to lemmas, word senses and instances of lexico-semantic relations, so that the resulting language resource could be a strong basis for practical applications with a high chance of retrieving semantic knowledge. Finally, we assumed that our wordnet should be developed in close correspondence to language data collected from very large corpora, so that it could become a robust, faithful description of Polish usage.

We have been fortunate in the past 10 years to have almost continual funding at a level that allowed us to reach our goals without compromising these fundamental assumptions. It was a rare chance to carry out a long-term plan of building a very large wordnet without worrying too much about cost.[1] The main purpose of this paper is to present plWordNet, to square its final state with the assumptions, and to compare it with several other lexical resources. We will also refer to hundreds of plWordNet's known applications and thus try and show that the effort was worth the price.

2 plWordNet in brief

2.1 The plWordNet model

Wordnets have become standard lexical-semantics resources in NLP, and have found thousands of applications. A wordnet is now considered a basic language resource, expected to be available for any language.

[1] There were three major releases. The development was carried out by researchers (linguists and computational linguists), wordnet editors (supporting linguists) and programmers (developing and maintaining tools to support linguists' work), at the approximate cost of 40 person-years.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2259–2268, Osaka, Japan, December 11-17 2016.

The plWordNet project, arising from a wish to fill a gap in language technology for Polish, and clearly inspired by WordNet, aimed to produce a faithful description of the system of Polish lexical semantics.

It must be noted that several fundamental definitions in the WordNet paradigm, *e.g.,* those of a synset, near synonymy or lexicalised concepts, were not clear enough to be used operationally (Fellbaum, 1998; Vossen, 2002), and to achieve good consistency among wordnet editors – see a longer discussion in (Piasecki et al., 2009). We decided against the transfer method (Vossen, 2002), so as to avoid influencing plWordNet's structure with some properties alien to the Polish lexical system. We also could not adopt the merge method, because no dictionaries or other lexical resources on open licenses were available.[2] We proposed a *corpus-based wordnet development process* instead: a large text corpus is a primary data source, and language tools and systems help wordnet editors explore the corpus.[3]

The corpus has been the main knowledge source for all phases of the development, from the systematic extraction of lemmas for inclusion in plWordNet to the automated acquisition of lexico-semantic relations for presentation to the editors. Dictionaries and encyclopaedias complement language competence of the editors, all of them trained linguists, and in all linguistic matters editors have the last word. Detailed instructions ensure a high degree of consistency of those decisions.

Corpora contain words, with senses discernible by context. Groups of synonyms are not a natural phenomenon in texts. We decided to make the *lexical unit* (LU) the basic building block in plWordNet, rather than the synset as in WordNet (Piasecki et al., 2009). We defined the LU in a rather technical way as a triple: a lemma, its part of speech and its sense indicator. We assumed that one LU belongs to exactly one *synset*. The synset, however, has been defined indirectly – and operationally – as a group of LUs which share lexico-semantic *constitutive relations* and *constitutive features* (Maziarz et al., 2013). Examples of the former are hyponymy, hypernymy, meronymy and holonymy; of the latter, stylistic register, aspect, and semantic classes for adjectives and verbs. With this definition of the synset, a relation between two synsets in plWordNet can be treated as a shorthand for the fact that LUs from the two groups share links by certain relation, *e.g.,* hypernymy.

Each relation has been given a clear definition meant to allow wordnet editors to make consistent decisions. There also are linguistic substitution tests, with slots to be occupied by two LUs possibly in this relation. The tests, which support wordnet editors' decisions very effectively, are automatically filled and presented in a wordnet editing system called WordnetLoom (Piasecki et al., 2013). We adhere intentionally to the *minimal commitment principle*: lexico-semantic relations are grounded in the Polish linguistic tradition and language data in very large corpora; plWordNet's structure is derived from the relations in a way which depends on no particular theory of meaning.

2.2 The content

description layer	instances
lexico-semantic relations	>700K
glosses	>100K
usage examples	83K
links to Wikipedia	55K
sentiment annotation	30K

Table 1: Multilayered semantic description in plWordNet: the statistics.

The relations are the backbone of a wordnet: they jointly describe a word's meaning; definitions and usage example come next. plWordNet has over 40 different relation types (100 when counting subtypes). many of them link LUs from different parts of speech. In addition to relations, plWordNet describes meaning in several ways. Table 1 presents the statistics of these descriptions.

- **Semantic domains** (Princeton WordNet calls them *lexicographer files*) are broad lexical fields of a given LU. They are quite general (*e.g.,* `animals`, `artifacts`, `place`).
- **Stylistic labels** describe the lexical register of a given LU. There are 11 registers in plWordNet: non-standard, obsolete, regional, terminological, argot/slang, literary, official, vulgar, coarse, colloquial, general; words in some registers (*e.g.,* vulgar and coarse) can co-exist in a synset, but normally distinct registers mean distinct synsets. The register thus affects the network of lexical relations.

[2]Unrestricted availability was an essential point for us in view of what we wanted plWordNet's licence to be.

[3]The corpus grew in size from the initial ≈260 million words during the work on plWordNet 1.0, through ≈1.8 billion tokens for plWordNet 2.3, to ≈4.0 billion for plWordNet 3.0.

	synsets	lemmas	LUs	avs
GermaNet	101,371	119,231	131,814	–
PWN	117,659	155,593	206,978	1.74
enWN	125,500	165,712	218,611	1.74
plWN	**197,721**	**179,125**	**260,214**	1.32

Table 2: The count of synsets, lemmas and lexical units (LUs), and average synset size (avs), in PWN 3.1 (PWN), enWordNet 1.0 (enWN), plWordNet 3.0 (plWN) and GermaNet 10.0 (`http://www.sfs.uni-tuebingen.de/GermaNet/`).

- **Glosses** are short definitions, a very important element of plWordNet. They help the user to understand the network, and plWordNet editors to work with high effectiveness.
- **Usage examples** are sentences which illustrate a particular lexical meaning. They are exemplars for sense usage and also real corpus evidence. Usage examples in plWordNet are due to the liguists' intuition, or taken from corpora in the public domain or published on a Creative Commons Licence.
- **Links to *Wikipedia*** are added to those LUs whose meaning is an exact equivalent of a Wikipedia entry.
- **Semantic verb classes**, part of plWordNet's structure, generalise the Vendler classes for typical Polish verb usage. They influence the network's shape, since only verbs of the same class may be linked with hyponymy.[4]
- **Sentiment and emotion annotation** marks word meanings as discussed below.

Sentiment analysis or the construction of a sentiment lexicon, perhaps based on plWordNet, has been a frequently stated intended use of plWordNet once it became publicly available.[5] We met this expectation in a pilot project, in which about 30,000 noun and adjective LUs were annotated with basic emotions (Plutchik, 1980), fundamental human values and sentiment polarity, illustrated by usage examples (Zaśko-Zielińska et al., 2015). LUs rather than synsets were annotated, because LUs from the same synset can differ with respect to sentiment polarity.[6] Annotation covers the sentiment polarity of a sense on a 5-level scale, and basic emotions.) and LUs are the object of linguistic tests or are included in usage examples. The annotation was performed by a group separate from the plWordNet editors, so it also served as a form of verification of the plWordNet content.

The newest release of plWordNet, version 3.0, complements the preceding versions. After version 2.3, the work concentrated on a modified system of relations for adjectives (Maziarz et al., 2012) and on the expansion of the adjective sub-database; the construction of the adverb subnetwork,[7] supported by a semi-automated method based on adjective-adverb derivational relations (Maziarz et al., 2016); and a major increase of the number of lexicalised multi-word expressions (Dziob and Wendelberger, 2016).

3 Comparative analysis

3.1 The lexical net

A wordnet is a lexical net, so it can be evaluated with statistical measures suitable for graphs (Lewis, 2009). We consider graph size, network volume, average graph density, corpus coverage, clustering coefficient, distance measure and connectivity. A wordnet of good quality ought to have a large, dense network, covering contemporary corpora well, and showing traits of "small-worldness".

Network volume and density. Table 2 shows the number of synsets, lemmas and LUs in three manually and independently constructed wordnets: Princeton WordNet, plWordNet and GermaNet, together with enWordNet, our extension of Princeton WordNet. We can say that plWordNet is comparable in size to Princeton WordNet (and the 5% larger enWordNet), and almost twice as large as GermaNet. Table 3 shows that the volumes of the two resources are also comparable. plWordNet has 208K LU relation instances and 324K synset relation instances; the WordNet counts are 91K and 195K, respectively. Taking into account that in WordNet the average synset size is higher than the average synset size in plWordNet (Table 2) one may want to calculate an average relation density per LU. This measure approximates an

[4]For example, *zgubić*$_2$ and *stracić*$_1$ 'to lose' (`HAPPPENINGS`) or *wybudować*$_1$ 'build$_{\texttt{PERF}}$' and *zrobić*$_2$ 'do$_{\texttt{PERF}}$' (`PERFECTIVE ACTIONS`).

[5]An independent attempt has been made (Haniewicz et al., 2013; Haniewicz et al., 2014).

[6]For instance, *pies*$_2$ 'Canis lupus familiaris' is unmarked, while *pies*$_3$ 'cop (policeman)' is negatively marked.

[7]Adverbs are usually neglected in wordnet: there are none in GermaNet, and less than 3% of all lexical units in WordNet are adverbs. Their proper relational description is not easy, as witnessed by WordNet's low synset relation density of 0.03 (Table 1).

WordNet 3.1	verbs		nouns		adverbs		adjectives		all	
	N	ρ	N	ρ	N	ρ	N	ρ	N	ρ
LU relations	24,840	0.99	44,185	0.28	720	0.13	21,636	0.72	91,381	0.42
synset relations	16,827	1.22	145,338	1.62	109	0.03	23,491	1.29	185,765	1.48
all relation types	80,280	3.20	492,457	3.12	1,015	0.18	86,221	2.87	659,973	3.02
plWordNet 3.0	**verbs**		**nouns**		**adverbs**		**adjectives**		**all**	
	N	ρ	N	ρ	N	ρ	N	ρ	N	ρ
LU relations	48,744	1.50	98,376	0.58	12,542	1.14	48,894	1.02	208,556	0.80
synset relations	36,616	1.66	219,266	1.75	19,716	2.18	48,258	1.17	323,856	1.64
all relation types	127,065	3.92	494,893	2.94	43,551	3.94	118,574	2.47	784,083	3.02

Table 3: The volume of the lexical networks and relation density with regard to parts of speech. N is the number of relation instances, ρ is the relation density measured either for LUs, or synsets, or for all relation types.

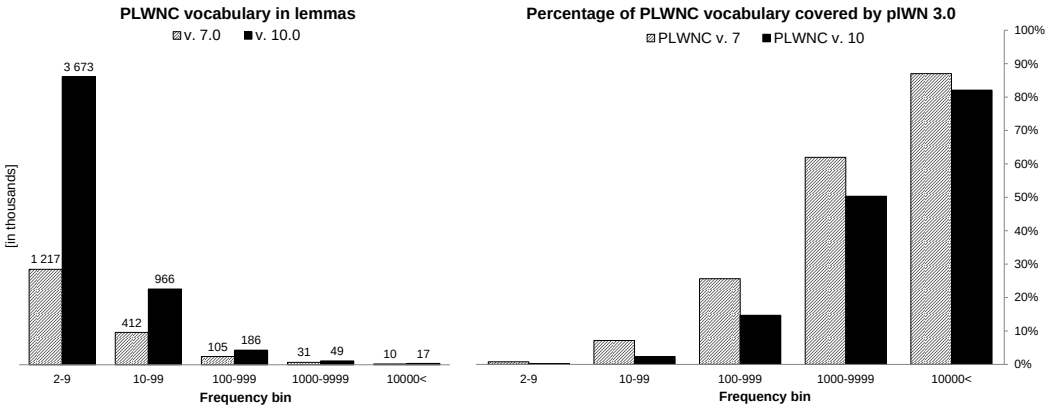

Figure 1: **Left**: The number of lemmas in PLWNC version 3.0 and 10.0 with regard to different freqency bins. The bin "100-999" contains those words that occur in the PLWNC 100 to 999 times. In agreement with Zipf's law, there are far more rare than frequent words in both corpora. **Right**: Coverage of the 7th and 10th version of PLWNC by plWordNet 3.0.

amount of information falling to a single LU, which in fact is very similar for both wordnets, 660K for WordNet and 785K for plWordNet, see row "all relation types" in the table.[8]

Corpus coverage. Figure 1, right, shows how well plWordNet 3.0's vocabulary covers PLWNC. plWordNet was developed on three corpora, the ICS PAS corpus (Przepiórkowski, 2004) (plWordNet 1.0, 250M tokens), plWordNet Corpus 7.0 (plWordNet 2.0 and 3.0, 1.8G tokens) and plWordNet Corpus 10.0 (plWordNet 3.0, 4.2G tokens). Note that the coverage of PLWNC 10.0 is lower than that of version 7.0. The chart also proves that plWordNet creators favoured more frequent lemmas over less frequent. Figure 2, left, presents the coverage of three versions of plWordNet (1.0, 2.0 and 3.0). The consecutive versions of plWordNet housed more and more low-frequenct lemmas. Now, words with frequencies lower than $f = 10$ account for merely 10% of plWordNet 3.0 (Figure 2, right).

Small world. Similarly to Princeton WordNet, plWordNet shows a small-world behaviour: short average path length and high clustering coefficient (Sigman and Cecchi, 2001).[9] In Figure 3 we plot the statistics for three versions of plWordNet (1.0, 2.0, 3.0), Princeton WordNet and a conglomerate, an effect of mapping from plWordNet 3.0 to WordNet 3.1 (WN-plWN3). For a classical random graph of plWordNet's size, a global clustering coefficient is close to $\frac{\langle k \rangle}{N} = 2.5 \times 10^{-5}$, where $\langle k \rangle$ is an average number of neighbours of a vertex (see ρ values in Table 3, we put here $\langle k \rangle = 3$), and N is the number of graph vertices (in this case synsets, see Table 2). The average path length for the random graph is very similar to the obtained values (see see Figure 3): $\frac{ln(N)}{ln(\langle k \rangle)} \approx 11$ (Omidi and Masoudi-Nejad, 2009).

For sure, plWordNet is denser now in terms of the clustering coefficient and the shorter path lengths than in the past (it is indeed a smaller world now). As compared to WordNet, plWordNet versions 2.0 and 3.0 have shorter average path length and higher clustering coefficient.

[8]This approximation was calculated thus: we choose synset relations within the same POS and multiply the number of relation instances by a square of the average synset size for a particular POS (synset relations are shorthand for relations between LUs from two synsets). If a synset relation holds between different POSs, we multiply the number of synset relations by the average synset sizes of the two distinct POSs.

[9]We calculate the classic *global clustering coefficient* (Opsahl, 2013).

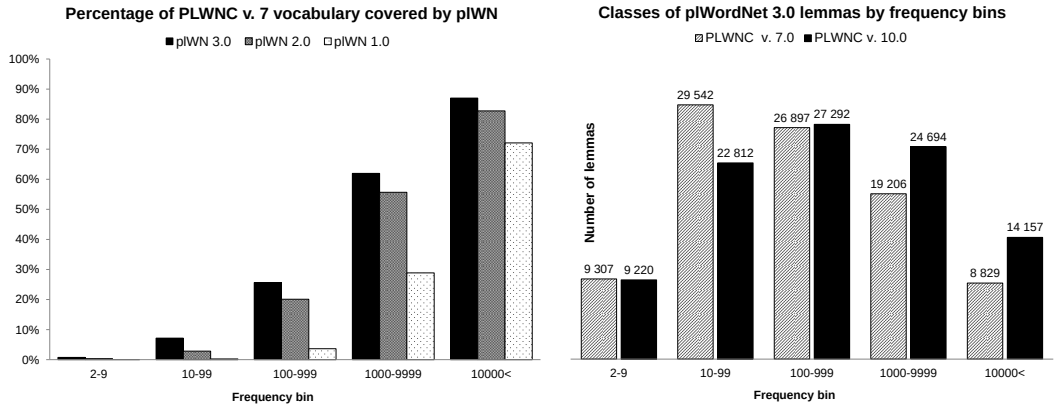

Figure 2: **Left**: Coverage of the 7th version of plWordNet Corpus (PLWNC) by three different stages of plWordNet development – versions 1.0 (from 2009), 2.0 (2013) and 3.0 (2016) – with regard to frequency bins. The bin "100-999" contains words which occur in the PLWNC 100-999 times. Percentages show how many lemmas in each corpus bin are found in plWordNet (version 1st, 2nd or 3rd). **Right**: The cardinality of frequency bins in plWordNet 3.0. Frequencies were calculated in two versions of plWordNet Corpus (7.0 i 10.0).

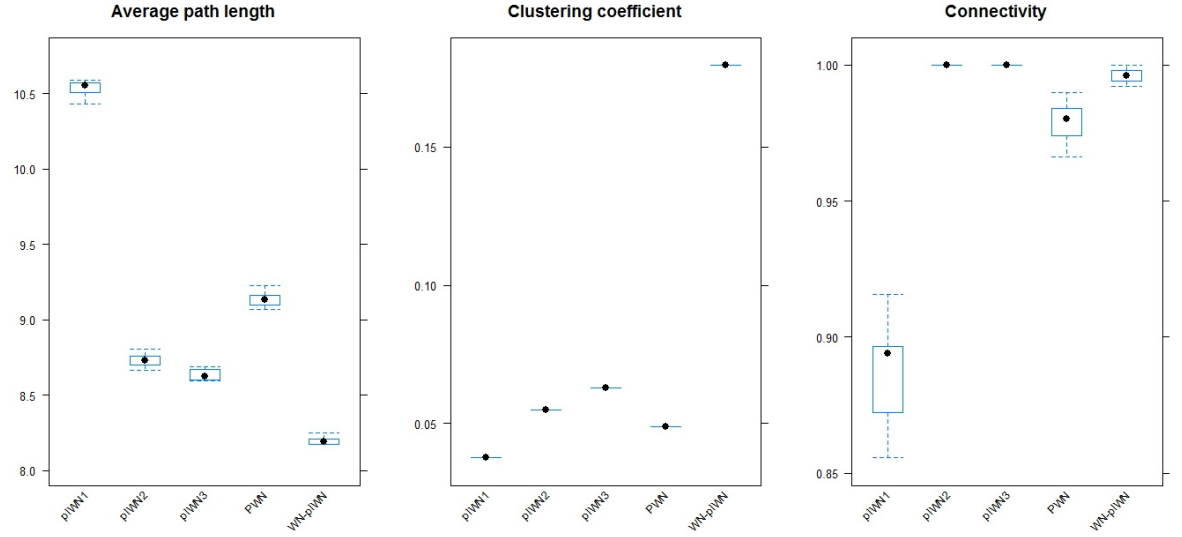

Figure 3: Average path length, clustering coefficient and connectivity in different lexical networks. plWN1, plWN2, plWN3: = plWordNet 1.0, 2.0, 3.0; PWN: WordNet 3.1, WN-plWN: mapping between plWordNet3.0 and WordNet 3.1. Clustering coefficients were calculated for the whole graphs. Average path lengths were obtained by randomly picking a pair of 2×500 synsets (without replacement) and seeking a way through the graph between the pairs; if a way could be found, the shortest path was chosen, and then the set of resulting calculations was averaged. The procedure was repeated 10 times for each graph. The connectivity was calculated simultaneously: it is a ratio of felicitously found paths.

Connectivity measures how often a path can be established between two synsets randomly chosen in a graph. For all wordnet versions, the statistic is high (>85%) or very high (>95%), with plWordNet 1.0 last in ranking and two other versions of plWordNet with the two highest ranks.

The mapping results, described in the next section, were very surprising. The merged networks of Polish and English lexical units gave impressive values of clustering coefficient (3 times larger than for plWordNet 3.0) and shortest path lengths. The conglomerate has small-world behaviour more than its separate parts. It seems that linking independently built resources creates a new quality.

3.2 Comparison by mapping

As noted, plWordNet has been developed independently from WordNet, without any transfer of structures between the two resources, thus avoiding any bias towards WordNet. Even so, the alignment of plWordNet and WordNet was needed for a variety of (bilingual and multilingual) applications and research tasks. We have designed a strategy of mapping plWordNet to WordNet (Rudnicka et al., 2012). The key element

I-relation	Noun	Adjective	Adverb	Total
I-Synonymy	36,367	4,077	448	40,892
I-Hyponymy	74,394	29,216	781	104,391
I-Hypernymy	4,121	167	51	4,339
I-Meronymy	6,982	-	-	6,982
I-Holonymy	3,471	-	-	3,471
I-Partial synonymy	4,339	1,544	4	5,887
I-Inter-register synonymy	1,672	54	22	1,748
I-Cross-categorial synonymy	-	19,286	-	19,286
Total	131,346	54,344	1,306	186,996

Table 4: Interlingual relation counts

of the strategy was a comparison of the two relation structures in order to find the corresponding nodes of synset graph structures and link them via one of eight interlingual relations (hierarchically ordered by varying strength and specificity). The mapping was done manually, in the WordNetLoom editor (Piasecki et al., 2013), bottom-up (leaves first), from plWordNet to WordNet. As a result, almost all plWordNet noun synsets are mapped in version 3.0, about $\frac{3}{4}$ of adjective synsets and about $\frac{1}{4}$ of adverb synsets.

The linguists' work was supported by an automatic prompt system which suggested interlingual links using a rule-based part-of-speech-sensitive algorithm, and a cascade dictionary (Kędzia et al., 2013; Rudnicka et al., 2015a). The final decisions, however, were made by linguists and the cost of the mapping process was comparable to that of editing plWordNet. That has turned out to be money well spent, for two reasons. The two interlinked, independently created wordnets provide a remarkable opportunity to run a comparative analysis; and the mapping process required a careful analysis of plWordNet's structure, so it was a kind of evaluation procedure.

Indeed, the mapping process enabled a comparative analysis and an evaluation of the lexical coverage and the construction methods of the two wordnets. The linguists discovered many gaps in the lexical coverage between plWordNet and Princeton WordNet, as well as numerous differences in the number, type and structure of synset and LU relations – all due to the different construction methods (Rudnicka et al., 2015b). These facts account for the final mapping results, with interlingual hyponymy counts doubling interlingual synonymy counts. This is illustrated in Table 4.

The results are striking. Interlingual synonymy was most highly favoured by the mapping procedure, yet its counts are much lower than those of interlingual hyponymy across all mapped categories. This is caused by the strict restrictions on the application of I-Synonymy. It could only be assigned given strong correspondence of the meanings and relation structures between plWordNet and WordNet synsets. Superficially, noun synset relation structures seem largely to correspond, with hyponymy forming the backbone of a relation network. However, on a closer look, various contrasts come to the fore.

First, plWordNet and WordNet differ in synset granularity, which affects relation structures. In general, plWordNet synsets are smaller and tend to include fewer lexical units than WordNet synsets. In plWordNet there are always distinct synsets for feminine, masculine and neuter forms, singular and plural, mass and count, diminutive, augmentative and stylistically marked forms. While mapping, we found many instances of mixed WordNet synsets grouping together marked and unmarked forms of such pairs. Moreover, the concept of hyponymy in plWordNet and in WordNet is different. plWordNet always understands hyponymy narrowly, as "and hyponymy": the hyponyms have to have all properties of their hypernym(s). That leads to many cases of multiple hyponymy, but it is always of the "and" type. WordNet also allows a more relaxed "or hyponymy", which lets hyponyms have *some* properties of their hypernym(s). We have also found places (both in plWordNet and in WordNet) where the same conceptual dependency was encoded variously by meronymy or by hyponymy.

Adjective and adverb relation structures diverge even more between plWordNet and WordNet than noun relations structures (Rudnicka et al., 2015a). In plWordNet, the adjective synset relation structure is a vertical, hyponymy-based network, partly similar to that for nouns. WordNet employs a completely different, horizontal dumbbell model, based on a rather vague "Similar to" relation. That has made designing an adjective mapping procedure a real challenge. We had to take into account the lexical unit relation network which displays more similarity to establish interlingual correspondence links between plWordNet and WordNet synsets. Since adverbs have been systematically derived from adjectives, we have also capitalised on the results of adjective mapping in designing the mapping procedure for adverbs. The relevant interlingual adjective relation links were copied to adverbs and presented in the form of automatic prompts to linguists. They verified them and introduced manual interlingual adverb links. That process

	plWordNet	WordNet
Nouns	2,733	43,575
Verbs	22,029	13,789
Adjectives	8,188	11,298
Adverbs	7,529	2,704
Total	40,479	71,366

Table 5: The number of synset not mapped yet in plWordNet 3.0 and Princeton WordNet 3.1.

also allowed for critical evaluation (sometimes followed by correction) of interlingual adjective links.

Having finished their work on mapping synsets from selected wordnet graphs (usually domain-restricted), bilingual linguists reported potential errors in plWordNet to the team responsible for the Polish side, who analysed and, if needed, corrected them. Despite meticulous quality control, it is inevitable that isolated errors – typos, flawed links, synsets too general or too specific – persist in plWordNet 3.0. Such errors will be rooted out when a reporting system for users has been implemented.

The mapping went in the usual "national wordnet to WordNet" direction. We were well-aware of substantial lexical, grammatical and cultural differences between English and Polish as well as different development processes of the two wordnets. Even so, we did not expect differences in the mapping coverage between the wordnets as large as those illustrated in Table 5.

The reasons for the discrepancies in the mapping coverage of nouns and adjectives have been already discussed. The mapping of adverbs has only started, while verbs have not been mapped yet.

In short, the results of mapping have shown large differences between plWordNet and WordNet in lexical content, coverage and relation structure. Differences in lexical content are due to lexico-grammatical differences between English and Polish and the existence of many lexical and cultural gaps between the two languages. Differences in lexical coverage are due to different construction methods of the two wordnets: merge method for WordNet and corpus-based method for plWordNet, as well as in the time span of their construction: mid 1990-ties to 2006 for WordNet 3.0 and 2005-2016 for plWordNet 3.0.

The differences in relation structure are due to different theoretical solutions assumed in the construction of two wordnets: lower vs higher synset granularity, "and" vs "or" hyponymy, and the use of hyponymy and meronymy to code the same conceptual distinctions. The effects of those differences are the prevalence of I-hyponymy over I-synonymy and the large part of WordNet not mapped yet, due to one-directional, plWordNet to WordNet mapping direction.

An I-hyponymy-based bilingual resource is clearly less valuable than one based on I-synonymy (due to the lower specificity of links). So, we have sought remedies. One idea was to exploit the existing I-hyponymy links to extend WordNet's coverage. The result was the construction of enWordNet 1.0, an extended version of WordNet. The lemmas of plWordNet leaf synsets linked by I-hyponymy to WordNet synsets were automatically translated by a large cascade dictionary. The obtained list of translations was then filtered by WordNet lemmas. Next, the results of this filtering were divided into lemmas for which the cascade dictionary found: (1) equivalents whose lemmas were not present in WordNet; (2) no equivalents; (3) equivalents whose lemmas were already present in WordNet.

Linguists started with the first group, carefully verifying the suggestions with corpora and all available resources; then they moved to the second group, trying to find equivalents on their own (in all available resources); lastly, they investigated the third group, verifying the existing mapping relations. Moreover, whenever linguists started work with a particular WordNet "nest", they were encouraged to look for its possible extensions on their own (not limiting themselves to cascade dictionary suggestions). The effect of that work is a substantially enlarged version of WordNet, with lexical material – some 10,000 lemmas – added in many places where a link from the Polish side would have been inaccurate. The result, enWordNet 1.0,[10] is also part of this release, which ought to encourage comparative studies and cross-lingual research.

4 Applications of plWordNet

Language resources are developed for applications: the higher the uptake, the better the perceived quality. plWordNet is a pivotal element of a system of language and knowledge resources; plWordNet's wide coverage helps a lot. The system has several layers, with plWordNet in the middle:

- top- and medium-level ontology SUMO with plWordNet semi-automatically mapped onto it (Kędzia and Piasecki, 2014),

[10]The symbol WordNet® is a registered trademark. We cannot use it.

- NELexion2, a very large lexicon of Polish Proper Names (PNs), ≈1.5 million, manually linked at the level of fine-grained semantic PN classes (Marcińczuk, 2016),
- a lexicon of ≈60,000 multiword expressions with syntactic structures described, linked to plWordNet's LUs by lemmas (Maziarz et al., 2015; Dziob et al., 2016),
- a syntactic-semantic lexicon of Polish valency frames (≈15,000 lemmas described) linked to plWordNet at the LU level and semantic restrictions of frame arguments (Kotsyba, 2014; Hajnicz, 2014).

The system is a very large network, linking knowledge elements to lexical meaning and descriptions of local syntactic-semantic structures. Given the mapping to WordNet, the system can be an anchor to a global Linked Data network,[11] a powerful cloud of heterogenous data webs. Manually crafted lexical-semantic resources could serve as a skeleton for the cloud, notably with plWordNet's comprehensive coverage. Lexical item descriptions therein would be the means of anchoring webs to text clouds.

plWordNet has become an important reference for research on the development of wordnets; (Fišer and Sagot, 2015) is the latest of numerous citations.

plWordNet's open license enables frequent use as a monolingual and bilingual dictionary: Web-based (`http://plwordnet.pwr.edu.pl`) via an Android application, and via WordnetLoom (Piasecki et al., 2013) (`http://ws.clarin-pl.eu/public/WordnetLoom-Viewer.zip`) a wordnet editor which offers advanced visual, graph-based browsing. plWordNet has also been included in a very large and popular Polish multilingual dictionary Lingo (`http://ling.pl`). Access to plWordNet as a dictionary amounts to tens of thousand of visits a month.

In addition to monolingual resources, plWordNet is part of multilingual resources, *e.g.,* WordTies (Pedersen et al., 2012), Open Multilingual WordNet (Bond and Foster, 2013) and multimodal resources, *e.g.,* the classification of gestures based on the verb categorisation in plWordNet (Lis and Navarretta, 2014). plWordNet was referred to in the resource for textual entailment (Przepiórkowski, 2015) and utilised for ontology mapping and linking ontology to lexicon (Jastrząb et al., 2016).

Assorted applications of plWordNet include language correction, relation extraction (Mykowiecka and Marciniak, 2014), text indexing (Kaleta, 2014), Text Mining (Maciołek and Dobrowolski, 2013), text classification (Wróbel et al., 2016; Mirończuk and Protasiewicz, 2016), Open Domain Question Answering (Przybyła, 2013), and use as a quasi-ontology in document structure recognition (Kamola et al., 2015).

Registered users of plWordNet declare its applications. Here is a selection of such declaration: education (at different levels) including Polish language teaching, building dictionaries, extraction of synonyms and semantically related words, detection of loanwords, cross-linguistic study on phonesthemes, classification of metaphorical expressions, corpus studies, grammar development, comparative and contrastive studies, language recognition, parsing disambiguation, semantic analysis of text, document similarity measures, semantic indexing of documents, semantic information retrieval, recommendation systems, construction of chatbots and dialogue systems, plagiarism detection, translation evaluation, data visualisation, research on complex networks and ontologies. An exceptional case is the practical use of plWordNet during the medical treatment of aphasia.

5 Always more to do

The release of plWordNet 3.0 is a caesura, but language resources never really reach a stable state. The wordnet is an NLP-friendly description of the Polish lexical system on a scale unheard of even in previously published large unilingual dictionaries.

And yet, each element of the system could stand improvement. For example, while many derivational relations (typical of strongly inflected languages such as Polish) have been introduced, there remains a motherlode of relations signalled by verbal prefixes, a highly productive operation similar to what phrasal verbs contribute to English. Relation density in plWordNet is quite satisfactory, but there can be semi-automatic methods of improving it further. Stylistic registers as a constitutive feature can lead the the natural introduction of sub-databases of specialised vocabulary for a variety of domains, interlinked across registers. Multi-word expressions and proper names need more work. Emotion annotations have to be extended onto the whole network.

Last but not least, user feedback in matters small (typos, omissions) and large (new functionalities, support for new kinds of applications) ought to be implemented.

Abstract

Multiword Expressions (MWEs) are crucial lexico-semantic units in any language. However, most work on MWEs has been focused on standard *monolingual* corpora. In this work, we examine MWE usage on Twitter - an inherently multilingual medium with an extremely short average text length that is often replete with grammatical errors. In this work we present a new graph based, language agnostic method for automatically extracting MWEs from tweets. We show how our method outperforms standard Association Measures. We also present a novel unsupervised evaluation technique to ascertain the accuracy of MWE extraction.

1 Introduction

Apart from being just a social media platform, Twitter has emerged as an authoritative source of breaking news and subsequent discussions (Kwak et al., 2010; Hu et al., 2012). Most "global" news stories, from terrorist attacks, political news, sports events to celebrity updates, not only *trend* on Twitter within minutes of the actual event but often in multiple languages. One challenge thus, in understanding the full story is being able to process all languages involved. One way to do this could be by partitioning data into the constituent languages (Bergsma et al., 2012) as there exist several sophisticated tools for Twitter (Pak and Paroubek, 2010; Ritter et al., 2012; Owoputi et al., 2013; Kong et al., 2014) designed specifically for various languages (Avontuur et al., 2012; Abdul-Mageed et al., 2012; Rehbein, 2013). However, such an approach might not be able to process all languages. Further, it faces an added disadvantage of ignoring valuable semantic, temporal and cross-lingual relationships between the tweets. In fact these relationships could instead be utilized to not only better understand the underlying story but also generate resources for resource poor languages in question.

Thus, as a cursory step in understanding such hashtags, our work focuses on extracting multiword expressions (MWEs) from Twitter data streams. MWEs are great starting points from two perspectives: (a) they are statistically "idiosyncratic" (Sag et al., 2002) and thus, require no prior knowledge of the text or the corresponding language for extraction and (b) form a considerable portion of the vocabulary for a given language (Fellbaum, 1998). Furthermore, their importance for a variety of NLP tasks like POS tagging (Shigeto et al., 2013), deep parsing (Nivre and Nilsson, 2004), sentiment analysis (Moreno-Ortiz et al., 2013), translation (Ren et al., 2009; Carpuat and Diab, 2010) etc: cannot be overstated. Also, as we explore in Section 4, MWE usage on Twitter shows some unique characteristics stemming from the nature of the medium like acronym usage, temporal sensitivity, etc. and thus, motivating a stronger need to develop MWE extraction techniques specific to such data streams.

However, most work (Van de Cruys and Moirón, 2007; Ramisch et al., 2010; Sinha, 2011) on automatic MWE extraction has either relied on (a) the knowledge of POS patterns that constitute MWEs and the availability of POS annotated corpora, or (b) enumeration of all possible n-grams and ranking them using Association Measures (AMs) (Pedersen et al., 2011). A third branch of work also exists that instead uses parallel corpora (Da Silva et al., 1999) and exploits distributional dissimilarity between words

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2269–2278, Osaka, Japan, December 11-17 2016.

S. no	Tag type	POS tags	Examples
1	ADJP	JJ JJ	*petits blancs*, ginger redhead
2		NN JJ	day gay, reunion special
5	NP	JJ NN	*delicioso cctel*, *sozialen netzwerken*
6		DT NN	*la eurocopa*
7		NN NN	clapback season, skai jackson, **fra rou**, *asie pacifique*
8		NN RB	*la arranca*
9	ADVP	PP RB	*mal den*
10	VP	NN VB	*je suis*, *kuch lana*, *nahi aayenge*
11		RB VB	verbally attacked, *heit aber*
12		VB JJ	breaking federal
13		VB NN	cry blood, banish demons, minimize disruption, *evitar el*
14		VB RB	starts tonight, acted honorably
15		VB VB	gotta catch, **lets rt**

Table 1: Examples of extracted MWEs and their syntactic classification

to extract phrases. However, we do not consider this approach further given the target domain and only mention it here for completeness.

However, as outlined above, the very nature of our problem invalidates the first line of approach. It is impractical to build corresponding systems (namely POS taggers, POS patterns and candidate extraction) for every applicable language. As far as the second approach is concerned, it is usually effective over time invariant datasets where one time enumeration of all n-grams would suffice. However, our setting would require frequent regeneration of N-grams as the corpus increases over time. Hence, we would like to find methods that do not require enumerating all N-grams and can yet find statistically significant phrases. An added challenge, as we discuss in Section 2, when working with multilingual data is that of evaluation. Thus, we must also find ways to evaluate the extracted MWEs that involves minimal manual intervention.

Thus, the primary objectives of this work can be enumerated as:

- Propose a new graph based method for MWE extraction that can circumvent the challenges of Twitter language usage, temporal nature of Hashtags and possible enumeration of all N-grams.
- Propose an automatic evaluation technique for the extracted MWEs
- Additionally, analyze the variance in extracted MWEs across different variables

The rest of the paper is organized as follows. Starting with Section 2, we first discuss the problem setting in a little more detail and then present our method in Section 3. We show why a word graph based method can overcome the enumerated problems - multilingualism, lack of grammar and relatively free word ordering to name a few. Then in Section 4, we describe our novel evaluation technique and also compare the performance of our method against different AMs. Finally, we conclude by discussing the scope of future work and conclusions from our results in Section 5.

2 Related Work

In this section, we consider the problem of extracting MWEs from a text corpus and evaluating the accuracy and nature of the extracted MWEs. As discussed in Section 1, nuanced extraction techniques rely on POS annotated corpora at the very least. Firstly, the lack of POS taggers for all applicable languages would reduce the size of the workable dataset. For example, some resource poor languages like Malay, Indonesian etc: have very little work in the said regard (Adriani and Van Rijsbergen, 2000; Rais et al., 2011). Secondly, as shown by (Derczynski et al., 2013), POS taggers trained on longer documents perform poorly on tweets. Further the extraction patterns vary widely (Kunchukuttan and Damani, 2008; Green et al., 2011; Tsvetkov and Wintner, 2014) based on the underlying language and thus, making it computationally intractable. Finally, as shown by (Solorio et al., 2014), it is much harder to detect the individual languages within code switched short text documents. Further, there is even lack of availability of standard annotated corpora beyond a handful of languages (Solorio and Liu, 2008; Vyas et al., 2014) for code switched text and thus, almost little to no research even exists in extracting MWEs from such text. Thus, at the very least we need to look at techniques that do not rely on POS tags.

As far as candidate evaluation is concerned, most techniques discussed thus far focus on evaluating the *efficacy* of the *POS extraction patterns*. Hence, a common technique (Pearce, 2002; Ramisch et al., 2012) involves measuring recall against standard corpora. Note that such methods assume that an exhaustive language specific list of MWEs is available. However, since our task is primarily concerned with MWE "discovery", such standard lexicons may not be used. A common alternative involves manual evaluation. However, our initial efforts at manual evaluation proved to be tedious primarily due to unfamiliarity with some of the languages. This prompted us to develop an automatic evaluation technique that we present in Section 4.2 that uses the Twitter Search API.

However, this raises a related yet contrary question on MWE classification. For the extracted MWEs to be useful for downstream processing, some nomenclature must be developed. Some of the earliest work in MWE extraction and classification was done by Sag et al. (2002). They initially introduced a structural classification for MWEs that relies on the differences in compositionality and fixedness between the different MWEs. Later work by Schneider et al. (2014) on MWE usage in social media uses two classification schemes. One, that deals with compositionality and classifies MWEs as either *strong* or *weak* based on their opaqueness and a second, detailed syntactic classification that relies on POS tags. In a multilingual scenario however, it is much easier to determine POS tags for a foreign phrase than to judge the compositionality or opaqueness of the MWE itself. Thus, in continuation with the list provided by Schneider et al. (2014) that deals specifically with social media, we adopted an abridged version[1] as depicted in Table 1. The table lists the tag type, the POS tags used and some extracted examples. Note that this scheme is used only for the purpose of classification and not utilized for MWE evaluation. For languages other than English, we determine membership by examining the translation of the given foreign language phrase. We largely use this nomenclature for analysis as presented in Section 4.

Having thus presented an overview of related work, we now turn our attention to our main algorithm.

3 System description & algorithms

3.1 Constructing Word Graphs

Thus, so far we have established that the nature and size of tweets are an hindrance for the standard tokenization process. However, using word graphs would circumvent both problems. On one hand, they would allow us to capture co-occurrence and statistical information within the graph structure but at the same time allow relaxed word ordering. Thus, given a set of tweets for a hashtag, which we will refer to as a *dataset*, we could construct a single graph $G = (V, E)$ from all tweets as follows. The vertices V represent the set of all unique tokens that occur within the dataset and two vertices share an edge if they co-occur within a tweet. The edge weight is set to the co-occurrence probability of the participating vertices and each vertex is annotated with the occurrence probability of the underlying token. The token set is obtained by simple whitespace tokenization followed by lowercasing and removing all mentions, URLs, emojis/emoticons and # prefixes.

For such a graph, we further contend that the tokens represented by a pair of vertices constitute a MWE if (a) the said tokens frequently co-occur but (b) rarely occur with other tokens. This could be ascertained by using the edge weights and examining the vertex neighborhoods of the said vertices. To that end, we looked at similar problems in other domains and found the method as presented by Londhe et al. (2014) for *Product title matching* to be promising. The authors essentially demonstrate how word graphs for product titles can be utilized to detect equivalences using a community detection algorithm viz. CDAM (Community Detection for Approximate Matching). We thus implemented equivalent algorithms, collectively called GRePE (**G**raph **Re**duction for **P**hrase **E**xtraction) in our problem setting which we now present.

3.2 Extracting MWE candidates

A block diagram of our system components is shown in Figure 1. Overall, the two main system components are the Indexer and the Graph Reducer. The *Indexer* ingests a given dataset to convert it into

[1] we only use bigrams and treat proper nouns as any other nouns

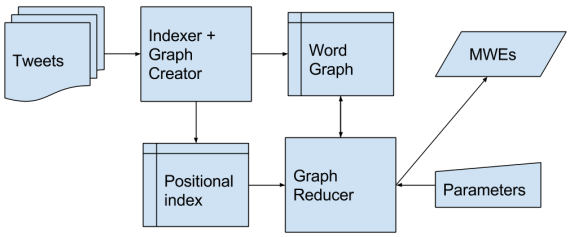

Figure 1: System block diagram

Algorithm 1 CROSS-VERTEX ENRICHMENT

Input: Pair of vertices V_1, V_2 and enrichment threshold η
Output: Enriched neighborhoods $\mathrm{N}^e(V_1), \mathrm{N}^e(V_2)$
for Vertex v in $\{V_1, V_2\}$ **do**
    Find v' in $\mathrm{N}(v)$ such that $p(v, v')$ is largest
    Define $\mathrm{N}_\eta(v)$ as all vertices x with $p(x, v) \geq \eta \times p(v, v')$
    Initialize $\mathrm{N}^e(v) = \mathrm{N}_\eta(v)$
    Let $v_o = V \setminus v$, $\mathrm{N}'_\eta(v) \coloneqq \mathrm{N}(v) \setminus \mathrm{N}_\eta(v)$, $\mathrm{C}(v) = \mathrm{N}'_\eta(v) \cap v_o$
    Let $S_v = getWJC(\mathrm{N}(v), \mathrm{N}(v_o))$
end for
for Each element c in C_1 **do**
    Let $S_c = getWJC((\mathrm{N}(1) \setminus c), \mathrm{N}(2))$
    if $w_c = p(V_1, c) + |S_c - S_1| \geq \eta_1$ **then**
        Add c to N^e_1
    end if
end for
Repeat above for C_2
Return $\mathrm{N}^e(V_1), \mathrm{N}^e(V_2)$

a *Word Graph* and a corresponding *Positional Index*. The *Graph Reducer* then iterates over the graph, detects MWEs and merges constituent nodes. The following subsections present more details.

Before we describe the graph reduction algorithms, we introduce some notation as follows:

1. i^{th} vertex is denoted as V_i
2. The neighborhood of a vertex V, i.e. a set of vertices up to a depth of k, is denoted as $\mathrm{N}_k(V)$
3. Immediate neighborhood of a vertex V i.e. $\mathrm{N}_1(V)$ is denoted simply as $\mathrm{N}(V)$
4. $p(V)$ and $p(V_i, V_j)$ represent the prior and joint probabilities respectively

The process of graph reduction occurs in three phases : (a) Context determination (b) Local graph reduction and (c) Candidate pruning. Phases (a) and (b) operate on a neighborhood of a pair of vertices. The third phase however iterates over the graph and determines which vertex pairs to examine as we explain below.

3.2.1 Context Determination

We first determine a context (i.e. a set of vertices) for comparison. The basic idea of the algorithm is to define a context by using only *valuable* vertices in a given neighborhood. The inherent value is established in two ways : (a) the edge weight as compared to the maximum edge weight and (b) the contribution of the said vertex to the similarity / dissimilarity between the vertices being compared. We present Algorithm 1 that determines this context (or *"cross-enriched" neighborhood*).[2]

[2] getWJC() refers to weighted Jaccard coefficient

Algorithm 2 LOCAL GRAPH REDUCTION

Input: The sets : $\mathrm{C}(i,j)$, $\mathrm{U}(i)$ and $\mathrm{U}(j)$
Output: MWE candidates M
Initialize $M \leftarrow \emptyset$
Let the set $\mathrm{U} \coloneqq \mathrm{U}(i) \cup \mathrm{U}(j)$, $|\mathrm{U}| = k$
Let $A = zeros(k,k)$
Construct adjacency matrix where $A(x,y) = p(\mathrm{U}_x, \mathrm{U}_y) + \sum_c^{\mathrm{C}(i,j)} p(c, \mathrm{U}_y)$
for All x,y within the same partition **do**
    if $A(x,y) \gg A(y,x)$ **then**
        Delete U_y locally
    else if $A(x,y) \approx A(y,x)$ **then**
        Add pair $< \mathrm{U}_x, \mathrm{U}_y >$ to M
    end if
end for
Return M

Algorithm 3 GENERATING MWE CANDIDATES

Input: A word graph $G = (V, E, W)$, cross-enrichment parameter η, word rarity parameter ζ, co-occurrence parameter κ, positional index idx
Output: MWE candidates
Initialize $M_{op} \leftarrow \emptyset$
Let V_d be the vertices V sorted by descending order of degree
Initialize $\mathrm{M} \leftarrow \emptyset$
for $< V_i, V_j >$ in V_d **do**
    $\mathrm{N}^e(V_i), \mathrm{N}^e(V_j)$ = $crossEnrich(V_i, V_j, \eta)$
    compute $\mathrm{C}(i,j), \mathrm{U}_i, \mathrm{U}_j$
    $\mathrm{M} \leftarrow reduce(\mathrm{C}(i,j), \mathrm{U}_i, \mathrm{U}_j)$
end for
$\mathrm{M} \leftarrow filter(\mathrm{M}, \zeta, \kappa)$
for Group g in M **do**
    $M_{op} \leftarrow expandPhrase(g, idx)$
end for
Return M_{op}, G

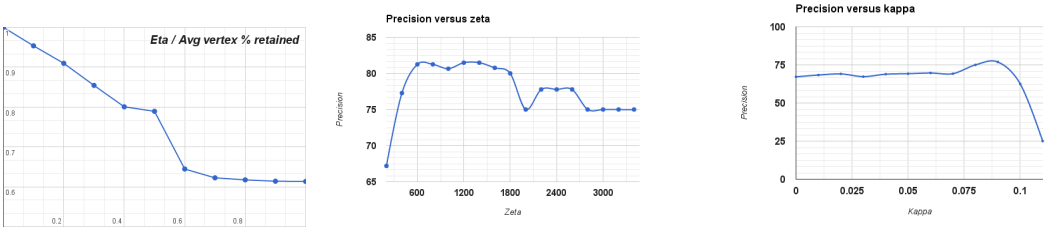
For a given vertices V_i and V_j, this algorithm effectively partitions their joint neighborhood into four disjoint sets:

1. Common vertices, $\mathrm{C}(i,j) \coloneqq \mathrm{N}^e(V_i) \cap \mathrm{N}^e(V_j)$
2. Uncommon vertices of i, $\mathrm{U}(i) \coloneqq \mathrm{N}^e(V_i) \setminus \mathrm{C}(i,j)$
3. Uncommon vertices of j, $\mathrm{U}(j) \coloneqq \mathrm{N}^e(V_j) \setminus \mathrm{C}(i,j)$
4. Ignored vertices, $\bigcup_k^{i,j} \mathrm{N}(V_k) \setminus \mathrm{N}^e(V_k)$

We only care about the common (C) and uncommon (U) vertices which act as inputs to the next phase.

3.2.2 Local Graph Reduction

In the next phase, we consider the sub-graph created by these three sets and perform local graph reductions as outlined in Algorithm 2. Essentially, we represent the local graph as a compressed adjacency matrix. For a given cell, $A(x,y)$, the weight in the matrix is set to the edge weight between vertices x and y plus the sum of weights from all common vertices to y. We then reduce the graph by either deleting



(a) Eta versus retained neighborhood

(b) Precision versus Zeta

(c) Precision versus kappa

Figure 2: Parameter tuning

a vertex if it is dominated by another node (i.e. this indicates that the dominated node never occurs independently) or by merging two vertices if their weights are equivalent (i.e. the given pair almost always co-occur - our original assumption). Note that these reductions are *local*.

3.2.3 Candidate Pruning & Phrase Expansion

In the final phase as illustrated in Algorithm 3, we output the final list of MWEs using a two step process. We first iterate over the graph that in turn calls Algorithm 1 and Algorithm 2. Next, we eliminate false positives based on two parameters : word rarity (ζ) and co-occurrence (κ). The former eliminates candidates that are composed of frequently occurring words, i.e. typical stopwords whilst the latter ensures a lower bound on the number of co-occurrences of the words that constitute the candidates. Finally, we use the positional index to reorder and expand the phrases as needed before outputting the final result.

A note about graph iteration is pertinent here. For a pair of vertices V_i and V_j input to the algorithms, it can be observed that the actual merge occurs on the vertices within the neighborhood of V_i, V_j and not on the vertices themselves. Thus, in order to cover as much graph as quickly as possible, the easiest strategy is to pick V_i, V_j in decreasing order of degree. Note that this also guarantees iteration in O(V) time.

Finally, although our method does seem similar to enumerating all n-grams and using some AM, we contend that this method can differentiate between nuances of usage due to the pairwise or cross-vertex iteration. In a typical n-gram approach, such contextual information is lost whereas in our method, it is equivalent to evaluating the n-grams in a limited context and is hence, more powerful. We now present details of parameter estimation and a short discussion on parameter sensitivity.

3.3 Parameter estimation

As we saw in Section 3.2, we use the following parameters:

- Enrichment parameter η : Determines which vertices in the current neighborhood will be considered
- Word rarity parameter ζ : Determines the level of rarity for a vertex to be considered
- Co-occurrence parameter κ : Determines the co-occurrence probability for an edge to be considered

We used the MH370 dataset (refer Table 2[3]) to find the optimum values of these parameters except for the *Enrichment parameter (η)* as described below. We obtained the value of η by evaluating the effect of varying η on a set of vertices and the neighboring vertices retained. We found a value of 0.6 to be a reasonable balance between over-pruning and retaining most vertices. Refer Figure 2 that demonstrates that a value of $\eta = 0.6$ does seem to have a large discriminatory power.

For estimating ζ and κ, we first used Algorithm 3 in a parameter-less mode (i.e. without filtering) and obtained all potential MWE candidates. For all such candidates, we established if the phrase indeed is a

[3]Collected when the MH370 flight had disappeared and investigation was underway

Sno	Dataset Name	# Tweets	Avg length	Vocabulary	Stopwords %	OOV (non English) %	Singleton %	Lang count
0	MH370	8,556	12.76	13,578	33.57	38.12	51.37	67

Table 4: Experimental results

4.1 Datasets and data collection

As outlined in Section 1, our primary focus lies in extracting and analyzing MWEs from short text documents, namely tweets. Given the diverse nature of users, languages employed and topics discussed on Twitter[6], we wanted to achieve as broad coverage as possible. For over two weeks[7], we collected tweets for selected trending topics at different times of day. The choice of the selected topics was based on volumes as reported by Twitter plus the perceived global reach of the topic itself. However, for the final analysis we only used a subset of our crawled data as any sets with less than 2000 unique tweets were discarded. Although Twitter provides its own language identification, we used *langid* (Lui and Baldwin, 2012) for our use to allow generalization to other data sources (like Facebook) later.

A summary of the datasets is provided in Table 2 that captures the language and vocabulary spread for each hashtag. Note that the volume of tweets notwithstanding, each HashTag has tweets in at least 30 different languages, the average tweet length is only about 10 words and the word frequency distribution has a significant long-tail with about 40% of the words occuring just once.

4.2 Automatic Evaluation

As outlined in Section 2, we evaluate our system on precision as against recall and compare the system generated MWEs with those generated by standard AMs. Since we are computing Average Precision,

[4]https://www.microsoft.com/cognitive-services/en-us/web-language-model-api

[5]We tested different AMs and found PMI to be the most effective in this scenario

[6]https://about.twitter.com/company

[7]Roughly June 21 2016 - July 10 2016

the metric value is sensitive to the size of the result set considered. Given that our system produces limited number of MWEs, we restrict the output of compared AMs to be equal to the number of MWEs generated by our system.

In order to ascertain if a generated phrase is indeed a MWE, we performed two levels of evaluation. At the first level we use the Twitter Search API[8] as follows. For every candidate $W = (w_1, w_2)$, we execute three queries while restricting each query to top 25 unique results [9] : (a) w_1 w_2 (which is equivalent to w_1 AND w_2) (b) the phrase "w_1 w_2" (c) concatenation w_1w_2. Each result set is then converted to a corresponding numeric score as below

1. DistanceScore = Average normalized token distance between tokens w_1 and w_2
2. PhraseScore = Number of returned results / 25
3. HashtagScore = Number of returned results / 25

While the latter two scores approximate the probability of the phrase occurring either as separate words or concatenated together, the first score is a proxy for how frequently do the constituent words appear next to each other (as in a phrase) versus co-occurring in a tweet. Additionally, we add a fourth parameter, an integer stopword score $[0, 2]$ that acts as a regularization parameter to penalize phrases that contain stopwords which are bound to return a large number of results. We present some examples to illustrate the need for all four values in Table 3. We trained a simple multinomial logistic regression classifier on the MH370 dataset on manually evaluated MWE candidates with a 70% true label precision.

As second layer of screening, we assign one of the 15 POS labels as listed in Table 1 and double check that the extracted candidates are in fact MWEs. Note that we translate phrases from languages other than English into English before assigning the POS tags. We admit this is slightly lossy but we view at as a way to project all MWEs in the same token space for simplicity. Thus, for each dataset, we compute the Average Precision by using the true class labels obtained as explained above. We present the results in Table 4 along with Mean Average Precision (MAP).

We additionally compare the overlap between our method and the different AMs in Table 5a as well as splits by POS tag type in Table 5b. These tables show that although the different AMs do not necessarily generate the same candidate list (except LogLikelihood and T-score), the comparable POS split percentages indicate inherent bias within the dataset.

4.3 Discussion of results

We must take a moment to explain and examine the results. Although, it may not seem that our method is a vast improvement over other AMs when looking at the MAP, it must be noted that we do not produce "ranked" results as such and only candidates. We used a fixed ordering based upon the co-occurrence probability of phrases and a better ranking mechanism may exist but was not explored. The performance of the AMs is also bound to suffer when the full result sets are used. Further, except for the PresidentObama dataset, our method places within top 3 where it is not the best performing method. Comparing against Table 2, the method seems to suffer for predominantly English datasets (low OOV% - Pride, PresidentObama etc) but better for multilingual datasets (Brexit, PokemonGO). Thus, we could in principle augment our method with either AMs or existing POS based approaches for English to further improve performance. However, it can be concluded that overall the method returns a small and fairly precise set of MWEs as compared to AMs and enumerating all bigrams.

5 Future Work and Conclusions

In summary, we can enumerate our contributions as (a) we presented a language agnostic method for extracting MWEs from Twitter (b) we explored the performance of different AMs in a similar setting and (c) we showed a method for automatic evaluation of extracted MWEs. As an extension to this work, we would like to further analyze our results and study the effect of Twitter and social media specific features

on MWE usage. Namely does internet language, hashtags and code switching impact how MWEs are used? We would also like to explore if the extracted MWEs can be utilized for other downstream tasks like generating summaries or automatic bilingual tweet alignment. We believe such work would help in developing resources for resource poor languages as well as aid in better understanding and modeling language usage on social media.

Incremental Global Event Extraction

Alex Judea and **Michael Strube**
Heidelberg Institute for Theoretical Studies gGmbH
Schloss-Wolfsbrunnenweg 35
69118 Heidelberg, Germany
(alex.judea|michael.strube)@h-its.org

Abstract

Event extraction is a difficult information extraction task. Li et al. (2014) explore the benefits of modeling event extraction and two related tasks, entity mention and relation extraction, jointly. This joint system achieves state-of-the-art performance in all tasks. However, as a system operating only at the sentence level, it misses valuable information from other parts of the document. In this paper, we present an incremental approach to make the global context of the entire document available to the intra-sentential, state-of-the-art event extractor. We show that our method robustly increases performance on two datasets, namely ACE 2005 and TAC 2015.

1 Introduction

*But the **strikes** prove controversial.*

In many cases, it is not sufficient to look at one sentence when extracting events. In our example, *strikes* has no potential event arguments, and the context is not sufficient to disambiguate it correctly: Is it the trigger of an ATTACK event because it actually means *bomb strikes*? Or is it not a trigger at all because it refers to the industrial action?

*Soon after dawn on this fourth day, confirmation of the ship's first **strike** arrived . . . This is the first of an unknown number of **strikes** we'll conduct during our watch in "operation enduring freedom" . . . But the **strikes** prove controversial.*

Given the other sentences it is easier to infer that *strikes* is indeed the trigger of an ATTACK event. In this paper, we present a system that makes the global context of a document available to a state-of-the-art event extractor. Looking at a broader context also benefits argument detection. For example, within one document entities play coherent roles in different events. Consider the following text:

*Sam Waksal was **sentenced** to seven years and three months in federal prison . . . He's being released on his own cog in a sans before he's to **report** to jail.*

Looking only at individual sentences, it is hard to predict that *report* triggers an ARREST-JAIL event, which in turn makes it hard to predict that *he* is the Person of this event. If the system looks at the entire document and knows that *he* and *Sam Waksal* are coreferent, it can better infer that the Defendant of a SENTENCE event can be the Person of an ARREST-JAIL event, which in turn makes it easier to infer that *he* is this person.

In this paper, we present a method to incorporate the global, document-wide context into the decision process of a system that predicts entity mentions, events, and relations jointly. We use features that are based on the 'one sense per discourse' assumption (Gale et al., 1992), a concept widely used in Word Sense Disambiguation (e.g., Navigli and Lapata (2007)), and on the coherence of roles an entity plays in different events. We show that our method robustly increases performance on two datasets, namely ACE 2005 and TAC 2015.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2279–2289, Osaka, Japan, December 11-17 2016.

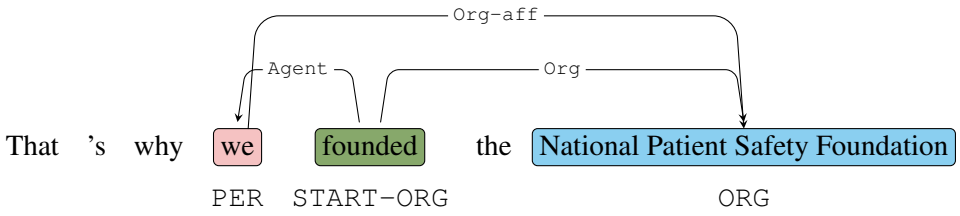

Figure 1: The configuration of a sentence. Depicted are two entities, a trigger, and the semantic relations and event argument relations between them.

The paper is structured as follows. Section 2 describes the task in more detail. Section 3 puts our work in context of other approaches to event extraction. Section 4 describes an intra-sentential, state-of-the-art system introduced by Li et al. (2014). In Section 5 we present *Incremental Global Inference*, a multi-pass procedure that makes the global context of a document accessible to the joint decoding of our intra-sentential event extractor. Section 6 reports evaluation results and Section 7 gives conclusions.

2 Task Description

Event extraction is an information extraction task where mentions of predefined event types are extracted from texts. We follow the task definition of the Automatic Content Extraction (ACE) program of 2005 which defines 33 event types, organized in eight categories. We also evaluate on another dataset, namely on the Event Nugget data of TAC 2015 (Mitamura et al., 2015).

In ACE, events are annotated only intra-sentential. Each event type has roles, e.g., `START-ORG`, an event indicating the founding of an organization, has the roles `Agent` and `Org`, whereas `DIE`, an event indicating the death of a person, has the roles `Agent`, `Victim`, and `Instrument`. The roles `Place` and `Time` are shared by all event types.

Roles are filled by zero or more *arguments*, that is, spans of text. The same span of text may be shared by multiple events as arguments, and may fill different roles in each of them. Finally, every event is indicated by a *trigger*.

Besides event annotations, ACE provides annotations of entity mentions and semantic relations. Detecting entity mentions is a task strongly related to event extraction because most arguments are mentions of persons, locations, organizations, etc.[1] Semantic relations and event arguments are also related because they coincide often with the start or end points of arguments.

Consider Figure 1. Depicted is the sentence *That's why we founded the National Patient Safety Foundation*. We can find two entity mentions, namely *we* as a `PER` and *National Patient Safety Foundation* as an `ORG` mention. Furthermore, there is one trigger of a `START-ORG` event, namely *founded*. This event has two arguments, namely *we* filling the role `Agent`, and *National Patient Safety Foundation* filling the role `Org`. Finally, there is an `Org-aff` relation between *we* and *National Patient Safety Foundation*.

While ACE provides annotations for all tasks involved (entity mentions, event triggers, event arguments), the TAC 2015 Event Nugget data provides only annotations for event triggers. The trigger annotation schemes are similar, the two data sets share many event types, and events occur only intra-sentential. However, some event types in TAC are more fine-grained, e.g., `TRANSPORT` in ACE was split into `TRANSPORT-PERSON` and `TRANSPORT-ARTIFACT` in TAC.

3 Related Work

The base system we use is the one described in Li et al. (2014)[2]. To our knowledge it is the only system to predict entity mentions, relations, event triggers, and event arguments jointly. It achieves state-of-the-art performance in all four tasks.

Many approaches to event extraction, including our base system, do not cross sentence boundaries (Grishman et al., 2005; Ahn, 2006; Lu and Roth, 2012; Li et al., 2013; Li et al., 2014). Only a few

[1] Some arguments are mentions of points in time, amounts of money, etc.

[2] This system is a combination of the systems described in Li et al. (2013) and Li and Ji (2014).

approaches go beyond sentences (Liao and Grishman, 2010; Hong et al., 2011) or beyond documents (Ji and Grishman, 2008) in order to exploit richer contexts for the extraction of events.

Recently, three deep learning systems were proposed. Nguyen and Grishman (2015) use a Convolutional Neural Network (CNN) to detect event triggers. They achieve good trigger detection performance, but they do not tackle the full event task. Chen et al. (2015) propose a more complicated version of a CNN which is able to detect multiple arguments in addition to triggers. Their system is a pipeline system (it predicts triggers and arguments separately) and suffers from error propagation. Nguyen et al. (2016) combine the advantages of joint models, explicit feature engineering and neural networks. They propose a joint, bi-directional recurrent network which additionally uses the features in Li et al. (2013). However, both Chen et al. (2015) and Nguyen et al. (2016) rely on gold entity mentions for trigger prediction.

The cross-sentential systems proposed in Liao and Grishman (2010) and Yang and Mitchell (2016) are closest to ours. We will describe them in the following.

Liao and Grishman (2010) propose a pipeline system that performs easy-first global inference. Local classifiers find triggers and arguments based solely on local information. Confident decisions are collected and used to inform global trigger and argument classifiers. In the local, intra-sentential phase the system performs pattern matching to align the entity mention context of a trigger to some known patterns. Similar to our approach, confident decisions are collected during the intra-sentential pass and used to infer harder cases.

Yang and Mitchell (2016) propose a pipeline system with global inference. In contrast to most other approaches, it also predicts entity mentions. Yang and Mitchell (2016) first train two Conditional Random Fields to generate mention and trigger candidates for a document. They only keep the 50 best mention candidates, and the 10 best trigger candidates. Then, they train three classifiers to capture entity mentions, within-event structures, and event-event relations. Finally, they formalize an Integer Linear Program that, given the local classifiers and the (global) event-event classifier, produces a globally optimal solution, instead of refining locally-optimal solutions with global information.

In terms of label inference (assigning types to candidates), our approach lies between Liao and Grishman (2010) and Yang and Mitchell (2016). The former apply global inference after local inference, the latter model both jointly. We let local and global inference inform each other and iteratively refine both.

A major difference between Liao and Grishman (2010) one the one hand, and Yang and Mitchell (2016) and our approach on the other is that the first approach uses gold entity mentions, while the other two use predicted entity mentions. Comparing full inference, we note that Yang and Mitchell (2016) use a pipeline approach: They first tag sentences for potential entity mention and event trigger candidates, and apply label inference afterwards. In contrast, we model both jointly.

4 Intra-Sentential Event Detection

In this section we describe our reimplementation of the system presented in Li et al. (2014), a state-of-the-art event detector. It employs joint decoding of entity mentions, events, and relations in order to make use of a rich feature set, including features which capture interdependencies of different subtasks. It uses a structured perceptron with beam search to explore different segmentations of a sentence and possible connections between segments.

4.1 Terminology

Following Li et al. (2014) we will call a specific segment of a sentence a *node* and a relation connecting two nodes an *arc*. The entire set of nodes and arcs for a sentence will be called *configuration*.

Formally, a node n is a tuple (b, e, n_t) where b and e are begin and end offsets, and n_t is an entity, event, or 'null' type. We encode offsets as token indices. An arc is a tuple (e_1, e_2, a_t) with $e_1 < e_2$, where e_1 and e_2 are the end offsets of the non-overlapping nodes of the connection, and a_t is a semantic relation or event argument type. Because semantic relations are directed and nodes are ordered by offset, we have to mark relation direction by defining an 'inverse' version of each semantic relation type.

4.2 Decoding and Training

Our decoding (producing configurations for a given sentence) is built around the idea of *Semi-Markov Chains* (Sarawagi and Cohen, 2004). Here, in contrast to more traditional token sequence labelers like CRFs, decoding produces segments of arbitrary length, possibly spanning multiple tokens and is therefore able to use features characterizing entire segments, and not only individual tokens. In the following we describe the decoding and training procedures in detail. Algorithm 1 formalizes the procedure.

We start our description with the method GENERATE NODES in Algorithm 1. Given a sentence s with tokens $t_1 \dots t_m$, the procedure generates nodes of different types and lengths ending at each t_i. It starts with t_1 and generates nodes of length one with different types, e.g., $(1, 1, \texttt{PER})$ or $(1, 1, \texttt{START-ORG})$. The procedure moves on to the next token, t_2. Now, it generates segments of length one and length two, e.g., $(2, 2, \texttt{PER})$ or $(1, 2, \texttt{PER})$, and adds them to the previously constructed configurations such that nodes do not overlap and there are no gaps.

Algorithm 1:
BEAM SEARCH$(s = t_1 \dots t_m, y, z, \textit{training})$

```
1  beam b ← ∅
2  for i = 1 ... m do
3      b(i) ← GENERATE NODES(b, i)
4      b(i) ← top_z(b(i))
5      if training ∧ y_i ∉ b(i) then
6          UPDATE(b(i, 1), y_i)
7          exit
8      for j = i − 1 ... 0 do
9          b(i) ← GENERATE ARCS(b, j, i)
10         b(i) ← top_z(b_i)
11         if training ∧ y_i ∉ b(i) then
12             UPDATE(b(i, 1), y_i)
13             exit
14 if training ∧ y ≠ b(m, 1) then
15     UPDATE(b(m, 1), y)
16     exit
17 return b(m, 0)
```

Some configurations may now contain two nodes which means that the procedure can predict arcs (GENERATE ARCS in Algorithm 1). It generates a compatible arc for each node pair, but does not overwrite configurations without arcs. This ensures that not predicting an arc between any two nodes is always a valid hypothesis. We collect type restrictions for arcs from the training data. For example, it is not possible that Organization-Affiliation relations hold between person mentions. Such restrictions keep the search space smaller and make learning easier.

Input to Algorithm 1 is a sentence s, a gold configuration y, and the beam size z. The beam b is a ranked list of hypotheses (that is, configurations) ending at any token position in the sentence. If the procedure is not in training mode, or if it did not make any prediction errors, it returns the top hypothesis ending at the last token position, $b(m, 1)$ for a sentence with m tokens.

Ideally, one would enumerate all possible configurations for a sentence and pick the best one. However, such an exhaustive enumeration is infeasible because the number of configurations grows exponentially with the number of tokens. Following Li et al. (2014) we approximate the enumeration by using *beam search*. We first expand configurations with new nodes and keep only the best z configurations. These are then expanded with arcs. During this process we again keep only the best z configurations. After arc generation, we move to the next position.

In training mode the procedure updates feature weights as soon as y_i, a prefix of the gold configuration, is not predictable anymore because it is no longer part of the beam. This is called *early update*. Huang et al. (2012) proved that, in structured perceptrons, standard updates may lead to bad performance with inexact search strategies such as beam search because there may be updates which actually lower the score of the gold solution, thus leading the model in a wrong direction. Early updates prevent this problem at the expense of higher training time. Note that we exit the procedure when early updates happen. There are two positions where early updates occur, namely after node generation and during arc generation (Lines 6 and 12).

4.3 Features

The feature set of our base system is complex because each subtask requires its own rich feature set. We can divide features into two broad categories: Static features, which do not depend on previous decisions, and dynamic features, which depend on previous decisions. Table 1 contains a feature summary struc-

Static	Common	lexical information* (segment tokens, context, dependencies)
		brown clusters, gazetteer entries*
	Mentions	character suffixes of length 3 and 4*
	Triggers	possible FrameNet frames in case of verbs*
	Arguments	trigger type, mention and mention context
		trigger-mention dependency/constituency paths
	Relations	entity types, contexts, extent overlaps
		mention-mention dependency/constituency paths
		syntactico-semantic structures (Chan and Roth, 2011)
Dynamic	Common	(event or entity) type bigrams
		consistencies (same text=same type, coordinations, pronouns)
	Triggers	dependency path between trigger pairs
	Arguments	characterize mentions filling the same role in the same event
		characterize triggers sharing a mention
	Relations	characterize triangles like A-C, B-C
		characterize constructions where the parts tend to have same relation types, e.g., coordinations
	Joint Argument-Relation	relation types and overlapping argument types

Table 1: A description of the base system's feature set. Static features marked with * apply to the entire segment and not to each token in the segment.

tured in this way. All features are concatenated with the node or arc type under consideration. Argument features additionally come without types in order to characterize properties of arguments in general.

In order to simulate the feature set of a more traditional sequence labeler, the base system adds a BILU-tag ("B" for first token of a segment, "I" for an intermediate token, "L" for the last token, and "U" in case of length-1 segments) to each token feature of the node under consideration. If this node is an entity and the last node in the configuration is also an entity, it additionally adds the entity type of the last segment to token features, otherwise it adds a 'null' label.

5 Incremental Global Inference

Our base system is limited in two ways. It operates intra-sententially and is thus limited to the information in a single sentence. In some cases this may be sufficient to predict all entity mentions, events, and relations, in many others it is not. An approach operating on the document level has access to a broader context and may be able to resolve more difficult cases.

Even within a sentence the base system is limited to the left context of the token under consideration. The entire sentence is only available when decoding reaches the last token. At that point many decisions are not reversible anymore because of the approximate search procedure.

In the following we present Incremental Global Inference, a method to cope with both limitations. It makes the global, document-wide context available to the local decoding of our base system.

Algorithm 2:
INCREMENTAL GLOBAL INFERENCE (d)

```
1  decision map r = ∅
2  for i = 1 ... k do
3      for Sentence s ∈ document do
4          r ∪ SEARCH(s, y, z, training, r)
           // no updates
5  for Sentence s ∈ document do
6      r_s = SEARCH(s, y, z, training, r)
7      if error(r_s) then
           // updates
8          UPDATE(x*, y*)
9      r ∪ r_s
10 return r
```

5.1 Procedure

Incremental Global Inference is a multi-pass approach. We iterate several times through the document. The decisions in each iteration are input to the next iteration. We first perform standard decoding as described in Section 4 for all sentences in a document, and feed back the decisions in this step for a second pass. In the second pass we extract global features, that is, features measuring the similarity of a new node or arc to decisions made in the last iteration. We again keep the decisions for the entire document and continue with a third decoding pass, etc. Algorithm 2 formalizes the procedure.

Feature type	Applies to	Condition	Description
Local	n is trigger, m is entity	dependency graph matching known	graph connecting event type and lemmas of n, and entity type of m
			indicator
	n is argument, m is trigger	dependency graph matching known	graph connecting role of n, event type, and lemmas of m
			indicator
Global	n and m are triggers	always	The event types of n and m
		lemmas equal	The event types of n and m
		coreferent arguments	The event types of n and m
	n and m are arguments	coreferent arguments	the roles and event types of n and m

Table 2: New local and global features for a node n. Global features are for node pairs (n, m), where m may come from the entire document.

Input to Algorithm 2 is a document d, output is a structure r holding the configuration for each sentence in the document. The algorithm can be divided in two parts, namely *collection* and *final decoding*. We will now describe the two parts.

In the collection phase (Lines 2 - 4), the procedure iterates k times through the document. In each iteration, and for each sentence, it performs SEARCH, a slightly different version of Algorithm 1, the only difference being that feature updates are omitted. We perform updates in *final decoding*. The decoding decisions are recorded per sentence in the decision map r. The decision map r is updated such that the decisions for a sentence in one iteration are overwritten with the decisions for the same sentence in the next iteration. r is input for the next iteration.[3] With each iteration, and with each update of r, SEARCH has a more reliable view on mentions, triggers, and arguments in the entire document, helping it to find new nodes and arcs which would be hard to get otherwise.

After collection comes final decoding (Lines 5 - 8). Here, we again perform SEARCH. Now, we also perform weight updates as soon as they are necessary. The final output of the algorithm is the final sate of r.

5.2 New Features

In this subsection we describe the new features we use. First, we will describe new local features. Then, we will describe the global features needed for our Incremental Global Inference. Table 2 summarizes the features we describe in the following. The first column reports feature types (local or global), the second column reports class requirements (triggers or arguments), the third column reports conditions under which features fire, and the last column gives short descriptions.

Local Features

The first local feature we introduce to event extraction is based on so-called *hidden units* (Das et al., 2014). The hidden units of an event type are the exclusive triggers it has in the training data. Hidden units define a semantic space for their event types. Measuring semantic relations of the node under consideration with this space helps to find triggers never seen during training. For example, let the candidate trigger be *meeting* and the candidate event type be `MEET`. We have several hidden units of `MEET` sharing semantic relations with the predominant sense of *meeting*: *convention* and *summit* as WordNet hypernyms (Fellbaum, 1998), and *meet* as a morphological variant. We can draw features from the hidden units themselves and from the semantic relations involved.

The second local feature we introduce to event extraction is based on dependency graphs between triggers and arguments. We collect all these graphs in the training data and index them by the involved argument and entity types. For example, we collect all graphs between `MEET` events and their `Place` arguments. One such graph is the following: `MEET` $\xrightarrow{\text{nsubjpass}}$ set $\xleftarrow{\text{nmod:in}}$ `LOC/Place` , coming from sentences like *The meeting was set in Beijing*, or *The conference was set in New York*. The graph encodes that a

[3] Initially, the decision map is empty.

MEET event trigger is the passive subject of *set*, and a LOC entity/a Place argument is connected via the nominal modifier *in* to the same word.

Note that the base system also uses dependencies to characterize syntactic connections of triggers and arguments. We extend this feature type in two important ways. First, we normalize dependency graphs by entity types, event types, or roles. Second, we can utilize dependency graphs during trigger prediction. The base system is always limited to the left context. When it predicts a trigger, it misses arguments to the right of it. Our Incremental Global Inference makes the entire sequence of entity mentions/event arguments available, regardless of the actual decoding position. This increases the chance to find the MEET trigger in our example, which may in turn influence other decisions in the next decoding pass.

eventmeet trigger. However, Incremental Global Inference makes the entire mention sequence available, regardless of the actual decoding position, increasing the chance to find the MEET trigger in our example, which may in turn influence other argument or entity mention decisions in the next decoding pass.

Global Features

We now describe the global features we use for our Incremental Global Inference. The global feature function takes two arguments (n, m), where n is the argument or trigger under consideration, and m is a trigger or argument coming from the entire document.

We have three types of global features. The first applies to triggers and catches all event types present in the document. As Liao and Grishman (2010) show, certain event types often co-occur, e.g. ATTACK and DIE often co-occur in news documents.

Another feature type fires if two triggers have equal event types and equal lemmas[4]. This is based on the observation that one word tends to trigger the same event type within one document (Ji and Grishman, 2008). This is strongly related to the 'one sense per discourse' assumption (Gale et al., 1992).

The third feature type applies to triggers and arguments. It catches event types of events with coreferent arguments, and the roles entities play in events. In ACE, an entity usually plays the same role for events with the same type (which is again realated to the 'one sense per discourse' assumption) and plays coherent roles for events with different types (Liao and Grishman, 2010). For example, if an entity is the Target of an ATTACK event, it rarely becomes the Attacker, at least not within one document. However, the same entity may be the Victim of a DIE event, but never the Agent. In order to increase recall of our coreference resolution system, we regard all non-pronoun string matches as coreferent, as well as partial string matches if the involved entities are persons.

6 Evaluation

In the following, we describe the data sets and the evaluation metrics we used. We report evaluation numbers and discuss them.

6.1 Data and Evaluation Metrics

We devise evaluation on two data sets, namely on ACE 2005 and on the Event Nugget data of TAC 2015. For the TAC evaluation, we use the official training and test sets. We manually split the training set into 132 documents for training and 26 for development. The test set consists of 202 documents. We removed the lemmas 'it' and 'say' from decoding because they proved to be highly ambiguous (Reimers and Gurevych, 2015).

For the ACE evaluation, we adopt the evaluation setting of Li et al. (2014). We train on English documents and remove the two smallest and most informal parts of the data, 'conversational telephone speech' and 'Usenet newsgroups'. From the remaining 511 documents, 351 are used for training, 80 for development, and 80 for testing. For direct comparison we use the same data split as Li et al. (2014). We set the beam size to 8. For Incremental Global Inference we perform 3 iterations. After each training epoch, we measure performance on the development set (in terms of trigger and argument F_1) and use the model with the best overall performance for evaluation on the test set.

[4]In case of multi-word triggers, we take the lemma of each token.

	Triggers						Arguments					
	Identification			Classification			Identification			Classification		
System	P	R	F_1	P	R	F_1	P	R	F_1	P	R	F_1
Baseline	**67.2**	62.2	64.6	**64.7**	59.9	62.2	70.7	36.6	48.2	57.3	29.7	39.1

(b) Trigger classification performance for the four most frequent event types.

	Triggers			Arguments		
System	P	R	F_1	P	R	F_1
Li et al. (2014)	67.9	62.8	65.3	64.7	35.3	45.6
Li et al. (2014) rerun	66.4	60.2	63.1	61.3	30.2	40.4
Baseline	64.7	59.9	62.2	57.3	29.7	39.1

(c) Trigger and argument classification performance. This is a comparison of results published by Li et al. (2014), a version retrained by us ('rerun'), and our reimplementation of the system.

Table 3: Micro-averaged precision, recall, and F_1 for the baseline and IGI on the ACE 2005 test set, and for our baseline compared to published results in Li et al. (2014) and our run using their code. Numbers in bold are the better numbers for the respective measure. Numbers in parentheses are frequencies in the test set.

	Triggers					
	Identification			Classification		
System	P	R	F_1	P	R	F_1
Baseline	**87.3**	47.0	61.1	**73.3**	39.5	51.3
IGI	77.1	**54.7**	**64.0**	64.1	**45.5**	**53.3**

(a) Trigger performance. 'Identification' reports performance without event type assignment.

	ATTACK(591)			CONTACT(587)			TRANSF.MNY(554)			BROADCAST(510)		
System	P	R	F1	P	R	F1	P	R	F1	P	R	F1
Baseline	**69.0**	38.4	49.3	**43.5**	**11.4**	**18.1**	**71.9**	29.1	41.4	**44.0**	20.8	28.2
IGI	67.3	**43.5**	**52.8**	33.5	11.1	16.6	55.4	**34.3**	**42.4**	42.5	**30.4**	**35.4**

(b) Trigger classification performance for the four most frequent event types.

Table 4: Micro-averaged precision, recall and F_1 for the baseline and IGI on the TAC 2015 test set. In TAC 2015 only event trigger annotations are available. Numbers in bold are the better numbers for the respective measure. Numbers in parentheses are frequencies in the test set.

We follow standard evaluation criteria for triggers and events (Ji and Grishman, 2008). A trigger is correct, if its span and event type match a reference trigger. An argument is correct, if its span, event type, and role match a reference argument.

Our evaluations report *identification* and *classification* of event triggers and arguments. An event trigger or argument is correctly identified if its offsets match a reference trigger or argument, and correctly classified, if there is an additional match in event type or role. In all evaluations, we report micro-averaged precision (P), recall (R), and F_1. We devise two evaluation lines: We evaluate trigger and argument identification and classification on the one hand, and trigger classification performance for the four most frequent event types in ACE 2005 and TAC 2015 on the other hand.

6.2 Experiments and Results

Table 3 reports evaluation results for triggers and arguments on ACE 2005. Comparing the baseline with IGI in Table 3a we can see that IGI gives a considerably higher recall and F_1 for triggers, and a higher precision, recall, and F_1 for arguments, both, in terms of identification and classification. For identification, IGI increases trigger performance by 1.9 F_1 points and argument performance by 4.9 F_1 points. For classification, IGI improves 1.5 F_1 points for triggers, and 2.7 F_1 points for arguments.

The same trends can be observed for TAC 2015 (Table 4a). TAC 2015 offers trigger annotations only. For IGI, trigger identification improves by 2.9 F_1 points, and classification improves by 2 F_1 points compared to the baseline.

We now look at the classification performance of the four most frequent event types for both, ACE 2005 (Table 3b) and TAC 2015 (Table 4b). On both data sets, IGI improves F_1 for three of the four most frequent event types. For ACE 2005, `Transport` and `Meet` have higher precision and recall compared to baseline performance. `Attack` loses precision with IGI, resulting in a similar F_1 as the baseline. For TAC 2015, `Contact` loses precision and recall with IGI, resulting in a lower F_1. In all other cases, IGI considerably increases recall, at the expense of precision. For ACE 2005, the event type with most F_1 improvement using IGI is `Transport` (+4.1 points), a very difficult event type. For TAC 2015, the event type with most F_1 improvement using IGI is `Broadcast`, again a very difficult event type.

Table 3c is as a comparison of our reimplementation of Li et al. (2014) and the numbers they report. The first column ('Li et al. (2014)') reports published results from the respective paper. Column 'Li et al. (2014) rerun' reports performance of the source code we received from the authors. 'Baseline' is our baseline, a reimplementation of their system. We first compare published results with our rerun of the reference system (Lines 1 and 2). We can see that the published evaluation numbers and the numbers for our rerun of the reference system (using source code we received from the authors) do not match. We can only speculate about the reasons. The biggest difference we can spot is that the source code we received does not use the output of a frame-semantic parser for FrameNet features. It uses all possible frames for a given word instead, if the number of possible frames does not exceed 2. Li et al. (2014) report a gain of 0.8 F_1 points for triggers, and a gain of 2.2 F_1 points for arguments when using a frame-semantic parser. Since the source code we received already uses frames, we expect to gain only a fraction of this improvements using a full-fledged frame-semantic parser. We believe the feature set has changed slightly until we received the source code. It is not easy to reproduce published results (Fokkens et al., 2013). Comparing our reimplementation with our rerun of the reference system (Lines 2 and 3) we can see that the respective performances are close.

7 Conclusions

We presented a method to make the global, document-wide context available to a state-of-the-art, intra-sentential event extractor. The method is an incremental approach: With every iteration it collects new triggers and arguments from the entire document and makes them available to the intra-sentential base system for another decoding pass. Our method leads to considerable increases in recall and F_1 for triggers across different data sets and different event types, and to considerable increases in all measures for arguments.

Lemma matches and coreferent arguments as nuclei for global decoding are only a start. Future research has to investigate other similarity measures based on, e.g., WordNet and word vectors, and to explore the benefits of discourse structure for event extraction.

Abstract

Recently, end-to-end memory networks have shown promising results on Question Answering task, which encode the past facts into an explicit memory and perform reasoning ability by making multiple computational steps on the memory. However, memory networks conduct the reasoning on sentence-level memory to output coarse semantic vectors and do not further take any attention mechanism to focus on words, which may lead to the model lose some detail information, especially when the answers are rare or unknown words. In this paper, we propose a novel Hierarchical Memory Networks, dubbed HMN. First, we encode the past facts into sentence-level memory and word-level memory respectively. Then, k-max pooling is exploited following reasoning module on the sentence-level memory to sample the k most relevant sentences to a question and feed these sentences into attention mechanism on the word-level memory to focus the words in the selected sentences. Finally, the prediction is jointly learned over the outputs of the sentence-level reasoning module and the word-level attention mechanism. The experimental results demonstrate that our approach successfully conducts answer selection on unknown words and achieves a better performance than memory networks.

1 Introduction

With the recent resurgence of interest in Deep Neural Networks (DNN), many researchers have concentrated on using deep learning to solve natural language processing (NLP) tasks (Collobert et al., 2011; Sutskever et al., 2014; Zeng et al., 2014; Feng et al., 2015). The main merits of these representation learning based methods are that they do not rely on any linguistic tools and can be applied to different languages or domains. However, the memory of these methods, such as Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Unit (GRU) (Cho et al., 2014) compressing all the external sentences into a fixed-length vector, is typically too small to accurately remember facts from the past, and may lose important details for response generation (Shang et al., 2015). Due to the drawback, these traditional DNN models encounter great limitation on Question Answering (QA), as a complex NLP task, which requires deep understanding of semantic abstraction and reasoning over facts that are relevant to a question (Hermann et al., 2015; Yu et al., 2015).

Recently, lots of deep learning methods with explicit memory and attention mechanism are explored for Question Answering (QA) task, such as Memory Networks (MemNN) (Sukhbaatar et al., 2015), Neural Machine Translation (NMT) and Neural Turing Machine (NTM) (Yu et al., 2015). These methods exploit a external memory to store the past sentences with a continuous representation and utilize attention mechanism to automatically soft-search for parts of the memory for prediction. Compared with NMT and NTM, MemNN, making multiple computational steps (termed as "hops") on the memory before making an output, is better qualified for textual reasoning tasks. However, for QA task, MemNN only conducts the reasoning on sentence-level memory and does not further take any attention mechanism to focus on words in the retrieved facts. More recently, Yu et al. (2015) constructed a *Search-Response*

*The first two authors contributed equally.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2290–2299, Osaka, Japan, December 11-17 2016.

pipeline where *Search* component uses MemNN to search the supporting sentences and *Response* component uses NMT or NTM to generate answer on the selected sentences. However, that work needs the supervision of the supporting facts to guide the training of *Search* component and the combination of these two components through a separate training way may hurt the performance. Along the direction of that work, we believe that a joint learning model can achieve a better performance by designing a hierarchical architecture, with sentence-level and word-level components, which has shown promising results on document modeling (Lin et al., 2015) and document classification (Yang et al., 2016).

Besides, rare and unknown word problem as an important issue should be considered in NLP tasks, especially for QA task, where the words that we are mainly interested in are usually named entities which are mostly unknown or rare words (Marrero et al., 2013; Gulcehre et al., 2016). In order to control the computational complexity, many methods limit the trained vocabulary size, which further leads to lots of low-frequency words outside the trained vocabulary (Li et al., 2016). Traditional methods directly mask the rare or unknown words with meaningless *unk* which may lose the important information for answer selection task. For example, given a set of sentences as follows:

1. Miss, what is your name?
2. Uh, my name is *Wainwright*.
3. Please tell me your passport number.
4. Ok, it is *899917359*.

Assume that the words *Wainwright* and *899917359*[1] are rare words or outside the trained vocabulary. If these words are discarded or replaced with *unk* symbol, any models may not be able to select the correct answers for response during testing.

Based on the above observations, this paper proposes a Hierarchical Memory Networks[2] (dubbed to HMN) for answer selection. Our method first maps the sentences into a sentence-level memory and reasoning module takes multiple hops on the sentence-level memory to soft-search the related sentences. Meanwhile, all words in the sentences are encoded into a word-level memory with recurrent neural networks. Then, we exploit k-max pooling to sample the most relevant sentences and feed these selected sentences into attention mechanism on the word-level memory to focus the words. Finally, the prediction is jointly learned over the outputs of the sentence-level reasoning module and the word-level attention mechanism. Our main contributions are three-fold:

(1). We proposed a novel hierarchical memory networks for answer selection, where the reasoning module is performed on sentence-level memory to retrieve the relevant sentences and the attention mechanism is applied on word-level memory to focus the words. This hierarchical architecture allows the model to have explicit reasoning ability on sentences and also focus on more fine-grained words.

(2). k-max pooling is exploited to sample the most relevant facts based on the results of the sentence-level reasoning and then feed these facts into word-level attention mechanism, which can filter the noise information and also reduce the computational complexity on word-level attention.

(3). We release four synthetic domain dialogue datasets[3], two from air-ticket booking domain and two from hotel reservation domain, where the answers are mostly rare or unknown words, and lots of answers should be reasoned based on some supporting sentences. The experimental results show that our approach can successfully conduct answer selection on unknown words.

2 Background: Memory Networks

Here, we give a brief description of memory networks which have shown promising results on QA tasks (Weston et al., 2015; Bordes et al., 2015; Sukhbaatar et al., 2015). Memory network first introduced by Weston et al. (2015) is a new class of learning models which can easily read and write to part of a long-term memory component, and combine this seamlessly with inference for prediction. Formally, besides the explicit memory which is an array of cells to memorize the pre-trained vector representations

[1]Note that the personal information used in our examples and datasets throughout this paper is all synthetic and not real.

[2]It is worth noticing that the term "Hierarchical Memory Networks" has been mentioned in (Chandar et al., 2016) where the intention was to organize the memory into multi-level groups based on hashing, tree or clustering structures to make the reader efficiently access the memory, whereas in our paper the term has a different meaning.

[3]Our code and dataset are available: `https://github.com/jacoxu/HMN4QA`

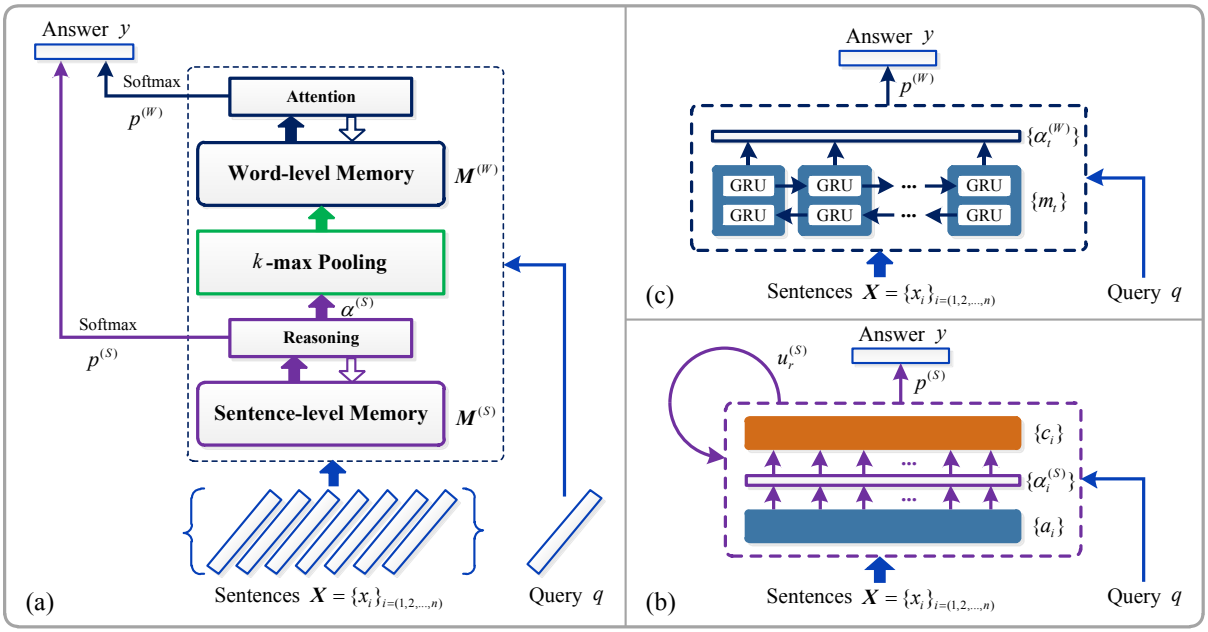

Figure 1: An illustration of our Hierarchical Memory Networks (HMN). (a): The overall architecture of the proposed HMN. (b): Reasoning module of our approach on sentence-level memory. (c): Attention module of our approach on word-level memory.

of the external data, a general memory network consists of four major components: (1). *Input feature map* which converts the incoming input to the internal feature representation. (2). *Generalization* which updates old memories given the new input. (3). *Output feature map* which produces a new output based on the new input and the current state. (4). *Response* which converts the output into the response format desired. Along the above framework, Sukhbaatar et al. (2015) put forward end-to-end memory networks which do not require the supervision of the supporting facts and are more generally applicable in realistic setting. Thus, we choose end-to-end memory networks, denoted as MemNN throughout our paper, as the foundation of our proposed approach.

3 Hierarchical Memory Networks for Answer Selection

3.1 Approach Overview

As described in Figure 1(a), we give an illustration of our HMN for answer selection. Given a set of n sentences denoted as: $\mathbf{X} = \{x_i\}_{i=(1,2,...,n)}$ and a query q, where i is the timestep of sentence x_i in the set. We first map these sentences $\mathbf{X}$ into the sentence-level memory $\mathbf{M}^{(S)}$ and the word-level memory $\mathbf{M}^{(W)}$ with low-dimensional distributed representations respectively. Then, reasoning on the sentence-level memory is utilized to soft-search the related sentences. We further exploit k-max pooling to sample the most relevant sentences based on the soft-searching results and take attention mechanism to focus on word-level memory of the selected sentences. The target answer y is used to guide the learning of the reasoning on sentence-level memory and the attention on word-level memory learning simultaneously.

3.2 Sentence-level Memory and Reasoning

In this section, we apply reasoning module to make multiple interaction on sentence-level memory based on the adjacent weight tying scheme of MemNN (Sukhbaatar et al., 2015), as shown in Figure 1(b). Given two word embedding matrices $\mathbf{A} \in \mathbb{R}^{|V| \times d}$ and $\mathbf{C} \in \mathbb{R}^{|V| \times d}$, where $|V|$ is the vocabulary size and d is the dimension of the word embedding, we first encode the word x_{ij} at timestep j in the sentence x_i into dual channels of word representation as $\mathbf{A}x_{ij} \in \mathbb{R}^d$ and $\mathbf{C}x_{ij} \in \mathbb{R}^d$.

In order to combine the order of the words into their representations, a positional encoding matrix $\mathbf{l}$ is applied to update the dual-channel word embeddings as $l_{gj} \cdot (\mathbf{A}x_{ij})$ and $l_{gj} \cdot (\mathbf{C}x_{ij})$, where

$$l_{gj} = (1 - j/J_i) - (g/d)(1 - 2j/J_i), \quad 1 \leq j \leq J_i,\ 1 \leq g \leq d, \tag{1}$$

and J_i is the length of the sentence x_i and g is the embedding index. This positional encoding scheme is also successfully applied in (Xiong et al., 2016).

Two temporal encoding matrices $\mathbf{T}_A \in \mathbb{R}^{n \times d}$ and $\mathbf{T}_C \in \mathbb{R}^{n \times d}$ are further utilized to encode the order of the sentences. Then, the sentence-level memory $\mathbf{M}^{(S)} = \{\{a_i\}, \{c_i\}\}_{i=(1,2,\ldots,n)}$ is reformed as:

$$a_i = \sum\nolimits_j l_j \cdot (\mathbf{A}x_{ij}) + \mathbf{T}_A(i), \quad c_i = \sum\nolimits_j l_j \cdot (\mathbf{C}x_{ij}) + \mathbf{T}_C(i), \tag{2}$$

where l_j is the j-th column vector of the position encoding matrix $\mathbf{l}$ according to the sentence x_i and the operation "$\cdot$" means the element-wise multiplication.

For the query q, the j-th word q_j is also embedded as $\mathbf{A}q_j \in \mathbb{R}^d$, where the $\mathbf{A}$ is the embedding matrix used in Eqn. (2). By encoding the word position j into the query representation, we get the probe representation of the query q as follows:

$$u_1^{(S)} = \sum\nolimits_j l_j \cdot (\mathbf{A}q_j), \tag{3}$$

where l_j is the j-th column vector of the position encoding matrix $\mathbf{l}$ according to the query q. Then the attention weights of the sentences according to the query can be calculated through the inner product of the two vectors as $\alpha_i^{(S)} = softmax(a_i^T u_1^{(S)})$, and the output of the sentence-level memory based on the activation of the query can be obtained as: $o_1 = \sum_i \alpha_i^{(S)} c_i$.

In order to perform reasoning on sentence-level memory to find the most relevant sentences, we make R hops to soft-search the sentences and output the final vector o_R. To be specific, during the $r+1$ hop of the reasoning operation, the process can be formalized as: $u_{r+1}^{(S)} = o_r + u_r^{(S)}$, $\alpha_i^{(S)} = softmax(a_i^T u_{r+1}^{(S)})$, $o_{r+1} = \sum_i \alpha_i^{(S)} c_i$, and the dual-channel memories are updated as follows:

$$a_i = \sum\nolimits_j l_j \cdot (\mathbf{A}^{r+1}x_{ij}) + \mathbf{T}_A^{r+1}(i), \quad c_i = \sum\nolimits_j l_j \cdot (\mathbf{C}^{r+1}x_{ij}) + \mathbf{T}_C^{r+1}(i), \tag{4}$$

where $1 \leq r \leq (R-1)$. Specifically, during the $r+1$ hop, the word embedding matrices $\mathbf{A}^{r+1}$ and $\mathbf{C}^{r+1}$ are mutually independent, so as the temporal encoding matrices $\mathbf{T}_A^{r+1}$ and $\mathbf{T}_C^{r+1}$. But during the adjacent two hops, $\mathbf{A}^{r+1} = \mathbf{C}^r$ and $\mathbf{T}_A^{r+1} = \mathbf{T}_C^r$. Finally, we can get the predicted word probability distribution by applying softmax on the output vector of the reasoning on the sentence-level memory as:

$$p^{(S)}(w) = softmax((\mathbf{C}^R)^T(o_R + u_R^{(S)})), \tag{5}$$

where $w = \{w_t\}_{t=(1,2,\ldots,|V|)}$ is the word set with a vocabulary size of $|V|$, the weight matrix is the same as the embedding matrix $\mathbf{C}^R \in \mathbb{R}^{|V| \times d}$ on the last hop, and T is the operation of matrix transposition.

3.3 k-max Pooling

Here, we exploit a pooling operation over the top attention weights $\alpha^{(S)}$ of the reasoning module on the sentence-level memory to sample the most relevant sentences. Given a value k and the top attention weights $\alpha^{(S)}$ of length $n \geq k$, we use the k-max pooling to select a subset of sentence sequences $\hat{\mathbf{X}} = \{\hat{x}_i\}_{i=(1,2,\ldots,k)}$, corresponds with their top-k maximum values of $\alpha^{(S)}$ on the sentences.

The k-max pooling operation makes it possible to pool the k most relevant sentences to the query and filter the noise information, which maybe more beneficial to select the correct answers. Moreover, this sampling module feeds a subset of sentences $\hat{\mathbf{X}}$ to the following attention mechanism on the word-level memory, which can reduce the computation complexity of the attention to focus on the relevant words.

3.4 Attention on Word-level Memory

For word-level memory, we first apply a Bi-directional GRU (BiGRU) to compute the hidden states of all the ordered words $\bar{w} = \{\bar{w}_t\}_{t=(1,2,\ldots,|t|)}$ in the sentence set $\mathbf{X}$, where $|t|$ is the time steps of the words in the sentences. In particular, for the t-th word $\bar{w}_t$, the forward GRU and the backward GRU encode

Domain (Lang)	Train/Dev/Test	Vocab	Unseen Answers (Dev/Test)	Max Len (P/S)
Air-Ticket (CH)	5,400/600/6,000	8,540	409 (68.2%)/4,020 (67.0%)	16/17
Hotel (CH)	5,400/600/6,000	7,586	367 (61.2%)/3,690 (61.5%)	16/16
Air-Ticket (EN)	5,400/600/6,000	7,537	342 (57.0%)/3,489 (58.2%)	16/18
Hotel (EN)	5,400/600/6,000	7,134	357 (59.5%)/3,452 (57.5%)	16/16
Total	21,600/2,400/24,000	29,092	1,406 (58.6%)/13,872 (57.8%)	16/18

Table 1: Statistics of the datasets, including the domain and the language of the dataset (CH: Chinese and EN: English), the number of train/dev/test set entries, the vocabulary size of datasets, the number and proportion of unseen answers on dev/test set, and the max paragraph length and sentence length of the datasets. The *Total* dataset consists all the samples of the above four datasets.

it as hidden states $\vec{h}_t = \vec{GRU}(\mathbf{C}^R \bar{w}_t)$ and $\overleftarrow{h}_t = \overleftarrow{GRU}(\mathbf{C}^R \bar{w}_t)$ respectively, where $\mathbf{C}^R$ is the word embedding matrix of the last hop on the sentence-level memory, and we set the dimension of $\vec{h}_t$ and $\overleftarrow{h}_t$ equals to the dimension of the word embedding. By summing the forward hidden states and the backward hidden states, we obtain the word-level memory as $\mathbf{M}^{(W)} = \{m_t\}_{t=(1,2,...,|t|)}$, where $m_t = \vec{h}_t + \overleftarrow{h}_t$. In this way, the memory m_t contains the context information of the t-th word $\bar{w}_t$ in the sentence set $\mathbf{X}$.

Then, we perform attention on the subset of the ordered words $\hat{w} = \{\hat{w}_t\}_{t=(1,2,...,|\hat{t}|)}$ in the selected sentences $\hat{\mathbf{X}}$ by using the probe vector $u_R^{(S)}$ of the last hop on the sentence-level memory and a subset of word-level memory $\{\hat{m}_t\}_{t=(1,2,...,|\hat{t}|)}$ selected form $\mathbf{M}^{(W)}$ according to the word subset $\hat{w}$. The normalized attention weights $\alpha^{(W)} = \{\alpha_t^{(W)}\}_{t=(1,2,...,|\hat{t}|)}$ on the word-level memory are calculated as:

$$\alpha_t^{(W)} = softmax(v^T tanh(\mathbf{W} u_R^{(S)} + \mathbf{U}\hat{m}_t)), \tag{6}$$

where $v \in \mathbb{R}^{d\times 1}$, $\mathbf{W} \in \mathbb{R}^{d\times d}$ and $\mathbf{U} \in \mathbb{R}^{d\times d}$ are all learning parameters updated during the training. Inspired by Pointer Networks (Vinyals et al., 2015), we adopt the normalized attention weights $\alpha^{(W)}$ on the word collection $\hat{w}$ as the probability distribution of the output words:

$$p^{(W)}(w) = trans(p^{(W)}(\hat{w})) = trans(\alpha^{(W)}), \tag{7}$$

where $trans(\cdot)$ means the operation to map the words probability distribution $p^{(W)}(\hat{w}) \in \mathbb{R}^{|\hat{t}|}$ into the probability distribution $p^{(W)}(w) \in \mathbb{R}^{|V|}$. To be specific, the map operation makes the probability distribution $p^{(W)}(\hat{w})$ of the word subset ($\hat{w} = \{\hat{w}_t\}_{t=(1,2,...,|\hat{t}|)}$) to be added into their corresponding positions in the vocabulary ($w = \{w_t\}_{t=(1,2,...,|V|)}$), and the probabilities of the words not in selected word subset $\hat{w}$ will be set to zero[4]. Finally, we get the new probability distribution $p^{(W)}(w) \in \mathbb{R}^{|V|}$.

3.5 Joint Learning

In this paper, we combine the probability distributions of the output words both on the sentence-level memory and the word-level memory to predict the joint probability distribution $p(w)$ as follows:

$$p(w) = p^{(S)}(w) + p^{(W)}(w). \tag{8}$$

Finally, we use the target answer y to guide the learning of the reasoning module on sentence-level memory and the attention module on word-level memory simultaneously. We choose the cross entropy as the cost function and apply Stochastic Gradient Descent (SGD) (Bottou, 1991) as the optimization method to train our joint model. The learned parameters include word embedding matrices $\mathbf{A}^1$ and $\{\mathbf{C}^r\}_{r=(1,2,...,R)}$, temporal encoding matrices $\mathbf{T}_A^1$ and $\{\mathbf{T}_C^r\}_{r=(1,2,...,R)}$ in Eqn. (2) and (4), the parameters $\{\theta_{BiGRU}\}$ of the BiGRU model and the attention parameters v, $\mathbf{W}$ and $\mathbf{U}$ in Eqn. (6).

[4]For example, if the word "airport", at two different timesteps in the ordered word subset $\hat{w}$, has two probabilities "0.1" and "0.3", the map operation would add up these probabilities and set "0.4" as the probability of the word "it" in the vocabulary.

Table 2: Comparison of predicted test error numbers of our HMN and MemNN with different components on four domain datasets (Test: 6,000 samples) and the *Total* dataset (Test: 24,000 samples). MemNN-H1: Memory network with 1 hop and temporal encoding, MemNN-NT: Memory network with 3 hops but without temporal encoding. MemNN: Memory network with 3 hops and temporal encoding. Note that HMN-Sent and HMN-Word, as the parts of HMN-Joint, are joint learning but give their predicted answers separately.

4 Experiments

4.1 Datasets and Setup

We conduct answer selection tasks on four synthetic domain dialogue datasets, two from air-ticket booking domain and two from hotel reservation domain. One complete dialogue history of each dataset has eight round responses. Besides greeting and ending sentences, one dialogue history consists six round responses to query and answer client's personal information, such as name, phone and passport number. The datasets contain hundreds of response patterns and thousands of entity information. More detailed descriptions can be found in our released datasets. The statistics of the datasets are summarized in Table 1. We use 45% of the data for training, 5% for validation and the remaining 50% for test. From the statistics, we can see that the proportions of the unseen answers on dev/test sets all overtake 57%.

In our experiments, the most of hyper parameters are set uniformly for the datasets as described in Table 3. The training gradients with an $l2$ norm larger than 40 are clipped to 40 and the learning rate is annealed every 15 epochs by $\lambda/2$ until 60 epochs are reached. The learned parameters are all initialized randomly from a Gaussian distribution with zero mean and 0.1 standard deviation. In order to make the comparison more intuitive, we use the number of predicted error samples on each dataset to evaluate the performance for answer selection and calculate the average result by repeating each experiment 5 times.

Hyperparameter	Hidden dim.	Hops	Max pooling	Learning rate	Batch size (*Total*)
Value	$d = 100$	$R = 3$	$k = 4$	$\lambda = 0.01$	30 (32)

Table 3: Hyperparameters used in our experiments. The dimension of word embeddings and the dimension of GRU hidden states are set equally to 100, batch sizes are 32 for *Total* and 30 for the others.

4.2 Comparison with Memory Networks

In order to evaluate the effect of multiple hops for reasoning module and temporal encoding on sentence-level memory, we design three MemNN (Sukhbaatar et al., 2015) based variants: MemNN-H1 (1 hop and temporal encoding), MemNN-NT (3 hops but not temporal encoding) and MemNN (3 hops and temporal encoding) on the datasets. We further evaluate the prediction performance of our HMN on different level memory components via HMN-Sent (prediction of reasoning module on sentence-level memory as Eqn. (5)), HMN-Word (prediction of attention module on word-level memory as Eqn. (7)) and HMN-Joint (joint prediction as Eqn. (8)). The comparison of these methods are reported in Table 2. From the results, we can see that MemNN-H1 without temporal encoding and MemNN-NT without multi-hop reasoning make the worst performances, which clearly demonstrate that multiple hops for reasoning module and temporal encoding on sentence-level memory play a very important role on our tasks. Despite that MemNN represents surprising results on this task, our HMN-Word and HMN-joint

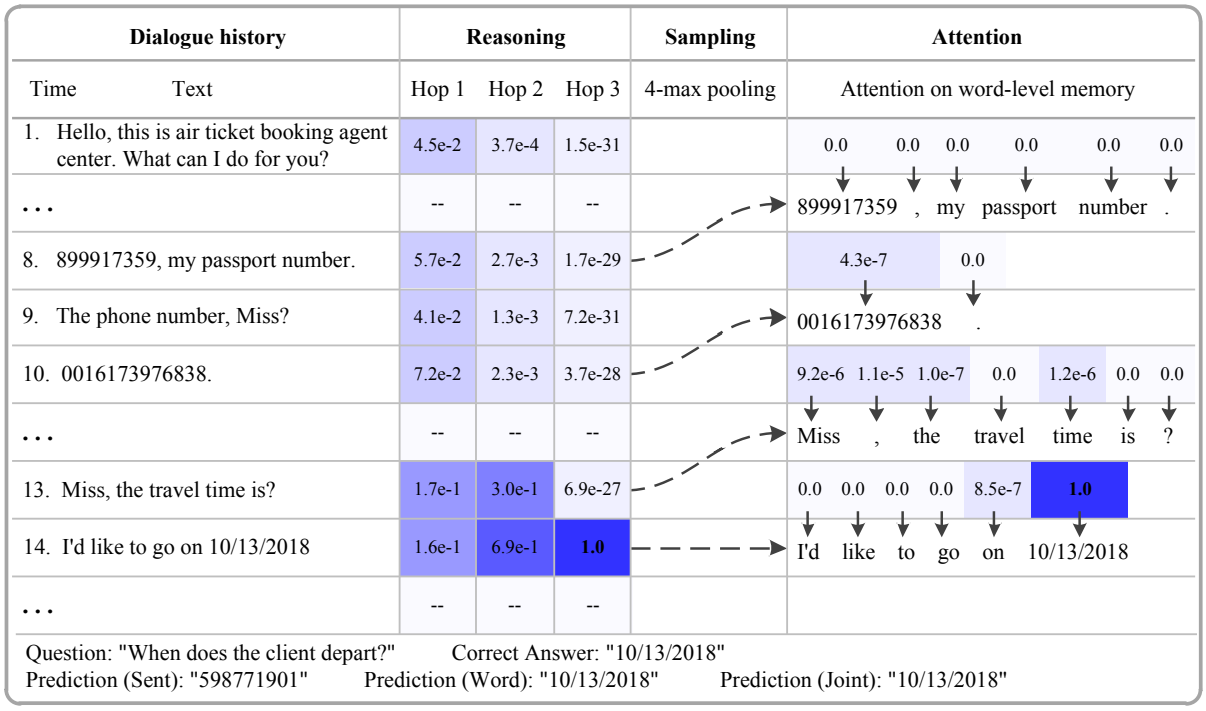

Figure 2: One example prediction by our HMN for answer selection. The hop columns in reasoning module show the probabilities of each hop, and the sampling module selects the 4-max relevant sentences and feeds these selected sentences to the attention module on word-level memory. In the experiments, all the sentences in the dialogue history are indexed in reverse order to reflect their relative distance.

further improve the answer selection performance on all the datasets. Compared with the results of HMN-Sent and HMN-Word, the results also show that the joint prediction can make a better performance.

4.3 How to Select the Correct Answers on Unknown Words

Here, we try to answer two questions: (1) How does the reasoning module focus on the related sentences and predict the rare and unknown words on sentence-level memory? (2) How does the attention module focus on the correct answers and distinguish multiple rare and unknown words on word-level memory? We give a visual example of our HMN over one dialogue history for answer selection in Figure 2 to get a better understanding of the effect of each module. The example is one dialogue history from air-ticket booking domain which contains 16 sentences associated with their temporal indexs.

From Figure 2, we can see that in the first hop, the reasoning module mainly focuses on the sentences 13 and 14, which have most semantic relevance to the question "When does the client depart?". As the effect of temporal encoding as Eqn. (4), the reasoning allocates more weight to the most related sentence 14 in the following hops. Another interesting result as shown in Table 2 is that MemNN and HMN-Sent represent surprising performance to predict the rare and unknown words on sentence-level memory. An explanation maybe that the way in which these methods use a simple way, rather than sophisticated LSTM or GRU, to encoding the sentence into memory as Eqn. (1). This simple sentence encoding strategy can remain the raw embedding representation of words, and MemNN and HMN-Sent utilize the transpose of the raw embedding matrix as the decoding weights to conduct answer match as Eqn. (5) in the raw embedding space. Nonetheless, sentence-level encoding may introduce other semantic information which may lead to predict an error answer, as the prediction (Sent) in the example.

After k-max pooling for sampling the most relevant sentences, a sophisticated attention mechanism is applied on the selected word-level memory. Two possible reasons make the attention successfully focus on the correct answers: One is that the probe vector $u_R^{(S)}$ as Eqn. (6), used in attention mechanism to interact with word-level memory, is generated from the reasoning module and has semantic relevance to the

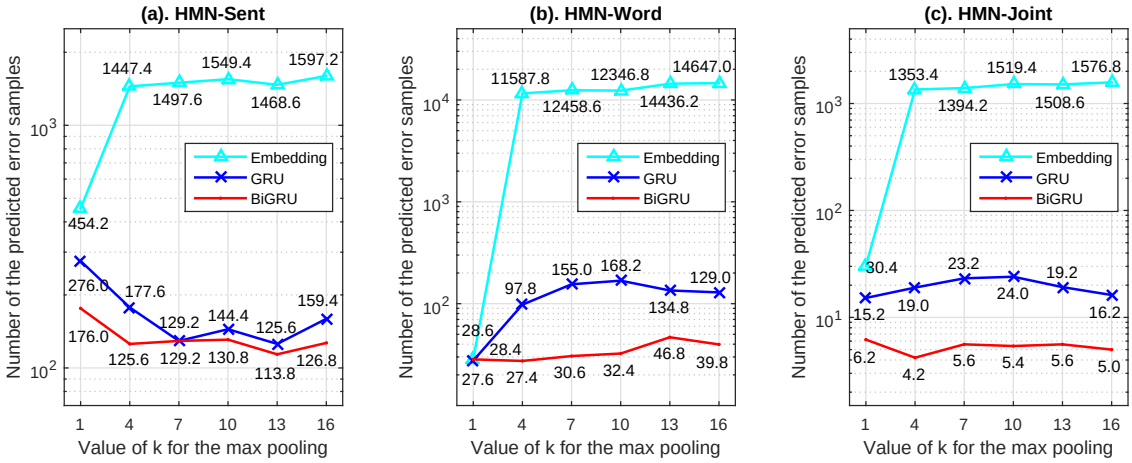

Figure 3: Answer selection evaluations of HMN-Sent, HMN-Word and HMN-Joint with different word-level memory encoding methods (BiGRU, GRU and Embedding) using various values of k on *Total*.

target answers. Another reason is that attention mechanism performs inhibitory effect on our task which can successfully filter the almost useless words, such as "time", "go" and "on" in the example. Besides the above reasons, we also investigate the influence of different word-level memory encoding methods, such as BiGRU ($\overrightarrow{GRU}(\mathbf{C}^R\bar{w}_t)+\overleftarrow{GRU}(\mathbf{C}^R\bar{w}_t)$), GRU ($GRU(\mathbf{C}^R\bar{w}_t)$) and Embedding ($\mathbf{C}^R\bar{w}_t$), by varying the values of k for max pooling, and the comparison of answer selection performance are present in Figure 3. The results show the expected effect that encoding the context information into word-level memory via BiGRU or GRU can help the attention module distinguish multiple rare and unknown words when we enlarge the value of k and introduce more unknown words to the attention mechanism.

From Figure 3, we further investigate the influence of k to the answer selection performance. We can see that the performances almost unchanged by using HMN-Joint with BiGRU when we vary the value of k. Considering that the more sentences k-max pooling samples from sentence-level memory, the more computational complexity the attention mechanism as Eqn. (6) costs on word-level memory, 4-max pooling used in our experiments is a good trade-off.

5 Related Works

Recently, lots of deep learning methods with explicit memory and attention mechanism have shown promising performance in Question Answering (QA) tasks. For example, Yu et al. (2015) applied Neural Machine Translation (NMT) (Bahdanau et al., 2015) with sophisticated attention mechanism and Neural Turing Machine (NTM) (Graves et al., 2014) with distributed external memory to solve QA tasks, and Sukhbaatar et al. (2015) designed end-to-end memory networks and introduced multi-hop reasoning component to solve various types of QA task. These representation learning based methods do not rely on any linguistic tools and can be applied to different languages or domains (Feng et al., 2015). However, most works of these deep learning based methods rarely focus on solving answer selection on unknown word problem. Recently, the unknown word problem has attracted more researchers' attention. Hermann et al. (2015) used NLP tools to recognize all the entity and establish co-references to replace all the rare entities by placeholders and trained an attention based model with softmax to predict the placeholder id. Li et al. (2016) replaced the rare words in a test sentence with similarity in-vocabulary words to solve machine translation task, where the representation of the rare words still can be learned from a large mono-lingual corpus. Gulcehre et al. (2016) utilized and extended the attention-based pointing mechanism (Vinyals et al., 2015) to point the unknown words for machine translation and text summarization. However, the sophisticated attention mechanism is applied on the all word-level representations which may result in high computational complexity, and lots of the fine-grained noise words should be filtered out by reasoning the relevant facts to the query in a high-level semantic space.

6 Conclusion

In this paper, we introduce hierarchical memory networks to solve answer selection problem on unknown words. We first encode the sentences into a sentence-level memory with temporal encoding. Then reasoning module conducts multi-hop interaction on the memory to retrieve the related sentences, and k-max pooling samples the k most related sentences. For word-level memory, BiGRU is utilized to encode the words and introduce context into the memory, then a sophisticated attention mechanism is applied on the selected word-level memory to focus the fine-grained words. We conduct answer selection experiments on four synthetic domain dialogue datasets which contain lots of unseen answers. The experimental results show that our hierarchical memory networks can achieve a satisfying performance.

Abstract

Guided by multiple heuristics, a unified taxonomy of entities and categories is distilled from the Wikipedia category network. A comprehensive evaluation, based on the analysis of upward generalization paths, demonstrates that the taxonomy supports generalizations which are more than twice as accurate as the state of the art. The taxonomy is available at http://headstaxonomy.com.

1 Introduction

Motivation. As possibly the largest resource of publicly available, semi-structured knowledge, Wikipedia (Remy, 2002) serves as a stepping stone towards the construction of collections of structured data (Remy, 2002; Hoffart et al., 2013; Vrandečić and Krötzsch, 2014). Data within Wikipedia benefits from new additions and distributed curation by human editors, and has proven beneficial in text analysis tasks ranging from co-reference resolution (Ratinov and Roth, 2012), word sense (Mihalcea, 2007) and entity disambiguation (Ratinov et al., 2011), to information retrieval (Hu et al., 2009) and information extraction (Wu and Weld, 2010; Nastase and Strube, 2013; Hoffart et al., 2013; Dong et al., 2014).

Wikipedia links millions of entities (e.g. *Barack Obama*) to thousands of inter-connected categories of different granularity (e.g. *Presidents of the United States*, *Political office-holders, Politicians*) to form what is often referred to as the Wikipedia category network (WCN). However, obtaining a taxonomy of increasingly general categories from WCN is by no means trivial because upward edges in WCN, from entities to categories and also from child to parent categories, are not confined to *is-a* relations (Ponzetto and Strube, 2007). In fact, consistently discarding *not-is-a* edges such as *Japan⇝660 BC* or *Award winners⇝Awards*, while retaining as many true *is-a* edges as possible, has been the object of a steady body of research (Ponzetto and Strube, 2007; Hovy et al., 2013; Flati et al., 2014). Recent methods still produce taxonomies with glaring gaps in precision and coverage. More importantly, even if the methods correctly identify individual *is-a* edges with an accuracy as high as 85% (Flati et al., 2014), it is not uncommon for upward paths to traverse at least some incorrect edges. The resulting taxonomies transitively connect entities (e.g., *Natural language processing*) to many ancestor categories (e.g., *Physical body*, *Mass*)[1] that are not true generalizations, thus limiting their utility in practice.

Contributions. This paper proposes a novel method for taxonomy induction from WCN. As described in Section 3, the method exploits syntactic evidence in category titles to connect entities (i.e., pages) with increasingly more general categories. A novel, comprehensive framework for taxonomy evaluation is proposed, focusing on the accuracy and granularity of longer generalization paths, as opposed to individual edges. Section 4 describes the evaluation framework and carries out an in-depth comparison of the proposed taxonomy against the state of the art. It shows significant gains in accuracy relative to current state of the art, while maintaining similar coverage.

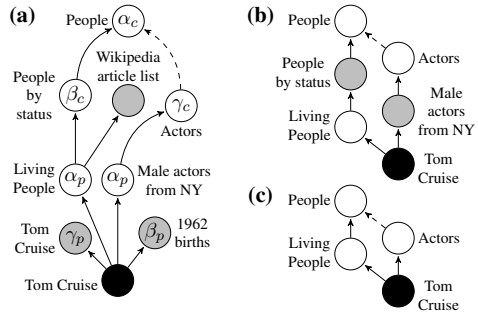

Figure 1: Taxonomy induction phases. Black circles denote entities. White circles denote categories. Dashed lines denote paths including possibly multiple edges. **(a)** Step 1: Page heuristics (α_p, β_p and γ_p) and category heuristics (α_c, β_c and γ_c) are applied sequentially to select candidate generalizations for each node (page or category), until one produces at least one candidate (white circles). Gray nodes show candidates that would have been produced by remaining heuristics. **(b)** Step 2: Nodes that encode redundant information are removed (grey). **(c)** Resulting taxonomy.

2 Related work

Thanks to continuous contributions and curation by many human editors, Wikipedia (Remy, 2002) recommends itself as a high quality resource of semi-structured knowledge. It enables multiple approaches to large scale knowledge acquisition and taxonomy induction (Hovy et al., 2013). One of the earliest attempts towards the latter is WikiTaxonomy (Ponzetto and Strube, 2007; Ponzetto and Strube, 2011). In WikiTaxonomy, relations are labeled as either *is-a* or *not-is-a*, using a cascade of heuristics based on the syntactic structure of category labels, the topology of the network and lexico-syntactic patterns for detecting subsumption and meronymy, similar to Hearst patterns (Hearst, 1992). WikiNet (Nastase et al., 2010) extends WikiTaxonomy by expanding *not-is-a* relations into fine-grained relations such as *part-of, located-in, etc*. YAGO, induces a taxonomy by employing heuristics linking Wikipedia categories to corresponding synsets in WordNet (Hoffart et al., 2013). YAGO's taxonomy forms the backbone of a variety of intelligent applications, including Watson (Ferrucci et al., 2010). DBPedia (Lehmann et al., 2015) aims to provide a fully-structured representation of semi-structured content of Wikipedia. It focuses on linking the extracted knowledge with existing resources such as YAGO, OpenCyc etc.

The Wikipedia Bitaxonomy project, or WIBI (Flati et al., 2014), the most recent effort towards large-scale taxonomy induction from Wikipedia, simultaneously induces a taxonomy for pages and a separate taxonomy for categories from WCN using the idea that information contained in pages can be useful in constructing a taxonomy of categories and vice-versa. First, an initial taxonomy over pages is constructed by extracting lemmas from their first sentences and resolving them to other pages in Wikipedia. Alternating between the two taxonomies, edges are added to each taxonomy based on the information available in the other. Finally, heuristics further enrich the category taxonomy by adding hypernym edges for nodes which are still orphans after the first two steps. In contrast to both WikiTaxonomy and our work, WIBI ignores the syntactic structure of category titles.

3 Taxonomy induction

A unified, high-accuracy taxonomy of pages and categories is induced from WCN through the application of a cascade of linguistically motivated heuristics, which exploit lexical and structural information (mainly the lexical head of categories) from Wikipedia to generate a set of candidate generalizations for pages (*page heuristics*) and categories (*category heuristics*). Subsequently, other heuristics are used to simplify the taxonomy by eliminating redundant nodes (see Figure 1). The heuristics, which are derived empirically or adapted from previous work, are described in this section using these notations:

- E: set of all WCN edges;
- h_c: lexical head of the title of category c;
- $C_a(n)$: set of *all* direct parents of node n (page or category) in WCN, $\{c \mid (n,c) \in E\}$[2];
- $C_{pl}(n) \subset C_a(n)$: subset of parent categories ($C_a(n)$) whose titles have a *plural* lexical head, such as *Administrative divisions*. Categories with plural heads have played an important role in earlier work on taxonomy induction from Wikipedia, as they are more likely to be genuine classes (e.g. *Countries*) as opposed to instances (e.g. *France*) (Suchanek et al., 2007; de Melo and Weikum, 2010);

[2]Wikipedia maintenance categories (e.g., *Sports award stubs*) are removed using a handful of blacklisted keywords such as "articles", "stubs" etc.

• L_p: set of *defining* lemmas attached to the root copular verb in the first sentence of the Wikipedia description of page p, e.g., *"William Shakespeare was an English poet, ..."* (Flati et al., 2014);

• $sup(h_{c_1}, h_{c_2})$: *global support* for an ordered pair of lexical heads h_{c_1} and h_{c_2}, defined as the number of edges in E, from a category with head h_{c_1} to a category with head h_{c_2};

• $\overrightarrow{v_h}$: vector of co-occurrence counts of plural head h with every unique plural head h' in WCN, where co-occurrence count is defined as the number of pairs of categories with heads h and h' which have at least one common child (page or category);

• $tsim\,(h_1, h_2)$: type similarity, defined as the cosine similarity between $\overrightarrow{v_{h_1}}$ and $\overrightarrow{v_{h_2}}$;

3.1 Category heuristics

Same head. Similarly to the head-matching heuristic in Ponzetto and Strube (2007), for any category c, pick all categories $c' \in C_a(c)$ as candidate generalizations, if they have the same lexical head as c. E.g. *Category:American actors* is picked as candidate generalization for *Category:American child actors*.

Global head support. For any category c, pick the category $c' \in C_{pl}(c)$ with the highest[3] global support $sup(h_c, h_{c'})$ as a candidate generalization, provided the support is above a fixed threshold T_{sup}. E.g. *Category:American entertainers* is picked as candidate generalization for *Category:American actors* because $sup(\textit{actors}, \textit{entertainers}) > T_{sup}$.

Type similarity. For any category c, pick the category $c' \in C_{pl}(c)$ which has head h' with the highest[3] type similarity $tsim(h, h')$ as a candidate generalization, if the similarity is above a fixed threshold T_{tsim}. E.g. *Category:People by occupation* is picked as candidate generalization for *Category:Entertainers* because $tsim(\textit{entertainers}, \textit{people}) > T_{tsim}$.

Only plural parent. For any category c, if $C_{pl}(c)$ contains only one category, pick it as a candidate generalization.

Only singular parent. For any category c with a non-plural head h_c, if $C_a(c)$ contains only one category, pick it as a candidate generalization.

Grouping child category. Categories whose titles match the pattern **X by Y** (e.g. *"Actors by nationality"*) usually indicate groupings of instances of *class* X by *attribute* Y (Nastase and Strube, 2008). Thus, for category c whose title matches the pattern **X by Y**, pick the category with title **X** (if one exists) as a candidate generalization.

Grouping parent category. For any category c, pick those categories in $C_{pl}(c)$ as candidate generalizations, whose titles match the pattern **X by Y**. E.g. *Category:Occupations by type* is picked as candidate generalization for *Category:Legal professions*.

Suffix head. For any category c, pick all categories $c' \in C_{pl}(c)$, whose lexical heads $h_{c'}$ are suffixes of h_c, as candidate generalizations. E.g. *Category:People by occupation* is picked as candidate generalization for *Category:Sportspeople*.

Lookahead candidates. For any category c, pick its grandparents (second-level ancestor categories) as candidate generalizations, if they satisfy the conditions in the SAME HEAD, GROUPING PARENT CATEGORY or SUFFIX HEAD heuristics. Higher-level ancestors are ignored as they are usually inaccurate.

Title head. For any category c, pick the category with the title h_c as a candidate generalization, if the lemma of h_c is in top T_l% most frequent lemmas among the defining lemmas L_p of the child pages of c. E.g. *Category:Writers* is picked as candidate generalization for *Category:Legal Writers*[4].

[3] If multiple categories satisfy the condition, all of them are picked.

[4] Key difference between **Same head** and **Title head** heuristic is that the latter does not require the candidate generalizations to be present in $C_a(c)$.

3.2 Page heuristics

Exact defining lemma. For page p, pick the category $c \in C_{pl}(p)$ as a candidate generalization if the lemma of its lexical head is in L_p. E.g. all parent categories of page *Johnny Depp* with lexical head *actors* are picked as candidate generalizations because *actor* is present in $L_{\text{Johnny Depp}}$.

Type-similar lemma. For page p, pick a category $c \in C_{pl}(p)$ as a candidate generalization, if the type similarity between the category's lexical head (h_c) and at least one of the defining lemmas in L_p is greater than a fixed threshold T'_{tsim}. E.g. all parent categories of page *Johnny Depp* with lexical head *people* are picked as candidate generalizations because *actor* is present in $L_{\text{Johnny Depp}}$ and $tsim\,(actors, people) > T'_{tsim}$.

Plural head. Similar to YAGO (Suchanek et al., 2007), for page p, pick all categories in $C_{pl}(p)$ as candidate generalizations.

Transfer. If a page p has an equivalent category[5], pick candidate generalizations generated by category heuristics for the equivalent category as candidate generalizations of p.

3.3 Construction of the HEADS taxonomy

The heuristics[6] are applied to individual pages or categories in order of decreasing edge-level precision, as measured on a manually annotated development set, which is the same order in which they have been presented above. For each node, the process stops when one of the heuristics produces at least one generalization, and the remaining heuristics for that node are ignored. For example, in Figure 1a, only the generalizations proposed by α_p for entity *Tom Cruise* are retained, namely *Living people* and *Male actors from NY*. Certain categories encode information that is orthogonal to types, and therefore superfluous as it may refer to time (*20th-century actors*), location (*Actors from Singapore*) or grouping by attributes (*Actors by nationality*). Such categories are detected using a few regular expressions and eliminated: their children are linked directly to their parents, and the redundant nodes are removed (Fig. 1b) producing a more compact taxonomy (Fig. 1c). This step is hereafter referred to as *simplification*.

The described process results in the HEADS taxonomy, which is evaluated in the next section. Taxonomy generation and evaluation in this submission is restricted to English Wikipedia. However, it can be easily adapted to other languages by porting the heuristics, a fairly straightforward task if a dependency parser is available in the target language. Adaptation to other languages is not explored in this study, and remains the object of future work.

4 Taxonomy evaluation

This section compares the HEADS taxonomy against the state of the art. It presents the standard edge-level evaluation (Ponzetto and Strube, 2011; Flati et al., 2014); demonstrates that, as popular as they might be, edge-level metrics do not reflect the real quality of a taxonomy; and proposes a more comprehensive evaluation, which takes into account the correctness of multi-edge generalization paths, overall probability of generalization errors, granularity of individual generalizations and accuracy of specializations. It is shown that performance along these newly-proposed dimensions is not necessarily correlated with edge-level metrics and cannot be estimated directly from them.

Experimental setup HEADS is constructed using a November 2015 snapshot of the English Wikipedia. To create a baseline for comparison, we initially attempted to re-implement the state-of-the-art taxonomy induction approach of Flati et al. (2014), but were unable to replicate the reported results. In particular, recall of the re-implementation was lower than expected. Since the source code for WIBI was not made public and was not available upon request, we instead compared HEADS directly against the entity and

[5] A page and category are considered equivalent if they have the same title after lemmatization of each token. If a disambiguation string is specified in the title (e.g., *biology* in *Family (biology)*), it should also match. e.g., *Families (biology)* ~ *Family (biology)* ≁ FAMILY.

[6] Threshold T_{sup} is set to 5, T_{tsim} and T'_{tsim} are set to 0.2 and T_l is set to 10.

Taxonomy	WIBI$_E$	WIBI$_C$	HEADS

WIBI$_C$	$C \rightarrow C$	0.852†	0.829†	0.973†	0.840

Table 2: Edge-level evaluation. $E \rightarrow C$ represents entity→category edges, $E \rightarrow E$ represents entity→entity edges and $C \rightarrow C$ represents category→category edges. †: results as reported in Flati et al. (2014). P: precision, R: recall, C: coverage, A: accuracy.

category taxonomies made available by Flati et al. (2014), referred to as WIBI$_E$ and WIBI$_C$, respectively. It is important to stress that WIBI taxonomies are generated using an older Wikipedia snapshot (October 2012). However, to the best of our knowledge, there is no evidence suggesting that taxonomy induction is easier or harder on more recent vs. older snapshots. Noisy edges between categories such as *Japan↝660 BC* can be found in both snapshots. Meanwhile, the network has grown significantly, with more than twice as many categories (1.37M vs. 619K) and 20% more entities (4.7M vs 3.8M), possibly adding to the complexity of the task.

4.1 Topological properties

The main topological properties of the HEADS and WIBI taxonomies are shown in Table 1. HEADS contains fewer categories and category→category edges than WIBI$_C$, due to the simplification step (cf. Section 3.3), which removes approximately 53% of parent categories from WCN. HEADS covers a larger number of entities than WIBI taxonomies, but a direct comparison of absolute sizes is not necessarily meaningful since the three taxonomies are defined in different spaces (WIBI$_E$ has entity→entity edges, WIBI$_C$ has category→category edges, while HEADS has entity→category and category→category edges). In addition, as already mentioned, WIBI taxonomies are generated using an older snapshot of Wikipedia. As shown in Table 1, the largest weakly connected component in HEADS and WIBI$_E$ covers over 99% of the nodes. HEADS has 50% fewer components, which is desirable, as each component is an enclave of isolated entities. WIBI$_C$, which is an order of magnitude smaller than WIBI$_E$ and HEADS, has even fewer connected components, but is overall less connected, with the largest connected component containing only 78% of the nodes. Lastly, HEADS contains about twice as many edges per node as the WIBI taxonomies (see avg. degree), which allows it to better account for multiple aspects of a concept or an entity, e.g., *Johnny Depp* being both an *Actor* and a *Film producer*.

4.2 Edge-level evaluation

The first comparison between HEADS and WIBI taxonomies follows the methodology introduced and consistently followed in prior literature, namely computing edge-level precision and recall scores against a gold standard (Ponzetto and Strube, 2011; Flati et al., 2014). To build the gold standard, 500 entities and 500 categories are randomly selected, and their parents in WCN are annotated by three human judges as correct or incorrect generalizations. [7] Table 2 shows *precision* and *recall* scores for HEADS and WIBI taxonomies by edge type. Precision and recall with respect to the golden edges are computed for each sampled node, and then averaged over all the nodes in the gold standard.

Compared to the WIBI taxonomies, HEADS shows significantly lower precision and recall scores in this evaluation. However, the losses can be largely attributed to the simplification procedure (cf. Section 3.3). For example, in Figure 1, the edge *Tom Cruise→Male actors from NY* would be missing from the final HEADS taxonomy as the node *Male actors from NY* would be removed by the simplification

[7] The inter-annotator agreement in terms of Fleiss' Kappa is 0.52. Annotations were harmonized by majority voting.

procedure, thus resulting in loss of precision and recall. Similarly, *Living People→People*, a correct edge, would be considered a precision loss, as it is absent from WCN (and hence, from the gold standard).

Table 2 also reports *coverage*, defined as the fraction of entities and categories in a taxonomy with at least one generalization, independent of its correctness. HEADS shows lower coverage on categories, because 65% of categories in WCN are removed from HEADS due to the simplification procedure.

As an additional metric, Table 2 reports edge-level *accuracy*, defined as the ratio of edges annotated as correct over the total number of edges sampled from a taxonomy. Accuracy scores are computed for each taxonomy by randomly sampling 450 edges of each type and annotating their correctness. HEADS is more accurate than WIBI$_E$ for entities, though a direct comparison is not meaningful, as WIBI$_E$ contains entity→entity edges while HEADS contains entity→category edges. For category→category edges, HEADS achieves a fairly significant > 10% improvement in accuracy compared to WIBI$_C$ taxonomy.

4.3 Beyond edge-level evaluation

Good performance at edge level, though widely used as an indicator of quality for a taxonomy (Ponzetto and Strube, 2007; Nastase and Strube, 2008; Flati et al., 2014), does not automatically translate into good performance at path level. For example, the generalization path *apples→fruits⇝vegetarians→people→organisms* is 75% edge-accurate (i.e., 3/4 edges are correct as indicated by the symbol →), but it can lead to the wrong inference that *apples* are *vegetarians* and, in turn, *people* and *organisms*. A single incorrect edge, namely *fruits⇝vegetarians*, causes a cascade of generalization errors for *fruits* and all its descendants, and a cascade of specialization errors for *vegetarians* and all its ancestors.

As an alternative to edge-level evaluation, the remainder of this section proposes a more structured scheme for evaluating a taxonomy. More specifically, it seeks to estimate the following: (1) What is the accuracy of multi-edge generalization paths ? (2) Are individual generalizations at the right level of granularity ? and (3) What is the accuracy of specializations of a concept.

4.3.1 Path-level evaluation

From the above example (*apples⇝organisms*), it is clear that during traversal of an upward generalization path, the correctness of individual edges is inconsequential to finding a good generalization for starting node (i.e., *apples*) once the first wrong edge (*fruits⇝vegetarians*) is encountered. Therefore, a good taxonomy should not only provide a large proportion of correct edges, but also provide correct generalization paths, i.e., paths which are correct in their entirety. However, since in practice it is common for relatively deep taxonomies to provide long generalization paths which pick at least one wrong edge, it would be still desirable to have a long *correct path prefix*, i.e., the maximal prefix of a path which is correct in its entirety.

This section evaluates HEADS and WIBI taxonomies on their ability to provide longer correct path prefixes and correct generalization paths. To avoid bias, it is desirable that paths sampled from different taxonomies start from the same node. Therefore, WIBI$_C$, which lacks the notion of entities, is first augmented with $E{\rightarrow}C$ edges from HEADS, resulting in a new hybrid taxonomy hereafter referred to as WIBI$_C$+H$_E$. For a sample of 250 entities present in HEADS, WIBI$_E$ and WIBI$_C$+H$_E$, one upward path is sampled per entity per taxonomy, for a total of 750 paths. Example paths are shown in Table 3, while Figure 2 shows the length distribution of the generalization paths sampled from each taxonomy. As expected, HEADS paths are generally shorter than WIBI taxonomies due to simplification.

To compare the three taxonomies, three human annotators[8] inspect each path starting from the entity and annotate the first incorrect generalization (e.g., *Film producer⇝Filmmaking* for the WIBI$_E$ example in Table 3). Figure 3 shows the average length of the correct path prefix in HEADS and WIBI taxonomies, along with 95% confidence interval bars[9], depending on the total length of a path. For a correct generalization path, the length of correct path prefix is the same as the path length, so an ideal taxonomy

[8] At least two annotators agreed for 93% of paths. All three annotators agreed for 53% of paths. Annotations are harmonized using majority voting.

[9] The confidence intervals reflect the distribution of the paths being sampled. A larger confidence bar indicates lower probability that a path of that length is chosen.

WIBI$_E$	WIBI$_C$+H$_E$	HEADS
Structure	Government	
↑Algebraic structure	... 23 more categories ...	**Apes**
↑Category (mathematics)	↑Cinema by region	**↑Humans**
↑Sequence	↑Cinema by continent	**↑People**
↑Process (science)	↑North American cinema	**↑Producers**
↑Filmmaking	↑Cinema of the United States	**↑American producers**
↑Film producer	**↑American film producers**	**↑American film producers**
Johnny Depp	**Johnny Depp**	**Johnny Depp**

Table 3: Upward generalization paths for *Johnny Depp* in three taxonomies. Correct path prefixes are shown in bold.

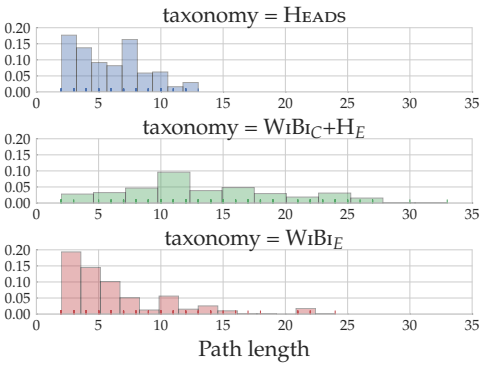

Figure 2: Length distribution of sampled generalization paths in different taxonomies.

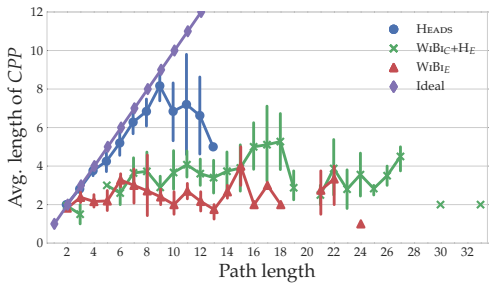

Figure 3: Average length of correct path prefix (*CPP*) in different taxonomies (computed using 750 annotated paths).

with only correct generalization paths would show up as the line $y = x$ in Figure 3. The behavior of HEADS is very close to an ideal taxonomy for the majority of path lengths, and outperforms WIBI$_E$ or WIBI$_C$+H$_E$ at all lengths, while WIBI$_C$+H$_E$ slightly outperforms WIBI$_E$. It is interesting to note that this difference does not translate into similar differences in edge-level evaluation, where all taxonomies consistently show relatively high accuracy (cf. Section 4.2). The superior performance of HEADS is further confirmed by Figure 4, which shows the probability of obtaining a correct generalization path of length $\leq k$. In contrast with WIBI taxonomies, HEADS generalization paths maintain high probability of correctness (> 0.7) at all lengths.

4.3.2 Path-granularity evaluation

A good taxonomy should not only provide correct generalization paths, but also ensure that each individual edge in the path provides generalization at the right level of granularity, i.e., neither too specific nor too general. To evaluate this aspect, 100 generalization paths originating from the same starting entities are sampled from different taxonomies. For each path, each individual edge is annotated by three human annotators with one of the following labels: 0 for wrong generalization (*fruits⇝vegetarians*); 1 for under-generalization (*fruits by country→fruits*); 2 for good-generalization (*edible fruits→fruits*); 3 for over-generalization (*edible fruits→physical bodies*). An edge under-generalizes if it adds or removes little information relative to the source node (e.g. *cricketers by team→cricketers*) or if it is a synonym or rephrasing of the original category (e.g. *coaches by sport→sport coaches*). An edge over-generalizes if it removes too much information. For example, for *bitstream→concept* one would expect the taxonomy to provide additional intermediate nodes (e.g. *binary sequences*) before generic node *concept*. Good-generalization label implies that edge is correct and neither over-generalizes nor under-generalizes. In order to ensure that the paths on which the comparison is performed are similar in length and complexity, we only consider pairs of shortest paths $\langle p_1, p_2 \rangle$ with the same final node, selected so as to minimize the difference in the length of the shortest paths $||p_1| - |p_2||$ in the two taxonomies, while ensuring that the paths are not identical ($p_1 \neq p_2$).

WIBI$_E$ is excluded from this experiment, since in contrast to HEADS and WIBI$_C$+H$_E$, WIBI$_E$ does not contain categories, hence the condition of same final node cannot be satisfied. Figure 5 graphically summarizes the results of this experiment. HEADS has fewer under-generalizations than WIBI$_C$+H$_E$

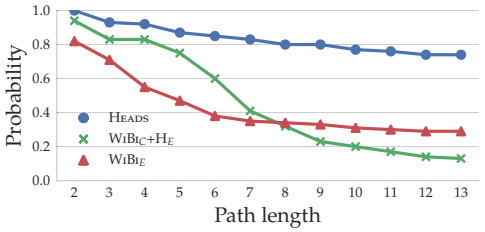

Figure 4: Probability of correct generalization paths vs. length (computed using 750 annotated paths). The probability at length k is the ratio of correct paths of length $\leq k$ to the total number of paths of length $\leq k$. Paths with length > 13 are omitted, as they are not present in HEADS samples, and always incorrect in WIBI$_E$ and WIBI$_C$+H$_E$ samples.

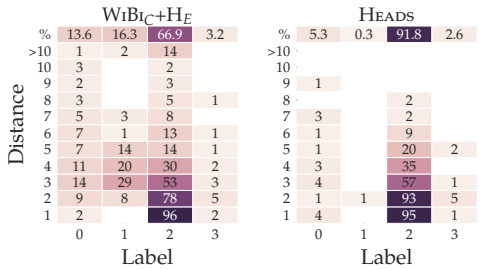

Figure 5: Generalization granularity evaluation for HEADS and WIBI$_C$+H$_E$ using 100 generalization paths. Labels on the horizontal axis indicate generalization granularity: 0 (wrong generalization), 1 (under-generalization), 2 (good-generalization) and 3 (over-generalization). Top row shows overall distribution of labels. Other rows represent number of sampled paths which have an edge with the corresponding label at the given distance from starting node.

Taxonomy	Overall accuracy	Per-node accuracy
WIBI$_E$	0.243	0.230
HEADS (entity)	**0.703**	**0.727**
WIBI$_C$	0.381	0.408
HEADS (category)	**0.670**	**0.725**

Table 4: Accuracy of specializations (computed using 100 (node, descendant) pairs). Overall accuracy is fraction of sampled (node, descendants) pairs which are correct, and per-node accuracy represents the average ratio of correct descendants per node. Results for entity and category descendants of HEADS are reported separately.

(0.3% vs 16.3%), which can be largely attributed to the simplification procedure (cf. Section 3.3). Despite the removal of 65% of categories through simplification, HEADS still does not suffer significantly from over-generalizations.

4.3.3 Specializations evaluation

A good taxonomy provides not only accurate generalizations going upwards in the taxonomy, but also accurate specializations going downwards. To evaluate this aspect, three human annotators annotate the correctness of a sample of descendants, for nodes in the taxonomies WIBI$_E$, WIBI$_C$ and HEADS. To avoid bias, nodes (entities for WIBI$_E$; categories for WIBI$_C$, HEADS) are sorted in decreasing order of the number of descendants in the respective taxonomies. 10 nodes at fixed ranks (5, 10, .., 50) from each list are selected for evaluation. To enable a comparison of WIBI$_E$ with WIBI$_C$ and HEADS, category nodes are manually mapped to equivalent entity nodes and vice-versa (e.g., *Category:Concepts* is mapped to the entity *Concept*). The annotators judge the correctness of 10 randomly sampled descendants for each selected node in each of the three taxonomies (see Table 4). HEADS is almost three times as accurate for entities as WIBI$_E$, and almost twice as accurate for categories as WIBI$_C$.

4.3.4 Extrinsic evaluation

This section compares HEADS, WIBI$_E$ and WIBI$_C$+H$_E$ on the task of selecting correct generalizations (e.g., *Countries*) for the variable slot in lexicalized templates such as *Passport of [X]*. These templates are mined by aggregation of Wikipedia page titles (e.g., *Passport of France*, *Passport of Canada*). The lexical fillers observed in the titles (e.g., *France*, *Canada*) are automatically disambiguated to a specific page (e.g., *France, European country* rather than *France, NY town*)[10], resulting in a set of filler entities for a template referred to as the template *support*.

To evaluate a taxonomy, for each template, the taxonomy is repeatedly traversed starting from subsamples of the support entities and equal-sized samples of random entities. Each non-leaf node in the taxonomy receives a score equal to the difference between the counts of support entities versus random

[10]Details of non-trivial problems of template mining and filler disambiguation are omitted due to space constraints, as they are not the main focus of this paper.

Template	Selected Generalizations		
	WIBI$_E$	WIBI$_C$+H$_E$	HEADS
railways in [X]	Tool, Entity, Publication, Operation (mathematics), Property (philosophy), Administrative division, Fine art, Material, Wealth, Combination	Geography, Countries, Statistics, Mathematical and quantitative methods (economics), Least developed countries, Capitals	Cities, Least developed countries, Administrative territorial entities
forestry in [X]	Entity, Wealth	Muslim-majority countries, Geography, Countries, Statistics, Mathematical and quantitative methods (economics), French-speaking countries and territories, Least developed countries	Muslim-majority countries, Least developed countries, Administrative territorial entities
[X] reader	Economic system, Entity, Document, Property (philosophy), Fine art, Material, Wealth	Philosophical concepts, Branches of philosophy, Concepts in metaphysics, Digital technology, Society, Psychology, Intelligence, Classification systems	Intellectual works, Concepts, Storage media, Literary characters
[X] ' day	Plurality (voting)	Public economics, Heavy metal subgenres, Intelligence, Economic policy, Heavy metal musical groups by nationality	Social groups, Occupations, Creative works
tomb of [X]	Tool, Value (mathematics), Publication, Proclamation, Official, Document, Instance (computer science), Fine art, Capital (economics), Material, Aesthetics, Electoral district, *[+2 more]*	People by nationality, Countries by continent, Hebrew Bible people, Ancient people, Religion, Genetics, Behavior, People by occupation, Fields of application of statistics, Jewish priests, Monarchy, Statistics, *[+16 more]*	People, Families, Ethnic groups, Noble titles

Table 5: Lists of selected generalizations for HEADS and WIBI taxonomies.

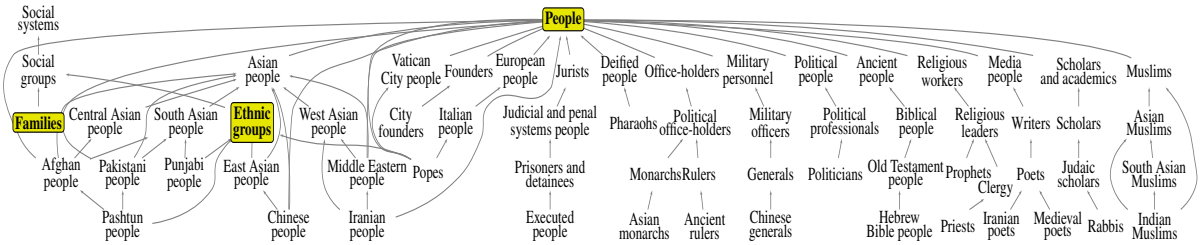

Figure 6: A view of the largest connected component of HEADS explored during the generalization of the template *Tomb of [X]*. The highlighted nodes are the selected generalizations.

entities from which the node can be reached in the given taxonomy. A node is selected as the generalization of fillers for the template, if its score is higher than both 1) the score of any of its parents, and 2) the sum of the scores of its children. For example, Figure 6 shows a subset of the largest connected component of HEADS explored while generalizing the fillers of the template *Tomb of [X]*. The selected generalizations are highlighted. The rationale behind this process is that in a good taxonomy, entities in the support (e.g., *France*, *Canada*) should consistently activate the same set of good generalizations (e.g., *Countries*).

Table 5 shows the lists of generalizations obtained with WIBI$_E$, WIBI$_C$+H$_E$ and HEADS for a few templates. A quantitative comparison of the results is inherently complex and outside the scope of this paper, yet it is immediately apparent that the generalizations obtained with WIBI$_C$+H$_E$ and WIBI$_E$ are generally quite noisy (e.g., *Genetics* for *Tomb of [X]*, *Wealth* for *railways in [X]*). On the contrary, HEADS shows a superior ability to select meaningful and compact generalizations that account for the polysemy of the templates without sacrificing precision (e.g., *People*, *Families*, *Ethnic groups* and *Noble titles* for *Tomb of [X]*).

5 Conclusion

Whether built from scratch or derived by filtering existing data, automatically-constructed taxonomies are accurate and useful only to the extent that they correctly assert not only short-range, but also longer-range generalizations among concepts or entities. The unified taxonomy introduced in this paper assembles entities and categories from Wikipedia that are in *is-a* relation relative to one another, primarily by detecting and analyzing lexical heads. A thorough evaluation framework is presented, and applied to the new taxonomy. In every respect, the taxonomy represents a significant improvement over the state of the art. It is more accurate along paths of arbitrary length and provides more accurate specializations.

Abstract

Previous studies have highlighted the necessity for entity linking systems to capture the local entity-mention similarities and the global topical coherence. We introduce a novel framework based on convolutional neural networks and recurrent neural networks to simultaneously model the local and global features for entity linking. The proposed model benefits from the capacity of convolutional neural networks to induce the underlying representations for local contexts and the advantage of recurrent neural networks to adaptively compress variable length sequences of predictions for global constraints. Our evaluation on multiple datasets demonstrates the effectiveness of the model and yields the state-of-the-art performance on such datasets. In addition, we examine the entity linking systems on the domain adaptation setting that further demonstrates the cross-domain robustness of the proposed model.

1 Introduction

We address the problem of entity linking (EL): mapping entity mentions in documents to their correct entries (called target entities) in some existing knowledge bases (KB) like Wikipedia. For instance, in the sentence "*Liverpool suffered an upset first home league defeat of the season.*", an entity linking system should be able to identify the entity mention "*Liverpool*" as a football club rather than a city in England in the knowledge bases. This is a challenging problem of natural language processing, as the same entity might be presented in various names, and the same entity mention string might refer to different entities in different contexts. Entity linking is a fundamental task for other applications such as information extraction, knowledge base construction etc.

In order to tackle the ambiguity in EL, previous studies have first generated a set of target entities in the knowledge bases as the referent candidates for each entity mention in the documents, and then solved a ranking problem to disambiguate the entity mention. The key challenge in this paradigm is the ranking model that computes the relevance of each target entity candidate to the corresponding entity mention using the available context information in both the documents and the knowledge bases.

The early approach for the ranking problem in EL has resolved the entity mentions in documents *independently* (*the local approach*), utilizing various *discrete* and *hand-designed* features/heuristics to measure the local mention-to-entity relatedness for ranking. These features are often specific to each entity mention and candidate entity, covering a wide range of linguistic and/or structured representations such as lexical and part-of-speech tags of context words, dependency paths, topical features, KB infoboxes (Bunescu and Pasca, 2006; Mendes et al., 2011; Cassidy et al., 2011; Ji and Grishman, 2011; Shen et al., 2014) etc. Although the local approach can exploit a rich set of discrete structures for EL, its limitation is twofold:

(i) The independent ranking mechanism in the local approach overlooks the topical coherence among the target entities referred by the entity mentions within the same document. This is undesirable as the topical coherence has been shown to be effective for EL in the previous work (Han et al.,

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2310–2320, Osaka, Japan, December 11-17 2016.

2011; Hoffart et al., 2011; Ratinov et al., 2011; He et al., 2013b; Alhelbawy and Gaizauskas, 2014; Pershina et al., 2015).

(ii) The local approach might suffer from the data sparseness issue of unseen words/features, the difficulty of calibrating, and the failure to induce the underlying similarity structures at high levels of abstraction for EL (due to the extensive reliance on the hand-designed coarse features) (Sun et al., 2015; Francis-Landau et al., 2016).

The first drawback of the local approach has been overcome by *the global models* in which all entity mentions (or a group of entity mentions) within a document are disambiguated *simultaneously* to obtain a *coherent* set of target entities. The central idea is that the referent entities of some mentions in a document might in turn introduce useful information to link other mentions in that document due to the semantic relatedness among them. For example, the appearances of "*Manchester*" and "*Chelsea*" as the football clubs in a document would make it more likely that the entity mention "*Liverpool*" in the same document is also a football club. Unfortunately, the coherence assumption of the global approach does not hold in some situations, necessitating the discrete/coarse features in the local approach as a mechanism to compensate for the potential exceptions of the coherence assumption (Ratinov et al., 2011; Hoffart et al., 2011; Sil et al., 2012; Durrett and Klein, 2014; Pershina et al., 2015). Consequently, the global approach is still subject to the second limitation of data sparseness of the local approach due to their use of discrete features.

Recently, the surge of neural network (NN) models has presented an effective mechanism to mitigate the second limitation of the local approach. In such models, words are represented by *continuous* representations (Bengio et al., 2003; Turian et al., 2010; Mikolov et al., 2013) and features for the entity mentions and candidate entities are automatically learnt from data. This essentially alleviates the data sparseness problem of unseen words/features and helps to extract more effective features for EL in a given dataset (Kalchbrenner et al., 2014; Nguyen et al., 2016a). In practice, the features automatically induced by NN are combined with the discrete features in the local approach to extend their coverage for EL (Sun et al., 2015; Francis-Landau et al., 2016). However, as the previous NN models for EL are local, they cannot capture the global interdependence among the target entities in the same document (the first limitation of the local approach).

Guided by these analyses, in this paper, we propose to use neural networks to model both the local mention-to-entity similarities and the global relatedness among target entities in an unified architecture. This allows us to inherit all the benefits from the previous systems as well as overcome their inherent issues. Our work is an extension of (Francis-Landau et al., 2016) which only considers the local similarities.

Given a document, we simultaneously perform linking for every entity mention from the beginning to the end of the document. For each entity mention, we utilize convolutional neural networks (CNN) to obtain the distributed representations for the entity mention as well as its target candidates. These distributed representations are then used for two purposes: (i) computing the local similarities for the entity mention and target candidates, and (ii) functioning as the input for the recurrent neural networks (RNN) that runs over the entity mentions in the documents. The role of the RNNs is to accumulate information about the previous entity mentions and target entities, and provide them as the global constraints for the linking process of the current entity mention. We systematically evaluate the proposed model on multiple datasets in both the general setting and the domain adaptation setting. The experiment results show that the proposed model outperforms the current state-of-the-art models on the evaluated datasets. To our knowledge, this is also the first work investigating the EL problem in the domain adaptation setting.

2 Model

The entity linking problem in this work can be formalized as follows. Let D be the input document and $M = \{m_1, m_2, \ldots, m_k\}$ be the entity mentions in D. The goal is to map each entity mention m_i to its corresponding Wikipedia page (entity) or return "*NIL*" if m_i is not present in Wikipedia. For each entity

mention $m_i \in D$, let $P_i = \{p_{i1}, p_{i2}, \ldots p_{in_i}\}$ be its set of Wikipedia candidate pages (entities)[1] where n_i is the number of page candidates for m_i. Also, let $p_i^* \in P_i$ be the correct target entity for m_i.

Following Francis-Landau et al. (2016), we represent each entity mention m_i by the triple $m_i = (s_i, c_i, d_i)$, where s_i is the *surface string* of m_i, c_i is the *immediate context* (within some predefined window) of m_i and d_i is the *entire document* containing m_i. Essentially, s_i, c_i and d_i are the sequences of words to capture the contexts or topics of m_i at multiple granularities. For the target candidate pages p_{ij}, we use the *title* t_{ij} and *body content* b_{ij} to represent them ($p_{ij} = (t_{ij}, b_{ij})$). For convenience, we also denote $p_i^* = (t_i^*, b_i^*)$ for the correct entity pages. Again, t_{ij}, b_{ij}, t_i^* and b_i^* are also sequences of words.

In order to link the entity mentions, the strategy is to assign a relevance score $\phi(m_i, p_{ij})$ for each target candidate p_{ij} of m_i, and then use these scores to rank the candidates for each mention. In this work, we decompose $\phi(m_i, p_{ij})$ as the sum of the two following factors:

$$\phi(m_i, p_{ij}) = \phi_{local}(m_i, p_{ij}) + \phi_{global}(m_1, m_2, \ldots, m_i, P_1, P_2, \ldots, P_i)$$

In this formula, $\phi_{local}(m_i, p_{ij})$ represents the local similarities between m_i and p_{ij}, i.e, only using the information related to m_i and p_{ij}. $\phi_{global}(m_1, m_2, \ldots, m_i, P_1, P_2, \ldots, P_i)$, on the other hand, additionally considers the other mentions and candidates in the document, attempting to model the interdependence among these objects. The denotation $\phi_{global}(m_1, m_2, \ldots, m_i, P_1, P_2, \ldots, P_i)$ implies that we are computing the ranking scores for all the target candidates of all the entity mentions in each document simultaneously, preserving the order of the entity mentions from the beginning to the end of the document.

The model in this work consists of three main components: (i) the encoding component that applies convolutional neural networks to induce the distributed representations for the input sequences s_i, c_i, d_i, t_{ij}, and b_{ij}, (ii) the local component that computes the local similarities $\phi_{local}(m_i, p_{ij})$ for each entity mention m_i, and (iii) the global component that runs recurrent neural networks on the entity mentions $\{m_1, m_2, \ldots, m_k\}$ to generate the global features $\phi_{global}(m_1, m_2, \ldots, m_i, P_1, P_2, \ldots, P_i)$.

2.1 Encoding

Let x be some context word sequence of the entity mentions or target candidates (i.e, $x \in \{s_i, c_i, d_i\}_i \cup \{t_{ij}, p_{ij}\}_{i,j} \cup \{t_i^*, b_i^*\}_i$). In order to obtain the distributed representation for x, we first transform each word $x_i \in x$ into a real-valued, h-dimensional vector w_i using the word embedding table E (Mikolov et al., 2013): $w_i = E[x_i]$. This essentially converts the word sequence x into a sequence of vectors that is padded with zero vectors to form a fixed-length sequence of vectors $w = (w_1, w_2, \ldots, w_n)$ of length n.

In the next step, we apply the convolution operation over w to generate the hidden vector sequence, that is then transformed by a non-linear function G and pooled by the sum function (Francis-Landau et al., 2016). Following the previous work on CNN (Nguyen and Grishman, (2015a; 2015b)), we utilize the set L of multiple window sizes to parameterize the convolution operation. Each window size $l \in L$ corresponds to a convolution matrix $M_l \in \mathbb{R}^{v \times lh}$ of dimensionality v. Eventually, the concatenation vector $\bar{x}$ of the resulting vectors for each window size in L would be used as the distributed representation for x:

$$\bar{x} = \bigoplus_{l \in L} \sum_{i=1}^{n-l+1} G(M_l w_{i:(i+l-1)})$$

where $\bigoplus$ is the concatenation operation over the window set L and $w_{i:(i+l-1)}$ is the concatenation vector of the given word vectors.

For convenience, let $\bar{s}_i$, $\bar{c}_i$, $\bar{d}_i$, $\bar{t}_{ij}$, $\bar{b}_{ij}$, $\bar{t}_i^*$ and $\bar{b}_i^*$ be the distributed representations of s_i, c_i, d_i, t_{ij}, p_{ij}, t_i^* and b_i^* obtained by the convolution procedure above, respectively. Note that we apply the same set of convolution parameters for each type of text granularity in the source document D as well as in the

[1]For comparison purpose, we use the target candidates provided by Francis-Landau et al. (2016). Essentially, a query generation is executed for each entity mention, whose outputs are combined with link counts to retrieve the potential entities (including "*NIL*"). The query generation itself involves removing stop words, plural suffixes, punctuation, and leading or tailing words.

target entity side. The vector representations of the context would then be fed into the next components to compute the features for EL.

2.2 Local Similarities

We employ the local similarities $\phi_{local}(m_i, p_{ij})$ from (Francis-Landau et al., 2016), the state-of-the-art neural network model for EL. In particular:

$$\phi_{local}(m_i, p_{ij}) = \phi_{sparse}(m_i, p_{ij}) + \phi_{CNN}(m_i, p_{ij}) = W_{sparse}F_{sparse}(m_i, p_{ij}) + W_{CNN}F_{CNN}(m_i, p_{ij})$$

In this formula, W_{sparse} and W_{CNN} are the weights for the feature vectors F_{sparse} and W_{CNN} respectively. $F_{sparse}(m_i, p_{ij})$ is the sparse feature vector obtained from (Durrett and Klein, 2014). This vector captures various linguistic properties and statistics that have been discovered in the previous studies for EL. The representative features include the anchor text counts from Wikipedia, the string match indications with the title of the Wikipedia candidate pages, or the information about the shape of the queries for candidate generations (Francis-Landau et al., 2016).

$F_{CNN}(m_i, p_{ij})$, on the other hand, involves the cosine similarities between the representation vectors at multiple granularities of m_i and p_{ij}. In particular:

$$F_{CNN}(m_i, p_{ij}) = [cos(\bar{s}_i, \bar{t}_{ij}), cos(\bar{c}_i, \bar{t}_{ij}), cos(\bar{d}_i, \bar{t}_{ij}), cos(\bar{s}_i, \bar{b}_{ij}), cos(\bar{c}_i, \bar{b}_{ij}), cos(\bar{d}_i, \bar{b}_{ij})] \quad (1)$$

The intuition for this computation is that the similarities at different levels of contexts might help to enforce the potential topic compatibility between the contexts of the entity mentions and target candidates for EL (Francis-Landau et al., 2016).

2.3 Global Similarities

In order to encapsulate the coherence among the entity mentions and their target entities, we run recurrent neural networks over the sequences of the representation vectors for the entity mentions (i.e, the vector sequences for the surface strings $(\bar{s}_1, \bar{s}_2, \ldots, \bar{s}_k)$ and for the immediate contexts $(\bar{c}_1, \bar{c}_2, \ldots, \bar{c}_k)$) and the target entities (i.e, the vector sequences for the page titles $(\bar{t}^*_1, \bar{t}^*_2, \ldots, \bar{t}^*_k)$ and for the body contents $(\bar{b}^*_1, \bar{b}^*_2, \ldots, \bar{b}^*_k)$)[2].

Let us take the representation vector sequence of the body contents of the target pages $(\bar{b}^*_1, \bar{b}^*_2, \ldots, \bar{b}^*_k)$[3] as an example. The recurrent neural network with the recurrent function Φ for this sequence will generate the hidden vector sequence $(h^b_1, h^b_2, \ldots, h^b_k)$ where: $h^b_i = \Phi(h^b_{i-1}, \bar{b}^*_i)$.

Each vector h^b_i in this sequence encodes or summarizes the information about the content of the previous target entities (i.e, before i) in the document due to the property of RNN.

Given the hidden vector sequence, when predicting the target entity for the entity mention m_i, we ensure that the target entity is consistent with the global information stored in h^b_{i-1}. This is achieved by using the cosine similarities between h^b_{i-1} and the representation vectors of each target candidate p_{ij} of m_i, (i.e, $cos(h^b_{i-1}, \bar{t}_{ij})$ and $cos(h^b_{i-1}, \bar{b}_{ij})$) as the global features for the ranking score.

We can repeat this process for the other representation vector sequences in both the entity mention side and the target entity side. The resulting global features would then be grouped into a single feature vector to compute the global similarity score $\phi_{global}(m_1, m_2, \ldots, m_i, P_1, P_2, \ldots, P_i)$ as in the local similarity section. An overview of the whole model is presented in Figure 1.

Regarding the reccurent function Φ, we employ the gated recurrent units (GRU) (Cho et al., 2014) to alleviate the "*vanishing gradient problem*" of RNN. GRU is a simplified version of long-short term memory units (LSTM) that has been shown to achieve comparable performance (Józefowicz et al., 2015).

Finally, for training, we jointly optimize the parameters for the CNNs, RNNs and weight vectors by maximizing the log-likelihood of a labeled training corpus. We utilize the stochastic gradient descent algorithm and the AdaDelta update rule (Zeiler, 2012). The gradients are computed via back-propagation. Following (Francis-Landau et al., 2016), we do not update the word embedding table during training.

[2]Note that we have different recurrent neural networks for different context vector sequences.

[3]In the training process, $(\bar{b}^*_1, \bar{b}^*_2, \ldots, \bar{b}^*_k)$ are obtained from the golden target entities while in the test time, they are retrieved from the predicted target entities.

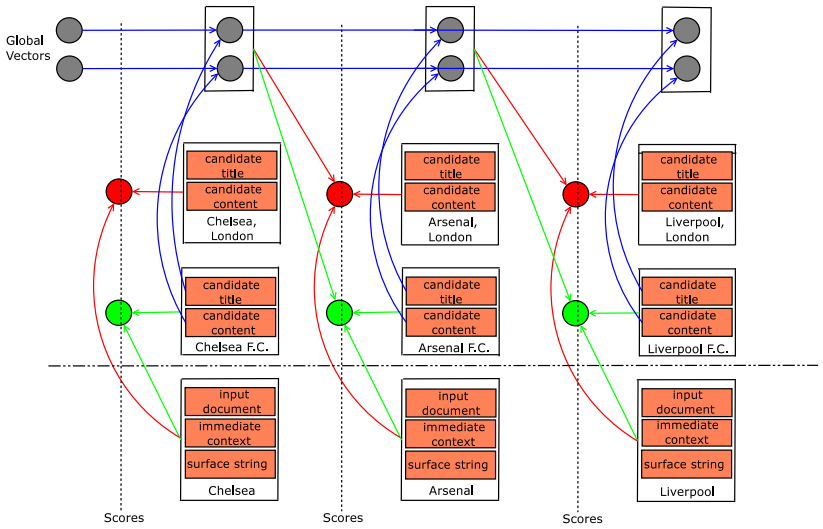

Figure 1: Joint model for learning local and global features for a document with 3 entity mentions: *Chelsea*, *Arsenal* and *Liverpool*. Each of the entity mentions has two entity candidate pages (either a football club or a city).The orange rectangles denote the CNN-induced representation vectors $\bar{s}_i$, $\bar{c}_i$, $\bar{d}_i$, $\bar{t}_{ij}$ and $\bar{b}_{ij}$. The circles in red and green are the ranking scores for the target candidates, in which the green circles correspond to the correct target entities. Finally, the circles in grey are the hidden vectors (i.e, the global vectors) of the RNNs running over the entity mentions. We only show the global entity vectors in this figure to improve the visualization.

3 Experiments

3.1 Datasets

Following (Francis-Landau et al., 2016), we evaluate the models on 4 different entity linking datasets:

i) ACE (Bentivogli et al., 2010): This corpus is from the 2005 evaluation of NIST. It is also used in (Fahrni and Strube, 2014) and (Durrett and Klein, 2014).

ii) CoNLL-YAGO (Hoffart et al., 2011): This corpus is originally from the CoNLL 2003 shared task of named entity recognition for English.

iii) WP (Heath and Bizer, 2011): This dataset consists of short snippets from Wikipedia.

iv) WIKI (Ratinov et al., 2011): This dataset contains 10,000 randomly sampled Wikipedia articles. The task is to disambiguate the links in each article[4].

For all the datasets, we use the standard data splits (for training data, test data and development data) as the previous works for comparable comparison (Francis-Landau et al., 2016).

3.2 Parameters and Resources

For all the experiments below, in the CNN models to learn the distributed representations for the inputs, we use window sizes in the set $L = \{2, 3, 4, 5\}$ for the convolution operation with the dimensionality $v = 200$ for each window size[5]. The non-linear function for transformation is $G = \tanh$.

We employ the English Wikipedia dump from June 2016 as our reference knowledge base.

Regarding the input contexts for the entity mentions and the target candidates, we utilize the window size of 10 for the immediate context c_i, and only extract the first 100 words in the documents for d_i and b_{ij}.

Finally, we pre-train the word embedings on the whole English Wikipedia dump using the word2vec toolkit (Mikolov et al., 2013). The training parameters are set to the default values in this toolkit. The dimensionality of the word embeddings is 300.

Note that every parameter and resource in this work is either taken from the previous work (Nguyen and Grishman, 2016b; Francis-Landau et al., 2016) or selected by the development data.

[4]As noted by Francis-Landau et al. (2016) and Nguyen et al. (2014b), the original Wikipedia dump in Ratinov et al. (2011) is no longer accessible, so we cannot duplicate the results or conduct comparable experiments with (Ratinov et al., 2011). We instead compare our performance with (Francis-Landau et al., 2016) that provides the access to their Wikipedia dump.

[5]As we need to compute the cosine similarities between the hidden vectors of the RNN models and the representation vectors of the target candidates, the number of hidden units for the RNN is set to $200|L| = 800$ naturally.

3.3 Evaluating the Global Features

In this section, we evaluate the effectiveness of the global features for EL. In particular, we differentiate two types of global features based on the side of information we expect to enforce the coherence. The first type of global features (***global-mention***) concerns the entity mention side and involves applying the global RNN models on the CNN-induced representation vectors of the entity mentions (i.e, the surface vectors $(\bar{s}_1, \bar{s}_2, \ldots, \bar{s}_k)$ and the immediate context vectors $(\bar{c}_1, \bar{c}_2, \ldots, \bar{c}_k)$). The second type of global features (***global-entity***), on the other hand, focuses on the target entity side and models the coherence with the representation vectors of the target entities (i.e, the page title vectors $(\bar{t}^*_1, \bar{t}^*_2, \ldots, \bar{t}^*_k)$ and the body content vectors $(\bar{b}^*_1, \bar{b}^*_2, \ldots, \bar{b}^*_k)$). Table 1 reports the development performance (F1 scores) of the proposed model on different cases where the *global-mention* and *global-entity* features are included or excluded from the model.

Global Features	Dataset		
	ACE	CoNLL	WP
No	86.1	89.3	84.0
global-mention	86.8	90.2	84.2
global-entity	**86.9**	**90.7**	**84.2**
global-mention + *global-entity*	86.2	90.6	84.0

Table 1: Performance of the global features on the development set. *No* means not using the global features.

The most important observation from the table is that the global features, in general, help to improve the performance of the model on different datasets. This is substantial on the ACE and CoNLL datasets when only one type of the global features (either *global-mention* or *global-entity*) is integrated into the model. The combination of *global-mention* and *global-entity* is not very effective as it is actually worse than the performance of the individual global feature types. This suggests that *global-mention* and *global-entity* might cover overlapping information and their combination would inject redundancy into the model. The best performance is achieved by the *global-entity* features that would be used in all the evaluations below.

3.4 Comparing to the Previous Work

This section compares the proposed system (called *Global-RNN*) with the state-of-the-art models on our four datasets. These systems include the neural network model in (Francis-Landau et al., 2016), the joint model for entity analysis in (Durrett and Klein, 2014) and the AIDA-light system with two-stage mapping in (Nguyen et al., 2014b)[6]. Table 2 shows the performance of the systems on the test sets with the reference knowledge base of the June 2016 Wikipedia dump. We also include the performance of the systems on the December 2014 Wikipedia dump that was used and provided by (Francis-Landau et al., 2016) for further and compatible comparison.

Systems	Wikipedia 2014				Wikipedia 2016			
	ACE	CoNLL	WP	WIKI	ACE	CoNLL	WP	WIKI
DK2014 (Durrett and Klein, 2014)	79.6	-	-	-	-	-	-	-
AIDA-LIGHT (Nguyen et al., 2014b)	-	84.8	-	-	-	-	-	-
Local CNN (Francis-Landau et al., 2016)	**89.9**	85.5	90.7	82.2	86.1	84.5	90.4	81.4
Global-RNN	89.7	**87.2**†	**91.2**†	**83.7**†	**87.8**†	**86.5**†	**91.2**†	**81.7**

Table 2: Performance of the systems. Cells marked with †designate the *Global-RNN* models that significantly outperform the *Local CNN* model ($\rho < 0.05$).

First, we see that the performance of the systems drop significantly when we switch from Wikipedia 2014 to Wikipedia 2016 (especially for the datasets ACE and CoNLL). This is can be partly explained by the inclusion of new entities (pages) into Wikipedia from 2014 to 2016 that has made the entity mentions in the datasets more ambiguous[7]. Second and more importantly, *Global-RNN* significantly outperforms

[6]We note that (Alhelbawy and Gaizauskas, 2014) and (Pershina et al., 2015) also use the CoNLL-YAGO dataset for their experiments. However, since they evaluate the models on the whole dataset rather than the test set as the other works do, they are not comparable to the performance we report in this paper.

[7]The number of Wikipedia pages in 2014 is about 4.5 million while this number is 5 million in June 2016.

the all the compared models (except for the ACE dataset on Wikipedia 2014 and the WIKI dataset on Wikipedia 2016), thereby demonstrating the benefits of the joint modeling for local and global features via neural networks for EL in this work.

3.5 Domain Adaptation Experiments

The purpose of this section is to further evaluate the models in the domain adaptation setting to investigate their cross-domain robustness for EL.

It is often observed in many natural language processing tasks that the performance of a model trained on a source domain would degrade significantly when it is applied to a different target domain (Blitzer et al., 2006; Daume, 2007; McClosky et al., 2010; Plank and Moschitti, 2013; Nguyen and Grishman, 2014a). Such a performance loss originates from a variety of mismatches between the source and the target domains, including the differences in vocabulary, data distributions, styles etc. This has motivated the domain adaptation research that aims to improve the cross-domain performance of the models by adaptation techniques.

One of the key strategies of the domain adaptation techniques is the search for the domain-independent features that are discriminative across different domains (Blitzer et al., 2006; Jiang, 2009; Plank and Moschitti, 2013; Nguyen and Grishman, 2014a). These invariants serve as the connectors between different domains and help to transfer the knowledge from one domain to the others. For EL, we hypothesize that the global coherence is an effective domain-independent feature that would help to improve the cross-domain performance of the models. The intuition is that the entities mentioned in a document of any domains should be related to each other. Eventually, we expect that the proposed model with global coherence features would be more robust to domain shifts than the local approach (Francis-Landau et al., 2016).

3.5.1 Dataset

We use the ACE dataset to evaluate the cross-domain performance of the models. ACE involves documents in 6 different domains: broadcast conversation (bc), broadcast news (bn), telephone conversation (cts), newswire (nw), usenet (un) and webblogs (wl). Following the common practice of domain adaptation research on this dataset (Plank and Moschitti, 2013; Nguyen et al., 2015c; Gormley et al., 2015), we use **news** (the union of **bn** and **nw**) as the source domain and **bc**, **cts**, **wl**, **un** as four different target domains. We take half of **bc** as the development set and use the remaining data for testing. We note that **news** consists of formally written documents while a majority of the other domains is informal text, making the source and target domains very divergent in terms of vocabulary and styles (Plank and Moschitti, 2013).

3.5.2 Evaluation

Table 3 compares *Global-RNN* with the neural network EL model in (Francis-Landau et al., 2016), the best reported model on the ACE dataset in the literature[8]. In this table, the models are trained on the source domain **news**, and evaluated on **news** itself (in-domain performance) (via 5-fold cross validation) as well as on the 4 target domains **bc**, **cts**, **wl**, **un** (out-of-domain performance). The experiments in this section are done with the 2016 Wikipedia dump.

Models	Domain				
	in-domain	bc	cts	wl	un
Local CNN (Francis-Landau et al., 2016)	90.6	87.8	88.7	80.2	82.1
Global-RNN	**91.0**	**88.7**†	**88.9**	**81.3**†	**83.1**†

Table 3: Cross-domain performance. Cells marked with †designate the *Glob-RNN* models that significantly outperform the *Local CNN* model ($\rho < 0.05$).

The first observation from the table is that the performance of all the compared systems on the target domains is much worse than the corresponding in-domain performance. In particular, the performance gap between the in-domain performance and the the worst out-of-domain performance (on the domain

[8]The performance of the model from (Francis-Landau et al., 2016) reported in this work is obtained by running their actual released system.

wl) is up to 10%, thus indicating the mismatches between the source and the target domains for EL. Second and most importantly, *Global-RNN* is consistently better than the model with only local features in (Francis-Landau et al., 2016) over all the target domains (although it is less pronounced in the **cts** domain). This demonstrates the cross-domain robustness of the proposed model and confirms our hypothesis about the domain-independence of the global coherence features for EL.

3.5.3 Analysis

In order to better understand the performance gap in the domain adaptation experiments for EL, we visualize the representation vectors of the entity mentions in different domains. In particular, after *Global-RNN* is trained, we retrieve the representation vectors $\bar{c}_i$ for the immediate contexts of the entity mentions in the source and target domains, project them into the 2-dimension space via the t-SNE algorithm and plot them. Figure 2 shows the plot.

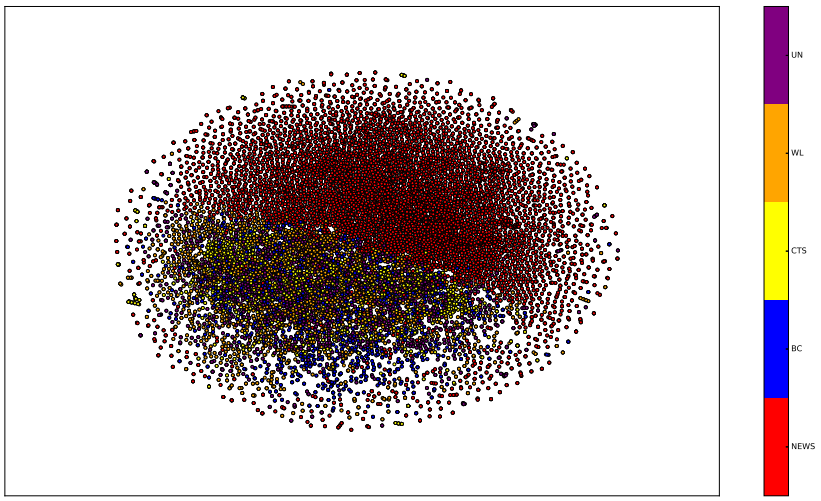

Figure 2: t-SNE visualization on the representation vectors c_i of different domains.

As we can see from the figure, the entity mentions in the target domains **bc**, **cts**, **wl** and **un** are quite separated from those of the source domain **news**, thereby explaining the performance loss in the domain adaption experiments.

It is not clear in Figure 2 why the models perform much worse on the target domains **wl** and **un** than the other domains (i.e, **bc** and **cts**). We further investigate this problem by computing the similarities between the target domains and the source domain. While there are several methods to estimate domain similarities (Plank and van Noord, 2011), in this work, we employ the mean of the cosine similarities of every mention pairs in the two domains of interest. Specifically, let E and F be the two domains of interest, and $E = \{e_1, e_2, \ldots, e_g\}$ and $F = \{f_1, f_2, \ldots, f_w\}$ be the sets of the representation vectors for the entity mentions in E and F respectively ($g = |E|, w = |F|$). The similarity between E and F is then given by:

$$Sim(E, F) = 100 \times \frac{\sum_{i=1}^{g} \sum_{j=1}^{w} cos(e_i, f_j)}{gw}$$

Table 4 shows the similarities between the source domain **news** and each target domains **bc**, **cts**, **wl** and **un** with respect to the representation vectors of the immediate context $\bar{c}_i$ (*context*) and the target entity titles $\bar{t}_i^*$ (*title*) for the entity mentions m_i. We also include the similarities in which the representation vectors are the local feature vectors $F_{CNN}(m_i, t_i^*)$ in Equation 1 (*interaction*). The goal of the local feature similarities is to characterize how the entity mentions in different domains interact with their target entities.

It is clear from the table that **wl** is the most dissimilar domain from the source domain. This is followed by **un** and partly explains the performance in Table 3.

Domain	*context*	*title*	*interaction*
bc	10.7	2.0	34.4
cts	11.4	2.0	32.6
wl	9.2	0.8	30.3
un	9.5	1.4	31.1

Table 4: Similarities to the source domain **news**.

4 Related Work

Entity linking or disambiguation has been studied extensively in NLP research, falling broadly into two major approaches: local and global disambiguation. Both approaches share the goal of measuring the similarities between the entity mentions and the target candidates in the reference KB. The local paradigm focuses on the internal structures of each separate mention-entity pair, covering the name string comparisons between the surfaces of the entity mentions and target candidates, entity popularity or entity type and so on (Bunescu and Pasca, 2006; Milne and Witten, 2008; Zheng et al., 2010; Ji and Grishman, 2011; Mendes et al., 2011; Cassidy et al., 2011; Shen et al., 2014). In contrast, the global approach jointly maps all the entity mentions within documents to model the topical coherence. Various techniques have been exploited for capturing such semantic consistency, including Wikipedia category agreement (Cucerzan, 2007), Wikipedia link-based measures (Kulkarni et al., 2009; Hoffart et al., 2011; Shen et al., 2012), Point-wise Mutual Information measures (Ratinov et al., 2011), integer linear programming (Cheng and Roth, 2013), PageRank (Alhelbawy and Gaizauskas, 2014; Pershina et al., 2015), stacked generalization (He et al., 2013a), to name a few. The entity linking techniques and systems have been actively evaluated at the NIST-organized Text Analysis Conference (Ji et al., 2014).

Neural networks are applied to entity linking very recently. He et al. (2013b) learn enttiy representation via Stacked Denoising Auto-encoders. Sun et al. (2015) employ convolutional neural networks and neural tensor networks to model mentions, entities and contexts while Francis-Landau et al. (2016) combine CNN-based representations with sparse features to improve the performance. However, none of these work utilize recurrent neural networks to capture the coherence features as we do in this work.

5 Conclusion

We present a joint model to learn the local context similarities and the global topical relatedness features for entity linking. CNNs are employed to capture the local similarities while RNNs are utilized to introduce the coherence. The model achieves the state-of-the-art performance on multiple datasets for entity linking. It is also shown to be more robust to domain shifts. Our future work is threefold: (i) integrating entity embedding models into the current work, (ii) exploring new neural models to jointly perform entity linking and entity extraction (Nguyen et al., 2016c), and (iii) further evaluating the models in the cross-lingual settings.

Abstract

Aspect extraction identifies relevant features of an entity from a textual description and is typically targeted to product reviews, and other types of short text, as an enabling task for, e.g., opinion mining and information retrieval. Current aspect extraction methods mostly focus on aspect terms, often neglecting associated modifiers or embedding them in the aspect terms without proper distinction. Moreover, flat syntactic structures are often assumed, resulting in inaccurate extractions of complex aspects. This paper studies the problem of structured aspect extraction, a variant of traditional aspect extraction aiming at a fine-grained extraction of complex (i.e., hierarchical) aspects. We propose an unsupervised and scalable method for structured aspect extraction consisting of statistical noun phrase clustering, cPMI-based noun phrase segmentation, and hierarchical pattern induction. Our evaluation shows a substantial improvement over existing methods in terms of both quality and computational efficiency.

1 Introduction

The abundance of web data has made information extraction (IE) of strategic importance for data-driven companies such as, e.g., retailers, because of its applications to information retrieval (Kannan et al., 2011), knowledge base construction (Shin et al., 2015), media intelligence (Zeng et al., 2010), and conversational agents (Cassell, 2000). Among all IE-related tasks, *Aspect extraction* (AE) (Zhang and Liu, 2014) is certainly one of the most challenging. AE aims at identifying features of an entity, e.g., a phone, from a free text description ans is commonly associated with (aspect-based) sentiment analysis as a means of extracting *aspect terms* and associated *opinions* in, e.g., product reviews or other forms of opinionated and evaluative text (Hu and Liu, 2004; Popescu and Etzioni, 2005). Similar methods have also been used for extracting *attributes* from, e.g., product listings and other forms of *descriptive* text (Ghani et al., 2006; Kannan et al., 2011). An obvious challenge in aspect extraction is dealing with noisy, unstructured text (NUT). NUT has consistently challenged traditional NLP tools, in particular POS taggers and dependency parsers, due to ungrammatical sentences and incorrect orthography.

Example 1: Aspect extraction

Victorian two bedroom mid terrace property located in Cambridge and comprising of living room with ORIGINAL!!! cupboards, and ORIGINAL!!! picture rail.Stairway off living room leads to two bedrooms.

↓

{ bedroom mid terrace, picture rail.Stairway, cupboards, bedrooms, property} {Cambridge, ORIGINAL}

Example 1 shows the output of IBM's Alchemy Language service[1] when asked to retrieve aspect terms and named entities. Alchemy Language extracts picture rail.Stairway as an aspect due to a missing space after the full stop, and ORIGINAL as a named entity, due to incorrect orthography. Another challenge is distinguishing aspect terms from their *modifiers*. The terms Victorian, mid terrace, and the (nested) expression two bedroom are *qualifying* the term property, while the term two *quantifies* the term bedroom.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2321–2332, Osaka, Japan, December 11-17 2016.

Problem definition This paper studies the problem of recognizing and extracting *structured* aspects. *Structured Aspect Extraction* (SAE) generalizes aspect term extraction (ATE) with the extraction and *linking* of modifiers of the aspect term, identifying the possibly hierarchical structure of the aspects. Consider the text Victorian two bedroom mid terrace property from Example 1. An SAE system is expected to produce a single extraction with explicit annotations for *(i)* the aspect terms, i.e., property, bedroom *(ii)* the aspect modifiers, correctly typed as qualifiers, i.e., Victorian, mid terrace, and quantifiers, i.e., two, and *(iii)* the hierarchical structure of the aspect, i.e., $\langle\{\text{Victorian}, \langle\{\text{two}\}, \text{bedroom}\rangle, \text{mid terrace}\}, \text{property}\rangle$.

Contributions (Zhang and Liu, 2014) termed the recognition of *flat* $\langle\text{modifier}, \text{aspect}\rangle$ structures (i.e., a simple form of SAE) a very challenging task. In this paper we go beyond that, proposing (Section 2) a method for unsupervised SAE consisting of: **(1)** An effective normalization strategy specifically engineered for NUT. **(2)** A statistical noun phrase clustering method for unsupervised discovery of aspect terms and (raw) modifiers. **(3)** A cPMI-based noun-phrase segmentation, to identify multi-word expressions and nested structures. **(4)** A controlled induction of *structured aspect patterns*. We evaluate our method against state-of-the-art aspect extraction systems using data from the widely-accepted SemEval benchmarks and a SAE-specific dataset. The evaluation (Section 3) shows that our method improves on existing unsupervised systems for aspect-term extraction and solves the harder SAE task reliably.

Positioning Existing work on aspect extraction focuses mostly on three tasks: **(1)** Entity extraction (Zhang and Liu, 2014; Yahya et al., 2014), i.e., classifying entities in a free-text fragment (e.g., car, phone). **(2)** Aspect term extraction (Yu et al., 2011; Zhang and Liu, 2014; Chen et al., 2014), i.e., extracting features of the entity (e.g., battery, performance). **(3)** Opinion extraction (Pang and Lee, 2008; Yang and Cardie, 2014), i.e., extracting sentiments or opinions and link them to aspects terms.

(Probst et al., 2007) was the first method to go beyond simple aspect terms, proposing a semi-supervised method for extracting $\langle\text{modifier}, \text{aspect}\rangle$ pairs from product descriptions. Despite being supervised, the method has issues distinguishing genuine pairs representing aspects from spurious ones. (Kelly et al., 2012) makes extractions more precise by targeting $\langle\text{modifier}, \text{relation}, \text{aspect}\rangle$ triples in verbal phrases. Although precise, applying this method is unrealistic in practice since it severely impairs recall. In fact, empirical evidence suggests that most of the interesting aspects occur in proximity of named entities and in noun phrases. This shows the need for more flexibility in extracting aspects.

Leveraging a dependency parser is a possible way to capture more complex aspect structures, or at least to provide clues about the presence of entity modifiers (e.g., via AMOD relations). However, deep parsing is known to be inaccurate on NUT, and training suitable models difficult, since NUT lacks proper grammatical structure in the first place. This has been clear since the works by (Popescu and Etzioni, 2005) and (Raju et al., 2009) proposing, as a solution, ATE methods based on noun-phrase clustering. More recently, (Kim et al., 2012) used noun-phrase clustering to extract $\langle\text{modifier}, \text{aspect}\rangle$ pairs where modifiers are arbitrary n-grams, generically typed as either modifiers or quantifiers. Although limited to flat structures, this is currently the closest work to SAE we are aware of.

Similarly to (Popescu and Etzioni, 2005; Raju et al., 2009), we use *frequency*-based noun-phrase clustering to detect aspect terms in an unlabelled corpus. Besides making clustering more accurate by normalizing the descriptions, our method detects the underlying structure of the aspect via a cPMI-based segmentation of noun phrases that simulates an aspect-oriented parsing of the sentence. PMI values are also used by (Popescu and Etzioni, 2005) but only for aspect-term detection. Another option is to use topic modeling for clustering (Titov and McDonald, 2008; Sauper and Barzilay, 2013; Zhang and Liu, 2014). Topic modeling is effective in ATE but can under-cluster when applied to SAE, e.g., noun phrases headed by bedroom and kitchen are clustered together despite having different modifiers, producing incorrect associations of modifiers to aspect terms.

The ability to identify arbitrary hierarchical structures distinguishes our work from other aspect extraction methods based on distributional analysis of syntactic features such as, e.g., (Qiu et al., 2011; Zhuang et al., 2006; Wu et al., 2009; Yu et al., 2011; Zhou et al., 2013; Liu et al., 2013), and rule-based methods such as, e.g., (Poria et al., 2014). Our method can deal with a wide range of aspect structures without resorting to supervision as commonly done in methods based on sequence labelling, such as, e.g., (Li et

al., 2010; Choi and Cardie, 2010; Jakob and Gurevych, 2010; Yang and Cardie, 2014). Our hierarchical extraction should not be confused with the mapping of flat aspects to taxonomies and knowledge bases as done, e.g., by (Yahya et al., 2014). The generalization of these hierarchical structures into patterns enables us to transfer these structures to the extracted aspects, thus labelling the extractions as in (Kim et al., 2012), distinguishing the aspect term, from its qualifiers and quantifiers. Let us stress out that these coarse hierarchical structures cannot be trivially derived from fine-grained dependency relations.

2 Structured Aspect Extraction

We now formally define the task of *structured aspect extraction* (SAE). We introduce some non-standard notation but we assume readers are familiar with aspect extraction terminology.

Definitions A *structured aspect* is a tuple $\langle \mathsf{M}, \mathsf{t} \rangle$, where t is an *aspect term* (or *head* of the aspect) and $\mathsf{M}=\{\mathsf{m}_1, \ldots, \mathsf{m}_n\}$ is a sequence of modifiers of the aspect term (or *tail* of the aspect). A labelling function $\lambda : \mathsf{M} \cup \{\mathsf{t}\} \mapsto \mathsf{L}$ maps aspect terms and modifiers to a set L of labels. Aspect terms are labelled as the real-world entities they represent, e.g., BEDROOM. Each modifier $\mathsf{m} \in \mathsf{M}$ is labelled as either $\lambda(\mathsf{t})$-QUANTIFIER or $\lambda(\mathsf{t})$-QUALIFIER where $\lambda(\mathsf{t})$ is the label of the aspect term t. Consider the text fragment Victorian two bedroom mid terrace property from Example 1. The corresponding SAE is $\langle \{\text{Victorian}, \langle \{\text{two}\}, \text{bedroom} \rangle, \text{mid terrace}\}, \text{property} \rangle$ where the aspect terms property and bedroom are labelled as PROPERTY and BEDROOM respectively, Victorian, mid terrace, and $\langle \{\text{two}\}, \text{bedroom} \rangle$ are labelled as PROPERTY-QUALIFIER, and two is labelled as a BEDROOM-QUANTIFIER. Structured aspects are obtained by matching *structured aspect patterns* (hence SAP) against free text. An SAP mirrors the structure of a structured aspect and consists of a tuple $\langle \mathsf{P}, \mathsf{T} \rangle$, where T is either the surface form of an aspect term or a POS tag, and $\mathsf{P}=\{\mathsf{p}_1, \ldots, \mathsf{p}_m\}$ is a sequence of surface forms of a modifier (e.g., two, mid terrace), POS tags (e.g., CD, JJ), or (nested) SAPs. An SAP is matched against free text in the usual way. For symmetry w.r.t. structured aspects, T and P are called the *head* and *tail* of the SAP respectively. A possible SAP matching the structured aspect above is $\langle \{\text{Victorian}, \langle \{\text{CD}\}, \text{bedroom} \rangle, \text{JJ terrace}\}, \text{property} \rangle$.

Overview and architecture SAPs are *induced* from a homogeneous corpus of texts, i.e., with texts coming from the same domain, e.g., restaurants, products. The induction operates in four phases: (1) normalization, (2) clustering, (3) segmentation and typing, and (4) generalization. Texts are processed to obtain a corpus of orthographically normalized and POS tagged noun phrases (NP). The normalized NPs are clustered around their head nouns, being these likely candidates for aspect terms. A cPMI-based (Damani and Ghonge, 2013) segmentation of the modifiers of the NPs locates *(i)* multi-word expressions and *(ii)* nested aspects. The segmented NPs are then taken as a first approximation of an SAP (ground), where the head noun becomes the head of the SAP and the (segmented) modifier of the NP becomes its tail. Modifiers are then typed as quantifiers or qualifiers. Ground SAPs are then generalized by replacing the surface forms of the modifiers by their POS tags, thus obtaining the final SAPs.

Normalization and POS tagging The normalization tackles issues that affect subsequent phases of the induction process. In particular, it improves the accuracy of noun chunking on NUT, avoiding an expensive (and possibly pointless) NUT-specific training. The first problem is the high number of tokenization errors, leading to incorrect sentence splits. To address this, we have built a NUT-specific tokenizer, producing correct tokens in the presence of, e.g., abbreviations, units of measures, and incorrect sentence boundaries. These customizations are domain independent. Incorrect orthography is another major problem in NUT. It directly affects the performance of POS taggers and, in turn, of noun chunking. To address this, we normalize the orthography of each token to its most common orthography in the whole corpus. We consider five orthographic classes: uppercase, lowercase, upper initial, lower initial, and alphanumeric. An occurrence of a token is normalized if more than a certain percentage (experimentally set at 90% across all domains) of its other occurrences in the corpus have a different orthography.

In the first sentence of Example 2, orthographic errors lead to wrong tags for, e.g., Fantastic (CD), Beds (NNPS), and OXFORD (VBD), while the missing space after the first full stop leads to an incorrect sentence boundary. The POS tagger cannot therefore produce the correct tags for Don't. The second sentence

Example 2: Normalization

Fantastic 2 Beds OXFORD property.Don ' t miss it !
CD CD NNPS VBD NN POS NN VBP PRP PUNC

↓

{fantastic 2 beds Oxford property . } {Do n't miss it ! }
JJ CD NN NNP NN PUNC VB RB VB PRP PUNC

shows how POS tagging improves after our improved tokenization and orthographic normalization. We do not only produce more sensible POS tags, but we also recover the correct sentence boundaries.

Normalized texts are then split into sentences and POS tagged. We use a state-of-the-art rule-based sentence splitter and Hepple's POS tagger tagger (Hepple, 2000) trained on the Penn TreeBank Corpus. The tagged sentences are handed over to a rule-based NP chunker (Ramshaw and Mitchell, 1999) to produce a corpus of noun phrases.

Noun-phrase clustering NPs are clustered around their head nouns. Head nouns are stemmed and lemmatized, e.g., by normalizing plurals, to avoid over-segmentation of the clusters due to different surface forms of equivalent head nouns. The modifiers of the NPs are also normalized to prevent non-content prefixes and numerical expressions from fragmenting the clusters.

NPs are generalized to abstract forms where non-content words and numerical expressions are replaced by POS tags. A non-content word is a token with a POS tag in {CC, DT, EX, IN, PRP, PUNC}, while a numerical expression has POS tag CD. Prefixes consisting only of non-content words are then removed from the NPs. The process is illustrated in Example 3.

Example 3: Clustering

Two further double bedrooms	CD further double bedrooms	{CD further double bedrooms, [BEDROOM]
Three further double bedrooms	CD further double bedrooms	further double bedrooms,
A further double bedroom	DT further double bedroom	CD first floor bedrooms}
Two first floor bedrooms	CD first floor bedrooms	

We start with four NPs with 2 different surface forms for the head noun (i.e., bedroom and bedrooms). For three of the NPs, the modifier starts with a numerical expression. This remains part of the NP but as a POS tag (CD). The non-content word prefix A (POS tag DT), is removed from the NP. The result of this process is a single cluster headed by BEDROOM and consisting of three partially-generalized NPs. The clusters are filtered based on their cardinalities, i.e., the number of (possibly duplicated) NPs belonging to the cluster. The top-k clusters whose elements cover at least a certain percentage (experimentally set at 70% across all domains) of all the NPs are retained. Clusters can also be fragmented by spelling errors. The head nouns of discarded clusters are therefore checked for similarity against the head nouns of the retained ones. Two clusters are merged if the Dameraau-Levenshtein string edit distance is less than an experimentally set threshold (20% across all domains). If multiple merging options are possible, the one with highest similarity is chosen. If only equivalent options are available, we merge in all possible ways. Clearly, the normalization of the noun-phrase modifiers described above can affect the ranking of the noun-phrases, since clusters can be merged thus increasing their ranking.

Segmentation and typing The segmentation phase identifies multi-word expressions and hierarchical structures in NP modifiers, thus producing a first approximation of an SAP. The key tool used in the segmentation is corpus-level significant point-wise mutual information (cPMI) (Damani and Ghonge, 2013). Our definition of cPMI uses the corpus of NPs instead of arbitrary descriptions. Let $\mathcal{C}$ be the set of all clusters produced as described above. We denote by $f_{\mathcal{C}}(\mathrm{t})$ the frequency of the string t in all clusters of $\mathcal{C}$, i.e., obtained by summing up all of the occurrences of t in all clusters. Let $0 < \delta < 1$ be the normalization factor defined as in (Damani and Ghonge, 2013), and t‖w, the concatenation of two strings

t and w. We then define $\text{cPMI}_{\mathcal{C}}(\mathsf{t}, \mathsf{w})$ as follows:

$$\text{cPMI}_{\mathcal{C}}(\mathsf{t}, \mathsf{w}) = \log \frac{f_{\mathcal{C}}(\mathsf{t}\|\mathsf{w})}{f_{\mathcal{C}}(\mathsf{t}) \cdot \frac{f_{\mathcal{C}}(\mathsf{w})}{|\mathcal{C}|} + \sqrt{f_{\mathcal{C}}(\mathsf{t})} \cdot \sqrt{\frac{ln(\delta)}{(-2)}}}$$

The cPMI value is used to determine whether a token should be associated with *(i)* the head noun, *(ii)* a nested token representing the head of a different cluster, thus possibly inducing a nested structure, or *(iii)* an adjacent token, thus forming a multi-word expression.

We model the segmentation as the problem of finding a cPMI-optimal *parenthesization* (or, equivalently, a parse tree) of the NP. In order to achieve this, we first have to define the notions of *(i)* valid parenthesization and *(ii)* cPMI of a parenthesization. A valid parenthesization is a balanced parenthesization such that, each k-th level of the parenthesization: **(1)** consists of at least two elements (i.e., tokens or subpatterns), and **(2)** it either terminates with a head of cluster or it contains no heads of cluster. The cPMI of a (valid) parenthesization is the sum of the cPMI values computed between each element (token or parenthesized sub-expression) in the parenthesization and the first head of cluster following the element at the same level of nesting. If no heads of cluster are present at the same level of nesting, then the sum of the cPMI values between subsequent tokens is taken. The cPMI of the parenthesized sub-expressions is then recursively added to this value.

Example 4: Segmentation

p	:	Victorian two bedroom mid terrace property
p_i	:	(Victorian (two bedroom mid) (terrace) property)
p_v	:	(Victorian (two bedroom) (mid terrace) property)
SAP	:	$\langle\{$Victorian, $\langle\{$two$\}$, bedroom$\rangle$, mid terrace$\}$, property$\rangle$

Consider the NP p of Example 4. A balanced but invalid parenthesization is shown as p_i. The parenthesization violates both conditions given above, i.e., the level-2 parenthesization (two bedroom mid) contains a head of cluster (i.e., bedroom) but terminates with the token mid, and the level-2 parenthesization (terrace) contains a single token. A valid parenthesization is p_v and its cPMI is computed as:

$$\begin{aligned}\text{cPMI}_{\mathsf{np}} \;=\; & \text{cPMI}_{\mathcal{C}}(\text{Victorian, property}) \;+\; \text{cPMI}_{\mathcal{C}}(\text{two bedroom, property}) \;+ \\ & \text{cPMI}_{\mathcal{C}}(\text{mid terrace, property}) \;+\; \text{cPMI}_{\mathcal{C}}(\text{two, bedroom}) \;+\; \text{cPMI}_{\mathcal{C}}(\text{mid, terrace})\end{aligned}$$

Notice that $\text{cPMI}_{\mathsf{np}}$ now includes the cPMI value between mid and terrace (i.e., a multi-word expression).

Algorithm 1 formalizes the process described above. The pseudocode focuses on the most technical aspect of the procedure, i.e., the generation of the different parenthesizations. We also omit minor technicalities related to, e.g., handling of punctuation and non-content words. The algorithm receives as an input the clustered noun phrases, here represented as a map $\mathcal{C}$ having as keys the heads of clusters and as values (denoted as `val`$(\mathcal{C})$) sets of noun phrases. The output of the algorithm is again a map P, having as keys the heads of the patterns, and sets of SAPs as values. The algorithm iterates over all noun phrases np in all clusters and converts them into a sequence of tokens P (Line 4). The function `optiPar` then produces a cPMI optimal parenthesization of P (Line 5) that is then transformed into an SAP via the `par2SAP` function (Line 6). The SAP is stored in P (Line 7). The notation P`(`k`)` represents the cluster of SAPs headed by k, while `head(`P`)` returns the head of the pattern P. The function `optiPar` is an adaptation of standard combinatorial parenthesization algorithms, where we keep track of the parenthesization producing the highest noun-phrase-wide cPMI. The function takes a sequence of tokens P and recursively parenthesizes it (Lines 4-9). The $\text{cPMI}_{\mathsf{np}}$ of the parenthesization is then computed by the function `npcPMI` and tested against the current maximum (Lines 11-13). The function `isValid` in Line 10 checks that only valid parenthesizations are considered. For the sake of readability, Algorithm 1 gives a straightforward recursive implementation of the procedure but more efficient dynamic programming implementations can be provided.

In SAPs, nested patterns, e.g., $\langle\{$two$\}$, bedroom$\rangle$ are replaced with a reference to the cluster of SAPs headed by the head of the nested pattern, e.g., BEDROOM. The reason for this is to enable parallel matching

Algorithm 1: Segmentation

```
Function segmentation(C)
    input: C: the clusters
    P ← ∅;
    for C ∈ val(C)
        for distinct np ∈C
            P ← split(np);
            P_max ← optiPar(P,C);
            P_sap ← par2SAP(P_max);
        P(head(P_sap)) ← P(head(P_sap)) ∪ {P_sap};
    return P;
Function optiPar(P,C)
    input: C: the clusters
    input: P: the sequence of tokens from the noun phrase
    if |P| ≤ 2 then
        return P;
    ⟨max_pmi, P_max⟩ ← ⟨0, ∅⟩;
    for i ∈ [0, |P|-1]
        for j ∈ [|P|-1, i+1]
            if i > 0 ∨ j < |P|-1 then
                P′ ← optiPar(sub(P,0,i)) || '(' || optiPar(sub(P,i,j)) || ')' || optiPar(sub(P,j,|P|-1));
            else
                P′ ← '(' || P || ')';
            if isValid(P′) then
                cur_pmi ← npcPMI(P′,C);
                if cur_pmi > max_pmi then
                    ⟨max_pmi, P_max⟩ ← ⟨cur_pmi, P′⟩;
    return P_max;
```

of the SAP at runtime, thus avoiding matching multiple times the same fragment of text. The elements of a ground SAP are then *typed* according to their role in the pattern (Example 5). The head of the pattern is labelled as the head of the SAP cluster it belongs to and is used to match the aspect term. Modifiers with a POS tag CD and linked to an aspect term t are labelled as λ(t)-QUANTIFIER. All other modifiers linked to t, including nested SAPs, are labelled as λ(t)-QUALIFIER. Extractions produced by matching SAP against free text are labelled according to the typing of the SAP.

Example 5: Typing

⟨{Victorian, ⟨{two}, bedroom⟩, mid terrace}, property⟩

property	→	PROPERTY	bedroom	→	BEDROOM
Victorian	→	PROPERTY-QUALIFIER	two	→	BEDROOM-QUANTIFIER
mid terrace	→	PROPERTY-QUALIFIER			
two bedroom	→	PROPERTY-QUALIFIER			

Generalization Ground SAPs are limited to what has been directly observed in the corpus. As a consequence, the elements of an SAP are generalized to their POS tags to increase recall. The process must be controlled because excessive generalization may also lead to inaccurate extractions. The generalization rules are illustrated in Example 6 and operate as follows: (1) Numerical expressions, non-content words, and punctuation are always generalized to their POS tags. (2) Multi-word expressions are generalized as both n-grams and unigrams since they "behave" like a single token. In the latter case, the POS tag of the last token is used. (3) Aspect terms are not generalized unless the tail of the pattern contains a nested SAP with a ground head. The nature of the modifiers is often strictly related to the aspect term they refer to. This is obvious for, e.g., the modifiers of bedroom and property in Example 6. We therefore have to prevent undesired associations between aspect terms and incompatible modifiers. (4) Qualifiers are also semantically related to other qualifiers at the same level of nesting. As a consequence, we generalize at most one qualifier per level of nesting to maintain this connection. Clearly, this process may give rise to more than one generalization for the same SAP. The ground pattern is also preserved.

Example 6: Generalization

⟨{Victorian, ⟨{two}, bedroom⟩, mid terrace}, property⟩

↓

⟨{JJ, ⟨{CD}, bedroom⟩, mid terrace}, property⟩
⟨{Victorian, ⟨{CD}, bedroom⟩, JJ}, property⟩
⟨{Victorian, ⟨{CD}, bedroom⟩, JJ terrace}, property⟩
⟨{Victorian, ⟨{CD}, bedroom⟩, mid JJ}, property⟩
⟨{Victorian, ⟨{CD}, bedroom⟩, mid terrace}, NN⟩

Patterns are scored based on their ability to discriminate between correct and incorrect extractions. We adapt the scoring mechanism of (Gupta and Manning, 2014), where the quality of a pattern is estimated by matching the extracted patterns against a manually labelled validation set. In our unsupervised setting, no labelled dataset is available. We take the heads of the noun-phrase clusters as a surrogate of the set of valid aspects. The analysis is limited to aspect terms. Let T be the set of valid aspect terms as defined above, and E be the set of aspect terms produced by an SAP P. The score of P is computed as:

$$\nu(\mathsf{P}) = \frac{|T|}{\sum_{e \in E}(1 - \max_{t \in T} \mathbb{1}(\frac{dist(t,e)}{len(t)} < 0.2))} \cdot \log |T| \qquad \nu(\mathsf{P}) \in [0, \infty]$$

where $dist(t, e)$ denotes the Dameraau-Levenshtein edit distance between two strings t and e and $len(\cdot)$ denotes the length of the string. Patterns scoring less than an experimentally set threshold (50% across all domains) are eliminated.

3 Evaluation

Our method (Oxtractor) is implemented in Java. All experiments are run on a quad-core desktop machine at 3.40GHz and 32GB RAM, running Linux. All resources used in the evaluation are made available for replicability at http://bit.ly/2dewzdd and include: the SAED dataset and GS, our reimplementations of IIITH and ATL, a compiled version of Oxtractor, and all output files generated by all systems.

Datasets and metrics We use three groups of datasets in our evaluation (Table 1): The first two consist of the SemEval14 and SemEval15[2] datasets used for the aspect term extraction (ATE) and opinion target expression (OTE) subtasks of the aspect-based sentiment analysis (ABSA) task. The datasets provide laptops, restaurants and hotel reviews with associated gold standard (GS) annotations. The hotel domain is meant to be used in a completely unsupervised setting and therefore no training data is available. The size of SemEval14 in Table 1 is expressed in number of sentences instead of number of texts since this information is unavailable. We complement the SemEval15 datasets with some specifically designed for SAE (SAED). We provide texts from six domains (50% for testing, 50% for validation). Four of them, i.e., chairs, real estate, shoes, and watches, describe products. The Amazon texts come from the Stanford's Snap Lab's web data corpus (McAuley and Leskovec, 2013). The two remaining domains, i.e., hotels and restaurants, can be classified as services. These descriptions are still feature intensive but, differently from the products, the features are loosely connected to the main entity, i.e., locations, services/facilities offered. The dataset consists of both NUT and (semi-) formal English texts. We provide GS annotations for 150 texts equally distributed across the six domains. The GS provides and average of 355 aspect terms, 30 quantifiers, 430 qualifiers, and 45 nested aspects per domain. Annotations were produced by 6 independent annotators (λ=87%). We use standard recall, precision, and F_1 score metrics. However, due to the different granularity of the output produced by the systems and of the GS annotations, the definition of a correct extraction varies slightly with each evaluation task.

Comparative evaluation – Simplified SAE The method by (Kim et al., 2012), hence ATL, is currently the closest to SAE we are aware of. We have obtained from the authors the dataset used in their evaluation but not an implementation of the system. We have reimplemented the method and successfully reproduced the experimental results described in the original paper. Figure 1 shows a comparison between ATL and Oxtractor on the SAED dataset. An extraction is correct if modifiers and aspect terms match exactly the GS annotations, and if modifiers are correctly typed as qualifiers or quantifiers. This is a simplified

Table 1: Datasets

DATASET	DOMAIN	SIZE (#texts)	SOURCES	CATEGORY	FORMALITY	TYPE
SemEval14	restaurants	3k + 800 GS (*)	Citysearch	service	NUT	evaluative
	laptops	3k + 800 GS (*)	N/A	product	NUT	evaluative
SemEval15	restaurants	254 + 96 GS	Citysearch	service	NUT	evaluative

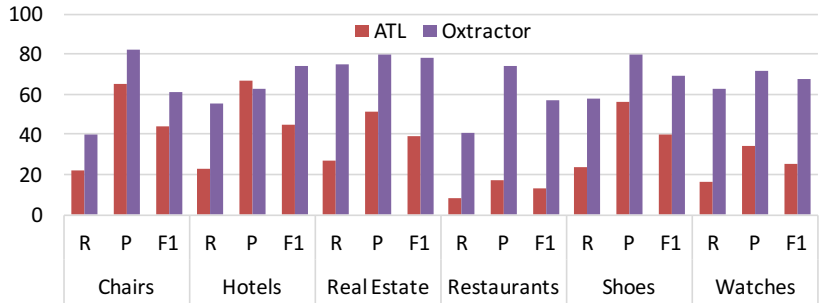

Figure 1: Oxtractor vs. ATL on simplified SAE (SAED dataset)

SAE setting where we do not require correct linking of modifiers to aspect terms. Oxtractor performs 33% better than ATL in average, outperforming it in all domains. Besides being unable to extract hierarchical structures, a visible issue in ATL is the inability to recognize semantic connections between modifiers and aspect terms. This leads to a number of incorrect extractions for both aspect terms and modifiers that could be avoided by leveraging, e.g., statistical co-occurrence or cPMI.

Comparative evaluation – ATE Restricting the evaluation to aspect terms makes it possible to compare Oxtractor against other ATE systems. We denote by IIITH and ATEX the methods proposed by (Raju et al., 2009) and (Zhang and Liu, 2014) respectively. IIITH uses unsupervised clustering of noun-phrases to derive aspect terms and is therefore similar to Oxtractor. We could not obtain the original IIITH system from the authors so the evaluation relies on our own implementation. ATEX, on the other end, is chosen because of its ATE method based on topic modeling. Moreover, it is freely available for testing. An aspect term is correctly extracted if it matches exactly a GS annotation. For Oxtractor, IIITH, and ATL we used the SAED corpora for training. Figures 2a and 2b show the results for the SemEval14 and SemEval15 datasets respectively. For all systems, except Oxtractor, IIITH, ATEX, and ATL, we report the scores provided in the corresponding SemEval papers. The symbol (U) denotes systems that have used additional data besides the training set provided by SemEval (i.e., *unconstrained* in SemEval terminology). Oxtractor outperforms all unsupervised systems and some of the supervised ones. Moreover, this is a lower bound for Oxtractor due to a difference between the granularity of the SemEval GS and the output produced by Oxtractor. E.g., Egyptian restaurant is considered a correct aspect term by SemEval but Oxtractor would only produce restaurant as the aspect term and Egyptian as its modifier (and thus a miss for SemEval). A striking result is the performance achieved by Oxtractor on the laptops domain in SemEval14, where also all supervised systems are outperformed. As for many other product-like domains, aspect terms in the laptops domain frequently fall within the scope of noun-phrases that are easily processed by our method. This is much less true for other service-like domains such as, e.g., restaurants and hotels. Figure 2c shows the performance of Oxtractor, IIITH, ATEX, and ATL on the SAED dataset. In this case, the GS differentiates between aspect terms and modifiers, thus explaining the lower performance of traditional ATE systems, e.g., IIITH and ATEX, and the higher accuracy of, e.g., ATL that is able to appreciate this difference. ATEX

(c) SAED Dataset

Figure 2: Oxtractor vs. others in ATE

also struggles on restaurants due to long sentences.

Full SAE We evaluate the performance of Oxtractor in the full SAE setting using the SAED dataset. An extraction is correct if aspect terms and modifiers match the GS annotations, including the correct (and possibly hierarchical) associations between modifiers and entities. In average (Figure 3), Oxtractor achieves an F_1 of 58.6% in the full SAE setting, sensibly below the one obtained in the ATE (i.e., 79.6%) and simplified SAE (i.e., 67.8%) settings. Linking modifiers to aspect terms in the presence of hierarchical structures is indeed a much more challenging task than simply identifying them. Another interesting aspect is the impact of the generalization on the performance. Generalized SAPs produce 444 correct extractions against the 386 of the ground ones (+15%).

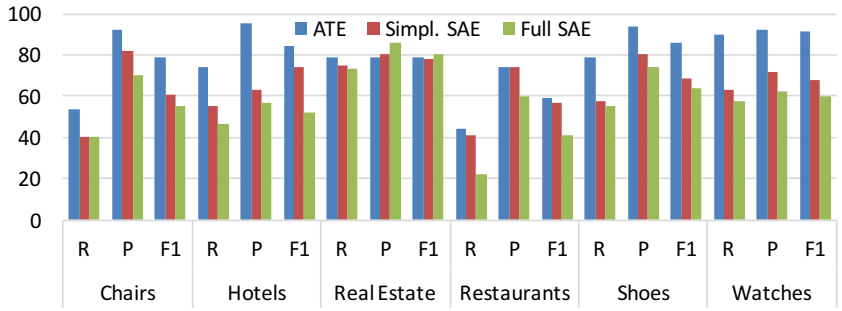

Figure 3: Oxtractor on full SAE

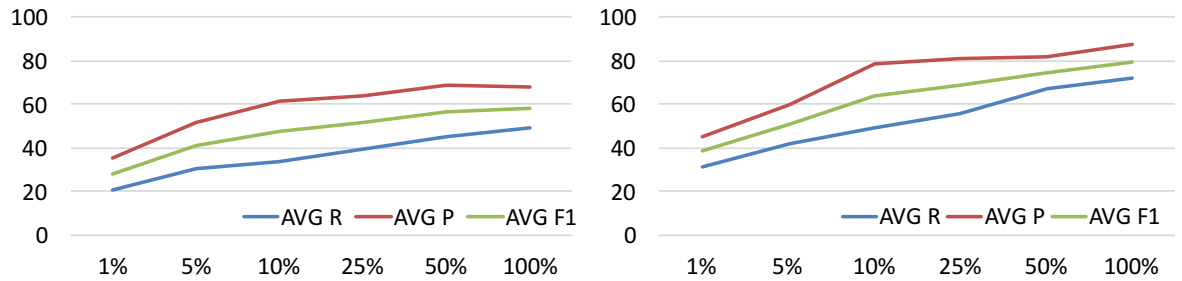
Corpus size One obvious question is how dependent our method is on the size of the training corpus. To measure this, we evaluated Oxtractor by inducing SAPs from increasing subsets of the original corpora corresponding to fractions of 1%, 5%, 10%, 25%, and 50% of their original size. Figure 4 shows the effect of the corpus size on the performance of Oxtractor in both the SAE and ATE settings. Clearly, larger corpora lead to better results in both settings. However, two interesting facts have been observed. Long-

tail aspects are only induced from sufficiently large corpora (thus the behavior between 10% and 50%). Larger corpora also have the disadvantages that sufficiently frequent but incorrect tokens can end up being extracted as modifiers. In other words, the increase in recall is not matched by a comparable increase of precision (Figure 4b). In the case of SAE we even observe a slight drop in precision (Figure 4a).



(a) SAE Task (b) ATE Task

Figure 4: Performance vs. corpus size (average – SAED dataset)

A breakdown of the data per domain allows us to draw further conclusions on the relationship between the size of the corpus and the performance of the SAPs. There is a relationship between the variety of features and the amount of data that is necessary to induce good quality SAPs. For domains such as, e.g., chairs, realestate, shoes, and watches, starting from 25% of the size of the corpus we do not notice substantial improvements in performance. This can be explained by the nature of the features in these domains that are intrinsically limited, e.g., make and models of the products, types of real estate properties, etc. In the restaurants and hotel domains the texts are much more variegated in features, e.g., restaurant and hotel names, dishes, locations, etc. Despite the large amount of texts available, it seems that our method would require even larger corpora before being able to converge to a stable set of aspects.

Efficiency Finally, we evaluate the efficiency of the SAP induction and matching phases. Oxtractor's efficiency mostly depends on the length of the sentences, due, e.g., to the morphological analysis, our cPMI-based segmentation, and pattern matching. Oxtractor induces SAPs at a rate of 14 $^{ms}/_{sent}$ and 6 $^{ms}/_{sent}$ for *long* (i.e., $\geq$10 tokens) and *short* (i.e., $<$10 tokens) sentences respectively. The matching time per sentence is almost negligible and ranges between $2ms$ and $3ms$ per text. We also notice a linear correlation between the size of the SAP and its matching time. This is achieved, despite the presence of hierarchical structures, by replacing nested patterns with references to the corresponding SAP clusters, enabling parallel matching of the nested SAPs. In terms of training time, Oxtractor induces patterns from $20k$ texts within $1hr$ on average. IIITH and ATL require more than $15hrs$ on the same dataset.

Discussion SAE is still in its infancy. A number of interesting problems can be studied in this area such as, e.g., semantic categorization of modifiers and aspect terms. Although the majority of structured aspects appear in noun phrases, a fair amount also appears in more complex syntactic structures. We extended our normalization to rewrite these structures into traditional noun-phrases with good results. Another issue is redundant SAPs, caused by aspect terms having the same "tail" and semantically belonging to a taxonomic hierarchy of concepts, e.g., two bedroom apartment, two bedroom house. We are currently investigating the use of knowledge bases such as, e.g., BabelNet (Navigli and Ponzetto, 2012) to reduce this redundancy. Finally, our evaluation shows that the gap between Oxtractor and supervised systems is still considerable. Oxtractor can be adapted to use supervision at different stages of the induction process, in particular during clustering and pattern scoring.

Robust Text Classification for Sparsely Labelled Data Using Multi-level Embeddings

Abstract

The conventional solution for handling sparsely labelled data is extensive feature engineering. This is time consuming and task and domain specific. We present a novel approach for learning embedded features that aims to alleviate this problem. Our approach jointly learns embeddings at different levels of granularity (word, sentence and document) along with the class labels. The intuition is that topic semantics represented by embeddings at multiple levels results in better classification. We evaluate this approach in unsupervised and semi-supervised settings on two sparsely labelled classification tasks, outperforming the handcrafted models and several embedding baselines.

1 Introduction

The objective of text classification is to label a scope of text according to predefined labels. While general domains tend to have sufficient amounts of labelled data, in specialised domains (e.g., scientific literature) such data are often scarce and labelled instances number in the hundreds, or low thousands at most. Such domains may also require highly specialised annotators, making labelled data expensive and difficult to obtain (Simpson and Demner-Fushman, 2012).

In order to mitigate the data sparsity problem, a lot of handcrafting is needed to engineer features specific to the task and domain. Typically this process involves a long NLP pipeline, e.g., POS-tagging, parsing, named entity recognition, semantic role labelling, feature selection, etc. Consequently, approaches based on handcrafting can be prohibitively time consuming, and since the resultant features are domain dependent, these systems are difficult to port to other domains (Sebastiani, 2002; Dai et al., 2007). While unsupervised and lightly-supervised methods can bypass the need for labelled data, they in turn tend to suffer from lower performance (Zhang and Elhadad, 2013; Quan et al., 2014; Aggarwal and Zhai, 2012).

In this paper, we present a novel approach to text classification that is especially beneficial in situations were labelled datasets are small. Our approach builds on the Distributed Memory (DM) model by Le and Mikolov (2014). The fast and simple unsupervised DM model acquires paragraph level embeddings. We improve on the model so that we jointly learn multi-level embeddings that encode class-label topical information in addition to text.

We jointly learn a model that captures embedding representation for the target class labels, as well as word-, sentence- and document-level representations in the same space. From these multi-level embeddings we derive a set of features. Our approach requires no manual feature engineering, can cope with small amounts of labelled data and produces features that are more robust to domain variation and portable across domains.

At the document-level, the overall "topic" is a mixture of the sub-topics of paragraphs in that document. The topics of the paragraphs are in turn mixtures of the sentence topics, all the way down to

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2333–2343, Osaka, Japan, December 11-17 2016.

word-level semantics. Our multi-level embeddings model captures this intuition elegantly; for example, an article about *cars* might have the first sentence discussing *car manufacturing*, followed by another discussing *car safety*, etc. Each of these topics can be represented by sentence-level embeddings, while a document-level embedding can capture the overall topic of the article.

We show that classifying text based on such multi-level semantics achieves superior performance both against very specialised handcrafted models and using word sentence or document embeddings alone. We demonstrate the effectiveness of our methodology on two real-world sparsely-labelled tasks: classification of biomedical text by (i) semantic categories, and (ii) rhetorical structure.

We apply our approach at two different levels of granularity: at document-level and at sentence-level. At the sentence-level, labelled data and contexts are even more sparse. In both cases, we compare our approach under a supervised setting against a handcrafted method and show that it rivals and in some cases clearly outperforms such methods. In addition, we compare against classifiers trained using standard embedding features and show that our approach outperforms them by a large margin. We also show that fast semi-supervised classification using our multi-level embedding features achieves promising results, even when compared against an SVM classifier using standard embeddings.

To our knowledge, this is the first work to introduce multi-level embeddings for text classification and to show their superior performance against handcrafted approaches and their robustness across domains which suffer from scarcity of labelled data.

2 Related Work

Embedded distributed representations have been used widely for document and sentence classification. For example, Huang et al. (2014) learn document-level embeddings using word-level embeddings as input. Yan et al. (2015) learn document-embeddings by combing a Deep Boltzmann Machine and a Deep Belief Network. Bhatia et al. (2015) learn embeddings for large multi-label classification in situations where the label set is extremely large. Liu et al. (2015) use latent topic models to learn a topic from each word, and then learn an embedding based on both the topic and the word. Yogatama and Smith (2014) use structured regularizers based on parse trees, topics, and hierarchical word clusters, as well as hierarchical sparse coding for regularization using stochastic proximal methods (Yogatama et al., 2015).

All of these works have been trained and evaluated on general domains such as newswire rather than on sparse domains with small labelled datasets.

There are works that target small labelled data text classification in sparse domains using techniques such as active learning (Guo et al., 2013; Figueroa et al., 2012; Nissim et al., 2015). The idea of active learning is to reduce annotation effort by iteratively selecting the most informative instances to be labelled by interactively querying an expert. Although good accuracy can be achieved, the approach relies on expert knowledge and interaction, and may still require feature engineering.

Other works tackle the sparsity of labelled data using distant supervision (Reschke et al., 2014; Vivaldi and Rodríguez, 2015). Here, a classifier is trained using data labelled automatically using approximate heuristics rather than annotators. However, due to the assumptions and bias that are inherent in such labelling heuristics, this may result in lower performance.

The work presented in this paper differs from the above as it focuses on learning embeddings for sparse domains with small labelled datasets; moreover, we focus on utilizing these embeddings specifically for text classification.

3 Approach

This section first describes the Distributed Memory model (Section 3.1), and then explains how we improved it for sparse domain text classification by introducing jointly learned multi-level representations (Section 3.2).

In Section 3.3 we describe three types of features that we extract from such representations, and in Section 3.4 we explain the fixed classification setup for our task-based evaluations.

3.1 The Distributed Memory model

The Distributed Memory model is an extension of the Continuous Bag of Words (CBoW) model of Mikolov et al. (2013). The DM model learns a representation of a paragraph that captures the semantics of a paragraph's "topic". In the model, every word is represented in a word embedding matrix, and every paragraph in a paragraph embedding matrix. Paragraph representations are averaged or concatenated to predict the next word in a context using a hierarchical softmax classifier.

DM introduces an additional component to the model that allows a representation of the paragraph (via paragraph ID), which is treated internally like any other word in the model's vocabulary. It acts as a memory that remembers what is missing from the current context. The model learns a vector representation of the paragraph that captures its overall topic semantics via stochastic gradient decent.

3.2 Joint learning of multi-level embeddings

We improve DM by learning distributed representations that capture the topical information at varying levels of granularity, that is, we learn embeddings at a word-, sentence- (or paragraph-), and document-level. We also learn a distributed representation of the class labels, since these can be viewed as another level of abstraction that is more abstract than the document-level.

Our intuition is that jointly learning representations at different levels of granularity (including that of class label) provides us with better embeddings for text classification than learning a representation at each level separately. Each level captures different topic semantics, ranging from word-level to the class label. Figure 1 illustrates our model.

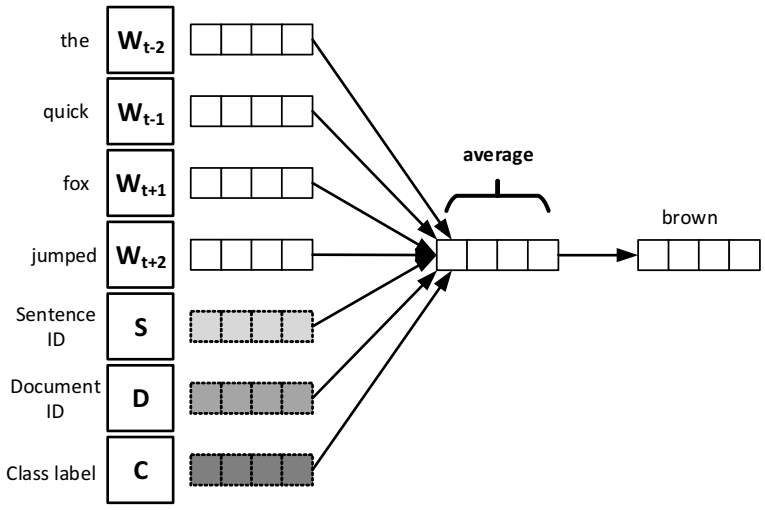

Figure 1: Illustration of distributed joint learning of different granularities of text contexts: words (W), sentences (S), documents (D) and classes (C). The model predicts the target word (w_t) based on the semantics captured by all these contexts. Shades represent level of abstraction/granularity.

In Figure 1, words from word embedding matrix **W**, sentences from sentence embedding matrix **S**, documents from document embedding matrix **D** and class-labels from class embedding matrix **C** are used as the context from which to predict the target word. That is, given a sequence of training words $w_1, w_2, w_3, ..., w_T$ that belongs to sentence s_t in document d_t, which has also a set of classification labels associated $c_1, ...c_m$. The objective of the model is to maximise the average log probability:

$$\frac{1}{T}\sum_{t=k}^{T-k} \log\ p(w_t|w_{t-k}, ...w_{t+k}, s_t, d_t, c_1, ...c_m) \tag{1}$$

We use a softmax output layer to obtain the probability of the target word given its context:

$$p(w_t|w_{t-k}, ...w_{t+k}, s_t, d_t, c_1, ...c_m) = \frac{e^{\vec{y}_{w_t}}}{\sum_i e^{\vec{y}_i}} \tag{2}$$

where each y_{w_t} is calculated as:

$$\vec{y}_{w_t} = \mathbf{U}\frac{\sum_{i=-k}^{k}\vec{w}_{t+i} + \vec{s}_t + \vec{d}_t + \sum_{i=1}^{m}\vec{c}_i}{2k+m+2} + b \tag{3}$$

where $k \neq 0$, $\mathbf{U}$ is the weight matrix, b is the bias, and we average the word vectors extracted from $\mathbf{W}$, the sentence vectors extracted from $\mathbf{S}$, similarly, the document vectors from $\mathbf{D}$ and class label vectors from $\mathbf{C}$.

3.3 Extracting features

We extract three types of features from the jointly-learned multi-level representations: the sentence or document embeddings (EMBED), the distances between word embeddings (WORD-DIST) and the similarities between classes (CLASS-SIM).

Embedding features: since embeddings are learned at different levels, when classifying at the document-level, we use the document-level embeddings. Likewise for sentence-level classification, we use only the sentence-level embeddings. Word-level embeddings are only used as part of extracting distance features.

Word distance features: We measure the cosine similarity between each unique non-stop word embedding occurring in the input sentence or document with the embedding representation for a given class label, i.e., $\delta_{w_i}^{c_i} = \cos(\vec{w}_i, \vec{c}_i)$, where $\vec{w}_i$ is embedding for word w_i in the input text, and $\vec{c}_i$ is the embedding representation of a class label that has been jointly learned from the training data. Since the input text has variable length, we represent these distances in sparse vector format using a dictionary of all non-stop words in the corpus labelled with the given class c_i; i.e., a "bag of word distances".

Class-similarity features: Word distance measures capture the similarity between words and class labels, but not between phrases or sentences. For this, we use word-level embeddings to measure the semantic similarity between a class and target text (sentence or document) using the so-called Earth Mover's Distance (EMD)[1], or the energy distance of moving a distribution.

EMD has been used successfully in image retrieval (Rubner et al., 2000), document topic similarity (Wan, 2007) and more recently in combination with word embeddings (Kusner et al., 2015). This method is useful for estimating the similarity between text with varying word count and overlap: the sentence *"sipping a cup of tea"*, for example, should have a relatively small EMD compared to *"wine tasting"*, despite them having no overlap and being of different length. Kusner et al. (2015) formulate the EMD problem as a linear program that can be expressed as the following optimisation:

$$\text{emd}(d, d') = \min_{\mathbf{T}\geq 0}\sum_{i,j=1}^{n}\mathbf{T}_{ij}||\vec{x}_i - \vec{x}_j||_2 \tag{4}$$

subject to the following flow constraints: $\sum_{j=1}^{n}\mathbf{T}_{ij} = \vec{d}_i$ and $\sum_{i=1}^{n}\mathbf{T}_{ij} = \vec{d'}_j$. Here, $\mathbf{T} \in \mathbb{R}^{n\times n}$ is a flow matrix, i.e., $\mathbf{T}_{ij}$ denotes how much of word i in the source document d travels to word j in the destination document d', and $\vec{x}_i$, $\vec{x}_j$ are embeddings for words i and j. Class-similarity features are obtained by finding the minimal distance between a given input (either document or sentence) and the given class, where only the most discriminatory word embeddings for the given class are combined, i.e., non-discriminatory words that occur in all classes are excluded[2]. We then use Equation 4 to measure the similarity between words occurring in the text and the class combined word list.

3.4 Supervised classification

We apply a fixed classification setup in order to compare our new method against several embedding baselines as well as handcrafted classification. We use Support Vector Machines with a linear kernel; implemented using scikit-learn (Pedregosa et al., 2011), and perform a standard grid search for kernel regularization parameter selection.

[1] Also known as the Wasserstein metric.

[2] We discarded all words that occur in more than 80% of all class contexts as non-discriminatory in the training set.

We use L1 and L2 normalization of input features, weighted equally according to the three aforementioned types (embedding, class-similarity and word-distance), i.e., features within each type are normalised separately and then combined.

We perform a 4-fold cross-validation setup and 5-fold nested cross-validation for kernel parameter tuning (using grid search); i.e., we do a 5-fold cross-validation grid search nested in each of the outer four folds.

3.4.1 Semi-supervised classification

In a semi-supervised setting, we use vast amounts of unlabelled data, i.e., documents/sentences unlabelled with any class information, and a much smaller amount of labelled documents/sentences. Instead of using a supervised classifier to learn the decision boundaries, we use the distance measurements and a tuned cut-off threshold for each class to determine class assignment.

We use WORD-DIST and CLASS-SIM (described in Section 3.3), and EMB-DIST: the cosine distance between the embedding of a sentence or document and an embedding of a class label. A cut-off threshold is used to determine positive or negative classification for each class. Under the WORD-DIST setup, we average all of the word distances. We perform a grid search for this threshold on 10% held-out data.

4 Task 1: Semantic text classification

We apply our methodology to a real-life biomedical text classification task. The aim of this task is to classify text at both document- and sentence-levels according to the Hallmarks of Cancer (HoC), a widely-employed framework in cancer research that was first introduced by Hanahan and Weinberg (2000). Motivated by the fact that cancer involves both genetic and epigenetic alterations (Marusyk et al., 2012), this framework provides an organizing principle to simplify the complexity of cancer biological processes (Baker et al., 2016).

4.1 Data

Baker et al. (2016) acquired a collection of PubMed abstracts using a set of search terms representative for each of the 10 hallmarks. The terms and their synonyms appearing in Hanahan and Weinberg (2000) and Hanahan and Weinberg (2011) were employed along with additional ones selected by a team of cancer researchers. Annotation was conducted by experts in cancer research, using the annotation tool described in Guo et al. (2012). Annotations are assigned at a sentence-level: a sentence is annotated if contains clear evidence relating to one or several hallmarks (Baker et al., 2016). Table 4.1 shows the distribution of 1,580 abstracts and sentences for each of the hallmark categories. The inter-annotator agreement is $k = 0.81$.

Hallmark	PS	GS	CD	RI	A	IM	GI	PI	CE	ID
# Abstracts	462	242	430	115	143	291	333	240	105	108
# Sentences	993	468	883	295	357	667	771	520	213	226

Table 1: Distribution of data for the ten hallmarks.

4.2 Handcrafted supervised model

We employ a fully supervised handcrafted baseline for this task, classifying using binary classifiers for each hallmark category. Sentences are first tokenised and part-of-speech tagged using the C&C tagger (Clark, 2002) trained on biomedical texts. The text is lemmatised using BioLemmatizer (Liu et al., 2012) and grammatical relations are extracted using the C&C Parser. The parser was trained using molecular biology annotations (Rimell and Clark, 2009). Finally, named entities are extracted from parsed data using ABNER (Settles, 2005), trained on the NLPBA and BioCreative corpora (Leitner et al., 2010).

We experimented with several types of handcrafted features for hallmark classification, chosen based on their inclusion in other state-of-the-art biomedical text classification systems. Only the first five are used for sentence-level classification, since the last two are only available at the document-level:

Lemmatised Bag of Words: the simplest feature employs all words occurring in input texts. We lemmatise the words in order to reduce sparsity.

Noun bigrams: Noun bigrams are used because they can be useful in capturing two word-concepts in texts (e.g., *Gene silencing*).

Grammatical relations: we use the *dobj* (direct object), *ncsubj* (non-clausal subject), and *iobj* (indirect object) relations, plus the head and dependent words in relations.

Verb classes: verb classes group semantically similar verbs together, abstracting away from individual words when faced with data sparsity. We used the hierarchical classification of 399 verbs by Sun and Korhonen (2009).

Named entities: domain-specific concepts, providing another way to group bags of words into meaningful categories. We use five types which are particularly relevant for cancer research: Proteins, DNA, RNA, Cell Line, and Cell Type.

Medical Subject Headings (MeSH): is a comprehensive controlled vocabulary for indexing journal articles and books in the life sciences. Most abstracts in our dataset contain an associated list of MeSH terms which we employ as features.

Chemicals list: a total of 3,021 associated chemicals (manually annotated). We use these as features, since processes involved with hallmarks might involve similar chemicals.

5 Task 2: Rhetorical text classification

Rhetorical text classification (also known as information structure analysis) segments scientific text into information categories. One such classification technique is argumentative zoning (Teufel and Moens, 2002) which captures the rhetorical progression of the scientific argument by segmenting a document into several zones, such as: "Objective", "Background", "Method", "Result", and "Conclusion".

This task differs from Task 1 in that the objective is to classify scientific text according to generic labels (i.e., unrelated to domain-specific knowledge) and the focus is on a different classification features, such as the position of the text in the document and the author's writing style. For example, the "Objective" zone of the argument generally appears very early in the article using an active voice.

5.1 Data

We evaluate using an expert-annotated dataset from (Guo et al., 2010) comprising of 1000 PubMed abstracts relevant to cancer biology. The dataset consists of 7985 labelled sentences, with an inter-annotator agreement of $k = 0.85$. There are five mutually non-exclusive classes, described together with their frequencies in Table 5.1.

Class	Description	# Abstracts	# Sentences
Objective (*OBJ*)	The background and the aim of the research	744	812
Background (*BKG*)	The circumstances pertaining to the current work	692	1517
Method (*METH*)	The way to achieve the goal	640	1617
Result (*RES*)	The principal findings	889	4028
Conclusion (*CON*)	Analysis, discussion and the main conclusions	859	1484

Table 2: Description of argumentative zones and their distribution in the annotated data.

5.2 Handcrafted supervised model

Many of the features used for this task are similar to those used in the Task 1, namely Bag-of-Words, Bigrams, Grammatical Relations. Here we also include Part-of-Speech tags, and the following task-specific features:

Location: categories tend to appear in typical positions in a document, e.g., *BKG* usually occurs at the beginning and *CON* at the end. The abstract is divided into ten equal parts and the location of a sentence is defined by the parts where the sentence begins and ends.

History: the category of the preceding sentence is used as a feature. This is because certain categories tend to appear before others. For example, *RES* tends to be followed by *CON* rather than other categories.

Voice: there is a correlation in scientific writing between the active and passive voice and certain categories, for example, passive voice is more frequent in *METH*.

6 Results

We now present the results of our experiments, where we compare our method to the handcrafted models, in addition to several baselines detailed below.

We train Skip-Gram with Negative Sampling (SGNS) representations on the corpus, and obtain sentence or document-level embedding using a composition function $f(w_i, ...w_n)$, where f is either addition (ADD), averaging (AVG) or the maximum (MAX). We do the same with Continuous Bag of Words (CBoW) representations. The resultant composed embeddings are used as input features for the classifier. For conciseness, we include only the best performing composite function here.

We also implemented using Keras (Chollet, 2015) a Convolutional Neural Network (ConvNet) for both sentence and document classification. We trained a binary classifier for each class, each consisting of the following layers: (i) input layer (domain trained embeddings using SGNS with $dim = 200$), (ii) 1-dimensional convolutional layer, (iii) max pooling layer with $dropout = 0.5$, (v) fully connected layer, and (vi) a binary softmax output layer. We use a binary cross-entropy loss function, and the Adam optimizer (Kingma and Ba, 2014). We also experimented with two key ConvNet parameters: the number of filters and the filter window size.

Finally, we compare against standard Bag of Words (BoW) classification, where each non-stop word in the corpus is a binary feature.

6.1 Task 1 results

The aim of Task 1 (semantic text classification) is to classify text into ten mutually non-exclusive classes, the Hallmarks of Cancer. The task has two sub-tasks: document-level and sentence-level classification. Table 6.1 shows the results for both levels. Sentence-level classification is more difficult, due to the smaller context information available. The table shows the results for the composed embedding baselines, the supervised BoW baseline and the handcrafted supervised model, as described in Section 4.2. This is followed by the three feature types (EMBED, CLASS-SIM, WORD-DIST) in all possible combinations and finally the full model, i.e., the one that uses all features.

With regards to the EMBED feature type, we distinguish between learning the representation independently (e.g., embeddings are learned without knowledge of the document) or jointly as described in Figure 1. We can see that the EMBED features by themselves perform better than any of the embedding baseline models. Jointly learning embeddings improves the F-score by approximately 4-5% for both document and sentence classification.

When considering the three features types, CLASS-SIM outperforms both EMBED and WORD-DIST, with an especially notable improvement in document classification.

When pairing the three feature types, the combination CLASS-SIM + WORD-DIST gives the best results, as is consistent with their individual results. Finally, when combining all three features, the full model outperforms all baselines with a significant margin, especially notable for sentence-level classification. Regarding the semi-supervised models, using class similarity CLASS-SIM alone significantly outperforms using word cosine distance WORD-DIST, and document-embedding to class-embedding distance EMB-DIST.

6.2 Domain variation

We also investigate the performance of our model and baselines when subjected to domain variation; that is, when we learn the embeddings from a different domain than that of the classification task. We experimented by learning the embeddings using the Wikipedia corpus. We seed the model with the labelled HoC training data and, then train on Wikipedia instead of domain specific literature acquired from PubMed.

	Document classification			Sentence classification		
Model	Precision	Recall	F-score	Precision	Recall	F-score
SGNS	43.7	25.9	32.5	13.6	23.3	17.2
CBoW	30.9	27.6	29.2	7.5	15.1	15.0
BoW	47.9	37.9	42.3	53.8	24.1	33.3
ConvNet	80.9	60.7	69.4	55.4	43.8	48.9
Handcrafted	82.8	69.4	75.5	59.2	46.4	51.4
EMB-DIST (semi-supervised)	24.3	28.5	26.3	25.4	25.4	21.9
WORD-DIST (semi-supervised)	30.9	36.5	33.5	43.7	24.6	31.5
CLASS-SIM (semi-supervised)	**44.1**	**38.8**	**41.3**	**26.7**	**42.1**	**32.6**
EMBED (independently)	44.0	37.4	40.4	26.5	48.0	34.2
EMBED (joint training)	54.2	46.4	49.9	37.6	39.6	38.6
CLASS-SIM	80.2	49.9	59.4	36.2	45.8	40.5
WORD-DIST	58.5	51.9	55.0	32.7	40.3	36.1
EMBED + CLASS-SIM	69.3	58.3	63.3	54.7	52.1	53.3
EMBED + WORD-DIST	60.9	60.4	60.7	54.6	56.3	55.4
CLASS-SIM + WORD-DIST	64.5	72.7	68.4	61.5	61.0	61.2
EMBED + CLASS-SIM + WORD-DIST	**85.5**	**69.8**	**76.4**	**77.7**	**60.1**	**67.6**

Table 3: Task 1 performance comparison. All figures are micro-averages (%).

Naturally, we expect all of the models to perform worse with Wikipedia-trained embeddings than with domain specific embeddings. This is indeed what happens (Table 6.2); however, some models prove more robust than others, i.e., their drop in F-score accuracy is smaller. By this measure, our full model and the semi-supervised models are less susceptible to domain variation with both document and sentence-level classification.

	Document		Sentence	
Model	Domain	Wikipedia	Domain	Wikipedia
SGNS	32.5	18.4	17.2	11.1
CBoW	29.2	14.3	15.0	10.4
ConvNet	69.4	38.3	48.9	29.7
Semi-supervised [3]	41.3	35.3	32.6	28.6
Full model	**76.4**	**61.5**	**67.6**	**54.6**

Table 4: Document and sentence classification micro-averaged F-score (%) using domain-specific and Wikipedia embeddings.

6.3 Task 2 results

The objective of Task 2 is to classify scientific text according to five argumentative zones. Table 6.3 summarises the results. Similar to Task 1, all three feature types perform significantly better than the embedding baseline models. When analysing the three feature types separately, WORD-DIST outperforms the other two. EMBED + WORD-DIST is the best-performing feature pair.

The full model significantly outperforms all baselines. However, it does not match the handcrafted approach. This is because the most influential feature in this task is the location of the text (Guo et al., 2011; Kiela et al., 2015). As our model does not take any word or sentence ordering into account, it would be difficult to compensate for the location feature. If, however, we include the location feature in addition to the three feature types in the SVM classification, our model outperforms the handcrafted

[3] Semi-supervised model uses CLASS-SIM.

baseline by a 1.4% difference. Admittedly, this would make the model slightly handcrafted by itself, but no additional work is necessary to get this feature and it does not vary across tasks or domains. This shows that our model including location information provides better features for this task than the handcrafted approach including location information. Looking at the semi-supervised models, the results suggest that CLASS-SIM outperforms the other feature types by an even larger margin than for Task 1.

Model	Precision	Recall	F-score
SGNS	45.6	31.5	37.3
CBoW	47.3	30.9	37.4
BoW	54.8	35.1	42.7
ConvNet	74.9	66.9	70.7
Handcrafted	88.9	85.0	86.9
EMB-DIST (semi-supervised)	23.7	38.9	29.4
WORD-DIST (semi-supervised)	36.6	28.8	32.2
CLASS-SIM (semi-supervised)	**57.1**	**40.9**	**47.7**
EMBED (sentences only)	43.3	41.9	42.6

7 Discussion and conclusions

The aim of this paper has been to produce a robust approach to text classification for domains suffering from sparsity of labelled data, and to alleviate the necessity for handcrafting features. Our novel methodology jointly learns distributed semantic representations at the level of words, sentences, documents and class.

The intuition is that embeddings at each level capture slightly different topical semantics. We therefore employ these embeddings to produce three types of features that require no additional data or labour, that are efficient to extract and much easier to port than handcrafted features. We have shown how these feature types can be used with standard classification algorithms such as SVMs and with semi-supervised classification where the decision boundaries are not learned from labelled data.

In the first task (semantic text classification) our approach matched or outperformed a handcrafted fully-supervised approach. The model performed substantially better at sentence-level classification which had much less context than the document-level classification. We also showed that our features are less susceptible to domain variation.

In the second task (rhetorical text classification), the proposed model outperformed all baselines, as well as the handcrafted approach when including location information in the classification process.

Mathematical Information Retrieval based on Type Embeddings and Query Expansion

Yiannos A. Stathopoulos **Simone Teufel**

Abstract

We present an approach to mathematical information retrieval (MIR) that exploits a special kind of technical terminology, referred to as a *mathematical type*. In this paper, we present and evaluate a type detection mechanism and show its positive effect on the retrieval of research-level mathematics. Our best model, which performs query expansion with a type-aware embedding space, strongly outperforms standard IR models with state-of-the-art query expansion (vector space-based and language modelling-based), on a relatively new corpus of research-level queries.

1 Introduction

Mathematical information retrieval (MIR) systems, such as MathWebSearch (Kohlhase and Prodescu, 2013; Hambasan et al., 2014), MIaS (Sojka and Líška, 2011) and Tangent (Pattaniyil and Zanibbi, 2014) have demonstrated that indexing and matching of formulae is beneficial to MIR. However, despite the sophistication of these methods, they leave elements of the natural language of mathematics largely unexploited. In contrast to general text, text in mathematics follows strong domain-specific conventions governing how content is presented (Ganesalingam, 2008). This is particularly so for research-level mathematics text (i.e., scientific articles), which is our main focus of interest. The conventionality of this text gives rise to many opportunities for the application of NLP to MIR. In this paper, we investigate the role of *mathematical types*, a special kind of technical terminology.

The term "type" refers to sequences of one or more words used to label mathematical objects (e.g., 'set", "smooth curve"), algebraic structures (e.g., "monoid", "group") and instantiable mathematical notions (e.g., "cardinality of a set"). Technical terms that are not used to refer to instances of these mathematical constructs are not types. Examples of non-types include references to the application of mathematical procedures (e.g., "proof by contradiction") and elements of the mathematical discourse (e.g., "theorem 4.1"). As a subclass of mathematical terminology, types are almost exclusively noun or prepositional phrases.

Types play a central role in communicating mathematical information by enabling mathematicians to name mathematical concepts, assign properties to objects and prove assertions about them. We consider types worthy of distinction from generic technical terms for two reasons: (a) types are used in the discourse to give sense to constituents of formulae and (b) types are used to consistently evoke mathematical concepts in textual argumentation and mathematical reasoning.

Our goal is to evaluate the usefulness of types as standalone lexical components in the retrieval of research-level mathematical information needs. Specifically, our hypothesis is twofold: (a) types are important discriminators in the mathematical discourse and (b) semantic relationships between types can be used to enrich queries and obtain significant improvements in retrieval efficiency.

A sub-task of our type-based approach is the construction of a type dictionary from a collection of documents. We address this in section 3 and describe a simple method for automatic identification of types. Furthermore, we evaluate our method using a gold standard set of type phrases which we have produced using judgements from 5 mathematicians.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2344–2355, Osaka, Japan, December 11-17 2016.

We focus on retrieving research-level mathematics because such material is rich in mathematical types. For instance, our system operates on queries such as the following (types are underlined):

> *Let P be a parabolic subgroup of $GL(n)$ with Levi decomposition $P = MN$, where N is the unipotent radical. Let p be an irreducible representation of $M(Z_p)$ inflated to $P(Z_p)$, how does $Ind_{P(Z_p)}^{GL_n(Z_p)}\pi$ decompose? It would be sufficient for me to know the result in the simplest case, where P is a Borel subgroup.*

Our experiments suggest that types are most effective when used to capture semantic relationships between mathematical concepts. Our top-performing type-based model, TypesExp, makes use of similarity in a type-aware word embedding space to identify semantically related types for query expansion. TypesExp outperforms state-of-the-art and traditional IR/query expansion models (described in section 4.3) demonstrating experimentally that types are valuable lexical components for IR in their own right (section 5).

2 Related Work

We use types to model mathematical concepts, but other constructs have been proposed in the literature for the same purpose. Grigore et al. (2009) take operators listed in OpenMath content dictionaries (CDs) to be mathematical concepts and use *term clusters* to model their semantics. A term cluster for a concept is composed of a label and a bag of nouns extracted from the operator description in the dictionary. This set is enriched manually using additional terms taken from online mathematical lexical resources. Grigore et al. assign the cluster that maximises the similarity (based on PMI and DICE) between the nouns in the local context of a target formula and those in the cluster, to represent the formula's semantics. Quoc et al. (2010) extract descriptions for formulae (phrases or sentences) from their surrounding context using a rule-based approach. Kristianto et al. (2012), on the other hand, used pattern matching on sentence parse trees and a "nearest noun" approach to extract descriptions, but these methods were later outperformed by SVMs (Kristianto et al., 2012).

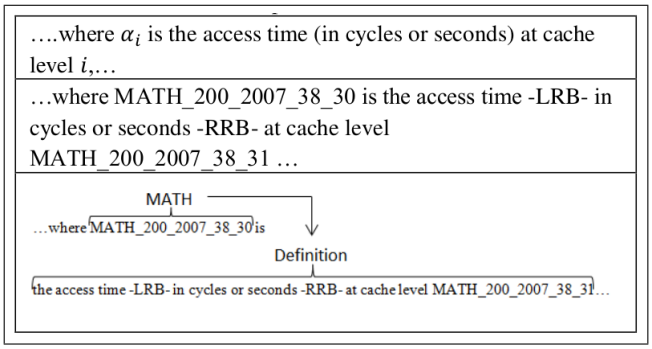

Figure 1: Example of extracting descriptions adapted from (Kristianto et al., 2012)

Our approach at modelling concepts with types incorporates the advantages of the described methods. Like term clusters, types label mathematical concepts and attach meaning in a distributional manner. However, rather than constructing type representations manually, we use types as concept labels and automatically compute distributional profiles for the concepts, based on word embeddings. Like formulae descriptions (Kristianto et al., 2012; Kristianto et al., 2014), our types are also extracted automatically from text. Although in some cases descriptions extracted by Kristianto et al. (2012, 2014) are noun phrases and resemble types, they often incorporate details that are particular to a specific context. For example, the extracted description for formula a_i presented in Figure 1 (adapted from (Kristianto et al., 2012)) contains information that is specific to the context (i.e., time at a particular cache level measured in cycles or seconds).

In our approach, we restrict types to relatively short technical terms which do not include context-specific information. This decision stems from our motivation to capture references to mathematical constructs in the form that they most consistently appear in scientific text.

3 Types for Math IR

Our definition of types is intended to model the perception of mathematical concepts shared between mathematicians and emerges from mathematical intuition. The notion of a type is intuitive to most mathematicians (as demonstrated in section 3.2). It is, however, hard to produce a concrete list of properties a technical term must adhere to in order to be considered a type.

Linguistically, types are a special kind of mathematical technical terminology. Technical terminology in general is well understood; for example, Justeson and Katz (1995) were among the first to define terminology as noun phrases with particular statistical properties. As lexical tokens, types are subject to a particularly high level of polysemy ("field" in Mathematics is a concept distinct to that in Physics) and synonymy (e.g., "karoubi envelope" is the same as "category of idempotent arrows"). Furthermore, many mathematical constructs are eponyms, i.e., named after their inventors, often additionally pre-modified by adjectives (e.g., "refined Noether normalization theorem", "abstract Hilbert space theorem"). New types can be formed through parameterisation (e.g.,"2-Group" and "G-Function" from "Group" and "Function" respectively) or by prepositional postmodification (e.g., "Ideal of a Ring", "Point on the Plane" and "Set of Matrices").

Conceptually, a type is any technical term that is (a) perceived by mathematicians to refer to mathematical objects, algebraic structures and mathematical notions and (b) can be instantiated in the discourse in the form of a variable. Here, we take mathematical objects to be anything that can be formally defined and manipulated in the discourse as part of formal deductive reasoning and/or proofs. This being said, it is important to highlight that some objects such as 'Number", "Matrix" and "Set" are considered basic and are never explicitly defined by mathematicians (Ganesalingam, 2008).

Like mathematical objects, algebraic structures also take part in mathematical manipulation but are defined as collections (or tuples) of other objects. Types can also refer to mathematical notions that can be instantiated as variables or can take the form of other objects. For example, an "envelope of elliptic trajectories" can be an "ellipse". Named axioms, theorems and conjectures are also considered to be types since they refer to universally accepted, formally defined constructs for the purpose of argumentation (e.g., to complete a proof).

Any technical term that does not fit the above description is not a type. Examples of non-types include properties of operators (e.g., "Associativity"), mathematical procedures (e.g., "Proof by contradiction"), processes (e.g., "Differentiation") and theories (such as "Chaos"). Note that mentions of mathematical theories are ambiguous: it is often unclear whether they refer to a branch of mathematics or to a formally defined construct. These examples are not types because either (a) they are not explicitly referring to mathematical constructions (i.e., they cannot assign meaning to variables), (b) their role in the discourse is indirect (e.g., properties capture relationships between concepts) and (c) they are used as discourse labels for anaphoric purposes.

Types can be organised hierarchically, with some types being specialised instances of other, more abstract constructions. This relationship is often mirrored linguistically: a type expressed by a longer string is often a subtype of the type corresponding to a sub-sequence string. For example, a "smooth curve" is a subtype of "curve". We consider sub-types to be distinct atomic units with discrete meaning despite the fact that they are constructed linguistically in a compositional manner with regards to their super-type. However, not all type/sub-type relationships are expressed on the surface. For example, it is not obvious that "Klein Bottle" is a sub-type of "Surface".

Types are relevant to both textual and mathematical contexts of queries and documents. As a result, types have potentially more impact than generic technical terms. Given that types communicate ideas shared between mathematicians, we anticipate that modelling the distributional profile of types (e.g., using an embedding space) will be beneficial to MIR.

3.1 Automatic Type Detection and Extraction

We address the problem of automatic detection and extraction of types so that we can perform large-scale experimentation. Our method proceeds as follows. First, we use the C-Value algorithm (Frantzi et al., 1998) on our corpus to extract technical terms (candidate types).

Given a collection of documents as input, the C-Value method identifies multi-word technical terms using both a linguistic and a statistical component. The linguistic component is employed primarily for eliminating multi-word strings that are unlikely to be technical terms. This is done by enforcing a stop-word list (high-frequency corpus terms) and through the application of linguistic filters (regular expressions) on sequences of part-of-speech tags. The statistical component assigns a "termhood" score to a candidate sequence based on its corpus-wide statistical characteristics and those of the sequences that contain it.

Each entry in the output of the C-Value algorithm corresponds to one technical term – an equivalence class of all variations of the term in the corpus. In the next step, our process selects technical terms that are likely to be types. We assume that technical terms that are types have an entry in the Encyclopedia of Mathematics[1] (8730 articles in total at the time of download) and/or an entry in Wikipedia (we used a 2014 Wikipedia dump) under the key categories "mathematical objects", "mathematical concepts" and "mathematical structures" and their sub-categories.

A dictionary of types is constructed by including technical terms that entirely match the title of one or more of these encyclopedia articles. We have opted to use this intersection of technical terms and article titles, as opposed to the titles alone, because not all titles are useful. For example, although the Wikipedia article[2] "The geometry and topology of three-manifolds" is filed under the categories of interest "Hyperbolic geometry", "3-manifolds" and "Kleinian groups", the title as a whole does not represent a single concept. In contrast, the technical term "Riemannian manifold" would completely match the title of the Wikipedia[3] (or Encyclopedia of Math) article for the concept and would thus be identified as a type by our method. The application of our method to the Mathematical REtrieval Corpus (MREC) (Líška et al., 2011)[4] has produced a dictionary of 10601 types.

3.2 Gold Standard Evaluation

Our definition of types is intricate and requires mathematical expertise. We also expect it to be subjective. We therefore evaluated the quality of accumulated types using 5 judges (third-year undergraduate and graduate mathematicians). Participants were shown a mixed list of types (as determined by our system) and non-types (technical terms that had been filtered out by our method as non-types). Without knowing what the source of each type was, they were asked to identify types using a 2-page definition of types (16 rules). The technical term list they were asked to judge consisted of 200 phrases and was constructed as follows: (1) two-thirds of the sample are sourced from the type list (10601 phrases). This set of 134 phrases is produced by sampling by observed distribution over phrase length. (2) The remainder of the sample (66 phrases) is sourced from the original list of C-Value technical terms not identified as types by our method. The termhood scores of these technical terms can range from very high to very low. As a result, we split the original technical term list (2.8 million phrases) into three equally-sized segments based on their C-Value score: (a) high score, (b) medium and (c) low score. From each segment, we removed any term already identified as a type and drew 22 phrases from the remainder. As before, segment samples are sampled by observed distribution based on phrase length. Sampling negatives from the three segments, as described above, enables us to compare the spread of positives and negatives across C-Value scores. (3) The two parts of the sample are concatenated and shuffled randomly. An HTML questionnaire is automatically produced and presented to annotators.

Precision and recall of our type identification method was $P = 73.9\%$ and $R = 81.8\%$ respectively, resulting in an F-score of 77.7%, with respect to the majority opinion. As expected, this is a subjective task, and without any specific training, annotator agreement, measured using Fleiss's Kappa (Fleiss, 1971), is in an intermediate range ($K = 0.65; N = 200, k = 2, n = 5$). We observed that judges often judged the following technical terms as types, although this contradicts our definition: author names, mathematical properties and non-sensical phrases.

[4] The MREC is a subset of ArXiv and is composed of over 439,000 scientific papers which have had all LaTeX formulae converted into MathML (Líška et al., 2011). It is the document collection underlying the test collection we use (section 4).

4 IR Experiments

Traditional retrieval models operate under the assumption that each constituent term in a multi-word type is an independent source of information. Our intuition is that the words in multi-word types carry more information as a group and should therefore be treated as atomic lexical units by these models. We propose two type-aware models, based on the traditional Vector-space model (VSM). In our evaluation we compare our type-aware models to established traditional, term-based[5] retrieval models. The motivation behind this approach is to clearly identify the effects of type information. We keep the comparison at the lexical level so that the effects of types to retrieval performance can be isolated – models employing formulae indexing and matching are not considered.

4.1 Computing a Type Embedding Space

We use our dictionary of types (section 3.1) to construct a type embedding space – a word embedding space that includes embeddings for types as atomic lexical units. The type embedding space is used to assign meaning (or denotation) to types in the form of vector embeddings and to expand queries with new types (section 4.3.1).

The type embedding space is constructed as follows. First, we apply sentence tokenisation over the MREC using the Stanford CoreNLP toolkit (Manning et al., 2014). Subsequently, we apply longest sequence matching on the words of each sentence and identify all instances of types in the the corpus. Once detected, word sequences belonging to types are replaced by a single token (a concatenation of the constituent words of the type). As we are interested in modelling the relatedness of meaningful linguistic tokens, rather than mathematical artefacts, we replace MathML blocks representing formulae in the sentence by a single token ("@@@"). Finally, the re-written sentences are passed on to `word2vec` in skipgram mode (Mikolov et al., 2013a; Mikolov et al., 2013b) with negative sampling and window size=10 to produce the type embedding space.

4.2 Test Collection

Evaluation is carried out using the Cambridge University MathIR Test Collection (CUMTC) (Stathopoulos and Teufel, 2015), which is composed of 120 real-life MIR topics procured from the MathOverflow (MO) on-line community. As illustrated in Table 1, each MO thread in the CUMTC is sentence-tokenized, with sentences either being part of the "prelude" (introduction to the mathematical subject of interest) or part of a concrete sub-question. We produced 160 queries from the CUMTC by emitting one query per sub-question in the collection. The body of each query is obtained by concatenating the text of the sub-question to the text of the associated prelude.

Prelude	Let P be a parabolic subgroup of $GL(n)$ with Levi decomposition $P = MN$, where N is the unipotent radical. It would be sufficient for me to know the result in the simplest case, where P is a Borel subgroup.
SQ-1	Let p be an irreducible representation of $M(Z_p)$ inflated to $P(Z_p)$, how does $Ind_{P(Z_p)}^{GL_n(Z_p)}\pi$ decompose? (at least until $g = 3$).

Table 1: Topic 175 (MO post 90038), prelude and sub-question

We chose this test collection because its topics represent real-life, research-level information needs, expressed in the natural language of mathematics, and are rich in mathematical types. This is in contrast to the NTCIR (Aizawa et al., 2013; Aizawa et al., 2014) test collections which emphasise formulae search (Guidi and Coen, 2015) with queries primarily taking the form of bags of keywords and formulae. Although the NTCIR Open Information Retrieval (OIR) is composed of free-text queries like those in the CUMTC, these are not accompanied by pre-determined relevance judgements[6]. Furthermore, textual descriptions in the OIR evaluation set are not as linguistically rich as the text in mathematics papers. Documents and queries are processed using a single pipeline that performs case normalisation and employs the Tika framework to flatten MathML consistently.

[5] A bigram model has also been considered but excluded from the comparison due to extremely poor performance.

[6] Relevance is judged using interactive sessions with humans.

4.3 Experimental Design

Performance is measured using mean average precision (MAP). Queries derived from the CUMTC are fairly long (averaging 88 words) and describe highly specialised information needs. As a result, they have relatively few relevant documents (only 19.17% have more than 1 relevant documents). Thus, our experimental setup is closer to that of the TREC HARD and TREC Robust tasks (Voorhees and Harman, 2005), than to more general-purpose retrieval (such as NTCIR and TREC ad-hoc) and low MAP values are to be expected. In the case of the CUMTC, the sparsity of relevant documents is attributable to the difficulty of the queries, rather than to the inherent uniqueness of the answer (as is the case in homepage search). One of the effects of the nature of the CUMTC is that the MAP scores of IR models will be numerically low. However, note that the small number of relevant documents per query does not make the evaluation per se unstable: we use a large number of queries and adopt the paired permutation test for significance testing. The permutation test is a non-parametric test for mean difference and is known to be reliable with MAP and its derivatives (Smucker et al., 2007).

In order to investigate the usefulness of mathematical types for retrieving research-level mathematics we adopt a two-level comparison of retrieval models. On one level, we compare traditional, term-based retrieval models to type-aware derivatives (see Figure 2 for the derivational relationship between models). On the second level, we compare the effectiveness of term-based query expansion to that based on types.

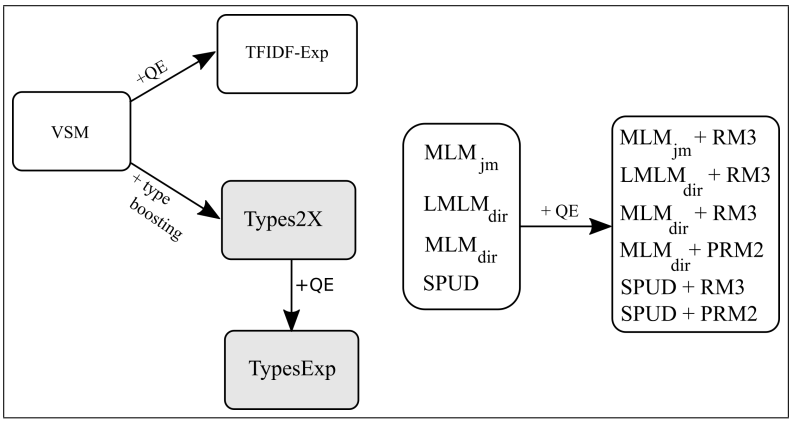

Figure 2: Relationships between basic models and their more sophisticated derivatives (grey boxes represent type-based models, white boxes represent term-based models).

The first level of comparison is performed across IR paradigms and includes term-based models that employ heuristic methods (e.g., VSM and BM25) as well as language modelling (e.g., classical multinomial language model (Zhai and Lafferty, 2001)). At this level, we wish to (a) determine the performance of traditional IR models on the CUMTC and (b) investigate if types are more useful than simple terms when retrieving research-level mathematics. A break-down of considered models based on this two-level comparison is presented in Table 2.

	No Expansion	**Query Expansion**
Terms	VSM	TFIDF-Exp
	BM25	-
	MLM_{jm}	MLM_{jm}+RM3
	MLM_{dir}	MLM_{dir}+RM3, MLM_{dir}+PRM2
	$LMLM_{dir}$	$LMLM_{dir}$+RM3
	SPUD	SPUD+RM3, SPUD+PRM2
Types	Types2X	TypesExp

Table 2: Overview of models.

4.3.1 Retrieval Models

We propose and evaluate two type-based heuristic models, based on VSM, that assign elevated significance to types through 2X boosting. One of our models makes use of inter-type similarity, encoded in a type embedding space, to expand queries.

Lucene VSM with 2X type boosting (Types2X). We apply the boosting pipeline described by Stathopoulos and Teufel (2015) to our type dictionary (section 3.1); i.e, we apply longest matching to a Lucene positional index and emit a type-aware "delta index". This type discovery and normalisation pre-processing step is also applied to queries. Our assumption is that types are a valuable source of information for an MIR system. Types2X assumes the role of a type-aware model that performs the simplest manipulation of those types that are physically present in the query (simple 2X boosting). Therefore, in our comparison, Types2X is used to measure the simplest possible way of incorporating types during retrieval (as opposed to just using terms). We expect Types2X to perform better than Lucene VSM (the term-based model it is based on) but no better than models incorporating type information in more sophisticated ways (such as TypesExp).

Lucene VSM with 2X type boosting and type-based query expansion (TypesExp). Unlike mathematical papers, queries are not always rich in types: on average each query contains around 13 type instances while documents in the MREC contain on average close to 548 type instances. TypesExp overcomes this problem by enriching queries with types. Queries are expanded using the types (as opposed to the terms) they contain. For each type in a query, the type-embedding space (using `word2vec` similarity as discussed in section 4.1) is used to discover n fresh related types. Semantic relatedness between types is modelled by the cosine similarity of their vector representations. The set of fresh types is appended to the original query and the new query is executed on a 2X type up-weighted VSM. The value for n is the only parameter of the model, which has been experimentally set to $n = 5$.

4.3.2 Baseline Models

Traditional, term-based retrieval and query expansion models [7] are used as baselines so that the effects of a-priori knowledge of types to retrieval performance can be isolated and quantified against uninformed approaches. Two query expansion (QE) methods based on pseudo-relevance feedback (PRF) are considered. The first method, known as RM3 (Abdul-jaleel et al., 2004; Lv and Zhai, 2009), assumes that documents and queries are generated by the same relevance model. The second, referred to as PRM2 (Lv and Zhai, 2011), makes use of proximity information in the feedback documents to expand queries.

Simple Baselines We use Lucene's default VSM (based on cosine similarity) and BM25 (Harter, 1975; Robertson et al., 1981; Robertson and Walker, 1994; Robertson et al., 1994) implementations. These models are considered not because of their strength per se, but because of their usefulness in identifying the effects of types in the performance of heuristic models: they are lingustically uninformed models. Furthermore, they are useful in quantifying the effects of boosting query types alone (Types2X).

Language Models (LM) Smoothed instances of the classical multinomial language model (Zhai and Lafferty, 2001) are also considered. The MLM_{jm} multinomial model employs Jelinek-Mercer (JM) smoothing. We rely on Lucene's implementation of the model and, in the absence of training data for the parameter λ, we use $\lambda = 0.7$ since there is strong evidence that this value is optimal for long queries (Zhai and Lafferty, 2001; Zhai and Lafferty, 2004). Two implementations of the multinomial model with Dirichlet smoothing are used in our comparison: the Lucene implementation ($LMLM_{dir}$) and the implementation by Cummins et al. (2015) (MLM_{dir})[8]. The smoothing parameter, μ, is set to $\mu = 2000$, which Zhai and Lafferty (2001, 2004) found to be near-optimal for large queries, such as those in our setup. These language models are included as more sophisticated, type-agnostic alternatives to the basic heuristic models.

[7] Technical issues have prevented us from incorporating the formula-aware Tangent and MiAS models in our evaluation.

[8] In correspondence with one of the authors of Cummins et al. (2015), it has come to our attention that there is suspicion in the community that the Lucene implementation of the classical multinomial language model may be incorrect for large queries, so we report two implementations for safety.

SPUD SPUD is a state-of-the-art unigram LM that models documents as draws from a multivariate Polya distribution (Cummins et al., 2015). Smoothing of the document model is performed using a linear combination of the unsmoothed document and background models and is controlled through a smoothing parameter ω. The SPUD ranking method estimates the probability that a query is generated from the expected multinomial drawn from each document model. We use the SPUD implementation by Cummins et al. (2015) with default parameters ($\omega = 0.8$), which have been shown to produce good results with long queries (Cummins et al., 2015). SPUD is included in our comparison as a state-of-the-art type-agnostic LM baseline against which we can benchmark the performance of our type-based models.

We also consider versions of the stated language models augmented with query expansion methods (RM3 and PRM2) implemented as part of the code accompanying (Cummins et al., 2015)[9]. Parameter values for these query expansion models are also taken from Cummins et al. (2015). LMs with QE are used to determine how type-based QE performs in comparison to state-of-the-art term-based QE.

Automatic QE using top TF-IDF terms (TFIDF-Exp). In this model, the query is expanded using the top s terms in the query as determined by document collection-wide TF-IDF scores. Stopwords and words with term frequency lower than 50 are excluded. Like before, each selected term is expanded using its n-nearest neighbours in a word embedding space (skip-gram, window size =10). The model has two parameters: *pool size* (n) and *seed size* (s). We found experimentally that the model performs best for $n = 1$ and $s = 1$. This baseline is used to determine whether any performance improvements obtained by type-based QE using an embedding space are due to types, rather than the use of embedding spaces in general.

5 Results and Discussion

Table 3 shows the results of all retrieval models considered[10]. The last two columns indicate the significance in MAP difference between each model and our proposed type-based models. As expected, absolute MAPs are low across the board, a phenomenon that can be attributed to the complexity of the underlying information needs and the resulting small number of relevant documents per query. But as long as the evaluation is stable, it is only the comparative performance of each model that we should be interested in.

	VSM	BM25	MLM_{jm}	$LMLM_{dir}$	MLM_{dir}	SPUD	TF-IDFExp	MLM_{jm} +RM3
MAP	.076	.079	.084	.072	.066	.090	.060	.063
TypesExp	$\gg$	$\gg$	$\gg$	$\gg$	$\gg$	$\gg$	$\gg$	$\gg$
Types2X	$\approx$	$\approx$	$\approx$	$\approx$	$\approx$	$\approx$	$\approx$	$\approx$
	$LMLM_{dir}$ +RM3	MLM_{dir} +RM3	MLM_{dir} +PRM2	SPUD +RM3	SPUD +PRM2	Types2X	TypesExp	
MAP	.051	.082	.061	.050	.072	.094	.150	
TypesExp	$\gg$	$\gg$	$\gg$	$\gg$	$\gg$	$>$	-	
Types2X	$>$	$\approx$	$\approx$	$>$	$\approx$	-	$<$	

Table 3: Model MAP performance and comparison to TypesExp and Types2X models.

The model utilising type-based expansion (TypesExp) is our best model; it outperforms every other model. In some cases the differences are dramatic; TypesExp's MAP score is twice that of the Lucene VSM and, to the best of our knowledge, 0.15 MAP represents the state-of-the-art on the CUMTC. We now discuss which of TypesExp's components contributed most to this improvement over existing IR models. Although the up-weighting of types on its own (Types2X) improves MAP over the VSM, the difference in performance is not statistically significant. This is also the case when comparing type up-weighting to the majority of alternative models. The best performing model not employing query expansion is SPUD, followed closely by MLM with JM smoothing. The traditional BM25, VSM and

[9] https://github.com/ronancummins/spud

[10] In Tables 3, 4 and 5, $\ll$ indicates that "column" is significantly better than "row" $\alpha = 0.01$; $<$ at $\alpha = 0.05$. $\approx$ indicates that difference is not significant.

Lucene MLM_{dir} models performed comparably, with no significant differences in MAP between them (as observed in Table 4).

VSM	-						
BM25	$\approx$	-					
MLM_{jm}	$\approx$	$\approx$	-				
$LMLM_{dir}$	$\approx$	$\approx$	$\approx$	-			
MLM_{dir}	$\approx$	$\approx$	$\approx$	$\approx$	-		
TFIDF-Exp	$\approx$	$\approx$	$\approx$	$\approx$	$\approx$	-	
SPUD	$\approx$	$\approx$	$\approx$	$\approx$	$>$	$\approx$	-
	VSM	BM25	MLM_{jm}	$LMLM_{dir}$	MLM_{dir}	TFIDF-Exp	SPUD

Table 4: Comparison of models not employing query expansion.

SPUD	$>$ **.028**	$>$ **.04**	.009	$>$ **.029**	$\gg$ **.04**	.019

Table 5: Absolute difference in MAP of unexpanded and query-expanded models.

General-purpose query expansion methods appear to be ineffective in retrieving research-level mathematics. From the results in Table 5 we observe that versions of the models augmented with state-of-the-art query expansion are either significantly outperformed or not significantly better than their corresponding basic versions. In other cases, the vanilla models significantly outperform their query expanding counterparts (e.g.,MLM_{dir} and $MLM_{dir} + RM3$, $SPUD$ and $SPUD + RM3$). This is in contrast to type-based query expansion, where the TypesExp model (2X type up-weighting+expansion using a type-aware embedding space) significantly outperforms both the VSM and Types2X models it is based on. The observations described above seem to point to the fact that, in the context of MIR, mathematical types encode more information than the sum of their individual, constituent terms.

On one hand, the performance of Types2X suggests that information coming from the types occurring in the queries alone may not be enough to produce significant improvements in retrieval efficiency. On the other hand, our experiments have shown that it is only the combination of query expansion with type information (rather than with simple terms) that yields significant performance gains on these difficult queries. Our intuition is that type-based expansion introduces semantically related concepts that elevate the score of topically relevant documents. Insight into why this method performs well can be obtained by looking into how types are expanded. The query in Table 6 is topic 175 (MO post 90038[11]). From an initial set of 6 types in the dictionary, our method expanded the query with 14 more types.

Query	Let P be a *parabolic subgroup* of $GL(n)$ with *Levi decomposition* $P = MN$, where N is the *unipotent radical*. Let p be an *irreducible representation* of $M(Z_p)$ inflated to $P(Z_p)$, how does $Ind_{P(Z_p)}^{GL_n(Z_p)}\pi$ decompose? It would be sufficient for me to know the result in the simplest case, where P is a *Borel subgroup*.
Query types	'levi decomposition', 'parabolic subgroup', 'unipotent', 'irreducible representation','borel subgroup'
Added Types	'reducible representation', 'regular element', 'conjugacy class', 'iwasawa decomposition', 'unipotent element', 'cartan decomposition', 'finite-dimensional representation', 'unitary representation','cartan subgroup', 'centralizer', 'subgroup', 'triangular decomposition', 'jordan decomposition','parabolic subalgebra'
TFIDF-Exp terms	'nilpotent', 'shredded', 'semi-simple', 'inflates', 'centralizer', 'pro-', 'puffed','engulfed', 'inflate', 'semisimple'

Table 6: Topic 175 (MO post 90038): Text and types in query, types in query and dictionary, expansion types and sample TFIDF-Exp expansion terms (n=5, $s = 2$).

Broadly speaking, all of the types expanded by our system are topically related to the types in the query. The types "iwasawa decomposition" and "cartan decomposition" in the expanded set strongly

[11] http://mathoverflow.net/questions/90038

relate to the types in the query (both are related to Levi decomposition of Lie algebras). However, there are also some instances of weak association between query and expanded types. For example, the type "subgroup" is almost certainly too general to do any good. On the other hand, the TFIDF-Exp expansion set for this query (bottom row of table 6) appears to be less likely to contain terms related to the topic subject. The "bag-of-types" model (Types2X) is inhibited by the fact that queries have a much smaller vocabulary of types compared to mathematical documents. Furthermore, we hypothesise that the model's limited performance and the effectiveness of topical relationships discovered through types and type embeddings are attributable to three characteristics of the mathematical discourse.

First, types can share algebraic structure, which permits mathematicians to perform mathematical reasoning by manipulating the shared components and properties. For example, both "monoid" and "semi group" have an underlying "set" and an associative binary operator. Thus, mathematics text may coerce either structure to its carrier set in formal argumentation and make statements that are true for both structures (Ganesalingam, 2008). Second, phenomena like polysemy and synonymy are frequent in mathematics. Lexically distinct terms can end up referring to the same concept: one name of the concept might come from its inventor, whereas another name is lexically descriptive (e.g., "Karoubi envelope" is synonymous to the type "category of idempotent arrows"). Third, concepts in mathematics can be abstracted using constructs from various mathematical frameworks. Often, a correspondence between concepts can be formed across different theories, each with its own palette of types. For example, a "magma" in group theory is a generalisation of a "groupoid", which can be defined as a special kind of "category" in category theory. Mathematicians have the flexibility to map mathematical concepts between theories, perform reasoning in one theory and then project back to another theory.

Methods that exploit semantic type relatedness, such as TypesExp, can be advantageous in cases where (a) lexical sparsity requires the use of some form of generalisation or similarity across concepts, of which QE is a simple variant, and (b) information about the similarity between types is more informative than similarity between raw words.

6 Conclusions

We have shown experimentally that types are a valuable, but currently underutilised aspect of the mathematical linguistic discourse. Our model improves MIR of research-level queries by automatically identifying types in text and building a similarity (embedding) space with which related types can be detected in documents more effectively than with existing methods. We find that type-based query expansion using this method of semantic proximity outperforms state-of-the-art IR/expansion models on a realistic, large-scale test collection. This strongly suggests that it is the identification of semantic relationships between types that can improve the quality of research-level MIR in the future even further. As an additional advantage, prior knowledge of types may also help improve parts of an NLP pipeline for mathematics texts, particularly in the absence of domain-specific training material.

Text Retrieval by Term Co-occurrences in a Query-based Vector Space

Abstract

Term co-occurrence in a sentence or paragraph is a powerful and often overlooked feature for text matching in document retrieval. In our experiments with matching email-style query messages to webpages, such term co-occurrence helped greatly to filter and rank documents, compared to matching document-size bags-of-words. The paper presents the results of the experiments as well as a text-matching model where the query shapes the vector space, a document is modelled by two or three vectors in this vector space, and the query-document similarity score depends on the length of the vectors and the relationships between them.

1 Introduction

Vector-space in text retrieval is old news. Cosine similarity by Salton and McGill (1986), along with the probabilistic retrieval model by Robertson and Spark Jones (1976), has dominated text retrieval for the last three decades. Much development has focused on improving the relevance scoring factors beyond term frequency and inverted document frequency, e.g., co-occurrence and proximity of query terms in the document help improve the relevance score (see Section 6).

This paper reports the results of an inductive research. We started with a practical task, then analyzed the prototype and spotted a text retrieval model, then twisted the model in order to improve it. The practical task was to increase automation of the "ask us" function on a municipal website: before the user submits his or her message, the system checks whether some answer-relevant pages are published on the website; if yes, the system delivers the pages to the user. Reuse of previously published information would save the user's time and the municipality's resources.

The municipality gave us 25 anonymized sample messages to experiment with, which was not enough for machine learning and text categorization methods. We knew that text-pattern matching yields superior results in automated email answering (Sneiders, 2016). Unfortunately, text patterns require learning, good text patterns are difficult to develop and maintain. We needed something new.

Our research problem is matching email-style query messages to webpages by a technique that does not require learning or development of a knowledge base. Our solution is a text-matching technique that relies on term co-occurrence in a limited text chunk (a sentence or a paragraph), yet without the complexity of good text patterns. The novelty and contribution of this paper are: (i) demonstration of the advantage of such term co-occurrence in text matching over matching of document-size bags-of-words, and (ii) a text-matching model where the query shapes the vector space, a document is modelled by two or three vectors in this vector space, and the query-document similarity score depends on the length of the vectors and the relationships between them. The model is easy to visualize.

Further in this paper, the next section presents the initial prototype, the test data, and the results of the initial tests. Sections 3 and 4 explain the text-matching model and show new test results. Section 5 discusses the advantages and limitations of the technique. Section 6 presents related and further research. Section 7 concludes the paper.

pages 2356–2365, Osaka, Japan, December 11-17 2016.

2 Initial Experiment

While web search is a well-established industry, matching email-style messages to web documents is a novel task. The main difference between the two tasks lies in the semantic strength of the terms in the query: while search queries consist of consciously selected keywords, a message is a short story without any indication which words embody the essence of the story.

2.1 Text Matching Method

The query – an email-style message – is a bag of words. The document is a webpage split into text chunks, where a chunk is a sentence or a block of text inside HTML block-level elements (Mozilla, 2016). Each text chunk is a bag of words. Thus, our "document collection" is a collection of text chunks. We do keep track of which chunk belongs to which document. Calculation of the query-document similarity score takes five steps; these steps were experimentally developed and refined.

Step 1. The system matches the query to each chunk separately and discovers term pairs – two terms that co-occur in the chunk and co-occur in the query. From now on, only these terms pairs are significant, single terms are ignored. We do not consider term triples, quadruples, etc. A triple is two term pairs.

Step 2. Each term t_i that belongs to a term pair T in a chunk *ch* obtains a term weight by formula (1). The term weight includes term frequency in the chunk, terms frequency in the query, inverted chunk frequency of the term, which is a counterpart of inverted document frequency in our chunk collection, as well as inverted chunk frequency of the term pair. The latter means that a term may have different weights in one chunk but in different term pairs.

$$w(t_i, T, ch) = tf(t_i, ch) \cdot tf(t_i, q) \cdot icf(t_i) \cdot icf(T) \quad (1)$$

We experimented with the document structure attribute – title, the main text, or H1-H3 heading – for term weights and discovered that term pairs appear in these structure elements somewhat equally for relevant and non-relevant documents. Therefore we do not use the document structure attribute.

Step 3. The weight of a term t_i in a term pair T for the entire document *d* is calculated by formula (2) as a sum across the chunks in the document where the term pair exists.

$$w(t_i, T, d) = \sum_{\{ch \in d | T \in ch\}} w(t_i, T, ch) \quad (2)$$

Step 4. The weight of a term pair $T(t_i, t_j)$ in the document *d* is the sum of the weights of both terms t_i and t_j calculated by formula (3).

$$w(T(t_i, t_j), d) = w(t_i, T, d) + w(t_j, T, d) \quad (3)$$

Step 5. The query-document similarity score is the sum of all term-pair weights of this document calculated by formula (4). The document score is largely a sum of selected term weights, but we did the summation following certain logic.

$$score_0(d) = \sum_{\{T \in d\}} w(T, d) \quad (4)$$

Alternative steps 4 and 5. We may want to skip weighing term pairs and continue with the weights of individual terms from the term pairs. Formula (5) calculates the weight of a term t_i in the entire document *d* across all the term pairs T where t_i exists. The query-document similarity score is the sum of the weights of the unique terms from all the term pairs in the document, calculated by formula (6). N is the number of these unique terms. While formulas (4) and (6) are equivalent, formulas (3) and (4) are easier to understand whereas formulas (5) and (6) will be used further in this paper.

$$w(t_i, d) = \sum_{\{T \in d | t_i \in T\}} w(t_i, T, d) = tf(t_i, q) \cdot icf(t_i) \cdot \sum_{\{T \in d | t_i \in T\}} \left(icf(T) \cdot \sum_{\{ch \in d | T \in ch\}} tf(t_i, ch) \right) \quad (5)$$

$$score_0(d) = \sum_{i=1}^{N} w(t_i, d) \quad (6)$$

2.2 Experiment Data

The source of the document collection was a municipal website in Swedish. The web pages were generated by a content management system and had quite uniform appearance. With a little bit of experimenting with learned to remove the headers, footers, side bars. After removing duplicate content pages, we obtained 2607 documents. These documents were split into chunks. If a chunk was a block of text, the collection of chunks got 26 064 chunks. If a chunk was a sentence, the collection got 37 420 chunks. We applied compound splitting (Sjöbergh and Kann, 2004) and lemmatization (Carlberger and Kann, 1999) to the words in a chunk before the chunk was turned into a bag of words.

We tested two options of stop-word removal. One option was using a standard list of Swedish stop-words (Text Tools, 2016). The other option was part-of-speech (POS) filtering. Analysis of 30 most frequent lemmas that matched text patterns in automated email answering (Sneiders at al., 2014) showed that only nouns and verbs were domain-specific words. Barr et al. (2008) explored Yahoo! search queries and found that 40.2% of the terms were proper nouns, 30.9% nouns, 7.1% adjectives, 2.4% verbs. Inspired by these findings, we grouped the terms in our document collection by their POS-tags and subjectively examined which parts-of-speech felt like good candidates for descriptive term pairs. Eventually, we decided that only nouns, verbs, proper nouns, adjectives, and unrecognized terms should be left in the documents after POS filtering.

The average size and standard deviation of the block-chunks were 8.9±8.45 unique lemmatized terms after removing standard stop-words, and 8.29±7.71 terms after POS filtering; both after compound splitting. For sentence-chunks, the respective sizes were 6.44±4.21 and 6.01±3.93.

We had 25 email-style messages in Swedish as test queries. Each message was spell-checked and pre-processed as a chunk. The average size of the messages was 12.68±6.25 unique lemmatized terms after removing standard stop-words, and 10.76±4.90 terms after POS filtering. Following are three sample messages – one short, one long, and one medium long. We Google-translated the Swedish originals, with minor manual corrections, and removed location names from the text.

- "Hello, I'm looking for a summer job as a gardener in <town> but I do not know which homepages I can go in and look for summer jobs. Which homepages I can go to and check?"
- "Hey, we're moving to <town> municipality in July. Today we live in <town> and have our children at <name> school. The new house is closest to <name> school but this is another municipality. When I spoke to the school they told me that our children were welcome there and they now have a number of students who attend the school but live across municipal borders. It requires, however, an approval of <town> municipality. My question now is how it works, if we want our children to go to <name> school because it is closest, and that several of the children's friends go to that school too. Thanks in advance."
- "Hello! On the pedestrian and bicycle path between <address> in <town> and <village> is a lamppost partially bent since a storm last fall. The post is standing but the light is directed in a wrong direction. Who is responsible for this to be corrected? Thanks for a quick response. If the lamppost number is needed I can find it out."

We used the website's search engine to find documents relevant to the test messages. We devised a number of search queries per test message and manually examined all the retrieved documents. We found two kinds of documents. *Closely relevant documents* could answer the message. *Related documents* had "good to know" information but did not answer the message. 3 of the test messages had no relevant information on the website. 4 messages had only closely relevant documents. 4 messages had only related documents. 14 messages had both closely relevant and related documents. Of those messages that had closely relevant documents, 8 messages had one such document and 10 had two such documents. Of those messages that had related documents, 15 messages had one to three such documents, 2 had six such documents, and 1 had eleven such documents.

2.3 Performance Measures

The system matches term pairs in the query and the document, therefore it inevitably removes relevant documents that do not have matching term pairs. Hence, we measured *recall* as the share of relevant documents that did have matching term pairs and therefore were included in the results. The average recall was calculated across the queries that had corresponding documents in the collection.

In order to quantify exposure of relevant documents to the user, we measured the *average rank* (the position in the result list) of relevant documents. We calculated the average rank for each query with non-zero recall, and then the average of these averages.

In order to simulate automated email answering, we measured *P@1* (precision among top n documents where n is 1) for closely relevant documents. The average P@1 was calculated across the queries with non-zero recall.

Our baseline method was *cosine similarity* between unigram-based document vectors. We tested cosine similarity in two settings. At first, we applied cosine similarity to all the 2607 documents and ranked them. The second option was to filter the 2607 documents by the term pairs first, which resulted in a much smaller set of documents with a higher density of relevant documents. Then we applied cosine similarity in this smaller set of documents. For cosine similarity, term frequency was counted in the entire document; inverted document frequency was calculated in the document collection. We realize that cosine similarity is a rather basic baseline. It did, however, serve the purpose. We leave a more thorough comparison of text-matching methods to further research.

Recall, the average rank of relevant documents, and cosine similarity were measured separately for closely relevant and related documents.

2.4 Test Results

The tests have three parameters – (i) two options of stop-word removal, (ii) two scopes of a text chunk, and (iii) two options of the minimum number of term pairs that the entire document (not one chunk) and the query must have in common for the document to be considered for relevance ranking. Table 1 shows the initial results according to these parameters. The average values have their standard deviation, except for P@1 where individual values are 0 or 1.

Recall and the number of selected documents. The average number of selected documents lies between 25 and 109 of the total 2607, i.e., on average the system selected 1-4% of the documents. Meanwhile, the average recall does not drop below 0.61 for closely relevant documents. The best average recall is 0.83, i.e., the selected 74 (average) of the 2607 documents contain 83% (average) of all the closely relevant documents. Recall for the related documents is lower. Because the semantic distance between the query and a related document is longer than that between the query and a closely relevant document, apparently there are fewer co-occurring terms and fewer selected messages.

Stop-words	**Avg num of selected docs**	**Avg recall**		**Avg P@1**	**Avg rank**	
		Close	**Related**		**Close**	**Related**
Documents selected by chunk-sentence, min 2 common term pairs. Ranked by $score_0$

Standard	74.28±204.48	0.83±0.33	0.58±0.38	0.63	7.16±13.95	7.09±9.01

Table 1. Results of the initial tests.

Average rank. For term-pair matching, the average rank (i.e., average of the averages, see Section 2.3) of closely relevant documents lies between 2.16 and 4.66 for different document selection options. The average rank of related documents is lower than that of closely relevant documents, as expected.

Cosine similarity in the entire document collection demonstrates rather low average ranks – 27.58 and 34.42. If, however, we first filter the collection by term pairs and then apply cosine similarity to the documents that have survived the filtering, then the average ranks are comparable with those by $score_0$. For cosine similarity after document filtering, the average rank of related documents is higher than that of closely relevant documents, although it should be the other way around. One reason for that could be the low recall for related documents and fewer documents that drag the average rank down. Cosine similarity disregards the added value of term pairs that helps $score_0$ distinguish between closely relevant and related document.

P@1 lies around 0.5, which means that roughly each second top document is a correct answer. This is too little if we want to use our technique for fully automated email answering with a relevant webpage as the answer. Notably, cosine similarity yields the best P@1 value 0.63. Because the average ranks for cosine similarity have large standard deviation, cosine similarity offers higher gains (also better P@1) and bigger losses (also lower average rank) than $score_0$.

We selected the result typed boldfaced in Table 1 as the *best initial result and the baseline* for further experiments with term-pair matching: the best recall for closely relevant documents (0.83) and the second best recall for related documents (0.58), while having the third best and still good average ranks (3.47 and 6.51).

2.5 Amount of Matching Text

In order to better understand term-pair matching, we counted the number of term pairs and unique terms per query-document match for closely relevant documents for the best initial result in Table 1. Of the total 28 closely relevant documents, 24 were selected by the system during the test. Figure 1 shows the number of term pairs and unique terms from these term pairs for each of the 24 successful query-document matches. In most cases, a query-document match required no more than 6-7 term pairs; the largest number of term pairs was 26. The number of unique terms in these term pairs was also up to 6-7 per match, 13 at most. In eight matching cases, the number of terms in the matching term pairs was only 3.

On average, the terms in the term pairs accounted for about 40% of the unique query terms and about 3% of the unique document terms after compound splitting, lemmatization, and stop-word removal. That means that quite a large portion of the query but a small portion of the document participated in a successful query-document match.

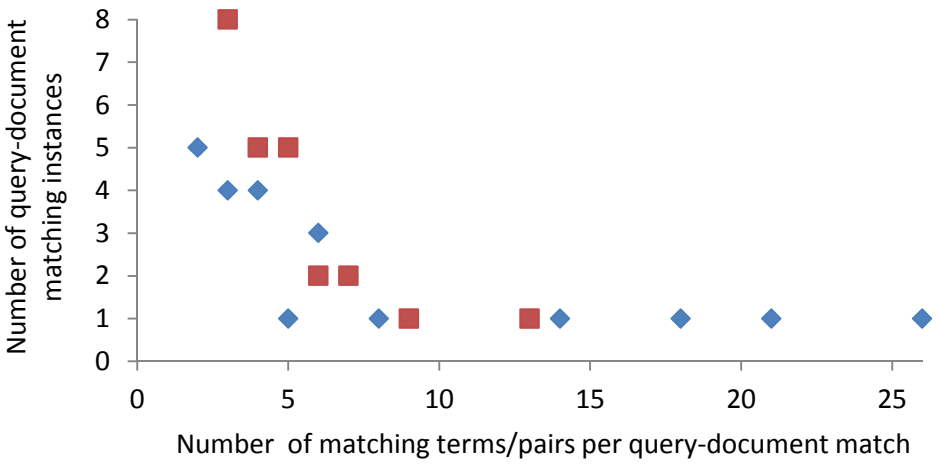

Figure 1. The number of term pairs (diamonds) and unique terms (squares) from these term pairs per query-document match, and the number of the corresponding matching instances. At (7; 2) a square hides a diamond, they overlap.

3 Text-Matching Model Based on Term Pairs in a Query-based Vector Space

While experimenting with the prototype, we designed formulas (1) to (6) according to our own perception of text relevance. Soon we realized that the formulas do have a representation in vector algebra. Let us imagine a term pair in the document *d* as a vector T_j; the term pair originates from one or several chunks of *d*. T_j has two coordinates $t_{ji} = w(t_i, T_j, d)$ each calculated by formula (2). The document vector P is the sum of all the term-pair vectors T_j as shown in Figure 2 (a). The document vector P has coordinates $p_i = w(t_i, d)$ each calculated by formula (5).

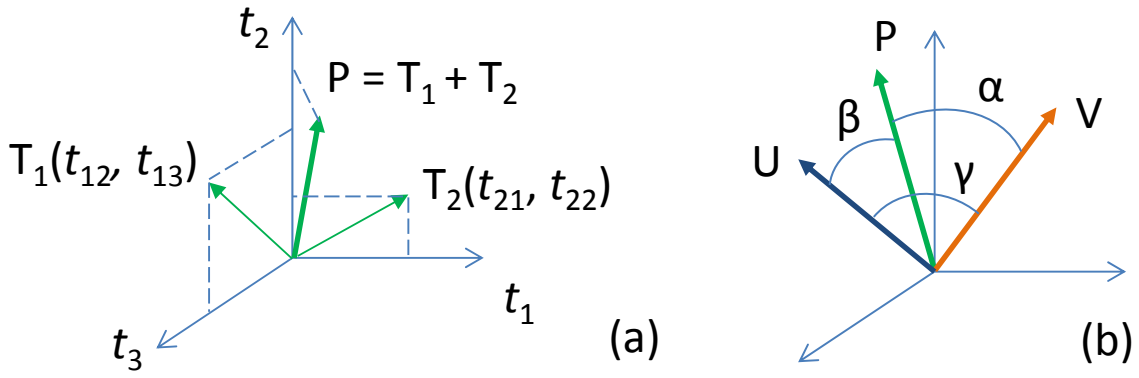

Figure 2. (a) Document vector P as the sum of term-pair vectors. (b) Document vector P, vocabulary vector V, unigram vector U (used in Section 4), and the angles between them.

Traditionally in a vector space, the query and the document are two independent vectors. In Figure 2 we do not have any query vector; the query is not clearly visible. Still, the query is in there. Together with each individual document, the query establishes term pairs whose terms define the dimensions of the vector space. Furthermore, the query participates in the term weight formula (1) and, thus, contributes to the coordinates of P. The query provides the building blocks for the document vector P. *The query is embedded in the vector space and shapes the vector space*: limited dimensions of the vector space and query-term frequency in the coordinates of the term-pair vectors are the only presence of the query in the text-matching process.

How do we calculate similarity between the query, which is embedded in the vector space, and the document, which is a vector? One measure could be the length of P: longer P means more query participates in the document, which means more similarity. Another measure could be the volume of the polygon created by P: the more the document "fills" the query the more similar they are. We tested both measures; the average ranks were inferior to those of the best initial result in Table 1.

Let us examine why simple summation of vector coordinates works better than the length and volume scores. We can rewrite $score_0$ in formulas (5) and (6) as shown in formulas (7) and 8:

$$score_0(d) = \sum_{i=1}^{N} p_i \cdot 1 = P \bullet V = |P||V| \cos\alpha \tag{7}$$

$$p_i = w(t_i, d) = tf(t_i, q) \cdot icf(t_i) \cdot \sum_{\{T \in d | t_i \in T\}} \left(icf(T) \cdot \sum_{\{ch \in d | T \in ch\}} tf(t_i, ch) \right) \tag{8}$$

N is the number of dimensions of P, which is the number of unique terms in the term pairs. That number is not particularly large, as we see in Figure 1. V is the vocabulary vector, it has the same dimensions as P but the coordinates are 1. The vectors P and V and cos α in formula (7) are illustrated by Figure 2 (b). $Score_0$ favors the following query-document match conditions:

- | P | grows if p_i grows, i.e., (i) the query and the document have more term pairs in common and (ii) each term pair is more document-unique with higher inverted chunk frequency, (iii) each term in the term pairs has higher frequency in the document and (iv) in the query, and (v) the term is also more document-unique with higher inverted chunk frequency.
- $|V| = \sqrt{N}$, it grows along with the diversity of the vocabulary in the term pairs.

- cos α between vectors P and V is highest if all p_i values are the same, because vector V has each coordinate 1. Equal p_i values suggest that all terms in the term pairs should be equally important, where the importance is maintained by the balance between the frequency of the term in the query and the document, its uniqueness in the document collection, and uniqueness of its co-occurrences with other terms (i.e., term pairs). Less frequent terms require more unique co-occurrences.

In formula (7), the vocabulary vector V states that all terms in the term pairs are equal. Let us change it so that each coordinate of V is inverted chunk frequency of the term, as in formulas (9) and (10). Now the p_i values are not expected to be equal but instead be bigger for more unique terms in order to maintain good alignment between vectors P and V.

$$score_1(d) = P \bullet V = \sum_{i=1}^{N} p_i v_i \tag{9}$$

$$v_i = icf(t_i) \tag{10}$$

We tested formula (9) with the same options that our best initial result in Table 1 had: removal of standard stop-words, a chunk is a sentence, the query and the document must have at least 2 term pairs in common. Table 2 shows that $score_1$ yields better average ranks than the best initial result.

Formula	**Avg P@1**	**Avg rank**	
		Close	**Related**
$score_1$ (9)	0.50	3.38±3.93	6.24±6.81

Table 2. Query-document similarity score based on term pairs in a query-based vector space. (The corresponding number of selected documents and the recall values are boldfaced in Table 1.)

4 The Model Enhanced by Unigrams from the Document

Roughly 3% of the document terms participated in a successful query-document match, as stated in Section 2.5. Arguably, term co-occurrences in limited text chunks identify relevant parts of the document and use only these parts to score the document. Imagine an FAQ list. There are many FAQs and their answers in the document, but only one FAQ and its answer contains the right term co-occurrences. The system uses that FAQ to score the document and ignores the rest of the list.

What happens if we include all the vocabulary of the document into our query-document similarity score? If the document is concise, it may help. If we have a multi-topic document, the non-co-occurring and possibly not so relevant terms from the entire document are likely to damage the score. Let us try and see what happens.

Figure 2 (b) shows the new arrangement. We have the old vectors P and V, as well as a new unigram vector U, which is the traditional document term vector. For the highest score, P and V are aligned (α is small), as well as U and P are aligned (β is small), or U and V are aligned (γ is small). Good alignment between U and P or V requires that most document terms end up in the term pairs.

$$score_2(d) = (P \bullet V)\cos\beta = \sum_{i=1}^{N} p_i v_i \frac{\sum_{i=1}^{N} p_i u_i}{\sqrt{\sum_{i=1}^{N} p_i^2}\sqrt{\sum_{i=1}^{N} u_i^2}} \tag{11}$$

$$score_3(d) = (P \bullet V)\cos\gamma = \sum_{i=1}^{N} p_i v_i \frac{\sum_{i=1}^{N} v_i u_i}{\sqrt{\sum_{i=1}^{N} v_i^2}\sqrt{\sum_{i=1}^{N} u_i^2}} \tag{12}$$

$$u_i = tf(t_i, d) \cdot tf(t_i, q) \cdot idf(t_i) \tag{13}$$

Formulas (11), (12), (8), (10) and (13) implement this similarity score. Please observe that u_i – the coordinates of the unigram vector U – include the traditional term frequency in the entire document and inverted document frequency. No chunks. N here is the number of dimensions in the document, which means that many p_i and v_i values are 0; they are non-zero for the dimensions of the term pairs.

Formulas (8) and (13) include query-term frequency $tf(t_i, q)$ in the coordinates of vectors P and U. If we move $tf(t_i, q)$ from the coordinates of P and U to the coordinates of V, then U and V will start resembling the traditional document and query vectors. The dot product P ● V will not change, the angles β and γ will. Let us redefine the coordinates p_i, v_i, and u_i as shown in formulas (14), (15), and (16). The new $score_4$ and $score_5$ are calculated as $score_2$ and $score_3$ but with p'_i, v'_i, and u'_i instead of p_i, v_i, and u_i.

$$p_i^{'} = icf(t_i) \cdot \sum_{\{T \in d | t_i \in T\}} \left(icf(T) \cdot \sum_{\{ch \in d | T \in ch\}} tf(t_i, ch) \right) \tag{14}$$

$$v_i^{'} = tf(t_i, q) \cdot icf(t_i) \tag{15}$$

$$u_i^{'} = tf(t_i, d) \cdot idf(t_i) \tag{16}$$

$$score_4(d) = score_2(d, p^{'}, v^{'}, u^{'}) \tag{17}$$

$$score_5(d) = score_3(d, p^{'}, v^{'}, u^{'}) \tag{18}$$

We tested the formulas with the same text processing and document selection options as in Section 3. Table 3 shows the results. In comparison with $score_1$, the average P@1 has improved in 3 of 4 cases. Notably, cosine similarity yielded the best P@1 in Table 1; now cosine similarity is somewhat smuggled in by the use of cos β and cos γ. As to the average ranks of closely relevant documents, $score_1$ with only term pairs and without the unigram vector U had a marginally better value. For related documents, vector U was beneficial for $score_4$ and $score_5$ where query-term frequency was in the coordinates of vector V.

Formula	Avg P@1	Avg rank	
		Close	Related
$score_2$ (11)	0.56	3.44±4.17	6.18±6.84
$score_3$ (12)	0.44	3.66±4.04	6.06±7.51
$score_4$ (17)	0.56	4.16±4.40	4.61±4.30
$score_5$ (18)	0.56	3.56±3.26	4.60±3.98

Table 3. Query-document similarity based on term pairs and unigrams from the document.
(The corresponding number of selected documents and the recall values are boldfaced in Table 1.)

5 Advantages and Limitations

Our term-pair-based text-matching technique has three *advantages*. First of all, it has a good average rank for closely relevant messages; we measured 3.38±3.93 at average recall 0.83±0.33. The second advantage is low maintenance costs, because the technique does not have any knowledge base to develop and maintain. Finally, we may argue that term co-occurrence identifies relevant parts of the document and ignores the rest (only about 3% of the document terms are used), which means the technique works pretty well with multi-topic documents.

The first *limitation* is email-size queries. The query is big enough to shape a vector space and small enough to be one text chunk. We have not yet considered this technique for other query sizes. Furthermore, we know that a message sent to a contact center is keyword-rich text because it describes the context and requires a response (Sneiders, Sjöbergh and Alfalahi, 2016). We do not know how the technique would work with queries where keyword density is lower than that of email-style messages.

The design of the technique had a question-answering task in mind. In our experiments, term-pair matching worked best for closely relevant documents. Topic-related text retrieval and categorization, which most of text retrieval is, does not deal with the concept of answer.

Because a successful query-document match relies on rather few term pairs (see Section 2.5), the technique relies on good text pre-processing tools – spelling correction, compound splitting, lemmatization – which lay the groundwork for a larger number of term pairs.

The average P@1 value around 0.5 is nice but not sufficient for fully automated email answering.

6 Related and Future Research

Utilizing term co-occurrence in a text chunk is not a new phenomenon in email answering at contact centers. Malik at al. (2007) match sentences in a query message to tag-questions (like FAQs) attached to standard answers. Marom and Zukerman (2005) cluster answers given to similar inquiries, and then pick out most representative sentences from the answers in one cluster in order to build a model answer. Sneiders, Sjöbergh and Alfalahi (2016) match manual text patterns to email messages for assigning standard answers. A text pattern looks for co-occurring terms in a paragraph of the query; a phrase in the text pattern considers the sequence and distance between the terms in a sentence.

Corpus-based question answering (QA) relies on term co-occurrence in a limited piece of text. Let us consider one of the earlier works (Kwok et al., 2001) which pinpoints the main steps of QA. Retrieval of source documents for candidate answers requires good search queries, which means a good set of co-occurring terms. Answer extraction involves locating regions in the documents with high density of the search keywords. Finally, answer selection calculates the weight of each candidate answer, which is a text snippet, based on co-occurrence of many and relevant terms in the snippet.

Term co-occurrence in a document (not a chunk) has been used to build new text categorization features, along with the unigrams (Figueiredo et al, 2011). The logic there is the same as ours – term co-occurrence creates new meaning that is not visible if we consider each term separately.

Proximity of the query terms in a document has been used to enhance the probabilistic retrieval model in BM25 for web search (e.g., He et al., 2011; Svore et al., 2010). Song at al. (2008) identify text spans that contain query terms in the document, and calculate relevance contribution of a span with respect to each query term in there. The relevance contribution is used instead of term frequency in the BM25 document score.

As for our own text-matching model, it needs tests with more data and more baseline systems in order to see whether the perceived value of the model is real.

Synonyms and semantic distance between terms is something to test. They would increase the number of both relevant and non-relevant term pairs. Domain-specific synonyms are likely to help, but that would mean developing a "knowledge base", something we wanted to avoid in the beginning.

Sneiders, Sjöbergh and Alfalahi (2016) have observed that the essence of the message comes in one sentence in half of the email messages sent to a contact center. If we learn to identify that sentence, then we can greatly reduce the number of non-relevant term pairs coming from the rest of the message.

So far we did not consider co-occurrence of more than 2 terms in a combination – a triple is two pairs. Whether the added value of a new term in the combination of terms is linear (the sum of pairs) or not, we do not know it yet.

Previously we argued that term-pair matching identifies the most relevant parts of a multi-topic document and calculates query-document similarity with respect to those parts. Currently the entire document is retrieved to the user the way search engines do, whereas a better option might be extracted relevant parts of the multi-topic document.

7 Conclusion

Traditionally in text retrieval, presence of terms in a document is the main information carrier. We have shown that term co-occurrence in a limited text chunk (a sentence or paragraph) is an information carrier in its own right. In our experiments, only about 3% of unique document terms were used to successfully match the document to the query (Section 2.5). These 3% came from the term pairs that text chunks in the document had in common with the query.

Table 1 shows the success of our term pair matching for document *filtering*. For example, the selected 74 (on average) out of 2607 documents yielded 83% (on average) recall for the closely relevant documents. Ranking among a few selected documents with high density of relevant documents is more effective than ranking in the entire document collection.

Furthermore, we used the term pairs to score the documents for *relevance ranking*. At the 83% recall, the system could reach the average rank of closely relevant documents 3.38 (Table 2) while cosine similarity in the same settings yielded 7.16 (Table 1).

Our main academic contribution is a simple but effective *text-matching model* where the query shapes the vector space and a document is modelled by two or three vectors. (i) The document vector is the sum of individual term-pair vectors; it favors many and subject-specific term pairs with subject-relevant terms. (ii) The vocabulary vector favors a large diversity of vocabulary in the term pairs and equally important terms in the term pairs. (iii) The optional unigram vector favors matches where most of the document terms end up in the term pairs. The model is easy to visualize.

Abstract

Relation classification is the task of classifying the semantic relations between entity pairs in text. Observing that existing work has not fully explored using different representations for relation instances, especially in order to better handle the asymmetry of relation types, in this paper, we propose a neural network based method for relation classification that combines the raw sequence and the shortest dependency path representations of relation instances and uses mirror instances to perform pairwise relation classification. We evaluate our proposed models on two widely used datasets: SemEval-2010 Task 8 and ACE-2005. The empirical results show that our combined model together with mirror instances achieves the state-of-the-art results on both datasets.

1 Introduction

Relation classification is a very important task for many Natural Language Processing (NLP) applications including question answering (Yao and Van Durme, 2014), knowledge base population (Socher et al., 2013) and opinion mining (Kobayashi et al., 2007). The goal of relation classification is to automatically identify the semantic relation between a pair of entities in free text. For example, a relation classification system should be able to capture the *Cause-Effect* relation between the entities *pressure* and *burst* in the sentence "The *burst* has been caused by water hammer *pressure*."

Like any classification task, a key research question of relation classification is the identification of a good feature representation for each relation instance. Traditional approaches focus on either combining many manually designed features (Zhou et al., 2005; Jiang and Zhai, 2007; Li and Ji, 2014) or leveraging various kernels to implicitly explore a large feature space (Bunescu and Mooney, 2005; Zhang et al., 2006; Qian et al., 2008; Nguyen et al., 2009), but both approaches suffer from their poor generalization ability on unseen words, and fail to achieve very satisfactory performance (Nguyen et al., 2015). Recently, with the advances of deep learning in NLP, neural networks (NNs) have exhibited their advantages in dealing with unseen words through pre-trained word embeddings and capturing meaningful hidden representations. Different NN architectures, including Convolutional Neural Network (CNN) (Zeng et al., 2014), Recursive Neural Network (ReNN) (Socher et al., 2012) and Recurrent Neural Network (RNN) (Xu et al., 2015b), have been applied to relation classification.

However, most existing NN-based approaches only exploit one of the following structures to represent relation instances: raw word sequences (Zeng et al., 2014; dos Santos et al., 2015), constituency parse trees (Socher et al., 2012; Hashimoto et al., 2013) and dependency parse trees (Xu et al., 2015a; Xu et al., 2015b; Miwa and Bansal, 2016). For the models based on raw sequence, despite maintaining all the information in relation instances, they cannot well handle long-distance relations. For the models based on constituency parse trees, one of the bottlenecks is handling long-distance relations (Ebrahimi and Dou, 2015). For the dependency tree-based models, although they focus on the condensed information

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2366–2377, Osaka, Japan, December 11-17 2016.

captured by the shortest dependency path between the two entities and thus are good at capturing long-distance relations, they lose some supplementary information in the original instance (Liu et al., 2015). Observing that the raw sequence and the dependency path representations highly complement each other, we expect a combination of the two structures to be more effective in capturing long-distance relations without losing any information.

Moreover, another important issue with the feature representation of relation instances is regarding the asymmetry of relation types. Most relation types are asymmetric. Take the *Cause-Effect* relation in the SemEval dataset as an example. *Cause-Effect*(e_1, e_2) indicates that e_1 is the cause and e_2 is the effect. If their roles are reversed, we need to represent the relation as either *Cause-Effect*(e_2, e_1) or *Effect-Cause*(e_1, e_2). Suppose we have K different asymmetric relation types. The current common practice to handle the relation directions is to transform the K+1 class labels (where the +1 is for the *Other* relation, which is symmetric) into $2K$+1 class labels, where each of the K asymmetric relations is expanded into two labels to capture the two directions. For example, from *Cause-Effect*, another label *Effect-Cause* is created. Given any sentence containing two entities, we can always treat the first entity as e_1 and the second entity as e_2. We can then classify their relation into one of the $2K$+1 labels.

Although this approach has been shown to be effective, it neglects the fact that the two class labels corresponding to the same original asymmetric relation are correlated. Take the above-mentioned *burst-pressure* sentence as an example. Most previous methods will treat it as a positive instance for the *Effect-Cause* relation only (because the first entity *burst* in the sentence is the effect). They will not relate the sentence to the *Cause-Effect* relation, although if we treat the second entity *pressure* as e_1, its relation to the first entity *burst* is *Cause-Effect*. We believe that if we represent each relation instance in two ways by swapping the order of the two entities, we can not only implicitly link the pair of relation labels from the same relation but also make a better prediction on a relation instance based on its two representations.

Based on the two observations above regarding the complementary nature of the raw sequence and dependency path representations and the asymmetry of relation types, in this paper, we propose a mirror instance based pairwise relation classification (MI) method using a convolutional neural network that combines raw sequence and dependency path representations. Our MI method creates mirror instances from the original relation instances by swapping the order of the two entities and using the reversed relation label. The method also learns appropriate weights to combine the predictions made on the original instance and the mirror instance for the final prediction.

Evaluation on SemEval-2010 Task 8 and ACE-2005 shows that both mirror instances and combining raw sequence and dependency path representations help improve the performance of relation classification. Our results also show that: (1) by using only half of the negative training instances to generate mirror instances, we can push the F_1 score to 85.0 on SemEval-2010 Task 8 without using any additional manually-crafted, linguistic-driven features; (2) and with only one additional linguistic-driven feature (entity type), we can obtain results competitive with the state-of-the-art results on ACE-2005.

2 Our Proposed Model

In this section, we first formally formulate the task and introduce our notation. We then present our proposed mirror instance method, including the mirror instance generation strategy and our pairwise relation classification framework. Finally, we present our proposed combined CNN models.

2.1 Problem Formulation

A relation instance consists of a sentence with two entities inside tagged as e_1 and e_2. Here e_1 always precedes e_2 in the sentence. Let $\mathcal{R}$ be a set of pre-defined asymmetric relation types, and $\mathcal{S}$ be a set of pre-defined symmetric relations including no relation. A labeled relation instance has a relation label that indicates both the relation existing between the two entities and the direction of the relation. For example, a relation label can be in the form of either $r(e_1, e_2)$ or $r(e_2, e_1)$, where $r \in \mathcal{R} \cup \mathcal{S}$. To

make our explanations simpler, we assume that we are always predicting the relation from e_1 to e_2, and therefore for each $r \in \mathcal{R}$, we introduce a reversed relation label $\text{rev}(r)$ to capture the cases when relation r is from e_2 to e_1. For example, if r is *Cause-Effect*, then $\text{rev}(r)$ is *Effect-Cause*. In total, we have $2K$+L class labels, where $K = |\mathcal{R}|$ and $L = |\mathcal{S}|$. For the SemEval-2010 Task 8 data, we list all the $2 \times 9 + 1$ class labels in Table 1, where the $+1$ is for the case when there is no relation, denoted by *Other*. For the ACE-2005 data, all the $2 \times 5 + 2$ class labels are listed in Table 2, where $+2$ indicates the symmetric person-social relation and no relation, denoted by *PER-SOC* and *None*.

We further assume that each relation instance has two kinds of word representations. The first is the raw sequence (RSeq) representation, which consists of the sequence of words in the original sentence. The second is the shorted dependency path (SDP) representation, which is the shortest path from e_1 to e_2 in the dependency parse tree of the original sentence.

Let us use $\mathcal{V}$ to denote the vocabulary that contains all unique words in our dataset and $\mathcal{E}$ the set of directed dependency relation labels such as $\xrightarrow{\text{pobj}}$. The RSeq representation of a relation instance contains a sequence of words $(w_1, w_2, \ldots)$ where $w_i \in \mathcal{V}$. In addition, inspired by the work by Zeng et al. (2014), to tag the positions of e_1 and e_2, we assume that each word w_i in the sequence is associated with two position indices p_i and q_i, which indicate the relative distances of w_i from e_1 and e_2, respectively. Take the token "caused" in the previous *burst-pressure* sentence as an example. Since its relative distance to the two entities "burst" and "pressure" are 3 and -4 respectively, its two position indices are 3 and -4. We use $\mathcal{P}$ to denote the set of all possible position indices in our dataset.

The SDP representation can also be regarded as a sequence of tokens $(t_1, t_2, \ldots)$, where each token is either a word or a directed dependency relation, that is, $t_j \in \mathcal{V} \cup \mathcal{E}$. Similar to the RSeq representation, we also use the relative distances of t_j to e_1 and e_2 to indicate the positions of e_1 and e_2, namely c_j and d_j. The left side of the bottom layer of Figure 2 shows the RSeq and the SDP representations of the relation instance "The $[\textit{burst}]_{e_1}$ has been caused by water hammer $[\textit{pressure}]_{e_2}$."

Formally, we assume that we are given a set of labeled relation instances $\{(x^{(n)}, y^{(n)})\}_{n=1}^{N}$, where $y^{(n)}$ is a relation label and $x^{(n)}$ has two kinds of word representations: $\text{RSeq}(x^{(n)})$ and $\text{SDP}(x^{(n)})$.

2.2 Mirror Instance Method

Our first proposal is a new framework to model each relation instance by a pair of representations. The key idea is to first generate a *mirror* instance from each original relation instance, and then perform joint training and testing by making use of both the original and the mirror instances.

Our method is motivated by the observation that each relation instance can provide us with a pair of examples with opposite directions. For example, "The $[\textit{burst}]_{e_1}$ has been caused by water hammer $[\textit{pressure}]_{e_2}$." is an original relation instance and is labeled as *Effect-Cause*. If we swap the order of e_1 and e_2, then the resulting mirror instance "The $[\textit{burst}]_{e_2}$ has been caused by water hammer $[\textit{pressure}]_{e_1}$." should be labeled as *Cause-Effect*. Recall that in standard practice the relation labels *Cause-Effect* and *Effect-Cause* are treated as two unrelated relations. But intuitively these two relation labels are highly

Raw Sequence (RSeq)	Shortest Dependency Path (SDP)	Label
The [*burst*]$_{e_1}$ has been caused by water hammer [*pressure*]$_{e_2}$ -1 0 1 2 3 4 5 6 7 -8 -7 -6 -5 -4 -3 -2 -1 0	[*burst*]$_{e_1}$ $\xleftarrow{\text{nsubjpass}}$ caused $\xrightarrow{\text{prep}}$ by $\xrightarrow{\text{pobj}}$ [*pressure*]$_{e_2}$ 0 1 2 3 4 5 6 -6 -5 -4 -3 -2 -1 0	Effect-Cause
The [*burst*]$_{e_2}$ has been caused by water hammer [*pressure*]$_{e_1}$ -8 -7 -6 -5 -4 -3 -2 -1 0 -1 0 1 2 3 4 5 6 7	[*burst*]$_{e_2}$ $\xleftarrow{\text{nsubjpass}}$ caused $\xrightarrow{\text{prep}}$ by $\xrightarrow{\text{pobj}}$ [*pressure*]$_{e_1}$ -6 -5 -4 -3 -2 -1 0 0 1 2 3 4 5 6	Cause-Effect

Figure 1: An example of the representations of a mirror instance (in the bottom row) by our method.

related, and should not be independent of each other. By generating a mirror instance from each original instance, we can not only double the number of training data but also implicitly link the two labels r and $\mathrm{rev}(r)$. More importantly, for each testing instance, we can better identify its relation label based on its two representations.

For a relation instance x, let us use $\bar{x}$ to denote its mirror instance that we generate, and for a relation label y, let us use $\mathrm{rev}(y)$ to denote its *mirror label*, which is the reverse of y. Note that if y corresponds to a symmetric relation label, then $\mathrm{rev}(y)$ also corresponds to the same relation label.

Our mirror instance generation idea is inspired by the negative sampling method by Xu et al. (2015a) but our practice is fairly different. In their method, they only create a negative instance for each positive instance by reversing the original SDP, which will cause the expanded training set more biased to negative instances and thus largely reduce the recall of positive instances, whereas in our method, our generated mirror instances are not simply labeled as *Other* (or *None*) but labeled as a reversed relation from the original relation label. As a result, the class distribution of our generated *mirror* training set is almost the same as that of the original training set because of the *mirror* relationship between the original and *mirror* instances. More importantly, they simply expand the original training set with additional negative samples and their training process is the same as that in standard practice, while we propose a different pairwise relation classification framework in which the original and the mirror representations are jointly used for each relation instance.

Mirror Instance Generation

The next question is how we should construct RSeq($\bar{x}$) and SDP($\bar{x}$), the word representations of the mirror instance, such that we can use the same CNN architecture to learn the hidden sentence representations of these mirror instances.

For both SDP($\bar{x}$) and RSeq($\bar{x}$), although we could simply reverse the original representation as was done by Xu et al. (2015a), we feel that this would result in a completely reversed sentence or shortest dependency path that is unnatural. So we adopt the following way of constructing RSeq($\bar{x}$) and SDP($\bar{x}$). We leave the sequence of words untouched. For the position indices, since they are used to indicate the positions of the two entities, we simply swap the two position indices for each word such that the original e_1 now becomes e_2 and the original e_2 now becomes e_1. The bottom row of Figure 1 shows RSeq($\bar{x}$) and SDP($\bar{x}$) for the mirror instance "The [*burst*]$_{e_2}$ has been caused by water hammer [*pressure*]$_{e_1}$."

Pairwise Relation Classification

Training: Once it is clear how the RSeq and the SDP representations of a mirror instance are constructed, the next challenge is how to train with these pairs of original and mirror instances such that we can make a final prediction for each relation instance.

Essentially, in addition to the original training data $\{(x^{(n)}, y^{(n)})\}_{n=1}^{N}$, we now have additional N training instances $\{(\bar{x}^{(n)}, \mathrm{rev}(y^{(n)})\}_{n=1}^{N}$, where $\bar{x}^{(n)}$ is the mirror instance of $x^{(n)}$ and $\mathrm{rev}(\cdot)$ is as defined previously. Moreover, these pairs of original and mirror instances have a one-to-one correspondence relationship, and therefore there should not be any disagreement between their labels.

We therefore design the following loss function to capture two components. The first component is to

maximize the log-likelihood of both the original and the mirror instances as follows:

$$J_c = -\sum_{n=1}^{N} \Big(\log p(y^{(n)}|x^{(n)}; \mathbf{\Theta}) + \log p(\mathrm{rev}(y^{(n)})|\bar{x}^{(n)}; \mathbf{\Theta}') \Big), \quad (1)$$

where $\mathbf{\Theta}$ and $\mathbf{\Theta}'$ are two sets of parameters respectively in the CNN model of the original instances and the mirror instances, which will be detailed in Section 2.3.

However, the Eqn. (1) above still treats each label separately and cannot link $y^{(n)}$ and $\mathrm{rev}(y^{(n)})$ to capture the relations between $x^{(n)}$ and $\bar{x}^{(n)}$. Consequently, we further construct a one-to-one correspondence relationship between $(x^{(n)}, y^{(n)})$ and $(\bar{x}^{(n)}, \mathrm{rev}(y^{(n)}))$. Intuitively, for $(x^{(n)}, \bar{x}^{(n)})$, the probability of the final label being $y^{(n)}$ should be a weighted combination of the probability of $x^{(n)}$ being $y^{(n)}$ and the probability of $\bar{x}^{(n)}$ being $\mathrm{rev}(y^{(n)})$. We therefore introduce another parameter $\omega \in \mathbb{R}^{2K+L}$ as a weight vector to combine the likelihood of the original and the mirror instances. The loss function is given as follows:

$$J_f = -\sum_{n=1}^{N} \log \Big(\sigma(\omega_{y^{(n)}}) p(y^{(n)}|x^{(n)}; \mathbf{\Theta}) + (1 - \sigma(\omega_{y^{(n)}})) p(\mathrm{rev}(y^{(n)})|\bar{x}^{(n)}; \mathbf{\Theta}') \Big),$$

where $\sigma(\omega_{y^{(n)}}) = \frac{1}{1+e^{-\omega_{y^{(n)}}}}$ is a tradeoff weight between the probability of $x^{(n)}$ being $y^{(n)}$ and the probability of $\bar{x}^{(n)}$ being $\mathrm{rev}(y^{(n)})$.

Finally, we minimize $J_c + J_f$ as our overall objective function. Since the overall objective function consists of two components and each component is related to the other, we propose to jointly optimize them via stochastic gradient descent with shuffled mini-batches, based on the practice by Kim (2014). In our implementation, the learning rate of each parameter is scheduled by Adadelta (Zeiler, 2012) (ϵ = 10^{-1}, ρ = 0.95 for ω, and ϵ = 10^{-6}, ρ = 0.95 for $\mathbf{\Theta}$ and $\mathbf{\Theta}'$).

Testing: After training with pairs of original and mirror instances, during the testing stage, how to predict the label of a relation instance becomes straightforward. For a test instance x^t, we should again generate its mirror instance $\bar{x}^t$. Thereafter, we can obtain two class distributions by using the trained model, one from x^t and the other from $\bar{x}^t$. Let us use $c(x^t)$ to denote the former and $c(\bar{x}^t)$ the latter. Finally, we can obtain the final class distribution $c(x^t, \bar{x}^t)$ based on $c(x^t)$ and $c(\bar{x}^t)$:

$$c_k(x^t, \bar{x}^t) = \sigma(\omega_k) c_k(x^t) + (1 - \sigma(\omega_k)) c_{\mathrm{rev}(k)}(\bar{x}^t), \quad 1 \le k \le 2K + L,$$

where $c_k(x^t)$ and $c_{\mathrm{rev}(k)}(\bar{x}^t)$ represent the probability of x^t having the relation k and $\bar{x}^t$ having the relation $\mathrm{rev}(k)$ respectively, and $c_k(x^t, \bar{x}^t)$ denotes the probability of the pair of relation instances having the relation k. The final predicted label is the relation with the highest probability among $c(x^t, \bar{x}^t)$.

2.3 Our Combined CNN Model

Under the mirror instance based pairwise relation classification (MI) framework, we further target at learning better representations for both the original and the mirror instances. Motivated by the observation that the raw sequence and the dependency path representations highly complement each other, we propose to combine the RSeq and the SDP representations of each relation instance (either the original or the mirror instance) together based on the multi-channel CNN architecture by Kim (2014).

Figure 2 illustrates the whole architecture of the MI framework, which contains two proposed combined CNN models. Each model obtains hidden representations of both the raw sequence and the shortest dependency path of a relation instance and then concatenates them for relation classification. It consists of a lookup layer, a convolution-pooling layer and an MLP layer.

Lookup: The lookup layer maps the input sequences to real-valued embedding vectors. Let $\mathbf{W}_e \in \mathbb{R}^{d_1 \times |\mathcal{V} \cup \mathcal{E}|}$ denote the lookup table for words and directed dependency relations, where each

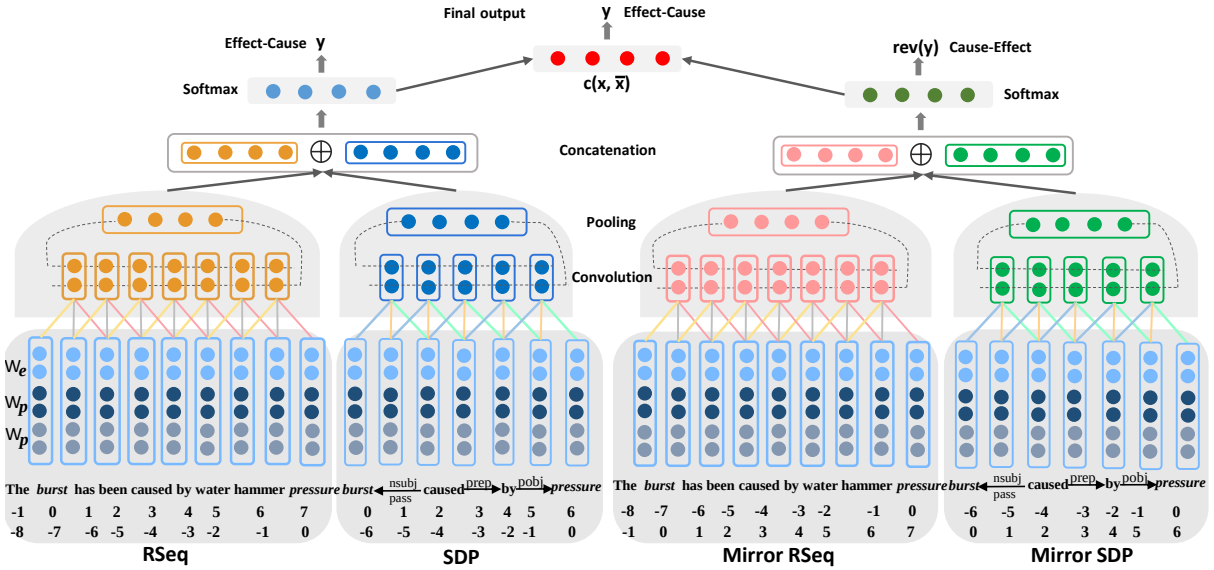

Figure 2: The architecture of the mirror instance based pairwise relation classification (MI) framework. The left and right components correspond to two combined CNN models (*Comb*) respectively for original instances and mirror instances.

column is a d_1-dimensional embedding vector for either a word in $\mathcal{V}$ or a dependency relation in $\mathcal{E}$. Let $\mathbf{W}_p \in \mathbb{R}^{d_2 \times |\mathcal{P}|}$ denote another lookup table for position indices, where each column is a d_2-dimensional embedding vector for a position index. Note that this position embedding idea is borrowed from the work by Zeng et al. (2014), and thus word representations of the raw sequence in our combined model is the same as theirs. After applying the lookup layer, both the RSeq and the SDP representations are transformed into a sequence of $(d_1 + 2d_2)$-dimensional vectors.

Convolution-Pooling: Two separate CNNs are used to process the RSeq representation and the SDP representation, and their mechanisms are the same. For each CNN, at position i of the original sequence, the embedding vectors inside a window of size n centered at i are concatenated into a new vector, which we refer to as $\mathbf{z}_i \in \mathbb{R}^d$. A convolution operation is then performed by applying a filter $\mathbf{F} \in \mathbb{R}^{h \times d}$ on $\mathbf{z}_i$ to produce a hidden vector $\mathbf{h}_i = g(\mathbf{F}\mathbf{z}_i + \mathbf{b})$, where $\mathbf{b} \in \mathbb{R}^h$ is a bias vector and g is a element-wise non-linear transformation function. Note that we pad the original sequence in front and at the back to ensure that at each position i we have n vectors to be combined into $\mathbf{h}_i$. After the convolution operation is applied to the whole sequence, we obtain $\mathbf{H} = [\mathbf{h}_1, \mathbf{h}_2, \ldots]$, and we apply a max-over-time pooling operator to take the maximum value of each row of $\mathbf{H}$ to obtain an overall hidden vector $\mathbf{h}^*$, which encodes the information from the entire sequence. Let $\mathbf{h}_r^*$ denote this hidden vector derived from RSeq and $\mathbf{h}_s^*$ the hidden vector derived from SDP.

MLP: The top layer of our model is a multilayer perceptron (MLP) with a softmax layer at the end to predict a $(2K + L)$-class distribution. This means the objective function for training our model is $J(\mathbf{\Theta}) = -\sum_{n=1}^{N} \log p(y^{(n)}|x^{(n)}; \mathbf{\Theta})$, where $\mathbf{\Theta}$ is the set of all model parameters including $\mathbf{W}_e$, $\mathbf{W}_p$, $\mathbf{F}$, $\mathbf{b}$ and the weights in the multilayer perceptron, $y^{(n)}$ is the true relation label for relation instance $x^{(n)}$, and $p(y^{(n)}|x^{(n)}; \mathbf{\Theta})$ is the probability of assigning $y^{(n)}$ to $x^{(n)}$ based on the softmax layer. As discussed in Section 2.2, in our implementation, the gradients are computed via back propagation.

3 Experiments

3.1 Dataset and Evaluation Metric

To evaluate our proposed method, we conduct our experiments on the SemEval-2010 Task 8 dataset and the English portion of the ACE-2005 dataset.

SemEval-2010 Task 8: This dataset contains 10,717 relation instances, including 8000 instances for training and 2717 for testing. Following Kim (2014), we randomly choose 10%, i.e., 800 of the training

instances as the development set. Following all previous work, we use the macro-averaged F_1 score to evaluate our model based on the SemEval-2010 Task 8 official scorer.

ACE-2005: This dataset consists of 6 domains: broadcast news (*bn*), newswire (*nw*), broadcast conversation (*bc*), telephone conversation (*cts*), weblogs (*wl*) and usenet (*un*). Following some previous work (Plank and Moschitti, 2013; Nguyen et al., 2015; Gormley et al., 2015), we consider a domain adaptation setting for coarse-grained relation extraction. Specifically, we take the union of *bn* and *nw* as the training set, half of *bc* as the development set, and the remainder (i.e., *cts* and *wl* as well as the other half of *bc*) as the test set. Following Plank and Moschitti (2013), we use the micro-averaged F_1 score to evaluate our model.

3.2 Experiment Settings

We use the pre-trained word embeddings from *word2vec*[1] to initialize the lookup table $\mathbf{W}_e$, and set the dimension d_1 to 300. For unknown words and directed dependency labels, we randomly initialize their 300-dimensional embedding vectors. We also randomly initialized the other lookup table of the position embeddings $\mathbf{W}_p$, and set the dimension d_2 to 50. Note that in our preliminary experiments for ACE-2005, we found that the performance without considering the entity types of the two entity mention heads is very limited. Hence, for ACE-2005, we also randomly initialize another lookup table of the entity type embeddings, whose dimension is set to 50, and represent each token by concatenating its word embedding, position embedding and entity embedding.

We want to compare our combined CNN model with models that use either RSeq or SDP alone, so we consider three experiment settings: *SDP* refers to a CNN model that uses only SDP representation of a relation instance, *RSeq* refers to a CNN model that uses only the RSeq, and *Comb* refers to our combined model. For each setting, we use the development set to tune the window size n and the dimension of the hidden states h. In a previous study by Nguyen and Grishman (2015), it was found that using multiple window sizes in CNN can bring significant improvements for the RSeq representation. We therefore also experiment with combining multiple window sizes for *RSeq* and *SDP*. In the end, we find that for *RSeq*, the optimal setting is to use a combination of windows with sizes 2, 3, 4 and 5 and to set h to 150. For *SDP*, the optimal setting is to use a single window of size 5 and to set h to 400. For *Comb*, we use the same window sizes and hidden sizes h as *RSeq* and *SDP*.

For the other parameters in $\mathbf{\Theta}$ and $\mathbf{\Theta}'$, we adopt the settings reported by Nguyen and Grishman (2015). That is, the non-linear transformation function g is $\tanh$, the mini-batch size is 50, the dropout rate α equals 0.5, and the hyperparameter for the l_2 norms is set to be 3.

3.3 Evaluation of our Proposed Approach

In this section, we evaluate the different components of our method.

Effect of the Mirror Instance Method

To evaluate the effect of the mirror instances, first, we apply the mirror instance method on top of the two baseline methods *RSeq* and *SDP*, and show the results on SemEval-2010 in Table 3 and the results

Table 7: Evaluation of our combined CNN model on ACE-2005.

on ACE-2005 in Table 6. We can see that with the help of the mirror instances, both *RSeq* and *SDP* can improve their performance in most cases, and the improvements are statistically significant. This indicates the usefulness of the mirror instances generated by our method.

The Combined CNN Model

To check the effect of combining RSeq and SDP representations, in Table 4 and Table 7, we compare *Comb* with *SDP* and *RSeq* on SemEval-2010 and ACE-2005 respectively. We can observe that *Comb* outperforms both *SDP* and *RSeq* on two datasets and the improvements are statistically significant. We can also see that the precision of *Comb* and that of the other two models are relatively close, especially on SemEval-2010, and the advantage of *Comb* is mainly from its recall. It suggests that the RSeq and the SDP representations complement each other and therefore can work better when combined.

The Combined CNN Model together with the Mirror Instance Method

We then apply our mirror instance method on top of *Comb*. In Table 5 and the top two rows of Table 9, we can observe that our mirror instance method (*Comb*+MI) can significantly improve the F_1 score of *Comb*, especially making high improvements in recall, which further verifies the usefulness of our mirror instance method.

Since the goal of our relation classification task is to improve the F_1 score for the positive relation types excluding the label *Other*, we further investigate the impact of reducing the number of mirror instances generated from the *Other* relation instances, i.e., the negative relation instances on SemEval-2010. By tuning the percentage of negative mirror instances to reduce, we achieve the best performance when reducing 50% of the negative mirror instances. We refer to this method as *Comb*+RMI and show its performance in Table 5 in the last row. We can see that it achieves a F_1 score of 84.96.

3.4 Comparison with the State of the Art

In this section, we compare our proposed method with all recently published results for SemEval-2010 Task 8 and ACE-2005.

SemEval-2010 Task 8: Since most existing studies have used additional hand-crafted linguistic features (AF) to help the classification task, we show two different F_1 scores, one with AF and one without in Table 8. It is easy to observe that without AF, Vu et al. (2016) obtained the best F_1 score of 84.9 by combining CNN and RNN models via a voting strategy; with AF, Xu et al. (2015b) achieved the best result with negative sampling and 8000 negative examples from the New York Times (NYT) dataset.

Method	Additional Features (AF)	F_1	
		with AF	without AF
SVM (Rink and Harabagiu, 2010)	POS, prefixes, morphological, WordNet, Levin classed, ProBank, FrameNet, NomLex-Plus, Google n-gram, paraphrases, TextRunner	82.2	-

FCM	-	-	-	66.6	57.9	61.9	65.6	44.3	52.9	57.8	44.6	50.4
Hybrid(FCM+Feat)	-	-	-	74.4	55.3	63.5	74.5	45.0	56.1	65.6	47.6	55.2
Hybrid(CNN+RNN+Feat)	69.3	66.3	***67.8***	65.8	66.5	***66.1***	63.6	51.7	57.0	56.4	57.2	***56.8***

Table 9: Evaluation of our combined CNN model together with the mirror instance method on ACE-2005. The results of the state-of-the-art systems are taken from Nguyen and Grishman (2016).

We can also see that without utilizing any AF, our *Comb*+RMI method can push the F_1 score to the state-of-the-art, 85.0. Furthermore, we also consider adding two kinds of lexical features to our model, namely, Named Entity type (NER) and WordNet hypernyms. We first obtain the NER features of all words and Wordnet hypernyms of the two entities using the tool developed by Ciaramita and Altun (2006). Then, we represent each token by concatenating its word embedding, position embedding and entity embedding. Finally, following the practice by Zeng et al. (2014), we also concatenate the Wordnet hypernyms of the two entities with the combined hidden vector. As we can see from the last line of Table 8, our method can achieve the state-of-the-art F_1 score, 85.7.

ACE-2005: In Table 9, it is easy for us to observe that on all three test domains, our proposed *Comb*+MI method can outperform the state-of-the-art single system FCM with a large margin, which combines traditional linguistic features with learned word embeddings by a log-bilinear model. In addition, we can also find that even in comparison with a competitive hybrid model, which integrates FCM and a traditional feature-based method, *Comb*+MI can still achieve slightly better performance on the *bc* and *cts* domains, and similar performance on the *wl* domain.

Recently, Nguyen and Grishman (2016) proposed an ensemble method by first combining CNN and RNN via a stacking strategy and then integrating it with a traditional feature-based method in a hyrid model. Although our result is slightly lower than Hybrid(CNN+RNN+Feat) on average, we believe that our model can be further improved with such an ensemble strategy, which we leave to our future work.

4 Related Work

Traditional work on relation classification can be categorized into feature-based methods and kernel-based methods. The former relies on a large number of human-designed features (Zhou et al., 2005; Jiang and Zhai, 2007; Li and Ji, 2014) while the latter leverages various kernels to implicitly explore a much larger feature space (Bunescu and Mooney, 2005; Nguyen et al., 2009). However, both methods suffer from error propagation problems and poor generalization abilities on unseen words. The most popular method to solve the two limitations is based on neural networks (NNs), which have been shown successful in extracting meaningful features and generalizing on unseen words for many NLP tasks (Kim, 2014). For relation classification, Socher et al. (2012) proposed a recursive matrix-vector model based on constituency parse trees. Zeng et al. (2014) and dos Santos et al. (2015) respectively proposed a standard and a ranking-based CNN model based on the raw word sequences. More recently, Xu et al. (2015b) and Miwa and Bansal (2016) respectively proposed a multi-channel sequential LSTM model and a bidirectional tree-LSTM model on the shortest dependency path for relation classification.

Although all these models have been shown to be effective, all of them only focus on learning a single representation for each relation instance. Different from all previous methods, we first design a strategy to generate a mirror instance from each original relation instance and then propose a pairwise relation classification framework to learn a pair of representations for each relation instance.

On the other hand, most existing NN-based approaches for relation classification are either based on the shortest dependency path or the raw sequence, although these two representations may complement each other. In this work, we propose to combine them together based on the multi-channel CNN architecture (Kim, 2014), aiming to capture long-distance relations without losing any information.

5 Conclusions

In this paper, we first proposed a mirror instance method to learn a pair of representations for each instance, which basically includes a mirror instance generation strategy and a pairwise relation classification framework. Based on this, we further proposed a combined CNN model based on both the RSeq and the SDP representations of relation instances. Our experimental results demonstrate that our mirror instance method can improve the baseline models and our combined model without mirror instances, and our combined CNN model is more effective than models only using the RSeq or the SDP representation of relation instances. Finally, with the help of some lexical features, our combined CNN model together with the mirror instance method achieves the state-of-the-art result on SemEval-2010 and highly competitive results on ACE-2005.

Abstract

Answer selection is a core component in any question-answering systems. It aims to select correct answer sentences for a given question from a pool of candidate sentences. In recent years, many deep learning methods have been proposed and shown excellent results for this task. However, these methods typically require extensive parameter (and hyper-parameter) tuning, which gives rise to efficiency issues for large-scale datasets, and potentially makes them less portable across new datasets and domains (as re-tuning is usually required). In this paper, we propose an extremely efficient hybrid model (*FastHybrid*) that tackles the problem from both an accuracy and scalability point of view. *FastHybrid* is a light-weight model that requires little tuning and adaptation across different domains. It combines a fast deep model (which will be introduced in the method section) with an initial information retrieval model to effectively and efficiently handle answer selection. We introduce a new efficient attention mechanism in the hybrid model and demonstrate its effectiveness on several QA datasets. Experimental results show that although the hybrid uses no training data, its accuracy is often on-par with supervised deep learning techniques, while significantly reducing training and tuning costs across different domains.

1 Introduction

Open-domain question answering (QA) aims to serve a user's information request by returning a list of direct answers. This problem has been receiving an increasingly amount of attention in the NLP and machine learning communities in the recent years (Ferrucci et al., 2012; Etzioni et al., 2011). Answer sentence selection (Yih et al., 2013; Tan et al., 2016; Yu et al., 2014; Severyn et al., 2013), which, given a user question, returns the correct sentences that contain the exact answer, is a core component in QA systems. The performance of QA systems critically depends on choosing the right candidate sentences which facilitate the extraction of final answers.

To be successful, in addition to accuracy, real-world systems must be scalable and select the most accurate answer sentences in a short amount of time. However, accuracy and speed/scalability are competing forces that often counteract each other. It is often the case that methods developed for improving accuracy incur moderate-to-large computational costs. For example, models based on neural networks have become very popular due to their strong accuracy for this task (Yu et al., 2014). However, they are typically slower at training and test time as compared to simple models, which may limit their use on very large datasets (Joulin et al., 2016). The speed issue is particularly important when working with new domains and datasets, as the model may have to be re-trained or adapted for the new dataset. Model re-training and adaptations, even with incremental techniques (Zhou et al., 2012; Chopra et al., 2013; Glorot et al., 2011) on state-of-the-art hardware (Chilimbi et al., 2014; Xing et al., 2015), could be prohibitively inefficient when working with time-critical applications or an impatient end-user – who may prefer a method with minimum (or no) training time spent, *and* getting similar accuracy as the expensively trained models.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2378–2388, Osaka, Japan, December 11-17 2016.

On the other hand, classical information retrieval (IR) models are extremely fast as compared to the deep models, but may not be as quite accurate. IR models use fast word matching features (e.g., unigram, bigram overlaps between question and answer) to quickly score candidate sentences. Typically no training is necessary, since these simple models are fairly robust and can be applied to different datasets without modification (Tao et al., 2007; Bendersky et al., 2010; Buttcher et al., 2006). This property makes them attractive for scaling to large number of new domains and datasets.

In this paper, we take a step to eliminate the virtual dichotomy between accuracy and scalability/speed by developing a hybrid model that is simultaneously effective (as the deep models) and extremely efficient at training and test time (as the simple models). We name our proposed structure *FastHybrid*. We introduce the concept of a fast (deep) model in Section 3, then describe the *FastHybrid* model which combines IR with the proposed fast (deep) model for the best possible accuracy and training speed.

Unlike many other deep learning models, the fast deep model skips the intermediate convolution steps altogether, and directly operates on the raw word vectors coming from the answer and a slightly modified question text, constructed from a simple attention approach we propose in Section 3.2, to perform standard pooling operations. The simple attention in the fast deep model (Section 3.2) works by focusing explicitly on the question's influence on the answer with respect to the answer's representation. While seemingly, important information from convolution may get lost, however, with the new simple attention, our model often beats its expectations – not only does it perform well for time, but for accuracy equally.

The fast deep model is combined with an IR model via a hybrid structure to handle answer selection accurately and efficiently. The IR model is used to create an initial ranking of candidate sentences, and for the questions that cannot be handled well by IR, the fast deep model is applied. The hybrid structure leverages complementary strengths by IR and the fast model (both in terms of accuracy and speed), as will be discussed in Section 3.4.

Our model is nearly hyper-parameter/parameter-free, so it is extremely efficient (no training) for different datasets, and as a result, it can scale very easily to a large number of new domains and users. The remainder of the paper is organized as follows: we start with a discussion of related work, Section 3 describes our fast model and the hybrid approach, and our methods are evaluated in Section 4, before discussing future work and concluding.

2 Related work

In recent years, the problem of answer selection, which is a sub-problem in question-answering, has been getting a lot of attention in the research community (Yih et al., 2013; Tan et al., 2016; Yu et al., 2014; Severyn et al., 2013). Moving away from the shallow word-level features, these deep learning approaches focus on extracting important features from low-level representations (word embeddings) by using various types of deep neural networks (Graves et al., 2013; Hochreiter et al., 1997). The resulting models can effectively work at a semantic-level (i.e., can match a correct answer with a question even if they do not have any words in common, however semantically related). This can be viewed as a big improvement in comparison to the standard information retrieval approaches for the same task, which typically use hand-crafted word matching features.

However, from an efficiency's point of view, the deep models are very time-consuming to train. In particular, to achieve good success, the models typically require a large number of parameters and weights, making parameter (and hyper-parameter) tuning an expensive process for large-scale applications. While many remedies have been proposed to address the efficiency issue, ranging from developing fast training hardwares (Chilimbi et al., 2014) to parameter sharing and simplifying model structures, in comparison to standard simple IR approaches (Tao et al., 2007; Bendersky et al., 2010; Buttcher et al., 2006), the training efficiency and scalability of these methods still significantly lack behind.

This issue is particularly significant when we have to adapt the model repeatedly for new domains. While domain-adaptation techniques have been proposed for many deep learning models (Chopra et al., 2013; Zhou et al., 2012; Ganin et al., 2015; Sun et al., 2016), the focus and starting point of these work have largely been on how to adjust the models for accuracy, rather than from an accuracy and scalability point of view.

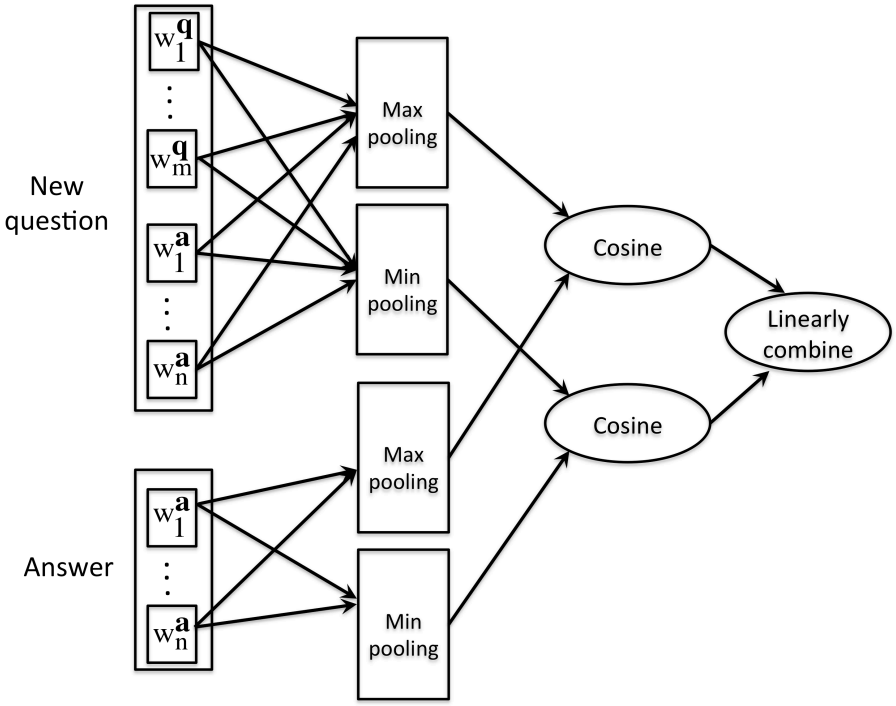

Figure 1: Model architecture for simplified deep learning model (a.k.a. fast model)

3 Methods

In this section, we describe our proposed hybrid model, *FastHybrid*, for effective and efficient answer selection. It combines a fast (deep) model[1] with an initial IR model to create an efficient and effective overall structure for this task.

A major area that distinguishes our work from the past deep learning models is that we directly operate on the raw word embedding vectors to perform standard aggregation operations (e.g., max, min-pooling) before computing similarity scores (Section 3.3). We completely discard the convolution operations used by many other deep models altogether. With the simple attention (Section 3.2) used by the fast model, our system is orders of magnitude faster in training than the standard deep models, while performing well for accuracy equally. We begin with a quick overview of the preliminary background on the Word2Vec embedding, then focus on the fast (deep) model in Section 3.2 and Section 3.3, before discussing the hybrid structure in Section 3.4.

3.1 Word2Vec Embedding

Recently (Mikolov et al., 2013) introduced *word2vec*, a word-embedding procedure. They use a shallow neural network language model to learn a vector representation for each word. More specifically, a neural network architecture (the skip-gram model) is proposed and consists of an input layer, a projection layer, and an output layer to predict words nearby. Each word vector is trained to maximize the log probability of neighboring words in a corpus. That is, given a sequence of words $w_1, \ldots, w_Z$,

$$\frac{1}{Z} = \sum_{z=1}^{Z} \sum_{i \in nb(z)} log\ p(w_i|w_z)$$

[1]We slightly abuse terminology and refer to it as a fast (deep) model. Note no convolution filters etc (representative of standard deep models) are used. We use this name mostly for comparison purpose with the state-of-the-arts deep learning models.

where $nb(z)$ denotes the set of neighboring words of w_z and $p(w_i|w_z)$ denotes the hierarchical softmax of the associated word vectors $\mathbf{v}_{w_z}$ and $\mathbf{v}_{w_t}$ (see (Mikolov et al., 2013) for more details). Due to the simple architecture and the use of hierarchical softmax, the skip-gram model can be trained on billions of words per hour using a conventional desktop computer. It is unsupervised to learn the word embeddings and it can be computed on the corpus of interest or pre-trained in advance. Note our framework is not limited to a particular type of word embeddings, any commonly-used embeddings for text can be substituted into our framework.

3.2 Efficient simple attention

Attention mechanisms (Mnih et al., 2014) have been shown to be useful in deep learning models. They help guide pooling to be more cognizant of the key answer tokens relative to the question. While useful, using attention brings another layer of complexity, more model parameters, hence longer training time.

In this section, we ask the question – can we design a more efficient attention method in the fast model that does not require additional parameters yet achieves good results? The answer is in the affirmative. Our new attention strategy in the fast model is extremely simple (only 1 line of code!), however, it is surprisingly effective. For a pair of question and answer, we replace the question text by an augmented version of the question, which is formed by a simple *concatenation* of the original question and the given answer. This exact process is illustrated by the left side in Figure 1, where each w_m^q denotes a word in the question q, and w_n^a is a word in the answer a. The new question consists of the combined tokens from the question and answer. A look-up on word-embeddings is then performed to get the corresponding word vectors for the new question tokens. Then max- and min-pooling will be performed (details in the next section) on these word vectors. The final cosine score will be computed between the new question and the answer. Note on the answer side, the representation of the answer text stays intact (i.e., a lookup on word vectors of the original answer tokens is performed, and the vectors are passed to the pooling stage).

Why do we call this simple strategy an *attention* mechanism? Adding question q's tokens into the answer will "corrupt" the answer's representation and the subsequent max- and min-pooling results of the answer, by *biasing* the answer's representation towards q's semantic meaning. Intuitively, if the answer is correct for q, then they are semantically identical, in which case the "corruption" of the answer a by q should not change the answer's semantic meaning, and the subsequent cosine similarity between the answer a and the combined text should be very close to one (i.e., strong similarity). One the other hand, if the answer is incorrect for q, they are semantically different, the corruption of a by q will make the answer's representation drastically different from its original, forcing the cosine score with its original representation far from one.

The simple "corruption" by q can be viewed as an *attention* placed on the answer, by *focusing explicitly* on q's influence on the answer with respect to the answer's original representation. This is exactly what is captured by Figure 1. The new question can be viewed as a corrupted version of a (by adding q's tokens into it), and after the subsequent pooling operations, cosine similarities between the original answer's representation and the new corrupted version are computed.

3.3 Pooling and similarity computation

The next step in the fast model is the max- and min-pooling as shown in Figure 1. They are directly performed on word vectors from the answer and the modified question to form one-dimensional vector representations. The pooling is performed along each dimension in the word vector, over the tokens in the input text.

We can think of max-pooling as a way for the model to ask whether a given semantic class is found anywhere in the input text, while the min-pooling captures the absence of it. Both pooling techniques have been used before in deep learning applications. In this work, each pooling is used to create a pair of representations for the inputs, from which a cosine similarity score is derived. The resulting two cosine similarity scores (based on two pooling strategies) are then combined via a weighted linear combination to form a final score for the answer:

$$Score(a) = w \cdot cosine(v_{max}^{q'}, v_{max}^{a}) + (1 - w) \cdot cosine(v_{min}^{q'}, v_{min}^{a})$$

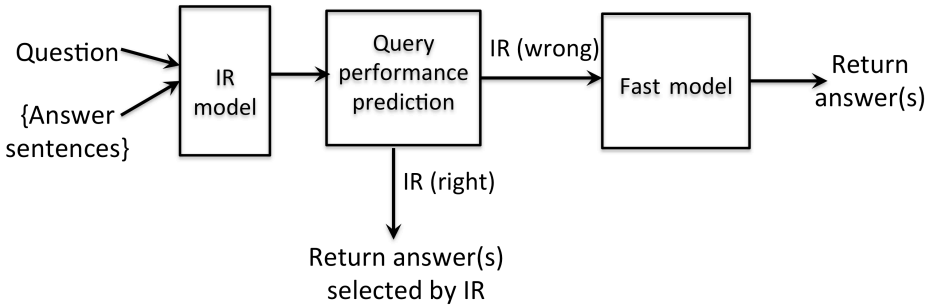

Figure 2: Hybrid approach combining IR with fast, simplified deep model (Figure 1)

where vectors $v_{max}^{q'}$ and v_{max}^{a} denote the outcome of max-pooling performed on the inputs (i.e., answer a and the augmented question q'). The vectors $v_{min}^{q'}$ and v_{min}^{a} are similarly defined. The single weight w in the linear combination is empirically set. We found in practice, this weight is fairly robust and insensitive to different datasets. In this work, it is simply set to a constant ($w = 0.7$) and does not change from datasets to datasets. Finally, $Score(a)$ is the score used to rank each candidate answer for the given question, and the one with the highest score is chosen as the best answer by this model.

3.4 Hybrid structure

A hybrid structure is used to combine the fast model with an IR retrieval model. In this work, we use the IR retrieval model in (Bendersky et al., 2010), which has shown dominant performance in a number of text and sentence retrieval tasks. The hybrid model is shown in Figure 2. It leverages complementary strengths of the IR model and the fast model. For accuracy, the IR retrieval model and the fast model each can cover a unique population of the questions. For example, the IR retrieval model excels at exact matching of the question with answer terms, if the answer contains sufficient word overlaps with the question. Predictably, a decent fraction of questions and answers may fall into this category, given the past wide usage and success of such retrieval models (Tao et al., 2007; Bendersky et al., 2010; Buttcher et al., 2006) for answer selection and retrieval. On the other hand, some correct answers may not share any words with the question, and in this situation, the fast model, which works from a semantic level, can be put into use.

A key component in the hybrid model is deciding when to return the IR results, and when to forward it to the fast model for scoring. This problem is formulated as "query performance prediction" (QPP), previously studied by the retrieval community (He et al., 2005; Hauff et al., 2009). A predictive model (usually of the form of a logistic regression) is used to predict the accuracy of the initial results for a given question, based on statistics extracted from IR answer scores for the question, such as the separation (ratio) between the maximum and minimum answer scores, etc. In this work, we follow the work by (He et al., 2005) to build the query performance prediction model, which is used to direct a question to either the fast model or return the IR results. It is beyond the scope of our paper to detail the QPP approach; we refer interested readers to (He et al., 2005) for more details about query performance prediction.

Finally, we would like to point out the entire pipeline is hyper-parameter free, relieving the need for expensive hyper-parameters tuning. This property allows our model to work with new domains and datasets more seamlessly – reducing the workload in model tuning.

4 Experiments

In this section we present a comprehensive set of experiments over three QA datasets: WikiQA, TrecQA, and InsuranceQA. WikiQA (Yang et al., 2015) is an open domain question-answering dataset. We use the subtask that assumes that there is at least one correct answer for a question. The TrecQA dataset was created based on TREC QA task (8-13) data (Voorhees et al., 2000). We follow the exact approach of train/dev/test question selections as in (Wang et al., 2015). InsuranceQA(v2)[2] is a recently released

[2]git clone https://github.com/shuzi/insuranceQA.git

	WikiQA	TrecQA	InsuranceQA(v2)
Train (# questions)	873	1162	12,889
Dev (# questions)	126	65	2000
Test (# questions)	243	68	2000
Avg # cand answers	9	38	500

Table 1: Dataset statistics: WikiQA, TrecQA, and InsuranceQA(v2)

large-scale non-factoid QA dataset from the insurance domain, which has drawn interests from the deep learning community for studying answer selections.

The statistics of these datasets are given in Table 1, including the number of questions, and the average number of candidate answers in the train/dev/test set. We study the following methods in our experiments:

- **IR retrieval model (Bendersky et al., 2010).** This IR model utilizes unigram and bigram overlaps between the question and answer, and represents the state-of-the-art in the IR field for effective answer selection and text retrieval (Bendersky et al., 2010). Similar to our approach, this model requires no training and it is applied the same way for all datasets.

- **FastHybrid**. The proposed hybrid model (Section 3) does not require any training. The tunable parameter (the weight w in the linear combination of cosine scores) is empirically set to 0.7 and stays the same for all datasets. Thus, the training and dev sets are not used by the hybrid model. In addition, the model uses standard word embedding vectors[3] trained from the Wikiepdia[4] and Gigaword [5] data collections. Although we do not re-train the word-embeddings and use the same pre-trained embeddings for all datasets, we could potentially re-train it on each dataset to achieve higher accuracy performance than reported here.

- **Supervised background models**. Since model scalability and efficiency are an issue, for supervised models, rather than re-training them for each new QA dataset, we could instead just train them on a big background dataset containing examples representative of the individual datasets, then apply the trained model to each QA data without re-training. This strategy refrains from repeated training, and scales better to large number of domains – thus, it serves as a direct comparison point to the hybrid model in the experiments. Here we use the Yahoo! answers dataset[6], which is a large Q&A corpus from which we extracted question-answer pairs as the training data. As the training method, we use two state-of-the-arts deep learning models (Feng et al., 2015; Santos et al., 2016), which apply convolutional neural networks to extract meaningful representations for each question and answer pair (Feng et al., 2015), and utilize bidirectional attentions on the questions and answers to enhance answer selection accuracy (Santos et al., 2016). We denote these two supervised background models as *Supervised background-1* and *Supervised background-2*, from applying (Feng et al., 2015) and (Santos et al., 2016) to the Yahoo background corpus, respectively.

- **Deep learning methods for answer selection**. As mentioned earlier, there is a recent surge on applying deep learning for answer selection. To be maximally effective, these techniques typically require in-domain training data for large-scale parameter tuning. Although our end goal is clearly different from that of standard in-domain supervised deep learning – we approach the problem from an accuracy *and* scalability point of view and develop light-weight models which require little tuning and adaptation across different domains – we present their results for completeness purpose whenever appropriate. As we will see, although the hybrid model uses no training data, its accuracy is often on-par (and sometimes slightly better) than supervised deep learning methods trained with in-domain data (Santos et al., 2016; Feng et al., 2015). This point echoes a similar observation made recently by related work on classification (Joulin et al., 2016).

Supervised background-2 model	6h/180K question-answer pairs		
FastHybrid	no training (0s)	no training (0s)	no training (0s)

Table 3: Training time on three QA datasets.

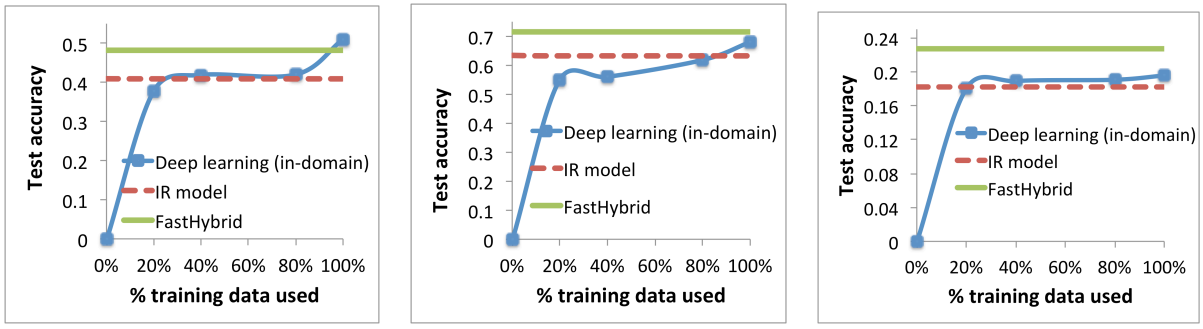
All experiments were run on a NVIDIA Tesla K20Xm GPU processor, with memory size per board (GDDR5) 5GB.

4.1 Model accuracy

Table 2 presents the top-1 accuracy for each QA domain test set[7]. Among the four comparison methods, IR and *FastHybrid* incur no training time (since no training is needed), while the supervised background models are trained on the large-scale background Yahoo Q&A corpus. We see that the hybrid model consistently achieves better accuracies for all QA domains in comparison to other techniques. An interesting observation is that while the hybrid model is simple, it is more robust than the supervised background models. For example, while in WikiQA and InsuranceQA, the supervised background models achieve decent performance relative to IR and *FastHybrid*, in TrecQA, their performance drops significantly (at 61.7%, and 60.2%, respectively) with respect to the hybrid model (71.5%). While utilizing the same training and tuning mechanism as the state-of-the-arts deep learning techniques (in terms of parameter tuning etc), it cannot make up for the domain gap between the TrecQA domain and the background Yahoo! Q&A corpus used as the training data. This points out that while the supervised background models can save some training time by doing a one-time offline training, it may potentially and significantly hurt the accuracy of new domains not well represented by the background corpus. This contrasts with the hybrid model, which aims to simultaneously achieve better efficiency, scalability, while not hurting accuracy.

Furthermore, while we try to build models that can scale to large number of domains more quickly and easily – a departure from standard in-domain supervised techniques (which can be used as an accuracy upper-bound), in many cases the hybrid model performs on-par with these methods for accuracy. As we will see in Section 4.3, the hybrid model (not using any training data) slightly outperforms supervised deep models (Feng et al., 2015) from in-domain training for two out of three datasets, while being significantly faster and more scalable – a highly desirable property for large-scale real-world applications. Note our original goal was to achieve no significant loss in accuracy while reducing costs. It is interesting

[7]Top-1 accuracy is one of the most commonly-used metrics to evaluate answer selection and question-answering. Other metrics include MRR (Radev et al., 2002) and MAP (Baeza-Yates et al., 1999). Since in this paper we focus on getting a correct answer rather than the entire ranking of answers, top-1 accuracy is reported.



(i) WikiQA (ii) TrecQA (iii) InsuranceQA(v2)

Figure 3: Top-1 test accuracy as the training dataset size is being varied from 0% to 100% of its original, in increments of 20%, for three QA datasets (i) WikiQA; (ii) TrecQA; and (iii) InsuranceQA(v2).

to see that the hybrid can surpass the expectation, and not only performs well for time, but for accuracy equally. This confirms our earlier observation that the simple attention mechanism used by the model works quite well in practice.

4.2 Training time

Table 3 presents the training time for each model. As mentioned earlier, all training and test experiments were carried out on a NVIDIA Tesla K20Xm GPU. As expected, both the IR model and *FastHybrid* are highly efficient. The supervised background models are more expensive, since they have to be trained on a large-scale background corpus. We note the training times of the supervised background models depend on the values of their hyper-parameters (e.g., # convolution filters, context window size etc). They are set in accordance to the settings used by the authors of these deep learning models. We also note that the supervised background models only have to be trained once. This is significant when we want to scale to a large number new domains (e.g., in the order of thousands). The saving in time across these many domains can add up to be quite noticeable. Nonetheless, when taking both accuracy and scalability/efficiency into account, we would like to have a model that has a higher accuracy yet not incurring too much costs (in training, tuning etc.), which is achieved by the hybrid model.

4.3 Test accuracy vs training set size

Next, we would like to ask the question – assume we follow the standard supervised setup where in-domain training data is used to train a model each time, can we improve deep learning model training efficiency by using a reduced set of the data and achieve similar test accuracy as using the full training set? Figure 3 and Figure 4 explore the effects of in-domain training set size on test accuracy and training time, respectively. Figure 3 shows the test accuracy as a function of the amount of training data used, and each reduced training set is a random sample from the full training data (i.e., sampled at 20%, ..., 80% of the full set). Figure 4 reports the corresponding training efficiency achieved at each training set size. Note it is clear for IR and the *FastHybrid*, they reside along the x-axis in Figure 4 which denotes their constant (0) training time.

Given the results shown earlier (Table 2) where the deep learning training method (Feng et al., 2015), when applied to the Yahoo background corpus (supervised background-1), slightly outperforms supervised background-2, we employ (Feng et al., 2015) for in-domain training, denoted by "Deep learning (in-domain)" in Figure 3 and Figure 4. Note at 100% training data, this represents a standard in-domain supervised deep learning model. As we can see from Figure 3, the hybrid model achieves equal/better accuracies for two out of three datasets (TrecQA and InsuranceQA), as compared to the supervised in-domain deep learning model from using *full* training data. Furthermore, for the deep learning model, it is clear that reduced training sets lead to much improved training efficiency. For example, at 20% of the original training set size (Figure 4), its training time drops to 0.35h, 0.75h, and 1.77h for WikiQA, TrecQA, and InsuranceQA, respectively – a decent improvement over its original time (1.21h, 3.3h, 4.6h, respectively). However, the enhanced training efficiency comes at a cost of reduced test accuracy. As

Figure 4: Training time as the training dataset size is being varied from 0% to 100% of its original, in increments of 20%, for three QA datasets (i) WikiQA; (ii) TrecQA; and (iii) InsuranceQA(v2).

shown by Figure 3, when no training data is used, its test accuracy drops to 0%. In the future, it would be interesting to look into how to deal with very few training data for these techniques, a problem that has been drawing much interest recently (Socher et al., 2013; Romera-Paredes et al., 2015; Palatucci et al., 2014; Ba et al., 2015).

5 Conclusion

In this work, we have developed the *FastHybrid* model, a hybrid model which combines a fast model with an IR model to form an efficient and effective hybrid structure for the answer selection task. Unlike the previous deep learning models for this task, our hybrid model is nearly hyper-parameter/parameter-free, so it is extremely efficient (no training) for different datasets, and as a result, it can scale very easily to a large number of new domains and users. We performed a set of extensive experimental studies that demonstrate both the accuracy and training efficiency of our new method, as compared to several strong baselines noted for their accuracy and efficiency. In the future, we plan to explore applying this model to related tasks such as recommendation. In addition, we are interested in building and plugging in additional query performance prediction (QPP) models into our hybrid model.

Abstract

A spatial information extraction system retrieves spatial entities and their relationships for geological searches and reasoning. Spatial information systems have been developed mainly for English text, e.g., through the SpaceEval competition. Some of the techniques are useful but not directly applicable to Korean text, because of linguistic differences and the lack of language resources. In this paper, we propose a Korean spatial entity extraction model and a spatial relation extraction model; the spatial entity extraction model uses word vectors to alleviate the over generation and the spatial relation extraction model uses dependency parse labels to find the proper arguments in relations. Experiments with Korean text show that the two models are effective for spatial information extraction.

1 Introduction

A spatial information extraction system retrieves spatially related lexical items and their relationships and then provides the information in a normalized form. This information is used for geological searches and reasoning, and ultimately, for understanding natural language text. For example, from the spatial relations that A is on B and B is on C, a human can simply infer the fact that A is on C. A spatial information extraction system retrieves the relations 'on (A, B)' and 'on (B, C)' from the text; then, a reasoning program can infer the relation 'on (A, C)' from the relations. This enables the system to build a knowledge base with a compact size from text for many intelligent systems such as robot navigation and question-answering systems.

A spatial information extraction task is usually carried out by two sub tasks: spatial entity extraction and spatial relation extraction. Because spatial entity extraction retrieves the entities to be used for spatial relationships, it is different from a place extraction task in named entity recognition systems (Lee et al. 2011), which only retrieves place-related entities. This implies that spatial entity extraction deals with all of the entities involved in spatial relations, such as trajectors, landmarks, and spatial signals. Moreover, spatial signals are usually articles or particles that do not have explicit arguments for spatial relations. Whether some entities or relations are extracted or not depends on the semantic roles in a sentence, which makes the task more complicated and challenging.

Many spatial information extraction systems have been developed for English text, especially those developed through the competition at the SpaceEval conference (Pustejovsky et al. 2015). The application of the techniques directly to Korean text is not simple because of its different linguistic features. The Korean language is a morphologically rich and agglutinative language, which is very different from English (Kim et al. 2016). Moreover, because Korean has a relatively free word order and words are frequently omitted, the order of neighboring words does not always have a significant meaning as in English, where it plays an important role in spatial word classification.

In this paper, we propose two models to extract spatial entities and spatial relations in Korean text. For entity extraction, an ensemble model is used to boost recall, and word vectors are used to tune the results for precision. For relation extraction, a sequence of the dependency labels from the trigger to the argument is used to calculate the argument probability. All of these extraction tasks are based on the ISO-Space mark-up scheme (Pustejovsky et al. 2015). In section 2, related works are briefly reviewed.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2389–2396, Osaka, Japan, December 11-17 2016.

The entity extraction method using GloVe word vectors (Pennington et al. 2014) and the relation extraction method using a Bayesian probability follow in sections 3 and 4, respectively. A discussion of the experiments and the conclusions follow in sections 5 and 6, respectively.

2 Related Works

There are generally two approaches to spatial entity extraction, similar to other natural language processing tasks: rule-based and data-driven approaches. The performance of a rule-based approach heavily depends on how much the dictionary covers the open words and how much the rule reflects the linguistic features. This approach usually needs a considerable amount of human labor to encode the rules and fill the dictionary entries manually. Moreover, it is language and domain dependent.

A data-driven approach uses machine learning tools such as CRFs and SVM. A spatial entity extraction task is considered to be a task of sequence labeling, which is solved by using CRFs (Kordjamshidi et al. 2010, Pustejovsky et al. 2015, Roberts and Harabagium 2012, Nichols and Botros 2015) and SVM (Bastianelli et al 2013). Data-driven approaches performed better than rule-based approaches in general and are easily portable to other domains.

The common features for spatial entity extraction based on machine learning are morphemes, named entities, word dependencies, semantic roles, and semantic information such as a WordNet category. Semantic information contributes to the performance. As resources such as WordNet are not easily available to many languages yet, word vectors were used by Bastianelli et al. (2013) and Nichols and Botros (2015), which are generated from a large raw corpus. The word vectors were used to provide semantic information as fine-grained lexical representations and clustered numbers. A spatial entity extraction system for Korean text has been developed by Kim et al. (2015) using a CRFs model, where morphemes, named entities, and parsing results are used as the features. It is based on the SpRL scheme corpus, and preliminary results were provided: with the test using 1,753 annotated sentences from Wikipedia, it was reported that the average F1 score of the entities is 0.610, whereas that of spatial relations is 0.318. As the entities and relations of the annotation scheme in ISO space are different, they are not compared directly to this paper's result.

Dependency parsing results are used for relation extraction. Cross et al. (2011) and Bastianelli et al. (2013) used a parse tree to construct a GRCT (Grammatical Relation Centered Tree) graph for an SVM tree kernel. Jeong et al. (2011) and Kwak et al. (2013) used dependency structures for the relation extraction of Korean sentences; the former used a composite kernel to extract general relations, and the latter built rules to extract spatial relations.

3 Entity Extraction

3.1 Base model

We define a base model called the E1 model, which incorporates the useful features used in prior systems that are applicable to the Korean language. Moreover, we have added more features to improve the performance, such as language-specific features, word phrase spacing, and morpheme-POS (part of speech) tag vectors. For describing the features for the base model, we define the acronyms for the feature description in Table 1. All of the CRFs features for the base model are defined in Table 2 using the acronyms, where a letter means an acronym defined in Table 1, and the attached number is the size of window. For example, MT3 means 'morpheme and POS tag pairs within a 3-morpheme window.' (We use a morpheme window here instead of word window in English text.)

Table 1. Acronyms for the feature elements.

M: morpheme	D: dependency label
T: part of speech tag	H: head's dependency label
B: BI tag of a word phrase spacing	W: main morpheme-POS tag of head
S: sense number of a morpheme	V: cluster number of a morpheme-POS tag vector
N: named entity tag	C: cluster number of the head's morpheme-POS tag vector

Fig 1. Examples of element features shown in vertical forms and composite features.

3.2 Ensemble model

As the Korean spatial tagged corpus is not large and not well-balanced, machine learning programs such as CRFs are not learned properly. Therefore, we use multiple sub models to overcome the skewness in the data distribution. We assigned the respective features to each entity type, as summarized in Table 3. After testing a candidate with multiple sub models of each entity type, the results are simply accumulated. This is called the E2 model, and this is an interim model for the following final model.

Table 3. Features of each sub model for the CRFs in the E2 model.

Entity type	Feature list
PLACE, PATH	M3, T3, MT3, MM3, TT3, MS3, B3, N3, V3
SPATIAL_ENTITY	M3, T3, MT3, MM3, TT3, MS3, B3
MOTION	M3, T3, MM3, TT3, MS3, B3, V3, D1
MOTION_SIGNAL	M3, T3, MM3, TT3, H1, W1, C1
SPATIAL_SIGNAL	M3, T3, MM3, TT3, N3, H1, W1, C1
MEASURE	M5, T5, MM3, TT3, N3, V3

3.3 Ensemble model using word vectors

As the multiple sub models still produce many false entities, a word vector is used to filter them. The idea is that the common characteristics of entities can be represented in entity tag vectors by summing all of the word vectors learned from the training corpus. The entity tag vectors are used later during testing to check the validity of the candidate entity vectors. Eq. 1 expresses a formula used for the entity tag vector calculation, where the function f converts w_i into a vector representation, and eq. 2 expresses an equation used for the validation method during testing, where θ is the minimum cosine similarity between the entity tag vector (centroid) and a tagged word vector (instance), which is determined during training.

The vectors for the spatial entities are the word vectors of the entities themselves in the training data, as expressed in eq. 3. The function *w2v* converts an argument word into a vector representation using deep learning programs such as GloVe (Pennington et al. 2014). However, the vectors of the signal entities are the context word vectors of the signal words, as expressed in eq. 4, because the Korean

signals are usually particles, which are too general to be characterized for tag vectors. We propose this model for spatial entity extraction and call it the E3 model.

$$\overrightarrow{STag_j} = \frac{1}{N}\sum_{i=1}^{N} f(w_i) \quad (1)$$

$$STag(w_i) = argmax_j(cos(\overrightarrow{STag_j}, f(w_i)) > \theta_j) \quad (2)$$

$$f(w_i) = w2v(w_i) \quad (3)$$

for STag(w_i) ∈ {PLACE, PATH, SPATIAL_ENTITY, MOTION} or candidates

$$f(w_i) = \frac{1}{2L}\sum_{l=1}^{L}(w2v(context_l(w_i)) + w2v(context_{-l}(w_i))) \quad (4)$$

for STag(w_i) ∈ {MOTION_SIGNAL, SPATIAL_SIGNAL} or candidates

4 Relation Extraction

In ISO-Space, a spatial relation consists of two static relations and one dynamic relation. The static relations are the topological relation (QSLink) and orientational link (OLink), which are triggered by SPATIAL_SIGNAL. The extracted relations are represented in a triple format: <trajector, trigger, landmark>. The dynamic relation is the move relation (MoveLink) triggered by a MOTION event. The extracted relation is represented in octuple format: <mover, trigger, source, goal, landmark, mid-point, path, motion signal>. However, it is not easy to extract all the octuplet arguments in most sentences. For a relaxed implementation, the octuple is converted into many triples; then, one or all of the triples are extracted (Nichols and Botros 2015, D'Souza and Ng 2015). We chose to extract one of those triples, <mover, trigger, goal>, because its arguments are filled in most cases, and the triple is also chosen for extraction target in (Nichols and Botros 2015).

4.1 Rule-based model

A rule-based method is straight-forward to implement, if linguistic regularities for spatial relation extraction are easily found. For a performance comparison, we also define a rule-based relation extraction model as a base model and call it the R1 model. Because of the free word order and frequent omission of words in the Korean language, regularities are not easily found. Therefore, the rules do not pose many restrictions, as summarized in Table 4.

Table 4. Relation extraction rules.

Rule 1	Static relations are triggered by SPATIAL_SIGNAL and dynamic relations by MOTION.
Rule 2	SPATIAL_SIGNAL with the type 'TOPOLOGICAL' generates QSLink, and that with the type 'DIRECTIONAL' generates both OLink and DIR_TOP.
Rule 3	The arguments for the relations are 'PLACE,' 'PATH,' and 'SPATIAL_ENTITY.'
Rule 4	All spatial entities for a relation are within the same dependency head (VP, VNP).
Rule 5	When there is more than one argument under a dependency head, the argument closest to the trigger in the dependency relation is classified as a landmark, and the other arguments are classified as trajectors, resulting in multiple relations.
Rule 6	If one and more triggers exist, the arguments cannot cross the other triggers at a sentence position.

4.2 Bayesian model

Dependency parsing is quite effective for free word order languages such as the Korean language and provides useful information for long-distance relations (Lim et al. 2014). We utilize the parsing result to find valid arguments for given triggers such as the SPATIAL_SIGNAL or MOTION tag. In this model, all of the possible argument candidates are searched and verified with a Bayesian probability, which is learned with the training corpus. The argument with the highest probability is chosen, as shown in eq. 5. The probability is calculated as the product of the prior probability of an argument and the conditional probability of the sequence of dependency labels (DPL). The DPL includes the labels from a trigger to the argument, and its conditional probability is approximated in eq. 6.

$$\mathrm{DPL} = (dpl_1, dpl_2, \ldots, dpl_n)$$
$$\mathrm{A} = \{\text{trajector}, \text{landmark}\}$$
$$argmax_{A_i} P(A_i, DPL) = argmax_{A_i} P(DPL|A_i) \cdot P(A_i) \quad (5)$$
$$\begin{aligned} \mathrm{P}(DPL|A_i) &= P(dpl_n, dpl_{n-1}, \ldots, dpl_1|A_i) \\ &= \mathrm{P}(dpl_n|dpl_{n-1}, \ldots, dpl_1, A_i) \cdot P(dpl_{n-1}|dpl_{n-2}, \ldots, dpl_1, A_i) \cdots P(dpl_1|A_i) \\ &\cong \mathrm{P}(dpl_1|A_i) \cdot \prod_{j=2}^{n} P\left(dpl_j \middle| dpl_{j-1}\right) \end{aligned} \quad (6)$$

5 Experiment

5.1 Experimental setup

As pre-processing steps, a morphological analysis and POS tagging, named entity recognition, and dependency parsing are carried out, and their sources and performance are summarized in Table 5. We used CRFsuite (Okazaki 2007) and the GloVe word vector (Pennington et al. 2014). The word vectors are trained with the morpheme-tagged data in the Sejong corpus (NIKL 2011) to build 300 vector clusters for a feature set.

For the test data, we used the Korean spatial annotation corpus (Kim et al. 2016), which is constructed from 175 documents (1593 sentences) from the Wikitravel web-site[1] following the SpaceEval annotation scheme (Pustejovsky et al. 2015). The testing corpus statistics are listed in Table 6.

The experiment was performed with 5-fold cross validation test. The experiment for entity extraction was directly carried out with the raw corpus data, and relation extraction was performed with the corpus annotated with spatial entities beforehand. (Each experiment corresponds to tasks 1.b and 3.a of SpaceEval)

Table 5. Performance of the pre-processing modules.

Modules	performance	source
Morph. analysis and POS tagging.	99.03% (pre)	(Lee et al. 2016)
Named entity recognition	86.86% (f1)	(Lee et al. 2011)
Dependency parsing	87.63% (LAS)	(Lim et al. 2014)

Table 6. Number of tags in the testing corpus.

Entity						relation		
name	num	ratio	name	num	ratio	name	num	ratio
PLACE	5,636	67.6%	M._SIGNAL	266	3.2%	QSLink	3,548	65.9%
PATH	320	3.8%	S._SIGNAL	1,299	15.6%	OLink	970	18.0%
S._ENTITY	270	3.2%	MEASURE	248	3.0%	MoveLink	868	16.1%
MOTION	294	3.5%						
			entity total	8,333	100.0%	relation total	5,386	100.0%

5.2 Results

Table 7 summarized the results of spatial entity extraction. The performance of MEASURE is the second-best because its typical surface form, e.g., the "number + unit" form, is very easily recognized by a program. PLACE is the best performer, which can also be easily found by a named entity recognizer. Moreover, as the ratio of PLACE tag is the largest, 67.6%, in the distribution as presented in Table 6, the prior probability contributes to find more PLACE tags. On the other hand, SPATIAL_ENTITY exhibits the worst performance. We conjecture that the first reason is that the size of the training corpus is too small; the number of Korean spatial entity tags is 270 (3.2%), as presented in Table 6, whereas that of English spatial entity tags is 1670 (23.6%) in the corpus used for SpaceEval 2015 (Pustejovsky et al. 2015). The second reason is that its part of speech tag is a general noun, which is not easy to distinguished from other spatial tags. Moreover, the same word can be either a SPATIAL_ENTITY tag or

[1] http://www.wikitravel.com/ko/

none tag depending on the context. In the following example, 'car' in the first sentence is tagged SPATIAL_ENTITY, but that in the second sentence is not. This is same for English, but it is more difficult for a free-word-order language to be disambiguated.

철수가 **자동차/spatial_entity** 에 탔다. (Cheolsu got in a **car/spatial_entity**.)

철수가 **자동차/none** 를 샀다. (Cheolsu bought a **car/none**.)

The E2 model increased the recall but decreased the precision, as indicated in Table 7. However, the E3 model using spatial tag vectors greatly increased the precision by 13.3% point compared to that of the E2 model. Consequently, the F1 measure performance of the E3 model increased by 2.1% point compared to that of the E1 model, which means that use of the tag vector is effective for selecting valid spatial entities.

Table 7 summarizes a comparison of the E3 model with SpRL-CWW (Nichols and Botros 2015), which was the best model at SpaceEval 2015 (Pustejovsky et al. 2015). The overall performance of the E3 model is better than that of SpRL-CWW for all precision, recall, and F1 measure criteria. The performance of SPATIAL_ENTITY and PATH for the E3 model, however, is relatively much lower than that of SpRL-CWW. This means that the ambiguity of general nouns in a semantic role is still problematic and the size of the training corpus is relatively smaller as fore-mentioned.

The performance of relation extraction is summarized in Table 8. All of the values of the precision, recall, and F1 measure for the R2 model are better than those for the R1 model. This implied that the use of the Bayesian probability for selecting arguments is effective. For a general comparison, we have listed the results of the two best approaches in the table, where CWW (Nichols and Botros 2015) is the best machine learning approach, and Pust (Pustejovsky et al. 2015) is the best rule-based approach. Unfortunately, the R2 model exhibits a very low performance compared with both of them.

The spatial relations in Korean text are relatively hard to be retrieved, because the related entities are relatively separated and their appearing order is not consistent. While all related entities are usually located closely to the spatial signal in English text, the entities are sometimes far from the spatial signal in a Korean sentence. Sentence 1 in Fig. 2 shows an example in which the trajector is far from the trigger. In addition, the appearing order is not consistent as shown in Korean sentence 2 in Fig. 2. Both landmark and trajectory appear before the trigger in the first OLINK, whereas landmark appears before and trajectory appears after the trigger in the second OLINK. We used the dependency relations of words to alleviate this problem and thus improved the performance. However, we still need to find more effective methods to overcome Korean linguistic barriers such as the free word order and the lack of language resources; and this problem will be studied in future research.

Table 7. Performance of spatial entity extraction.

6 Conclusion

We have proposed two models for Korean spatial entity extraction and spatial relation extraction. For entity extraction, we utilized the features of prior systems with an adaptation to Korean linguistic features. Moreover, we proposed a new approach to filter false entities using spatial tag vectors, which can be learned automatically from a raw corpus. The experiment showed that the spatial tag vectors are effective for spatial entity extraction and showed better performance than English state-of-the-art performance.

For relation extraction, we proposed a model that uses the dependency label probability to select proper arguments, which is effective and better than a simple rule-based model but much lower than the state-of-the-art performance of an English one. We conjecture that this mainly originates from linguistic differences, especially syntactic structures such as the free word order and word omission, which still require further investigation.

Abstract

Recent trend in question answering (QA) systems focuses on using structured knowledge bases (KBs) to find answers. While these systems are able to provide more precise answers than information retrieval (IR) based QA systems, the natural incompleteness of KB inevitably limits the question scope that the system can answer. In this paper, we present a hybrid question answering (hybrid-QA) system which exploits both structured knowledge base and free text to answer a question. The main challenge is to recognize the meaning of a question using these two resources, i.e., structured KB and free text. To address this, we map relational phrases to KB predicates and textual relations simultaneously, and further develop an integer linear program (ILP) model to infer on these candidates and provide a globally optimal solution. Experiments on benchmark datasets show that our system can benefit from both structured KB and free text, outperforming the state-of-the-art systems.

1 Introduction

Recently, with the emergence of large structured knowledge bases (KBs) like DBpedia (Auer et al., 2007), Freebase (Bollacker et al., 2008) and Yago (Suchanek et al., 2007), increasing research efforts on automatically answering natural language questions has shifted from using text corpora only to large scale structured KBs like DBpedia, Freebase (known as KB-QA). Compared to pure text resources used in IR-based QA systems, structured knowledge bases may help to provide users with more accurate and concise answers, especially for factoid questions.

Generally, the traditional KB-QA paradigm assumes that world knowledge can be encoded using a closed vocabulary of formal predicates. In this paradigm, the system is given a knowledge base as input, and the question answering problem reduces to semantic parsing, i.e., mapping from text to logical forms containing the predicates from the given knowledge base. However, the closed predicate vocabulary assumed by the traditional KB-QA paradigm has inherent limitations. First, a closed predicate vocabulary has limited coverage, as such vocabularies are typically powered by community efforts. Second, a closed predicate vocabulary may abstract away potentially relevant semantic differences. Third, even a logical form was produced, the answers may be incomplete due to the imperfection of the KB, which has been addressed by (Riedel et al., 2013; Chen et al., 2014). For example, no logical form could be produced for the question *who is the front man of the band that wrote Coffee & TV*. Because the semantics of *front man* cannot be adequately encoded using Freebase or DBpedia predicates.

On the other hand, knowledge bases like DBpedia capture real world facts, and web resources like Wikipedia may provide a large repository of sentences that complement those facts. For instance, we can find in Wikipedia a sentence *In August 2009, Debelle performed at Africa Express in Paris, an event set up by Blur and Gorillaz front-man Damon Albarn*, which indicates the front man of the band in the example question is *Damon Albarn*[1]. Moreover, text corpora is also shown effective in refining the answers retrieved from the KBs (Xu et al., 2016). Motivated by these observations, we tackle the

[1]The Blur band wrote the Coffee & TV song.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2397–2407, Osaka, Japan, December 11-17 2016.

question answering task by integrating these two types of heterogeneous data, i.e., structured knowledge bases and free text, while is rarely investigated before.

This task involves three main challenges. The first is how to represent the meaning of a question by the clues from two types of heterogeneous resource. Secondly, for each phrase, there exist multiple grounded candidates over the KB and text corpora, how to perform inference on these candidates itself is a problem. The third challenge is how to properly incorporate the coherence of two types of heterogeneous resource, KB predicates and textual relations, into the inference model.

In this paper, we propose a joint inference approach to simultaneously solve these disambiguations. Specifically, our method consists of two main steps as outlined in (§2). In the first step, we employ preliminary models to perform the entity linking and relation extraction (§3). Next, we develop an integer linear program (ILP) model, where the candidate mapping of phrases to KB items and textual relations are the variables restricted by several designed constraints, and they could be determined simultaneously through joint inference (§4). The main contributions of this paper are two folds:

- We introduce a new task paradigm of the question answering community, and present a novel hybrid-QA framework to accommodate the structured KB and free text.
- We propose a joint inference model to solve the disambiguation among entities and relations across text and KBs.

Our evaluation results on benchmark datasets show that our system benefits from the integration of the KB and free text outperforming the state-of-the-art systems.

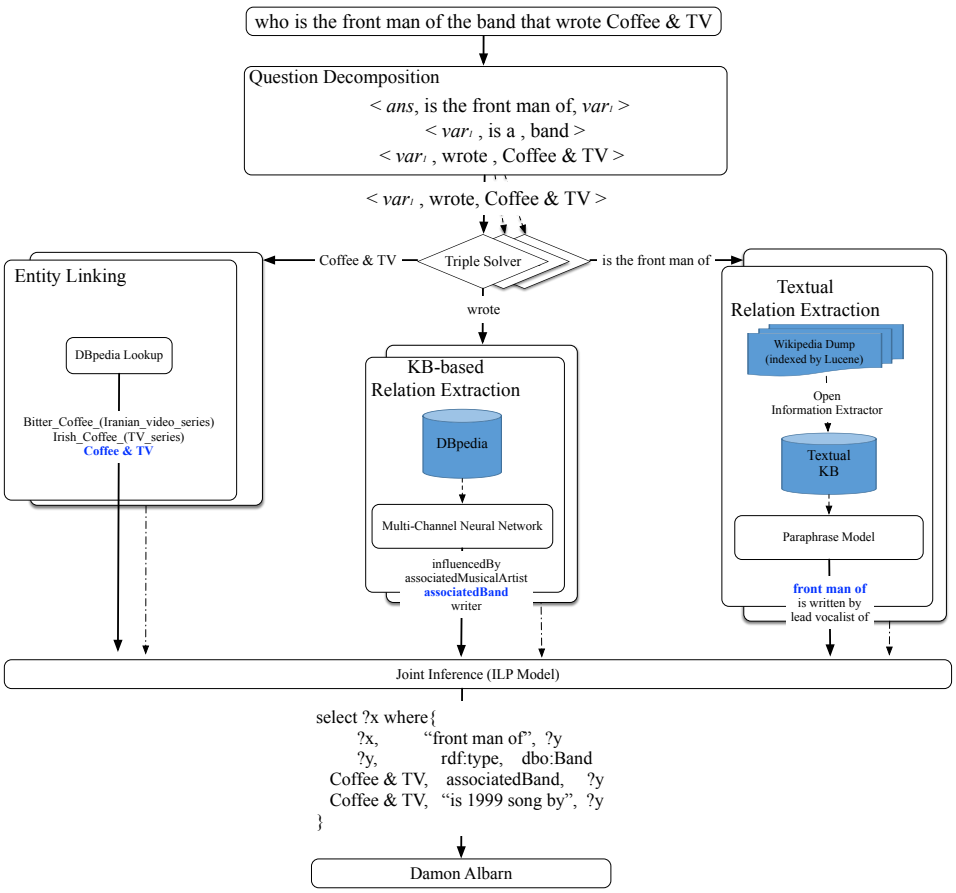

Figure 1: A running example of our hybrid-QA system for the question *who is the front man of the band that wrote Coffee & TV*, where the blue annotations are correct.

2 Our Method

Figure 1 gives an overview of our method for the aforementioned question "*who is the front man of the band that wrote Coffee & TV*". We have two main steps: (1) perform the local predictions, i.e., Entity Linking (EL) and Relation Extraction (RE); and (2) further infer on the retained candidate entities, KB predicates and textual relations to find an optimal assignment under certain constraints.

Let us take a close look into step 1. Here we first perform entity linking to identify possible KB entities in the question. Then we employ two types of relation extractors to predict both KB predicates and textual relations existing between two entities or question word and entities in the question. Specifically, we propose a neural network based method to map relational phrases to KB predicates, and apply a paraphrase model to find most likely textual relations that describe the phrases. In Step 2, we perform a joint inference over the local predictions of EL and RE models to find a best configuration through an ILP model.

As shown in Figure 1, it is often the case that a question may involve multiple relations. Consider the example question, the answers of this question should satisfy the following two constraints: (1) the person is the front man of a band (textual relation); and (2) the band wrote the song *Coffee & TV* (KB predicate). We use the 6 syntax-based rules as introduced in (Xu et al., 2016) to preprocess such *multi-relational* questions, i.e., decomposing them into a set of simple questions formulated as *ungrounded* triples. For instance, the example question can be decomposed into three ungrounded triples: $<$*ans*, *is the front man of*, $var_1>$, $<var_1$, *is a*, *band* $>$ and $<var_1$, *wrote*, *Coffee & TV*$>$[2].

3 Prelimiary Models

Since we represent the meaning of a question using clues from two types of heterogeneous resources, we tackle the QA problem in an IE-based fashion involving entity linking and relation extraction. In particular, we simultaneously map relational phrases to KB predicates and textual relations.

3.1 Entity Linking

The preliminary entity linking model can be any approach which outputs a score for each entity candidate. Note that a recall-oriented model will be more than welcome, since we expect to introduce more potentially correct local predictions into the inference step. In this paper, we adopt DBpedia Lookup[3] and S-MART (Yang and Chang, 2015) to retrieve top 10 entities from DBpedia and Freebase, respectively. These entities are treated as candidate entities that will be eventually disambiguated in the joint inference step.

3.2 KB-based Relation Extraction

The choice of KB-based relation extraction model is also broad. In this paper, we employ the **M**ulti-**C**hannel **C**onvolutional **N**eural **N**etworks (MCCNNs) model presented in (Xu et al., 2016) to learn a compact and robust relation representation. This is crucial since there exist thousands of relations in a KB, using lexicalized features inevitably suffers from the sparsity problem and their poor generalization ability on unseen words (Gormley et al., 2015).

The MCCNN model treats the conjunction of three parts in a ungrounded triple as a sentence (**subject** relational phrase **object**). The first channel takes the shortest path between the subject and object in the dependency tree[4] as input, while the other channel takes the relational phrase itself as input. Each channel uses the network structure described in (Collobert et al., 2011), which uses a convolutional layer to project the word-trigram vectors of words within a context window of 3 words to a local contextual feature vector, followed by a max pooling layer that extracts the most salient local features to form a fixed-length. The global feature vector is then fed to feed-forward neural network layers to output the final non-linear semantic features, as the vector representation of the relational phrase.

[2]Here ans denotes the answer and var_1 denotes an intermediate variable.

[3]http://wiki.dbpedia.org/projects/dbpedia-lookup.

[4]We use Stanford CoreNLP dependency parser.

Learning The model is learned using pairs of relational phrase and its corresponding KB predicate. Given an input phrase, the network outputs a distribution vector over the predicates o. We denote t as the target distribution vector, in which the value for gold relation is set 1, others are set 0. We compute the cross entropy error between t and o as the loss function. The model parameters can be efficiently computed via back-propagation through network structures. In experiment, we train two distinct relation extractors over DBpedia and Freebase, respectively. For DBpedia, we use the PATTY dataset (Nakashole et al., 2012) which consists of 127,811 pairs of relational phrases and DBpedia predicates involving 225 DBpedia predicates. For Freebase, we use 3,022 phrase-predicate pairs of WEBQUESTIONS used in (Xu et al., 2016), which involves 461 Freebase predicates.

3.3 Open Relation Extraction

Despite huge amounts of precise knowledge facts, structured KBs still have natural limitation in the coverage of knowledge domains compared to the vast information on the web. For example, out of 500,000 relations extracted by the ReVerb Open IE system (Fader et al., 2011), only about 10,000 can be aligned to Freebase (Berant et al., 2013). To alleviate this problem, we propose a paraphrase based method that can map relational phrases to proper textual relations. Specifically, we first apply an open information extractor (Angeli et al., 2015) on the English Wikipedia to construct a repository of $<$*argument*$_1$, *relation*, *argument*$_2>$ triples, where the *arguments* are entity phrases found in the input sentence and the *relation* represents certain relationship between the arguments. By linking these arguments to KB entities, we can obtain a textual knowledge repository.

Paraphrasing Once the candidate set of textual relations $TR = \{tr_1, tr_3, ..., tr_{|TR|}\}$ are constructed, given a relational phrase rp, our goal is to find the tr that has the same meaning as rp, which can be treated as a paraphrase task. Our framework accommodates any paraphrasing method, such as the method based on dynamic pooling and recursive autoencoders (RAE) (Socher et al., 2011), which we adopt in our framework. Generally, the RAEs are based on a novel unfolding objective and learn feature vectors for phrases in syntactic trees. These features are used to measure the word-wise and phrase-wise similarities between two sentences. Since sentences may be of arbitrary length, the resulting matrix of similarity measures is of variable size. Then a dynamic pooling layer is introduced to compute a fixed-sized representation from the variable-sized matrices. Finally the pooled representation is used as input to a classifier $\mathcal{C}_p$.

Learning In our experiment, we directly used the pre-trained RAE which is trained on a subset of 150,000 sentences from the NYT and AP sections of the Gigaword corpus. To train the classifier $\mathcal{C}_p$, we use the PARALEX corpus (Fader et al., 2013), which is a large monolingual parallel corpora, containing 18 million pairs of question paraphrases from `wikianswers.com`, which were tagged as having the same meaning by the users of the website.

4 Joint Inference

The goal of the inference step is to find a global optimal configuration of entity phrases and relational phrases with semantic components. As the result of disambiguating one phrase can influence the mapping of other phrases, we consider all phrases jointly in one disambiguation task. Now, we will first describe three key criteria that are used to evaluate the configuration in details.

KB Predicate and Entity's Coherence If the relational phrase rp is grounded to a KB predicate kr, we should examine whether the semantic types of the entities fulfill the expectations of KB predicates. Particularly, we first obtain the type of subject entity e, which is collected from the KB's schema, and examine whether there exists another entity with the same type taking the subject position of this predicate in the KB. If such an entity exists, it indicates this entity is compatible with the KB predicate, $Coh_{e,kr} = 1$, otherwise 0.

Textual Relation and Entity's Coherence Similarity, we also need to capture the coherence, $Coh_{e,tr}$, between a textual relation tr and entity e. Since the textual relation does not have well-defined schemas

like the KB, we practically treat the types of collected entities that take the subject and object position of tr as the type expectations of tr. For instance, *written by* takes `Coffee&TV` (a song) and `Blur` (an English band), which indicates the type expectations of *written by* should include `Song` and `Band`. We then determine whether e is compatible with tr by examining whether the type of e fulfills the type expectations of tr. If e is compatible with tr, $Coh_{e,tr} = 1$, otherwise 0.

KB Predicate and Textual Relation's Coherence Notice that, we allow a relational phrase to be simultaneously mapped to a KB predicate and a textual relation. In this case, the KB predicate kr and textual relation tr should be compatible with each other. For this purpose, we first determine if kr and tr have the same argument expectations. If so, we use the trained MCCNN to capture the coherence of a KB predicate kr and textual relation tr, $Coh_{kr,tr}$. In practice, we treat this problem as a variant of relation classification, i.e., the coherence score is the probability of mapping word sequence tr to KB predicate kr. Otherwise, $Coh_{kr,tr}$ is set to -1.

Integer Linear Program Formulation Now we describe how we aggregate the above components, and formulate the joint inference problem into an ILP framework. Given the above definitions, our objective function is to maximize the score of entity linking, relation extraction and their coherence among them:

$$\max \quad \alpha \times conf^e + \beta \times conf^r + \delta \times conf^{er} \tag{1}$$

where α, β and δ are weighting parameters tuned on development set. $conf^e$ is the overall score of entity linking:

$$conf^e = \sum_d \sum_{ep \in d, e \in C_e(ep)} w_{ep,e} Y_{ep,e} \tag{2}$$

where d is the ungrounded triple, $C_e(ep)$ is the candidate entity set of the entity phrase ep, $w_{ep,e}$ is the entity linking score, and $Y_{ep,e}$ is a boolean decision variable that indicates if entity phrase ep maps to entity e. $conf^r$ represents the overall score of relation extraction:

$$conf^r = \sum_d \sum_{rp \in d, kr \in C_{kr}(rp)} q_{rp,kr} Z_{rp,kr} + \sum_d \sum_{rp \in d, tr \in C_{tr}(rp)} v_{rp,tr} W_{rp,tr} \tag{3}$$

where $C_{kr}(rp)$ is the set of candidate KB predicates of relation phrase rp, $C_{tr}(rp)$ is the set of candidate textual relations corresponding to rp, $q_{rp,kr}$ and $v_{rp,tr}$ are the scores of relational phrase rp mapped to KB relation kr and textual relation tr. We define two boolean decision variables $Z_{rp,kr}$ and $W_{rp,tr}$ to denote whether rp is mapped to kr and tr. coh^{er} evaluates the coherence between the candidate entities and relations in the framework:

$$conf^{er} = \sum_d \sum_e \sum_{kr} o_{e,kr} Coh_{e,kr} + \sum_d \sum_e \sum_{tr} o_{e,tr} Coh_{e,tr} + \sum_d \sum_{kr} \sum_{tr} o_{kr,tr} Coh_{kr,tr} \tag{4}$$

where $o_{e,kr}$, $o_{e,tr}$ and $o_{kr,tr}$ are the coherence scores among entities, KB predicates and textual relations. We introduce three boolean decision variables $Coh_{e,kr}, Coh_{e,tr}, Coh_{kr,tr}$ to denote whether two semantic components are both selected.

Constraints Now we describe the constraints used in our ILP problem. The first kind of constraints is introduced to ensure that each entity phrase should be disambiguated to only one entity:

$$\forall d, \forall e \in C_e(ep), \sum_{ep \in d, e \in C_e(ep)} Y_{ep,e} \leq 1 \tag{5}$$

The second type of constraints ensure that each relational phrase should be disambiguated to only one KB relation or one textual relation *at most*:

$$\forall d, \forall kr \in C_{kr}(rp), \sum_{rp \in d, kr \in C_{kr}(rp)} Z_{rp,kr} \leq 1 \tag{6}$$

$$\forall d, \forall tr \in C_{tr}(rp), \sum_{rp \in d, tr \in C_{tr}(rp)} W_{rp,tr} \leq 1 \tag{7}$$

The third constraint ensures the decision variable $Coh_{e,kr}$ equals 1 if and only if both the corresponding variables $Y_{ep,e}$ and $Z_{rp,kr}$ equal 1.

$$\forall d, \forall e \in C_e(ep), \forall kr \in C_{kr}(rp), \forall tr \in C_{tr}(rp) \tag{8}$$

$$Coh_{e,kr} \leq Y_{ep,e} \quad Coh_{e,kr} \leq Z_{rp,kr} \quad Y_{ep,e} + Z_{rp,kr} \leq 1 + Coh_{e,kr} \tag{9}$$

Similarly, we further add the following constraints for $Coh_{e,tr}$ and $Coh_{kr,tr}$:

$$Coh_{e,tr} \leq Y_{ep,e} \quad Coh_{e,tr} \leq W_{rp,tr} \quad Y_{ep,e} + W_{rp,tr} \leq 1 + Coh_{e,tr} \tag{10}$$

$$Coh_{kr,tr} \leq Z_{rp,kr} \quad Coh_{kr,tr} \leq W_{rp,tr} \quad Z_{rp,kr} + W_{rp,tr} \leq 1 + Coh_{kr,tr} \tag{11}$$

We use Gurobi[5] to solve the above ILP problem.

5 Experiment

In this section we evaluate our system on two benchmark datasets, QALD-6 and WEBQUESTIONS. After describing the setup, we present our main empirical results and analyze the components of our system.

The QALD-6 task[6] includes a hybrid QA dataset which contains 50 training questions and 25 test questions. We select 15 questions from the training set as the development set and use the remaining 60 ones to evaluate our system.

We also use the WEBQUESTIONS dataset (Berant et al., 2013), which contains 5,810 question-answers pairs. We further split this dataset into the same training and test sets as other baselines, which contain 3,778 questions (65%) and 2,032 questions (35%), to evaluate the system.

As shown in Table 2, these two datasets vary significantly in both syntactic and semantic complexity. For example, 85% questions of WEBQUESTIONS can be directly answered via a single Freebase predicate. However all questions of QALD-6 involve at least one DBpedia predicate and one textual relation, thus can not be accurately answered using DBpedia only.

5.1 Experimental Settings

We have 6 dependency tree patterns based on Bao et al. (2014) to decompose a question into sub-questions. We initialize the word embeddings with Turian et al. (2010)'s word representations with dimensions set to 50. The hyper parameters in our model are tuned using the development set. The window size of MCCNN is set to 3. The sizes of the hidden layer 1 and the hidden layer 2 of the two MCCNN channels are set to 200 and 100, respectively. For each relational phrase, we retain 20 candidate KB predicates and textual relations to the ILP model. The hyper parameters of the ILP objective function (i.e., α, β and δ) are set to 1, 3 and 4, respectively.

[5]http://www.gurobi.com/

[6]http://qald.sebastianwalter.org/index.php?q=6

5.2 Results and Discussion

We use the average question-wise F_1 as our evaluation metric. To give an idea of the impact of different configurations of our method, we consider the following variations with existing methods.

KB. This method involves prediction relying on the KB only in a pipelined fashion. First the entity linking system is run to predict the entity. Then we run the KB-based relation extraction system (described in §3.2) and select the best relation that can cooccur with the entity. We choose this entity-relation pair to predict the answer.

KB + Joint. In addition to selecting local optimal results, we further perform the joint inference over entity and KB predicates.

Text. Instead of applying a KB-based RE method, we map the relation phrase to textual relations as described in §3.3 and find a local optimal solution.

Text + Joint. This method augments the above method with a joint inference step.

KB + Text + Joint. This is our main model. We perform the entity linking, map the relation phrase to KB predicates and textual relations simultaneously, and then infer on the local predications to find a global optimal assignments of the phrases.

Table 1 summarizes the results on the test data along with the results from the literature[7]. We can see that the joint inference gives a performance boost of at least 3% (from 44.1% to 47.1%) regardless of using which type of relation extractor. In addition, text corpora can significantly improve the system performance when using the KB only, and vice versa. The combination of structured KB and free text along with the joint inference outperforms the default model by at least 3.5% (from 37.4% to 40.9%). On the WEBQUESTIONS, our method achieves a new state-of-the-art result beating the previous reported best result of Xu et al. (2016) (with one-tailed t-test significance of $p < 0.05$). And our results on QALD-6 also establishes a new baseline.

5.3 Impact of Textual Relations and KB Predicates

As shown in Table 1, KB-based relation extractor performs better than textual relation extractor on WEBQUESTIONS, but worse on QALD-6. This is due to the fact that WEBQUESTIONS is designed to evaluate the KB-QA systems, therefore the involved relations are guaranteed to be explicitly mapped to KB predicates. In contrast, QALD-6 is proposed to evaluate hybrid-QA systems, and almost no question can be answered using a KB only. Although different datasets have different appetites for the relation extractors, we find the combination of them significantly improves the overall performance.

We also compared our paraphrase model (RAE) with two baselines: EDIT-based and VECTOR-based paraphrase models. Specifically, the former computes the token edit distance between the textual relation tr and relation phrase rp as the similarity score, obtaining 43.6% and 35.4% F_1 on the development set of WEBQUESTIONS and QALD-6, respectively.

The latter obtains the vector representations of tr and rp by summing the word vectors (Turian et al., 2010), and compute the cosine similarity as the similarity score, obtaining 45.7% and 39.3% F_1 on the development set of WEBQUESTIONS and QALD-6, respectively. We find the RAE paraphrase model boosts the performance at least by 6% on QALD-6 and 2% on WEBQUESTIONS.

5.4 Impact of ILP's Constraints

One question of interest is when the ILP model prefers to mapping relational phrases to KB predicates and textual relations simultaneously. We mainly rely on the coherence score between KB predicates and textual relations, i.e., $Coh_{kr,tr}$, to guide the inference model to find a proper assignments. Specifically, if kr and tr have the same argument type expectations, we compute the $Coh_{kr,tr}$ as the probability of mapping tr to kr using the neural network as described in §3.2. Otherwise, $Coh_{kr,tr}$ is set to -1. The

[7]We list several recent results on WEBQUESTIONS. We use development data for all our ablation experiments. Similar trends are observed on both development and test results.

intuition behind is that the selected pair of KB predicates and textual relations should first be coherent, and then semantically similar. If there does not exist such a coherent pair, the model prefers to choosing the one which has higher overall score and neglects the other.

5.5 Error analysis

We analyze the errors of *KB + Text + Joint* model. Around 2% of the errors are caused by incorrect entity linking, and around 5% of the errors are due to incorrect question decomposition. The remaining errors are due to the relation extraction: (i) unbalanced distribution of KB predicates heavily influences the performance of MCCNN model towards frequently seen relations as observed in (Xu et al., 2016); (ii) the RAE model can hardly find proper assignments of textual relations for short-length relational phrases.

5.6 Limitations

While our inference on the structured KB and free text allows the system to answer more open questions to some extent, we still fail at answering some semantically complex questions such as *what is the second longest river in USA* involving aggregation operations. Our current assumption that free text could provide useful textual relations may work only for frequently typed queries or for popular domains like movies, politics and geography. We note these limitations and hope our result will foster further research in this area.

6 Related Work

Over time, the QA task has evolved into two main streams – QA on unstructured data, and QA on structured data. TREC QA evaluations (Voorhees and Tice, 1999) have been explored as a platform for advancing the state of the art in unstructured QA (Wang et al., 2007; Heilman and Smith, 2010; Yao et al., 2013; Yih et al., 2013; Yu et al., 2014; Yang et al., 2015; Hermann et al., 2015). While initial progress on structured QA started with small toy domains like GeoQuery (Zelle and Mooney, 1996), recent trend in QA has shifted to large scale structured KBs like DBPedia, Freebase (Unger et al., 2012; Cai and Yates, 2013; Berant et al., 2013; Kwiatkowski et al., 2013), and on text repository (Banko et al., 2007; Carlson et al., 2010; Krishnamurthy and Mitchell, 2012; Fader et al., 2013; Parikh et al., 2015). An exciting development in structured QA is to exploit multiple KBs (with different schemas) at the same time to answer questions jointly (Yahya et al., 2012; Fader et al., 2014; Zhang et al., 2016).

Our model combines the best of both worlds by inferring over the structured KB and unstructured text. Our work is closely related to Joshi et al. (2014) who aim to answer noisy telegraphic queries using both structured and unstructured data. Their work is limited in answering single relation queries. Our work also has similarities to Sun et al. (2015) who does question answering on unstructured data but enrich it with Freebase.

Joint inference methods over multiple local models has been applied to KB-QA systems (Yahya et al., 2012). In contrast to this prior work concentrating on the structured KB, our constraints are more complex, as we address the joint mapping of relational phrases onto KB predicates and textual relations.

7 Conclusion and Future Work

We have presented a hybrid-QA framework that could infer both on structured KBs and unstructured text to answer natural language questions. Our experiments reveal that integrating structured KB and unstructured text along with a joint inference method improves the overall performance. Our main model achieves the state-of-the-art results on benchmark datasets. A potential application of our method is to improve open domain question answering using the documents retrieved by a search engine.

Since we recognize the query intention inherent in the question using shallow methods, our method is less expressive than the deep meaning representation methods like semantic parsing. Our future work involves developing a shallow semantic parser based on relation extraction in order to better understand the meaning of the questions.

Improved Word Embeddings with Implicit Structure Information

Jie Shen **Cong Liu***

shenjie5@mail2.sysu.edu.cn, liucong3@mail.sysu.edu.cn

Abstract

Distributed word representation is an efficient method for capturing semantic and syntactic word relations. In this work, we introduce an extension to the *continuous bag-of-words* model for learning word representations efficiently by using implicit structure information. Instead of relying on a syntactic parser which might be noisy and slow to build, we compute weights representing probabilities of syntactic relations based on the Huffman softmax tree in an efficient heuristic. The constructed "implicit graphs" from these weights show that these weights contain useful implicit structure information. Extensive experiments performed on several word similarity and word analogy tasks show gains compared to the basic *continuous bag-of-words* model.

1 Introduction

Unsupervised word embeddings have been shown to improve many downstream NLP tasks, such as dependency parsing (Chen and Manning, 2014; Kong et al., 2014), part-of-speech tagging (Collobert et al., 2011), sentiment analysis (Socher et al., 2013) and machine translation (Devlin et al., 2014). Low-dimensional embeddings are generally learnt in a language model by maximizing the likelihood of a large corpus of raw text data. Word vectors that are close to each other are semantically related based on the *distributional hypothesis* (Harris, 1954), which states that words in similar contexts have similar meanings.

Based on the *distributional hypothesis*, many methods of building word vectors were explored. Examples of these are *SENNA* (Collobert and Weston, 2008), the *hierarchical log-bilinear* model (Mnih and Hinton, 2009), `Word2Vec` (Mikolov et al., 2013a; Mikolov et al., 2013b) and *GloVe* (Pennington et al., 2014). In this work, we introduce an extension to the *continuous bag-of-words* (CBOW) model (Mikolov et al., 2013b). The CBOW model is widely used for learning word embeddings from raw textual data, popularized via the `Word2Vec` tool. Not only does it build useful word embeddings, but it is also efficient for training and scales well to huge corpora.

In (Levy and Goldberg, 2014), based on the fact that nearby words are not necessarily syntactically related, word context is derived from dependency parse-trees relying on a syntactic parser instead of simply using the surrounding words. Only the words that have dependency relations with the center word are used as the context words, as illustrated in Figure 1.

However, syntactic parsing is a more difficult and time-consuming task than finding word embeddings. The challenge is to absorb the advantage of using syntactic information while avoiding the complexity of parsing. In this paper, we use a simple method to attach different weights to the context words to approximate the context obtained from explicit syntactic trees, such as dependency parse-trees. The method of obtaining contextual weights is based on the Huffman softmax tree in softmax period. Our method is as efficient as CBOW since we do not explicitly construct syntactic trees but only use the weights representing implicit syntactic structures.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2408–2417, Osaka, Japan, December 11-17 2016.

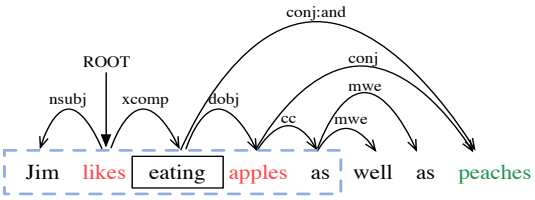

Figure 1: The enhanced dependency parse-graph for sentence "*Jim likes eating apples as well as peaches*". The blue dashed rectangle means the context window when predicting *eating* in the CBOW model.

In order to qualitatively inspect our implicit structure weights, we construct "implicit graphs" using our computed weights for different sentences. By comparing with their dependency parse-trees, these "implicit graphs" show that these weights contain useful implicit structure information.

To quantitatively evaluate the quality of the word embeddings generated from our proposed model, we experiment on several word similarity and word analogy tasks. Experiment results show gains using our method compared to the CBOW model.

The rest of the paper is organized as follows. Section 2 introduces related work on word representations. The CBOW model is briefly reviewed in Section 3. In Section 4, we present the proposed method. Evaluation and results are discussed in Section 5. Finally, Section 6 concludes the paper with future work.

2 Related Work

Word embedding is a key component in many downstream NLP tasks. Prior works explore effective and efficient methods to learn word embeddings. Bengio et al. (2006) proposed a *Neural Network Language Model* (NNLM) which predicts the distribution of the center word through several previous words. Mnih and Hinton (2007) proposed the *Log-Bilinear Language* (LBL) model which has been later accelerated by using hierarchical softmax (Mnih and Hinton, 2009) to exponentially reduce the computational complexity. Pennington et al. (2014) introduced *GloVe* which combines global matrix factorization and local context window together. Mikolov et al. (2013a; 2013b) proposed `Word2Vec` which contains two models: CBOW and Skip-Gram.

While `Word2Vec` is not sensitive to word order, many models have been proposed to deal with this problem. Ling et al. (2015) present two simple modified models: "Structured Skip-n-gram" and "Continuous Window", solving syntax-based problems. From another perspective, Levy and Goldberg (2014) use another type of context which uses word contexts derived from dependency parse-trees.

3 Continuous Bag-of-Words (CBOW)

Our departure point is the *continuous bag-of-words* (CBOW) model introduced in (Mikolov et al., 2013b). The CBOW model predicts the center word w_t given the representations of the surrounding words $w_{t-c}, \ldots, w_{t-1}, w_{t+1}, \ldots, w_{t+c}$, where c is a hyper-parameter defining the window size of context. The objective function is to maximize the average log probability:

$$\frac{1}{T}\sum_{t=1}^{T}\log p(w_t|w_{t-c}^{t+c}),$$

where T is the size of a sequence of words. The basic CBOW defines the probability of predicting the center word w_t using the softmax function:

$$p(w_t|w_{t-c}^{t+c}) = \frac{\exp({\mathbf{v}_t'}^{\top}\mathbf{v}_{t-c}^{t+c})}{\sum_{i=1}^{V}\exp({\mathbf{v}_i'}^{\top}\mathbf{v}_{t-c}^{t+c})},$$

where $\mathbf{v}_t^{'}$ is the word embeddings of w_t and $\mathbf{v}_{t-c}^{t+c}$ is the context representation. V is vocabulary size. $\mathbf{v}_{t-c}^{t+c}$ is calculated by summing the word representations of context words:

$$\mathbf{v}_{t-c}^{t+c} = \sum_{-c \leq j \leq c, j \neq 0} \mathbf{v}_{t+j},$$

where $\mathbf{v}_{t+j}$ is the word representation of word w_{t+j}.

In order to improve the computation speed of the full softmax layer, several efficient extensions are proposed including hierarchical softmax and negative sampling (Mikolov et al., 2013b).

4 CBOW with Implicit Structure Information

We will discuss the proposed CBOW-CW model in three parts. Section 4.1 explains the advantages of adding implicit structure information to CBOW. In Section 4.2, we introduce a more advanced model using implicit structure information to offer theoretical soundness of the later CBOW-CW model. Then we derive a simplified method CBOW-CW what we actually have done in this paper in Section 4.3.

4.1 Motivation

While the window size c is a hyper-parameter of the CBOW model which is fixed before the training starts, the model samples the actual window size between 1 and c uniformly for each token in actual implementation. This scheme is equivalent to weighting according to distances from the center word divided by the window size (Levy et al., 2015).

However, this might not be reasonable, since a word from a large distance away can also be informative. For instance, in Figure 1, the words *apples* and *peaches* are equally important for predicting the word *eating*, while their relative distances to *eating* are different.

To solve this problem, Levy and Goldberg (2014) use word contexts derived from the dependency parse-trees. Figure 1 shows an enhanced dependency parse-graph which is generated using the Stanford parser (Chen and Manning, 2014). In the CBOW model, when predicting the word *eating*, the context words are *Jim*, *likes*, *apples* and *as* for a size-2 window. However, in the model of Levy and Goldberg (2014), the context words are words that have dependency relations with the center word *eating*: *likes*, *apples* and *peaches*. Note that the word *peaches*, one of the modifiers of *eating* that is not a context word in CBOW model, is now taken into the set of context words.

However, this method relies on syntactic parsing which is time-consuming. The challenge is how to absorb the advantages of a syntax-based context while avoiding the complexity of parsing. In the following, we first introduce a more advanced model using implicit structure information. Then we derive a simplified method CBOW-CW to attach different weights to the context words to approximate the effect of different context words obtained from syntactic trees.

4.2 Advanced Implicit Syntax-based Model

In this section, we present a more advanced implicit-syntax-based model. The implicit-syntax-based model assigns a weight α_{t+j} to each context word w_{t+j} given a center word w_t. If we could rely on a syntactic parser, we could compute α_{t+j} by summing up the number of syntactic relations between w_{t+j} and w_t on syntactic trees. Alternatively, in the implicit-syntax-based model, we assume a neural network to predict the weights $\boldsymbol{\alpha}$ using the center word and its context words, without relying on explicit syntactic trees.

To summarize, the implicit-syntax-based model contains two components as illustrated in Figure 2. The first component sums up the word vectors of the context words with weights, and then passes the sum to the softmax layer to predict the probability of the center word. The second component is a neural network that predicts these weights. To train them, we can use the alternative optimization method which optimizes one component at a time assuming the other component is optimal. To simplify discussion, we temporarily assume that a full softmax model is used. The first CBOW-with-weights component predicts the center word by:

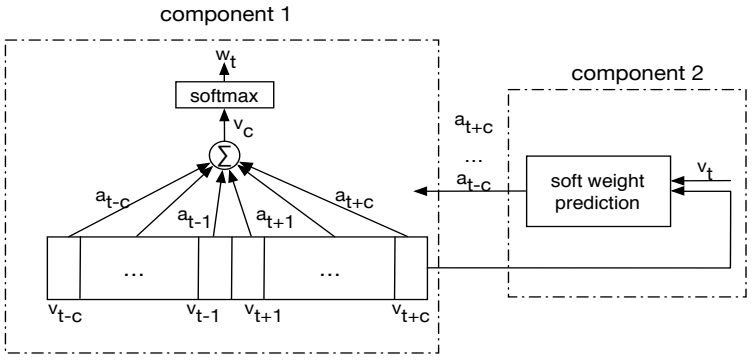

Figure 2: The two components in the implicit syntax-based model.

$$p(w_t|w_{t-c},\cdots,w_{t-1},w_{t+1}\cdots,w_{t+c}) = softmax(U \sum_{-c\leq j\leq c, j\neq 0} \alpha_{t+j}\mathbf{v}_{t+j}) = softmax(U\boldsymbol{\alpha}_t V_t^\intercal),$$

where U is the parameter in the full softmax layer, and the i-th column in U represents the expected context vector $\mathbf{u}_i$ of each word w_i in the vocabulary, $\boldsymbol{\alpha}_t$ is a vector consists of weights $\alpha_{t-c},\cdots,\alpha_{t-1},\alpha_{t+1},\cdots,\alpha_{t+c}$ and $V_t^\intercal$ is the transpose of the matrix concatenating the word embeddings of the context words, i.e. $\mathbf{v}_{t-c},\cdots,\mathbf{v}_{t-1},\mathbf{v}_{t+1}\cdots,\mathbf{v}_{t+c}$. During an iteration in the alternative optimization, the "soft weights" predictor component is optimized in order to predict a weight α_t for each center word w_t, such that the weighted sum $\mathbf{v}_c$ of the context word vectors approximates the expected context vector $\mathbf{u}_t$ of the center word. However, we can use a simple method to approximate the "soft weights" predictor component, since the optimal $\boldsymbol{\alpha}_t$ such that $\boldsymbol{\alpha}_t V_t^\intercal = \mathbf{u}_t$ can be solved analytically, assuming that the CBOW-with-weights is optimal, by $\boldsymbol{\alpha}_t = \mathbf{u}_t(V_t^\intercal)^{-1}$.

However, the actual CBOW model uses a Huffman softmax tree instead of a full softmax tree for improving performance, where context vectors $\mathbf{u}_t$ cannot be obtained directly. Therefore, we design a simple heuristic to calculate $\boldsymbol{\alpha}_t$ as described in Section 4.3. To sum up, our simple CBOW-CW model is an efficient approximation to the more advanced implicit-syntax-based model described above.

4.3 CBOW with Context Weights (CBOW-CW)

Now that the advanced implicit-syntax-based model offers the theoretical soundness of our idea, we can design our model to be simple, so that it is efficient to run and incremental to implement based on CBOW and, hopefully, other word embedding algorithms. We introduce the CBOW-CW model which is actually what we have done in this paper.

This work generalizes the CBOW model by attaching different weights α's to different context words. We denote $\mathbf{v}_{t-c}^{t+c}$ as the context representation of a center word w_t. It is the weighted sum of the word vectors $\mathbf{v}_{t+j}$ of context words of w_t, and is defined below:

$$\mathbf{v}_{t-c}^{t+c} = \sum_{-c\leq j\leq c, j\neq 0} \alpha_{t+j}\mathbf{v}_{t+j}.$$

In Levy and Goldberg (2014), a dependency parse-tree is used to determine the context of each word. For a center word, its neighbor nodes, including its head word and its modifier words in the dependency parse-tree are assigned a weight 1, and the other words are assigned a weight 0 in a sense. Instead of using a single best dependency parse-tree and assigning context words with "hard weights", i.e. 0's and 1's, a natural alternative is to ask a dependency parser to return a number of best dependency parse-trees and their probabilities, and then assign context words with "soft weights". In CBOW-CW, we define "soft weights" in the same sense, but we compute them using a simple and efficient method that does not explicitly rely on dependency parse-trees. The concrete method we use to compute the "soft weights" is described in the following part.

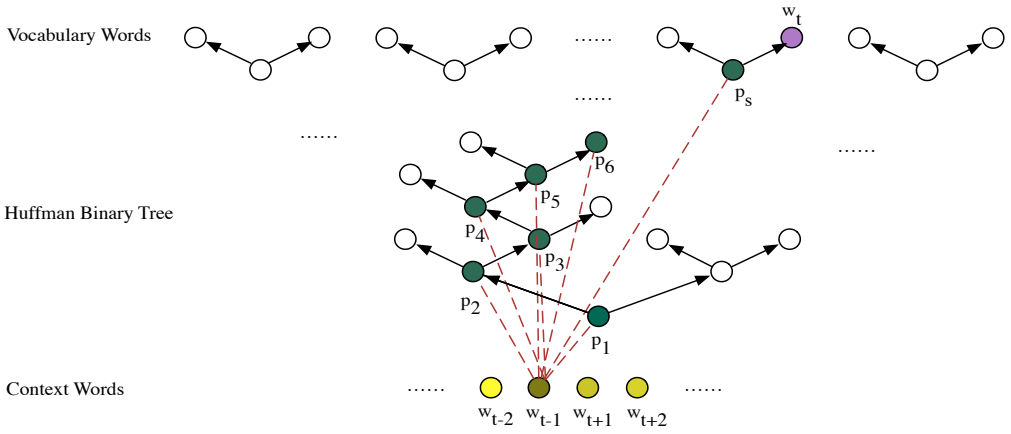

Figure 3: Computing the "soft weight" for each word w_{t+j} in the Huffman softmax tree of CBOW. Nodes on the top are the words in the vocabulary, which are leaf nodes of the binary softmax tree. The $P_t = \{p_1, p_2, \ldots, p_s\}_t, w_t$ is a path from the root node to the center word w_t in the Huffman softmax tree, where p_1 is the root node. The red dashed lines indicate the dot product of a context word vector and an vector associated with the nodes in the softmax tree.

Computation of the "Soft Weights" Before discussing the details of CBOW-CW, we need to talk about the Huffman softmax tree in CBOW. CBOW uses a Huffman softmax tree to accelerate its softmax layer. As shown in Figure 3, the leaf nodes of the Huffman softmax tree are the words to predict in the vocabulary, and each internal node is associated with a vector. To predict a word given its context vector $\mathbf{v}_c$, a path $P = \{p_1, p_2, \cdots, p_s, w_t\}$ is found from the root node p_1 of the tree to the predicted leaf node w_t. This path is determined hop-by-hop: the next node p_{k+1} of the partially computed path $\{p_1, p_2, \cdots, p_k\}$ is determined by the sign of the inner-product $\mathbf{v}_c \cdot \mathbf{v}_k$, where the vector $\mathbf{v}_k$ is associated with p_k. If the inner product is positive, p_{k+1} is the left child of p_k, otherwise the right child of p_k.

In CBOW-CW, we compute the "soft weight" α_{t+j} of context word w_{t+j} given the center word w_t as follows. Let $P_t = \{p_1, p_2, \cdots, p_s, w_t\}$ be the path from the root p_1 to the center word w_t in the Huffman softmax tree. We know that for a particular context word, once a "hop" is wrong, the rest of the path will be wrong. The weight α_{t+j} is vaguely defined as its "contribution" in finding the path P_t. This "contribution" is here defined as the number of correct next hops on path P_t that are computed, if the context vector $\mathbf{v}_c$ was replaced by $\mathbf{v}_{t+j}$. That is, the number of correct hops on the path that can be predicted, if we use context word w_{t+j} alone instead of the complete set of context words of w_t. The weight is a measure of similarity between a context word vector and the sum of context vectors. Concretely, the weight α_{t+j} for the context word w_{t+j} is defined as:

$$\alpha_{t+j} = \frac{\sum_{1 \le k \le s} 1\{(\mathbf{v}_k \cdot \mathbf{v}_{t+j}) \cdot (\mathbf{v}_k \cdot \mathbf{v}_c) > 0\}}{Z},$$

where s is the length of the path P_t. The indicator function $1\{x\}$ returns 1 iff x is $true$. $\mathbf{v}_k$ is the vector associated with node p_k on path P_t. $\mathbf{v}_{t+j}$ is the word vector of context word w_{t+j}. Z is the normalization factor: $Z = \sum_{-c \le j \le c, j \ne 0} \alpha_{t+j}$.

5 Experiments

To qualitatively analysis our method of attaching implicit syntactic weights, we make comparisons of CBOW-CW and CBOW, and we also visualize "implicit graph" for several sentences to compare with dependency parse-trees. To quantitatively evaluate the quality of the word embeddings generated from the proposed model, we experiment on several word similarity and word analogy tasks.

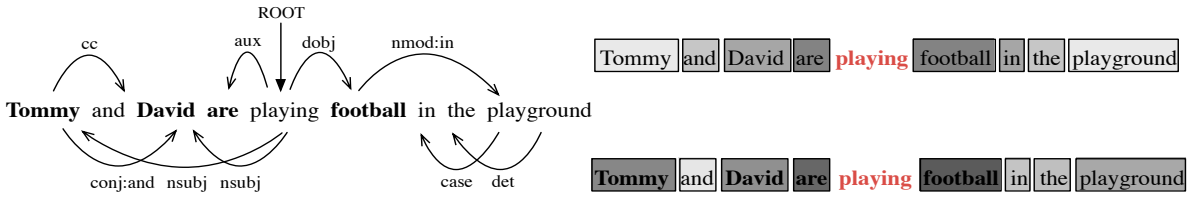

Figure 4: A sentence "*Tommy and David are playing football in the playground* " and its extended dependency parse-tree (top). The context weights in CBOW model (middle). The context weights in CBOW-CW (bottom). The center word is "playing". Darker colors indicate larger weights.

5.1 Comparison of CBOW-CW and CBOW

As illustrated in Figure 4, we show the difference between CBOW-CW and the CBOW using the sentence "*Tommy and David are playing football in the playground* " with the center word *playing* and the context window size 4. The dependency parse-graph is generated using the Stanford parser (Chen and Manning, 2014). In the CBOW model, the context words are *Tommy*, *and*, *David*, *are*, *football*, *in*, *the* and *playground*. The weights of the context words become smaller as their distances to the center word increase. However, one can see that *Tommy*, *David*, *are* and *football* are modifiers of *playing* so that they should be more important for predicting *playing*. In contrast, the proposed CBOW-CW model is able to attach more reasonable weights to the context words: the weights of *Tommy*, *David*, *are* and *football* are higher than most of the other words in the sentence.

5.2 Visualization of Implicit Syntactic Graph

In order to inspect our implicit syntactic weights, we visualize the "implicit graph" constructed using the "soft weights" for several sentences as illustrated in Figure 5. These sentences have different grammatical structures and they are chosen randomly. We draw undirected edges between two words if the inner-product of their word vectors exceed a threshold. The constructed graphs are not identical to the dependency parse-graphs. The dependency parse-graphs are built on human defined syntactic relations. There are other relations between words in reality, and therefore our "soft weights" are less restricted. Nevertheless, from the comparison of the "implicit graphs" and the enhanced dependency parse-graphs, we can find that our efficiently computed "implicit graphs" implicitly contain some dependency relations. This shows that our "soft weights" contain useful implicit structure information.

5.3 Word embeddings

We experiment with a large number of hyper-parameters. The space of hyper-parameters explored in this work is shown in Table 1. `win`, `neg`, `dim` and `ite` denote the window size, the number of negative examples, the dimension of word vectors and training iterations, respectively. The model will discard words that appear less than `min` times.

Training Corpora We built word embeddings using the original CBOW implementation[1] and our modified model on an English Wikipedia dump[2] containing about 1,989 million words, pre-processed by removing non-textual elements, sentence splitting and tokenization. The default value of the hyper-parameter `min` is 5, which means filtering out words with less than 5 instances and resulting in a vocabulary of 1,953,057 words. We also use the text8 corpus provided in `Word2Vec` package as a smaller dataset. The text8 corpus is the first 10^8 bytes of fil9, which is a 715 MB file filtered from the 1 GB file enwiki9.

Training Details For both the original CBOW and our CBOW-CW, we set the learning rate to the default value 0.05 and decrease it as the training process (Mikolov et al., 2013a). The settings of other hyper-parameters are showed in Table 1.

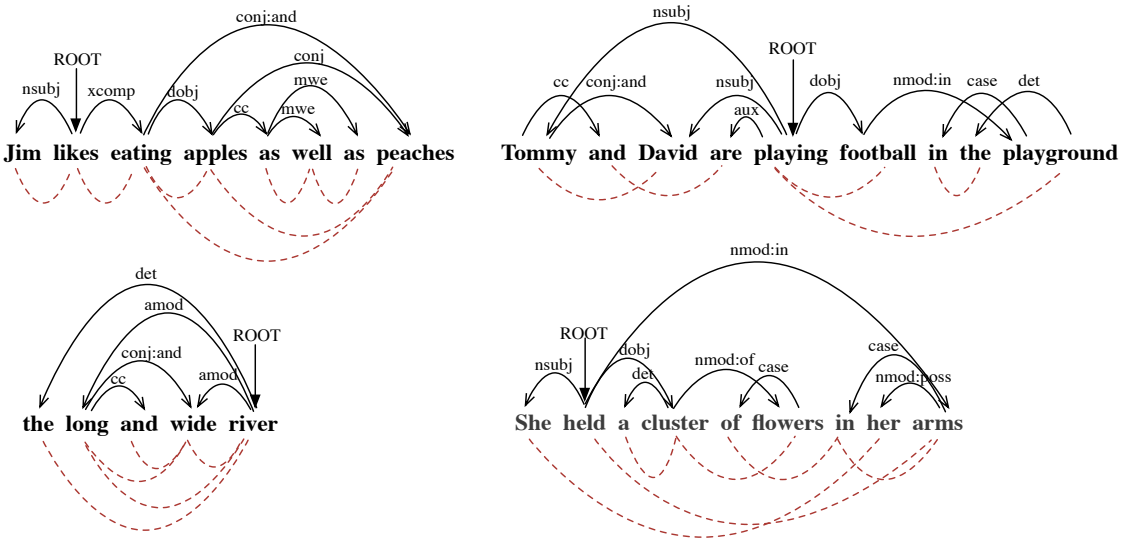

Figure 5: Constructed "implicit graphs" for several sentences. The enhanced dependency parse-graphs (shown in dark solid curves) above the sentences and the visualization of "implicit graphs" using our implicit syntactic weights (shown in red dashed curves) below the sentences.

Hyper-params	values	enwiki	text8
`win`	3, 5, 10, 20	10	10
`neg`	0, 8	8	8
`dim`	50, 100, 200, 300	300	200
`min`	5, 20, 50, 400	5	5
`ite`	5, 10	10	10

Table 1: The space of hyper-parameters explored in this work (the second column). The setting of hyper-parameters at which we report the results when using the enwiki corpus (the third column). The setting of hyper-parameters at which we report the results when using the text8 corpus (the forth column).

5.4 Test Datasets

We evaluate the word representations on several word similarity and word analogy tasks.

Word Similarity The word similarity computation is a traditional task for evaluating word embeddings. We used four datasets to evaluate word similarity including *WordSim353* (ws) (Finkelstein et al., 2001) partitioned into two datasets, *WordSim Similarity* (wss)and *WordSim Relatedness* (wsr) (Zesch et al., 2008; Agirre et al., 2009); Bruni et al.'s (2012) *MEN* dataset; Radinsky et al.'s (2011) *Mechanical Turk* (MTurk) dataset; the *TOEFL* dataset (Landauer and Dumais, 1997).

The first three datasets contain word pairs together with human-annotated similarity scores. The word embeddings are evaluated by ranking according to their cosine similarities and calculate the Spearman's rank correlation(Spearman's ρ) with the human-assigned scores. For the *TOEFL* set, we choose the nearest neighbor of the question word from the 4 candidates based on the cosine distance and use the accuracy to measure the performance.

Word Analogy The analogy dataset presents questions in the form of "a is to a^* as b is to b^*" in which b^* needs to be guessed from the entire vocabulary. Mikolov et al. (2013c) found that the learned word representations capture meaningful syntactic and semantic regularities referred to as *linguistic regularities*. We apply the Google's analogy dataset (Mikolov et al., 2013a) to evaluate word analogy performance. It contains 19,544 questions divided into two categories: 8,869 semantic questions and 10,675 syntactic questions. Such questions are answered through finding the word vector v_{b^*} which has the maximum cosine distance to the vector "$v_{a^\star} - v_a + v_b$" (Levy et al., 2014): $\arg\max_{b^\star \in V}(\cos(b^\star, b + a^\star - a)$. The

Results on the enwiki corpus (%)

Table 2: Performance of CBOW and CBOW-CW (our work) on different word similarity and word analogy tasks. The best result for each dataset is highlighted in **bold**.

evaluation metric for word analogy is the percentage of questions for which the $\arg\max$ result is the correct answer.

5.5 Results and Analysis

We compare the proposed CBOW-CW model with the original CBOW model and report the results using the settings in Table 1 for the text8 and enwiki corpus, respectively. Other settings of hyper-parameters can also obtain similar results.

Word Similarity The left of Table 2 shows the results for several word similarity tasks. The best result for each dataset is highlighted in **bold**. We found that in almost all of these datasets, except for the *TOEFL* dataset when training on enwiki corpus, the proposed model performs better than the original CBOW model. The results indicate that the method of appending different weights to different context words is effective and the heuristic for computing the "implicit weights" is helpful for building word embeddings. When training on the enwiki corpus, the CBOW-CW model can obtain similar results compared to the CBOW model on the *TOEFL* dataset. We suspect this maybe due to the fact that the *TOEFL* dataset is composed of low-frequency words and our model favors only high-frequency words since the Huffman softmax tree is built according to word frequency.

Word Analogy Table 2 also shows the results of the word analogy tasks. The CBOW-CW model does not perform well as it does on the word similarity tasks compared with the CBOW. When training on the large enwiki corpus, the proposed model performs better in terms of semantic accuracy but not so well in terms of syntactic accuracy. When training on the text8 corpus, CBOW-CW achieves pretty well improvement, especially on semantic accuracy where it increases nearly 12 percent compared with CBOW. Those results show that CBOW-CW is better in catching semantic information than syntactic information.

By comparing the results training on enwiki and text8, we interestingly find that our model provides a large accuracy gain over CBOW with small training data. This provides an advantage for small training corpora and indicates that our model has higher convergence rate than the original CBOW model. We are still exploring the reason of this, and we suspect that maybe due to that the method of computing weights is biased by the depth of the word in the Huffman tree. The shallow of the word in the Huffman tree, the higher accuracy of computing the weights.

Regarding the computation speed, the CBOW-CW model runs at a rate around a quarter of the rate of CBOW due to the additional computation for context weights. Even so, our model is capable of training word embeddings on the largest corpora in one day.

6 Conclusions

We proposed an extension to the CBOW model by adding implicit structure information. Our method absorbed the advantage of using a dependency tree-based context while avoiding the complexity of it. In future work, we will conduct more evaluations with other weighting schemes.

Abstract

With the development and the advancement of social networks, forums, blogs and online sales, a growing number of Arabs are expressing their opinions on the web. In this paper, a scheme of Arabic sentiment classification, which evaluates and detects the sentiment polarity from Arabic reviews and Arabic social media, is studied. We investigated in several architectures to build a quality neural word embeddings using a 3.4 billion words corpus from a collected 10 billion words web-crawled corpus. Moreover, a convolutional neural network trained on top of pre-trained Arabic word embeddings is used for sentiment classification to evaluate the quality of these word embeddings. The simulation results show that the proposed scheme outperforms the existed methods on 4 out of 5 balanced and unbalanced datasets.

1 Introduction

A growing number of people get used to give their opinions on social network websites, forums, video sharing websites, blogs and e-commerce websites, leading to a most rising research fields caused by the important opinionated web contents. The opinions could be used for many applications such as consumer modeling, sales prediction, opinion survey or user intent understanding. Sentiment analysis which is used to identify, extract and classify subjective information in the opinions, has attracted a lot of attention. Sentiment analysis can be divided into several levels: document level (Yessenalina et al., 2010), sentence level (Farra et al., 2010), word/term level (Engonopoulos et al., 2011) or aspect level (Chifu et al., 2015).

Currently, sentiment analysis is commonly used for English, while sentiment analysis on the Arabic language is still recognized at its early stages (Nabil et al., 2015; ElSahar and El-Beltagy, 2015), since sentiment analysis on Arabic is considered as a more challenging work. Firstly, Arabic has a very complex morphology and structure. Inflectional and derivational nature of Arabic language makes the monophonically analysis on Arabic more difficult (Hammo et al., 2002). Secondly, Arabic Internet users mostly use dialectal Arabic rather than Modern Standard Arabic (MSA), while MSA is the formal written language but dialectal Arabic is used in informal daily communication. Moreover, dialectal Arabic is not included in education systems or standardized (Habash, 2010). The diversity of different writings and the language cultural creates more challenges to learn and build language models for representations. Nowadays, more than 267 million people speak Arabic as the first language, and more than 250 million as the second language covering 58 countries[1]. There are around 168.1 million Arabic Internet users with a user growth rate of 6,592.5% (November 2015 by Internetworldstats[2]) , making research of sentiment analysis on the Arabic language important.

In this paper, we try to solve the problems of word embeddings and sentiment classification for Arabic text. We firstly use a web-crawler to build a 10 billion Arabic words corpus, and we realize an word embeddings model to produce Arabic word representations using this corpus. Finally, a convolutional

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2418–2427, Osaka, Japan, December 11-17 2016.

neural network (CNN) trained on top of pre-trained Arabic word embeddings is used for sentiment classification. The simulation results show that the proposed scheme has a better performance than existed approaches for the Arabic sentiment classification on different datasets. For the convenience of the evaluation of our scheme, we distribute freely the source code and the generated word embeddings on the web[3].

The rest of the paper is organized as follows. The related work will be introduced in Section 2. Section 3 refers to the construction of word embeddings model for Arabic, and Section 4 refers to the CNN model for sentiment classification of Arabic text. Experiments and analyses will be given in Section 5. The conclusion is drawn in Section 6.

2 Related Works

In this Section, we review existing works related to the proposed scheme. We start with the works on word embeddings, which represent individual words of a language as vectors onto a lower dimensional vector space. Then we introduce the works related to sentiment classification. These methods and techniques can be used to generate semantic representations of texts and perform classification for various tasks in NLP, which are the interesting and related works to our study.

Via neural language models, various deep learning methods have been proposed to learn word vector representations. WORD2VEC (Mikolov et al., 2013) has been proposed for building word representations in vector space, which consists of two models, including continuous bag of word (CBOW) and Skipgram (Skip-Gram). Global vectors for word representations are also used to build word representations (Pennington et al., 2014), where training is based on statistics of word to word co-occurrence from a corpus.

Recently, sentiment classification becomes one of the most motivating research area among natural language processing (NLP) community. Many tools and applications have been applied to Arabic sentiment classification. (Abdul-Mageed et al., 2011) reported efforts for classifying MSA news data at the sentence level for both subjectivity and sentiment using support vector machine (SVM) classifier. (Abdul-Mageed et al., 2014) presented an SVM-based system for subjectivity and sentiment analysis for Arabic social media named SAMAR. (Farra et al., 2010) proposed an Arabic sentence level classification based on syntactic and semantic approaches. (El-Halees, 2011) proposed a combined classification approach for document level sentiment classification using different classifiers, including lexicon based classifier, maximum entropy classifier and k-nearest neighbors (KNN) classifier. More recently, CNN have achieved remarkably strong performance tackling NLP tasks and gotten some interesting results (Kalchbrenner et al., 2014; Kim, 2014). (Kalchbrenner et al., 2014) introduced a dynamic CNN for modeling sentences, and (Kim, 2014) proposed an improved scheme which employs dynamic-updated and static word embeddings simultaneously for sentence classification based on CNN.

3 Arabic Word Embeddings

Machine learning offers significant benefits for representations of a word from text and understanding natural language. The WORD2VEC tool[4] (Mikolov et al., 2013) remains a popular choice benefited from its fast training and good results. CBOW and Skip-Gram in WORD2VEC use a probabilistic prediction approach which captures syntactic and semantic word relationships from very large data sets. In this work, we explore several architectures to build neural word embeddings for MSA and dialectal Arabic. In particular, we perform a comprehensive analysis to train and evaluate word representations using CBOW and Skip-Gram models, with the goal of generating a better quality representations for Arabic sentiment classification. Fig. 1 shows the steps from collecting the corpus to building word representations.

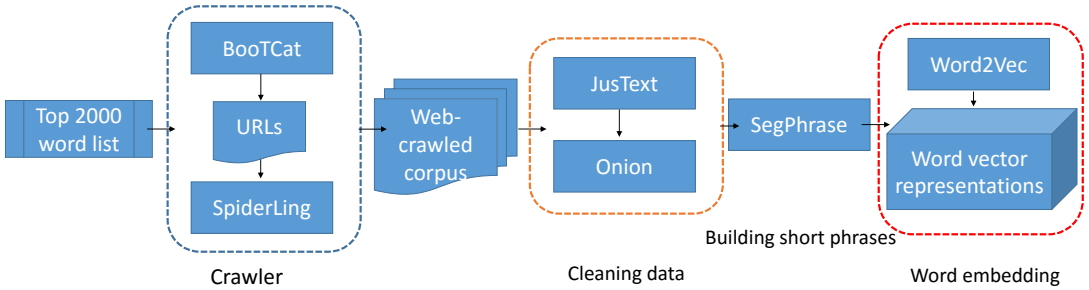

Figure 1: The processes of building Arabic word embeddings

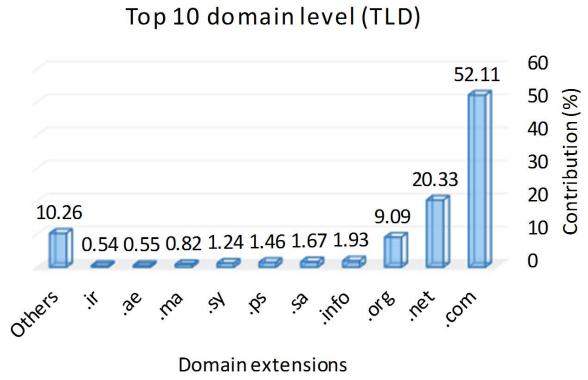

Figure 2: Top 10 Internet top-level domains (TLD).

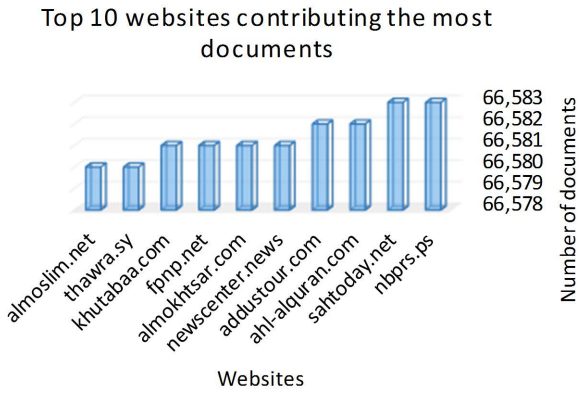

Figure 3: Top 10 websites exploited from the crawler seeding list which contribute the most documents.

3.1 Crawling and Preparing the Corpus

The existing corpora are rare freely accessible for download and are typically not large enough for CNN based Arabic sentiment classification. In order to generate Arabic word representations, we create a huge web-crawled corpus for MSA and dialectal Arabic text.

The acquisition of the corpus is performed by means of SpiderLing[5] (Suchomel et al., 2012), which is an open-source and free crawler for effective creation and annotation of linguistic corpora.

The steps for creating the corpus are described as follows:

1) The seeds for the crawler consist of 10,421 URLs, which are generated using Bing queries, after feeding BootCAT [6] with a word-list of top 2000 words based on their frequency. It should be noticed that the word-list has to be filtered from stop words. Then, the seeds are filtered from duplicated URLs, while the filtered seeds are fed to SpiderLing as a start point for Arabic web pages crawling. The top-10 level web domains used by SpiderLing to produce our corpus are shown in Fig. 2, while Fig. 3 presents the list of top-10 domains that contributed the most of documents.

2) For data normalization, we used jusText[7] (Pomikálek, 2011) which is a heuristic based boilerplate removal tool, which is used to exclude contents such as navigation links, advertisements and headers from downloaded web pages. It only keeps paragraphs containing full sentences and removes contents which are not in the desired language. Also, we used Onion[8] (Pomikálek, 2011) for near-duplicate detection and removing. The deduplication is performed on paragraph level and threshold is set to 0.5.

3.2 Pre-processing and Normalization

An intrinsic limitation of word representations for the Arabic language is that sometimes we need two words to represent one meaning. For example, the word “acceptable” and its antonym “unacceptable”.

[5]http://corpus.tools/browser/spiderling.
[6]http://bootcat.sslmit.unibo.it/.
[7]http://code.google.com/p/justext/.
[8]https://code.google.com/p/onion.

However, the antonym word has no direct (word-to-word) Arabic translation, غير and مقبول can't be easily combined to obtain "غير_مقبول" which is the closest translation to the antonym word. Motivated by this kind of limitation, we thus use SegPhrase[9] (Liu et al., 2015) to learn these phrases.

Based on a data-driven approach presented in (Mikolov et al., 2013) which relies on the count of unigram and bigram to form phrases, we run an experiment using the following equation:

$$score(w_i, w_j) = \frac{count(w_i w_j) - \delta}{count(w_i) \times count(w_j)}, \quad (1)$$

where δ is a discounting coefficient to prevent the formation of phrases with infrequent words. Bigrams with a score over the chosen threshold are then formed as phrases.

We use an Arabic text consisted of 1.3 billion words and a vocabulary[10] of 3.5 million words to form short phrases based on equation (1). From this experiment, we notice that the average amount of formed phrases occupy 47.42 % of the new vocabulary when we set the threshold to 100. These short phrases occupy 16.18 % from the total number of tokens in the Arabic text. We also notice that raw frequency methods could not reflect the quality of these phrases, since both good and bad phrases can possess high frequency.

To learn these semantical and meaningful phrases and to generate better word embeddings for Arabic, we choose SegPhrase rather than the previous approach. SegPhrase is a framework that aims to extract and mine quality phrases from a large text, combined with a module for phrase segmentation. Thus, text data is transformed from word granularity to phrase granularity. To use SegPhrase for Arabic text, we also need to build two knowledge bases, where the smaller one consists of 94,544 labels and contains high-quality phrases for positive labels. Moreover, the larger one contains 121,127 labels, which is used to filter medium and low-quality phrases for negative labels.

Some examples are سان فرانسيسكو (San Francisco), المملكه العربيه السعوديه (Kingdom of Saudi Arabia) and هواري بومدين (Houari Boumediene) labeled to be positive. In contrast, phrases like تسويق دولي (International marketing), تسلسل زمني (Chronology) and تحت المجهر (Under the microscope) were labeled as negative. A threshold of raw frequency with value 10 is specified for frequent phrase mining, which will generate a candidate set. Another parameter is used to parse our corpus using the generated model which is the ratio of top ranked phrases with value 0.5.

The processing steps for cleaning and normalizing the corpus are as follows : 1) Remove punctuation, diacritics, non letters , and non Arabic. 2) Normalization of the different writings of the latter (Alef) إ , أ , آ with ا. 3) Convert the letter (Teh Marbuta) ة to ه.

3.2.1 Training Parameters

By using Word2Vec tool, we build several models based on different architectures and word vector dimensionality. Table 1 shows the training parameters used for various models based on CBOW and Skip-Gram architectures.

Model	dimensionality	Window size	Sample	Negative	Freq. thresh.	Max iterations
CBOW	100,200,300	5	$1 \times e^{-5}$	10	10	3
Skip-Gram	100,200,300	10	$1 \times e^{-5}$	10	10	3

Table 1: Word vector representations training parameters

For the quality evaluation of the generated Arabic word embeddings, we use word analogy questions task. We compare the vectors in (Zahran et al., 2015) with our vectors.

[9]https://github.com/shangjingbo1226/SegPhrase.

[10]We did not set a frequency threshold because we want to use all the words even the rare words.

4 CNN for Sentiment Classification

In this Section, we tackle our downstream semantic task which is Arabic sentiment classification relying on the Arabic word embeddings model from the previous section. It is a binary classification task between positive and negative and covers two domains: reviews and tweets. Here, the standard 10-fold cross validation is applied to the balanced and unbalanced datasets to report accuracy on all different used datasets.

4.1 CNN Architecture

We consider a CNN architecture similar to that described in (Kim, 2014), with one channel that allows the adaptation of pre-trained vectors for each task. The hyper-parameters used for the training of all models[11] will be discussed in later paragraphs.

Due to the absence of a large supervised training set and as described in (Socher et al., 2011; Iyyer et al., 2014), the training word vectors are initialized by a pre-trained model, in our case the CBOW58[12] model. Where each vector has a dimensionality of $k = 300$ and is trained using CBOW architecture. An initialization of word vectors for all words which are out from CBOW58 model's vocabulary has been performed by sampling from a uniform distribution in the range of [-0.25,0.25] following (Kim, 2014) work.

Here, we define S as a sentence of n words, and let m_i be the ith word in the sentence S[13], where each $m_i \in S$ is represented by x_i a k-dimension vector such as $x_i \in \mathbb{R}^k$.

To perform convolution operation via linear filters over S, we convert S to a sentence matrix of shape $(n \times k)$. Where each row corresponds to a vector x_i [14]. Considering our filter $w \in \mathbb{R}^{hk}$ we set 3 different window widths (of h words) from $D \subset \mathbb{N}^*$, where $D = \{3, 4, 5\}$, with a fixed length k for each filter dimensionality. The application of a convolution operation using one filter window size $h \in D$ over the sentence matrix produces new features.

To capture most relevant global features, and deal with variable sentence lengths. We use a *max-over-time* pooling operation (Collobert et al., 2011) to downsample the feature maps.

After concatenating all feature maps in one single vector with a fixed length, we feed this vector through a fully-connected layer with $Dropout$ (Hinton et al., 2012). Here, the $Dropout$ rate is set to 0.5, and a sigmoid function to generate the final classification. A gradient based optimization named Adagrad (Duchi et al., 2011) with Mini-batch size of 32 is used. The output is the probability distribution over labels. Fig.4 provides a schematic illustrating of the model architecture.

5 Experiments and Analyses

In this section we explore the process of analyzing the quality and the impact of word embeddings using two major evaluations. We start by the intrinsic evaluation using word analogy questions task in Section 5.1. Secondly, we do an extrinsic evaluation by performing Arabic sentiment classification task after defining a CNN model trained on top of the generated word embeddings model in Section 5.2.

5.1 Vector Quality Evaluation

The goal of word analogy questions is to correctly identify the relationship between *C* and *D*, given a relationship between words *A* and *B*. The questions will be in the form of $A : B : C : D$, where the pairs of word (*A*, *B*) and (*C*, *D*) are sharing the same relation (e.g. "man:woman", "king:queen"). We hide the identity of the fourth word D and we predict it based on the other three words, using similarity measure functions like cosine similarity, or Euclidean distance. To find a word that is closest to *D* measured by cosine distance, an algebraic computation can be performed on word embeddings. Here, we simply compute vector $vector(D) = vector(C) - vector(A) + vector(B)$

[11] All experiments run with Keras and Theano on an NVIDIA GeForce GTX 780 Ti GPU.

[12] CBOW58 is the best model of Arabic word embeddings built in Section 3 and the results are listed in Section 5.1.

[13] We use the same zero-padding strategy as in (Kim, 2014).

[14] x_i refers to word vector extracted from $CBOW58$ model with $k = 300$.

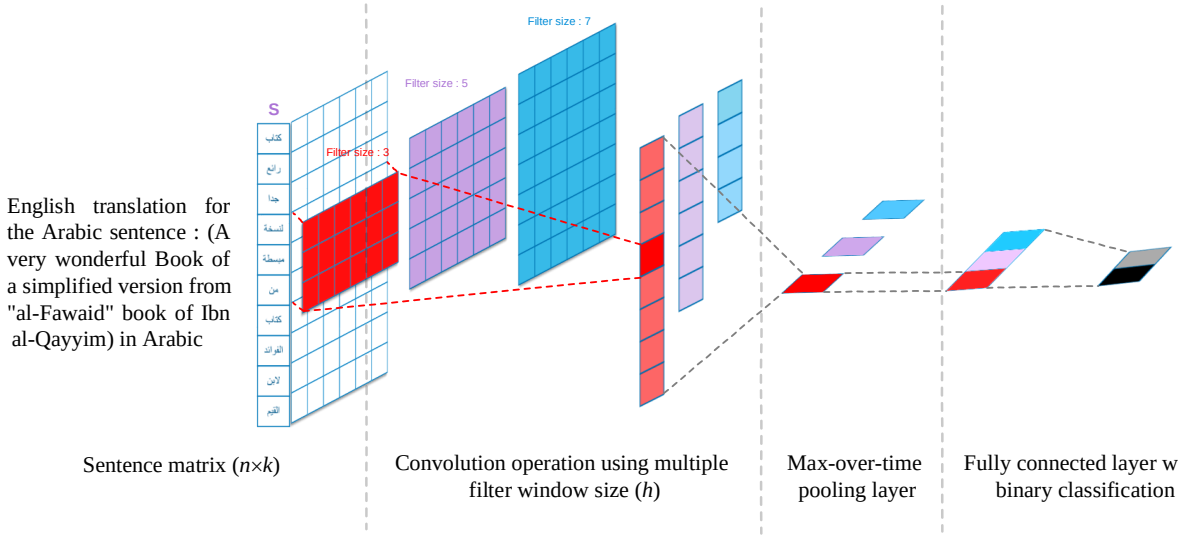

Figure 4: Model architecture for an Arabic example sentence.

To test the quality of the vectors, we used the test cases from (Zahran et al., 2015) with the correction of few Arabic spelling errors and the adding of new analogy questions for opposite words such as opposite 2-gram. The generated new test cases for Arabic contains 24,294 questions. Overall, there are 10,463 semantic and 13,831 syntactic questions. It covers 15 analogy questions, 5 types of semantic questions, and 10 types of syntactic related questions. Some examples are shown in Table 2. The cosine similarity measure we used is defined as:

$$\cos(u, v) = \frac{u \cdot v}{\|u\|\|v\|} \tag{2}$$

Analogy question	Word pair 1				Word pair 2			
Common-capital-countries	Rome	روما	Italy	ايطاليا	Bagdad	بغداد	Iraq	العراق
Oppisite 1-gram	Short	قصير	Tall	طويل	Sad	حزين	Happy	سعيد
Opposite 2-gram	Certain	مؤكد	Uncertain	غير مؤكد	Acceptable	مقبول	Unacceptable	غير مقبول

Table 2: Examples of word analogy questions test set

Equation (3) is used to calculate the cosine similarity of the analogy questions to predict the closest word. Where V is the used vocabulary ignoring the three question words *B*, *A* and *C*. An answer on one of the question analogy is counted correct only if one of the top five predicted words matches the fourth word *D*.

$$\arg\max_{D \in V}(\cos(D, C)\cos(D, A) + \cos(D, B)) \tag{3}$$

Here we use Equation (3) for the evaluation. The results for all different word vector models are shown in Table 3, where "Cov" is an abbreviation for coverage and "Acc" for accuracy, and we represent different dimension as $i-$d where i denotes the dimension size (100-D describe a dimensionality of 100).

In Section 3, we have shown the processing steps to build the corpus and the training parameters for our word embeddings. Collecting a big corpus for these tasks is a major step, but the most important is the evaluation part for the quality of the collected data and the pre-processing operation. The used data to build Arabic word embeddings models consist of 3.4 billion words and a vocabulary of 2.2 million words, In (Zahran et al., 2015), they used 5.8 billion words in their corpus with a vocabulary of 6.3 million words. More iterations improved the accuracy significantly during the training process of our models. Pre-processing the crawled corpus by mining quality phrases to avoid forming incorrect or low-quality phrases could help to enhance the quality of short phrases. As shown in opposite-2gram analogy

Table 3: Total accuracy of (Zahran et al., 2015) word embeddings model and our Arabic word embeddings models on word analogy questions test set. All numbers in the table are percentage.

questions type of Table (3), the coverage rate is 69.05 % compared to 28.57 % in a trained model based on Equation (1). According to comparisons based on the word embeddings dimensionality, it could be found that using low dimensionality does not help much to improve the quality of these vectors when trained on a large corpus. Therefore, a major drawback in these neural based language models is that training on a higher dimensionality is time consuming.

These analogy evaluation scores for different models and architectures are not a great estimator of real-world tasks performance. The use of these word embeddings in a downstream task such as Arabic sentiment classification in our case will be determined by whether these vectors are of good quality or not. These scores provide us with a general idea of what our data looks like.

5.2 Arabic Sentiment Classification

We apply a binary sentiment classification for different corpora from two different domains: reviews and tweets. We run the experiments on the LABR book reviews dataset (Aly and Atiya, 2013) which consists of over 63,000 reviews downloaded from Goodreads[15] in 2013, Arabic Sentiment Tweets Dataset (ASTD) (Nabil et al., 2015) which consists of over 10,000 Arabic tweets, Arabic Gold-Standard Twitter Sentiment Corpus (Refaee and Rieser, 2014) (GS-dataset) collected in 2014, Twitter data set for Arabic sentiment analysis collected by (Abdulla et al., 2013) that consists of 2000 labeled tweets, and also datasets collected by (ElSahar and El-Beltagy, 2015) that covers five domains:

1) *Hotel Reviews (HTL)*: For the hotels domain 15K Arabic reviews are scrapped from TripAdvisor[16].
2) *Attraction Reviews (ATT)*: Attraction reviews are scrapped from TripAdvisor.
3) *Restaurant Reviews (RES)*: Two sources are scrapped to cover restaurants reviews: Qaym[17] and TripAdvisor.
4) *Movie Reviews (MOV)*: collected from 1k movies in Elcinemas.com website, and consists of around 1.5K movies reviews.
5) *Product Reviews (PROD)*: For the Products domain, a dataset of 15K reviews is scraped from the Souq[18] website. The dataset includes reviews from Egypt, Saudi Arabia, and the United Arab Emirates.

We pre-processed all datasets by extracting positive and negative sentences, and splitting them to two main classes. The first one is the balanced class where the numbers of reviews and tweets are equal,

[15] www.goodreads.com.
[16] www.tripadvisor.com.
[17] www.Qaym.com
[18] www.souq.com

and the number is set to the minimum number of positive or negative sentences. The second one is the unbalanced class, where the numbers of reviews and tweets are unequal, and the numbers are set to the maximum numbers of positive and negative sentences, respectively. Datasets preparation statistics are shown in Table 4.

Datasets	Polarity	LABR	ASTD	Gold-Standard	Twitter Data set	ATT	HTL	MOV	PROD	RES
Balanced	Positive	8012	665	858	972	204	6192	384	807	9092
	Negative	8012	665	858	972	204	6192	384	807	9092
Unbalanced	Positive	42689	665	858	978	5242	27428	969	2882	25858
	Negative	8012	1496	1897	972	204	6192	384	807	9092

Table 4: Dataset preparation statistics

Models	LABR	ASTD	Gold-Standard	Twitter Data set	ATT	HTL	MOV	PROD	RES
CNN-balanced	**86.7**	75.9	73.8	86.3	74.2	**88.6**	**83.2**	**83.3**	77.1
CNN-unbalanced	**89.6**	79.07	75.8	85.01	96.2	**91.7**	**80.7**	**87.3**	78.5
(ElSahar and El-Beltagy, 2015)-Linear SVM	78.3	-	-	-	-	87.6	74.3	75.8	83.6
(Abdulla et al., 2013)-SVM	-	-	-	87.2	-	-	-	-	-
(Refaee and Rieser, 2014b)-SVM-BOW	-	-	87.74	-	-	-	-	-	-

Table 5: Comparison of existing methods with our CNN models on the same datasets. SVM (Abdulla et al., 2013), SVM+BOW SVM and Bag of Word from (Refaee and Rieser, 2014), Linear SVM (ElSahar and El-Beltagy, 2015).

Concerning Section 4 and Section 5.2 which evaluates the ability of a CNN based model to perform Arabic sentiment analysis. Table 5 presents results of our CNN models against other methods listing their best classification experimental results. Each cell has numbers that represent the accuracy of the evaluation performed on each dataset. There is a huge gap between different datasets in their sizes. A bigger dataset has better performance in terms of model accuracy. LABR dataset reaches 89.6 % when it has been trained in unbalanced form. The existence of sarcastic and dialectal Arabic (reviews/tweets) really could have a severe impact on the model accuracy. One problem is that there is not that much consecutive semantic/syntactic content in a single tweet. These datasets are examined in their balanced and unbalanced form. The results show that a CNN architecture with one non-static channel and one convolutional layer outperform the listed techniques on a scale 4 of 5 when using balanced datasets. By using all the data in an unbalanced form for the training and validation, the model is more accurately, showing a significant good performance compared to other models.

Additionally, the accuracy of the proposed model for Gold-Standard dataset is lower than that listed in (Refaee and Rieser, 2014), the reason is the used data set in our work is smaller than the original one, and the full dataset of (Refaee and Rieser, 2014) is not available for free. The CNN model provides a remarkable accuracy improvement over the Linear SVM approach used by (ElSahar and El-Beltagy, 2015), which is the previous best-reported result for their collected datasets. Initializing word vectors using our pre-trained vectors (CBOW58) gives a significant accuracy increase. Random initialization of words out of CBOW58 vocabulary can affect the vectors quality during the training. Although, exploring the effect of hyper-parameters for the CNN model still to be investigated in a detailed way, to observe the impact of these parameters on the network performance tackling different tasks.

6 Conclusions

In this study, we have introduced a crawling scheme for a large multi-domain corpus in order to build an Arabic word embeddings model. We have provided short practical and empirically informed procedures for exploring Arabic word embeddings and convolutional neural network (CNN) for sentiment classification.

The experiment results of building Arabic word embeddings from a web-crawled corpus illustrate that the performance increases along with the quality of the data. The results also show that high dimensionality vectors perform well on a large corpus. The results of CNN for sentiment datasets show that

initializing word vectors using a pre-trained word embeddings gain a remarkable performance. They also indicate that a bigger dataset usually has better performance regarding model accuracy.

Abstract

Sentiment analysis of short texts is challenging because of the limited contextual information they usually contain. In recent years, deep learning models such as convolutional neural networks (CNNs) and recurrent neural networks (RNNs) have been applied to text sentiment analysis with comparatively remarkable results. In this paper, we describe a jointed CNN and RNN architecture, taking advantage of the coarse-grained local features generated by CNN and long-distance dependencies learned via RNN for sentiment analysis of short texts. Experimental results show an obvious improvement upon the state-of-the-art on three benchmark corpora, MR, SST1 and SST2, with 82.28%, 51.50% and 89.95% accuracy, respectively. [1]

1 Introduction

The rapid development of the Internet, e-commerce and social networks brings about a large amount of user-generated short texts on the Internet, such as online reviews for products, services and blogs. Such short texts as online reviews are usually subjective and semantic oriented. To discriminate and classify the semantic orientation of such short texts properly is of great research and practical value.

Sentiment analysis of short texts is challenging because of the limited contextual information and the sparse semantic information they normally contain. The existing research on sentiment analysis of short texts basically include emotional knowledge-based methods and feature-based classification methods. The former mainly focuses on the extraction and the sentiment classification based on opinion-bearing words and opinion sentences (Hu and Liu, 2004; Kim and Hovy, 2005). The latter focuses on the sentiment classification based on features. Turney (2002) presented the unsupervised PMI-IR (Pointwise Mutual Information and Information Retrieval) algorithm to measure the similarity of words or phrases. Pang et al. (2002) and Cui et al. (2006) used n-grams and POS tags and applied them to NB, ME and SVM classifiers. Based on these studies, Kim and Hovy (2006) introduced the positional features and opinion-bearing word features. Mullen and Collier (2004) combined various features and used SVM for classification.

With the development of deep learning, typical deep learning models such as convolutional neural networks (CNNs) and recurrent neural networks (RNNs) have achieved remarkable results in computer vision and speech recognition. Word embeddings, CNNs and RNNs have been applied to text sentiment analysis and gotten remarkable results. Kim (2014) applied CNN on top of pre-trained word vectors for sentence-level classification. Some studies utilized recursive neural networks to construct the sentence-level representation vector in sentiment analysis (Socher et al., 2011; Socher et al., 2012b; Socher et al., 2013b). Le and Mikolov (2014) presented the paragraph vector in sentiment analysis. Tai et al. (2015) put forward the tree-structured long short-term memory (LSTM) networks to improve the semantic representations. The improved performance of these algorithms mainly benefits from the following aspects: (1) The high-dimensional distributional vectors endow similar semantic-oriented words with high similarity. Word embeddings can better solve the semantic sparsity of short texts compared with the one-hot representation. (2) Similar to the translation, rotation and scale invariance of images in CNN, CNN is able to learn the local features from words or phrases in different places of texts. (3) RNN takes words in

[1]Code and data are available at `https://github.com/ultimate010/crnn`

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2428–2437, Osaka, Japan, December 11-17 2016.

a sentence in a sequential order and is able to learn the long-term dependencies of texts rather than local features.

In this paper, we present a jointed CNN and RNN architecture that takes the local features extracted by CNN as input to RNN for sentiment analysis of short texts. We develop an end-to-end and bottom-up algorithm to effectively model sentence representation. We take the word embeddings as the input of our CNN model in which windows of different length and various weight matrices are applied to generate a number of feature maps. After convolution and pooling operations, the encoded feature maps are taken as the input to the RNN model. The long-term dependencies learned by RNN can be viewed as the sentence-level representation. The sentence-level representation is taken to the fully connected network and the softmax output reveals the classification result. The deep learning algorithm we put forward differs from the existing methods in that: (1) We apply windows of different length and various weight matrices in convolutional operation. The max pooling operates on the adjacent features and moves from left to right instead of on the entire sentence. In this case, the feature maps generated in our CNN model retain the sequential information in the sentence context. (2) The deep learning architecture of our model takes advantage of the encoded local features extracted from the CNN model and the long-term dependencies captured by the RNN model. We experiment on three benchmarks for sentiment classification, MR, SST1 and SST2 and achieve the state-of-the-art results.

This work is organized as follows. In section 2, we discuss some background knowledge about word embeddings, sentence-level representation, convolutional neural network and recurrent neural network. In section 3, we describe our jointed CNN model and RNN model in detail. Section 4 presents our experiment results and some discussion. Finally, in section 5, we conclude and remark on our work.

2 Background

In this section, we discuss some background knowledge on word embeddings, sentence-level representation, convolutional neural network (CNN) and recurrent neural network (RNN).

2.1 Word Embeddings and Sentence-Level Representation

When applying deep learning methods to a text classification task, we normally need to transform words into high-dimensional distributional vectors that capture morphological, syntactic and semantic information about the words. Let d be the length of word embeddings and l be the length of a sentence. The sentence-level representation is encoded by an embedding matrix $C \in \mathbb{R}^{d \times l}$, where $C_i \in \mathbb{R}^d$ corresponds to the word embeddings of the i-th word in the sentence.

2.2 Convolution and Pooling

Convolution is widely used in sentence modeling (Kim, 2014; Kalchbrenner et al., 2014; dos Santos and Gatti, 2014). The structure of convolution varies slightly in different research fields, among which the structure used in natural language processing is shown in Figure 1.

Generally, let l and d be the length of sentence and word vector, respectively. Let $C \in \mathbb{R}^{d \times l}$ be the sentence matrix. A convolution operation involves a convolutional kernel $H \in \mathbb{R}^{d \times w}$ which is applied to a window of w words to produce a new feature. For instance, a feature c_i is generated from a window of words $C[*, i : i + w]$ by

$$c_i = \sigma(\sum(C[*, i : i + w] \circ H) + b) \quad (1)$$

Here $b \in \mathbb{R}$ is a bias term and σ is a non-linear function, normally tanh or ReLu. $\circ$ is the Hadamard product between two matrices. The convolutional kernel is applied to each possible window of words in the sentence to produce a feature map. $c = [c_1, c_2, \ldots, c_{l-w+1}]$, with $c \in \mathbb{R}^{l-w+1}$.

Next, we apply pairwise max pooling operation over the feature map to capture the most important feature. The pooling operation can be considered as feature selection in natural language processing. The max pooling operation is shown in Figure 2.

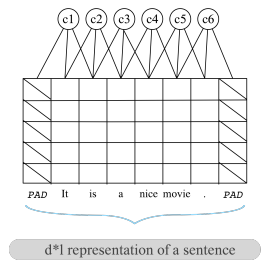

Figure 1: (1) A sentence matrix with padding. (2) Convolution with a window of three words.

Specifically, the output of convolution, the feature map $c = [c_1, c_2, \ldots, c_{l-w+1}]$ is the input of the pooling operation. Let the input be downscaled by 2, namely, the adjacent two features in the feature map be caculated as follows:

$$p_i = \max(c_{2\times i-1}, c_{2\times i}) \tag{2}$$

The output of the max pooling operation is $p = [p_1, p_2, \ldots, p_{\lfloor \frac{l-w+1}{2} \rfloor}]$, $p \in \mathbb{R}^{\lfloor \frac{l-w+1}{2} \rfloor}$.

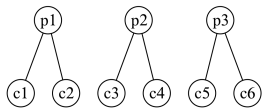

Figure 2: Pairwise max pooling operation on a scaling of 2

2.3 Recurrent neural network

Recurrent Neural Networks (RNNs) have shown great promise in machine translation tasks(Liu et al., 2014; Sutskever et al., 2014; Auli et al., 2013). Unlike feedforward neural networks, RNNs are able to handle a variable-length sequence input by having a recurrent hidden state whose activation at each time is dependent on that of the previous time. Figure 3 shows what a typical RNN looks like.

The diagram shows a RNN being unrolled into a full network. For example, if the input sequence is a four-word sentence, the network would be unrolled into a 4-layer neural network, one layer for each word. The formulas that govern the calculations in a RNN are as follows.

- x_t is the input at time step t. For example, x_i could be a one-hot vector or word embeddings corresponding to the i-th word of a sentence.
- h_t is the hidden state and the "memory" of the network at time step t. h_t is calculated according to the previous hidden state and the input at the current step:

$$h_t = \sigma(Ux_t + Wh_{t-1}) \tag{3}$$

  Here h_0 is typically initialized to a zero vector in order to calculate the first hidden state.
- o_t is the output at time step t. For sentiment classification of short texts, it would be a vector of probabilities across all the sentiment categories. o_t is calculated as follows:

$$o_t = softmax(Vh_t) \tag{4}$$

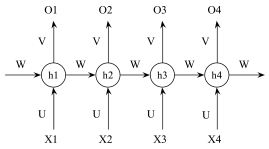

Figure 3: An unrolled recurrent neural network

Similar to a traditional neural network, we can use a twisted backpropagation algorithm Backpropagation Through Time (BPTT) to train a RNN (Mozer, 1989). Unfortunately, it is difficult to train RNN to capture long-term dependencies because the gradients tend to either vanish or explode (Bengio et al., 1994). Hochreiter and Schmidhuber (1997) proposed a long short-term memory (LSTM) unit and Cho et al. (2014) proposed a gated recurrent unit (GRU) to deal with the problem effectively.

2.4 LSTM and GRU

2.4.1 LSTM

The Long Short-Term Memory (LSTM) was first proposed by Hochreiter and Schmidhuber (1997) that can learn long-term dependencies. See Figure 4 for the graphical illustration.

Different from traditional recurrent unit, LSTM unit keeps the existing memory $c_t \in \mathbb{R}^n$ at time t. The input at time t is x_t, h_{t-1}, c_{t-1}, the output is h_t, c_t, they can be updated by the following equaions:

$$i_t = \sigma(W_i x_t + U_i h_{t-1} + b_i) \tag{5}$$
$$f_t = \sigma(W_f x_t + U_f h_{t-1} + b_f) \tag{6}$$
$$o_t = \sigma(W_o x_t + U_o h_{t-1} + b_o) \tag{7}$$
$$g_t = tanh(W_g x_t + U_g h_{t-1} + b_g) \tag{8}$$
$$c_t = f_t \odot c_{t-1} + i_t \odot g_t \tag{9}$$
$$h_t = o_t \odot tanh(c_t) \tag{10}$$

where $\sigma(\cdot)$ denotes the logistic sigmoid fuction. The opration $\odot$ denotes the element-wise vector product. At each time step t, there are an input gate i_t, a forget gate f_t, an output gate o_t, a memory cell c_t and a hidden unit h_t. h_0 and c_0 can be initialized to 0 and the parameters of the LSTM is W, U, b.

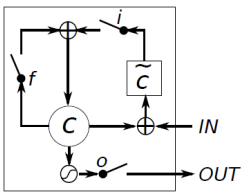

Figure 4: LSTM unit (Chung et al., 2014)

2.4.2 GRU

A gated recurrent unit (GRU) was initially proposed by Cho et al. (2014) to make each recurrent unit to adaptively capture dependencies of different time scales. See Figure 5 for the graphical illustration of GRU.

The parameters can be updated by the following equations

$$r_t = \sigma(W_r x_t + U_r h_{t-1}) \tag{11}$$

$$z_t = \sigma(W_z x_t + U_z h_{t-1}) \tag{12}$$

$$\hat{h}_t = \tanh(W x_t + U(r_t \odot h_{t-1})) \tag{13}$$

$$h_t = (1 - z_t) h_{t-1} + z_t \hat{h}_t \tag{14}$$

Where σ denotes the logistic sigmoid function, $\odot$ denotes the element-wise multiplication, r_t denotes the reset gate, z_t denotes the update gate and $\hat{h}_t$ denotes the candidate hidden layer.

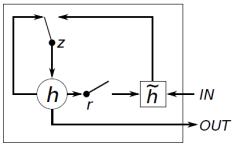

Figure 5: GRU unit (Chung et al., 2014)

3 Model

Convolutional neural networks (CNNs) are likely to extract local and deep features from natural language. It has been shown that CNN has gotten improved results in sentence classification (Kim, 2014). Recurrent neural networks (RNNs) are various kinds of time-recursive neural network that is able to learn the long-term dependencies in sequential data. Seeing that we can view the words in a sentence as a sequence from left to right, RNNs can be modeled in accordance with people's reading and understanding behavior of a sentence. Socher et al. (2012a) presented a convolutional-recursive deep model for 3D object classification that combined the convolutional and recursive neural networks together. The CNN layer learns the low-level translation invariant features which are inputs to multiple, fixed-tree RNNs (recursive neural networks) in order to compose higher order features. Kim et al. (2015) described a model that employed a convolutional neural network (CNN) and a highway network over characters, whose output is given to a long short-term memory (LSTM) recurrent neural network language model (RNN-LM). These two models both get better results than prior methods. However, the recursive neural networks need to build a tree structure that is usually based on the parser result of sentence. The recurrent neural network is particularly suited for modeling the sequential pattern. Inspired by those works and the fact that CNN can extract local features of input and RNN (recurrent neural network) can process sequence input and learn the long-term dependencies, we combine both of them in sentiment analysis of short texts. The model architecture is shown in Figure 6.

Our model consists of the following parts: word embeddings and sentence-level representation, convolutional and pooling layers, concatenation layer, RNN layer, fully connected layer with softmax output.

3.1 Word Embeddings and Sentence-Level Representation

Word embeddings play an important role in word representation. The commonly used are random initialization and unsupervised pre-training of word embeddings. In our experiment, we perform unsupervised learning of word-level embeddings using the $word2vec$ method and also test random initialization. Let ν be the size of bag-of-words and d be the length of a word embedding, then the word embeddings of all the words in the vocabulary are encoded by column vectors in an embedding matrix $Q \in \mathbb{R}^{d \times \nu}$. A sentence can be represented by:

$$S = [w_1, w_2, \ldots, w_l] \tag{15}$$

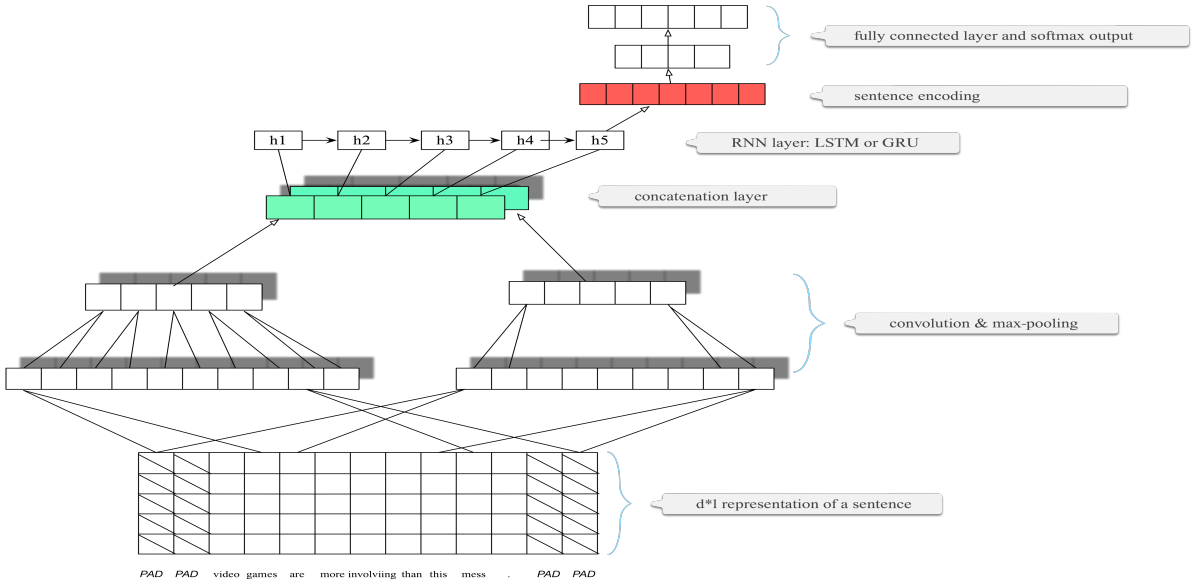

Figure 6: Model architecture for an example sentence

$$w_i \in [1, \nu], i \in [1, l]$$

Here is the sentence-level representation:

$$C_i = Q[w_i], C_i \in \mathbb{R}^d \tag{16}$$
$$C = [C_1, C_2, \ldots, C_l], C \in \mathbb{R}^{d \times l} \tag{17}$$

The column vector C_i corresponds to the word embedding of the i-th word in the sentence.

3.2 Convolution and Pooling

The convolutional layer applies a matrix-vector operation to each window of size w of successive windows in the sentence-level representation sequence. Let $H \in \mathbb{R}^{d \times w}$ be the weight matrix of the convolutional layer, we then add a bias item b to the result of the matrix-vector operation and get a feature mapping $c \in \mathbb{R}^{l-w+1}$. The i-th element of the feature map is:

$$c_i = \sigma(\sum(C[*, i : i + w] \circ H) + b) \tag{18}$$

where $C[*, i : i + w]$ is the i-th to the $i + w$-th column vectors of the sentence-level representation.

The same weight matrix is used to extract local features for each window of the given sentence. Using the matrix over all word windows of the sentence, we extract the n-grams feature vector of size $l - w + 1$. We also apply various kinds of weight matrices and multiple filter lengths to get various and sufficient features.

We apply the max and average pooling operations and find that the former performs better with less computational complexity. Thus, we apply the max pooling operation to the output of convolutional layer which transform the feature map of size $l - w + 1$ to $\lfloor \frac{l-w+1}{2} \rfloor$,

$$p = [p_1, p_2, \ldots, p_{\lfloor \frac{l-w+1}{2} \rfloor}] \tag{19}$$

We apply m kinds of matrix weight to get m feature maps.

$$P = [p^1, p^2, \ldots, p^m] \tag{20}$$

where $P \in \mathbb{R}^{\lfloor \frac{l-w+1}{2} \rfloor \times m}$.

We borrow the experience from the literature (Zhang and Wallace, 2015; Kim, 2014) and choose window size 4 and 5 to get matrix P_4, P_5. After trunking longer result, we concatenate P_4 and P_5 together to get Z, where

$$Z = \oplus(P_4, P_5), Z \in \mathbb{R}^{\lfloor \frac{l-w+1}{2} \rfloor \times (m \times 2)} \tag{21}$$

where $\oplus$ is the concatenation operator, Z can be viewed as the convolutional coding of a sentence.

3.3 Recurrent Neural Network

The features generated from convolution and pooling operation can be viewed as advanced features like n-grams. Since recurrent neural network (RNN) can process sequential input and learn the long-term dependencies, we take these features as the input of the recurrent neural network. We apply LSTM and GRU that are mentioned in previous chapter and both get good results. The output of RNN $T \in \mathbb{R}^n$ is deemed as the encoding of the whole sentence.

3.4 Fully Connected Network with Softmax Output

The features generated from RNN form the penultimate layer and are passed to a fully connected softmax layer whose output is the probability distribution over all the categories. The softmax operation over the scores of all the categories is calculated as follows:

$$\hat{P}_i = \frac{exp(o_i)}{\sum_{j=1}^{C} exp(o_j)} \tag{22}$$

We take cross entropy as the loss function that measures the discrepancy between the real sentiment distribution $\hat{P}^t(C)$ and the model output distribution $\hat{P}(C)$ of sentences in the corpora.

$$loss = -\sum_{s \in T} \sum_{i=1}^{V} \hat{P}_i^t(C) log(\hat{P}_i(C)) \tag{23}$$

Here T is the training corpora, V is the number of the sentiment categories. $\hat{P}^t(C)$ is the V-dimension one-hot coding vector where the elements corresponding to the sentence's real sentiment category is 1 and other elements 0. The entire model is trained end-to-end with stochastic gradient descent.

4 Experimental Setup and Results

We conduct experiments to empirically evaluate our method by applying it to three benchmarks as follows.

- MR: Movie reviews with one sentence per review. Classification involves detecting positive/negative reviews (Pang and Lee, 2005).[2]
- SST1: Stanford Sentiment Treebank - an extension of MR but provided five kinds of labels, very negative, negative, neutral, positive and very positive (Socher et al., 2013a). [3]
- SST2: Same as SST1 but with neutral reviews removed and binary labels.

The experiment runs on Tesla K40c GPU. Summary statistics of the datasets are in Table 1.

[2] https://www.cs.cornell.edu/people/pabo/movie-review-data/
[3] http://nlp.stanford.edu/sentiment/

Data	c	l	$\lvert V_{train}\rvert$	$\lvert V_{val}\rvert$	$\lvert V_{test}\rvert$
MR	2	20	8655	961	1046
SST1	5	18	151525	0	2200
SST2	2	19	76836	0	1811

Table 1: Summary statistics for the datasets after tokenization. c: Number of target classes. l: Average sentence length. $|V_{train}|$: Training set size. $|V_{val}|$: Validation set size. $|V_{test}|$: Test set size. The training set of SST1 and SST2 includes phrases extracted from sentences and sentences themselves, and test set only includes sentences.

4.1 Model Variations

We experiment with several variants of the model.

- CNN-GRU-word2vec: A model with pre-trained vectors from word2vec, max pooling and GRU recurrent unit.
- CNN-LSTM-word2vec: A model with pre-trained vectors from word2vec, max pooling and LSTM recurrent unit.
- AGV-GRU-word2vec: A model with pre-trained vectors from word2vec, average pooling and GRU recurrent unit.
- CNN-GRU-rand: A model with randomly initialized vectors, max pooling and GRU recurrent unit.
- CNN-LSTM-rand: A model with randomly initialized vectors, max pooling and LSTM recurrent unit.

4.2 Results and Dicussion

Results of our models against other methods are listed in tabel 2. Specially, our models with pre-trained vectors from word2vec[4] and max pooling perform best among all the models, of which the one with the GRU recurrent unit performs better on MR and SST2 while the one with LSTM performs better on SST1. The classification accuracy is raised by 0.7% on MR and 1.8% on SST2, when implementing CNN-GRU-word2vec model compared with the existing models. At the same time, the CNN-LSTM-word2vec model raises the classification accuracy by 0.1%. Furthermore, LSTM reveals good performance on SST1 while GRU performs better on MR and SST2.

In the meantime, we find that our models with pre-trained vectors all perform better than the others with randomly initialized vectors on all three corpora. Thus, we infer that the pre-trained vectors on large-scale corpora can solve the semantic sparsity problem to some degree.

Compared with the existing methods and experiment results, we find that our jointed architecture of CNN and RNN model performs better than the CNN and RNN models alone in sentiment classification of short texts. We take advantage of both the CNN model and the RNN model thus get higher classification accuracy than the existing models. CNN extracts the local features of input and RNN processes sequence input while learning the long-term dependencies and get sentence-level feature representation. The experiments substantiate the validity of our idea.

5 Conclusion

In this work we present a deep neural network architecture that takes advantage of the construction of convolutional neural network (CNN) and recurrent neural network (RNN) and joint them together for sentimental analysis of short texts. In particular, our pooling operation on adjacent words is able to retain the local features and their sequential relations in a sentence. Besides, RNN can learn the long-term dependencies and the positional relation of features as well as the global features of the whole sentence.

Stance Classification in Rumours as a Sequential Task Exploiting the Tree Structure of Social Media Conversations

Abstract

Rumour stance classification, the task that determines if each tweet in a collection discussing a rumour is supporting, denying, questioning or simply commenting on the rumour, has been attracting substantial interest. Here we introduce a novel approach that makes use of the sequence of transitions observed in tree-structured conversation threads in Twitter. The conversation threads are formed by harvesting users' replies to one another, which results in a nested tree-like structure. Previous work addressing the stance classification task has treated each tweet as a separate unit. Here we analyse tweets by virtue of their position in a sequence and test two sequential classifiers, Linear-Chain CRF and Tree CRF, each of which makes different assumptions about the conversational structure. We experiment with eight Twitter datasets, collected during breaking news, and show that exploiting the sequential structure of Twitter conversations achieves significant improvements over the non-sequential methods. Our work is the first to model Twitter conversations as a tree structure in this manner, introducing a novel way of tackling NLP tasks on Twitter conversations.

1 Introduction

Rumour stance classification is a task that is increasingly gaining popularity in its application to tweets. While Twitter is a generous source of reports of breaking news, outpacing even news outlets (Kwak et al., 2010), it also comes with the caveat that some of those reports are still rumours at the time of posting and so are yet to be verified and corroborated (Mendoza et al., 2010; Procter et al., 2013b; Procter et al., 2013a). The rumour stance classification task intends to assist in this verification process by determining the type of support expressed in different tweets discussing the same rumour (Qazvinian et al., 2011). Aggregation of the stance of multiple tweets discussing a rumour can then be of help to determine its likely veracity, enabling – among other benefits – the flagging of highly disputed rumours that are likely to be false.

Previous research on rumour stance classification for tweets has been limited to the tweet as the unit to be classified. However, such approaches ignore the additional context and knowledge that can be gained from the structure of Twitter interactions within conversational threads (Zubiaga et al., 2016; Procter et al., 2013b; Tolmie et al., 2015). The latter are formed as Twitter users reply to one another's posts and ultimately users build on each others' stance towards the rumour, leading to a potential consensus. For example, a tweet may report a rumour (source tweet) and others may reply to it by further supporting it or providing counter-evidence. Our objective here is to mine the sequence of stance types encountered in conversational threads collected from Twitter. The ultimate goal could be to aggregate such views to help determine the veracity of a rumour, which we hypothesise our task could be helpful for.

In order to make use of the sequence of stance types, we analyse conversations arising from tweets posted by users who are replying to one another. These replies result in tree-structured conversations, often nested, where replies are triggered by a source tweet that initiated the conversation. We make the following contributions:

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2438–2448, Osaka, Japan, December 11-17 2016.

- We hypothesise that making use of the sequential structure of conversational threads can improve stance classification in relation to a classifier that determines a tweet's stance from the tweet alone. To the best of our knowledge, the structure of Twitter conversations has not been studied before for classifying each of the underlying tweets and our work is the first to evaluate it for stance classification.
- We introduce a novel way of analysing tweets by mining the context from conversational threads. To do this, we propose two different models for capturing the sequential structure of conversational threads, viewing them as a) separate linear branches and b) as a tree structure.
- We evaluate the effectiveness of two flavours of Conditional Random Fields (CRF) in addressing stance classification on rumourous Twitter conversations. We compare the performance of these two CRF settings with other non-sequential baselines, including the non-sequential equivalent of CRF, a Maximum Entropy classifier. Our results show that while there is no significant difference when performance is measured based on micro-averaged F1 score (equivalent to accuracy and influenced by the majority class), sequential approaches do perform substantially better in terms of macro-averaged F1 score, proving that exploiting the conversational structure improves the classification performance.
- We also show that the use of tree CRF leads to an improvement over the linear-chain CRF, suggesting that in stance classification for conversational threads it is important to consider the whole tree structure rather individual linear branches. Our results advocate the merit of further exploring the use of sequential approaches to exploit conversational structures mined from Twitter posts for a wider range of NLP tasks.

2 Related Work

Following early work by Qazvinian et al. (2011) introducing the task of rumour stance classification for tweets, interest in this problem has increased substantially. However, the line of research initiated by Qazvinian et al. (2011) is significantly different to the one tackled in this paper. They perform 2-way classification of each tweet as *supporting* or *denying* a long-standing rumour, such as disputed beliefs that *Barack Obama is reportedly Muslim*. The authors use tweets observed in the past to train a classifier, which is then applied to new tweets discussing the same rumour. In recent work, rule-based methods have been put forward as a way to improve on the performance of the Qazvinian et al. (2011) baseline. This is the approach followed by Liu et al. (2015), who introduced a simple rule-based method that looks for the presence of positive or negative words in a tweet. One draw back of such rule-based approaches is that they may not generalise to new, unseen rumours. Similarly, Hamidian and Diab (2016) have recently studied the extent to which a model trained from historical tweets can be used for classifying new tweets discussing the same rumour. While Zhao et al. (2015) did not study stance classification, they showed that tweets that trigger questioning responses from others are likely to report disputed rumours, which reinforces the motivation of our work of determining the stance of tweets to then deal with rumours.

Classification of stance towards a target on Twitter has been addressed in SemEval-2016 task 6 (Mohammad et al., 2016). Task A had to determine the stance of tweets towards five targets as 'favor', 'against' or 'none'. Task B tested stance detection towards an unlabelled target, which required a weakly supervised or unsupervised approach. The dataset of this competition was not related to rumours or breaking news, it only considered a 3-way classification and did not provide any relations between tweets, which were treated as individual instances.

Our work presents different objectives in three aspects. First, we aim to classify the stance of tweets towards rumours that emerge while breaking news unfold; these rumours are unlikely to have been observed before, and hence rumours from previously observed events, which are likely to diverge, need to be leveraged for training. As far as we know, only Lukasik et al. (2015; 2016a; 2016b) have tackled stance classification in the context of breaking news applied to new rumours. Lukasik et al. (2015; 2016a) used Gaussian Processes to perform 3-way stance classification into supporting, denying or questioning, while comments where not considered as part of the task. Lukasik et al. (2016b) did include comments to perform 4-way stance classification; they used Hawkes Processes to exploit the temporal sequence

of stances towards rumours to classify new tweets discussing rumours. Work by Zeng et al. (Zeng et al., 2016) has also performed stance classification for rumours around breaking news, but overlapping rumours were used for training and testing.

Second, recent research has posited that a 4-way classification is needed to capture responses seen in the unfolding of breaking news (Procter et al., 2013b; Zubiaga et al., 2016). Moving away from the 2-way classification above, which is somewhat limited for our purposes, we adopt this expanded scheme including tweets that are *supporting*, *denying*, *querying* or *commenting* rumours. This adds two more categories to the scheme used in early work, where tweets would only support or deny a rumour. Moreover, our approach takes into account the interaction between users on social media, whether it is about appealing for more information in order to corroborate a rumourous post (*querying*) or to say something that does not contribute to the resolution of the rumour's veracity (*commenting*). Finally, instead of dealing with tweets as single units in isolation, we exploit the conversational structure of Twitter replies, building a classifier that learns the dynamics of stance in tree-structured conversational threads. The closest work when it comes to exploiting conversational structure in tweets is that of Ritter et al. (2010) who modelled linear sequences of replies in Twitter conversations with Hidden Markov Models for dialogue act tagging, but the structure of the tree as a whole was not exploited.

As far as we know, no work has leveraged the conversational structure of Twitter postings for stance classification, and hence its utility remains unexplored. A work that is related is that of Lukasik et al. (2016b), who exploited the temporal sequence of tweets, although the conversational structure was ignored and each tweet was treated as a separate unit. In other domains where debates or conversations are involved, the sequence of responses has been exploited to make the most of the evolving discourse and perform an improved classification of each individual post after learning the structure and dynamics of the conversation as a whole. For instance, Qu and Liu (2011) found Hidden Markov Models to be an effective approach to classify threads in on-line fora as successfully solving or not the question raised in the initial post. This was later further studied in a SemEval shared task, where each post in a forum thread had to also be classified as good, potential or bad (Màrquez et al., 2015). FitzGerald et al. (2011) used a linear-chain CRF to identify high-quality comments in threads responding to blog posts.

In a task that is related to stance classification, researchers have also studied the identification of agreement and disagreement in on-line conversations. To classify agreement between question-answer (Q-A) message pairs in fora, Abbott et al. (2011) used Naive Bayes as the classifier, and Rosenthal and McKeown (2015) used a logistic regression classifier. However, in both cases only pairs of messages were considered, and the entire sequence of responses in the tree was not used. CRF has also been used to detect agreement and disagreement between speakers in broadcast debates (Wang et al., 2011), which our task differs from in that it solely focuses on text. It is also worthwhile to emphasise that stance classification is different to agreement/disagreement detection, given that in stance classification one has to determine the orientation of a user towards a rumour. Instead, in agreement/disagreement detection, one has to determine if a pair of posts share the same view. In stance classification, one might agree with another user who is denying a rumour, and hence they are denying the rumour as well, irrespective of the pairwise agreement. To the best of our knowledge Twitter conversational thread structure has not been explored in the stance classification problem.

3 Stance classification using the conversational structure of Twitter threads

The rumour stance classification task consists in determining the type of support that each individual post expresses towards the disputed veracity of a rumour. The task is especially interesting in the context of Twitter, where unverified reports about breaking news are continually being posted and discussed as they unfold. This problem was originally tackled as a 2-way classification task, where each tweet was classified as supporting or denying a rumour. However, recent research (Procter et al., 2013b) found this categorisation to be insufficient to encompass all the different kinds of reactions to rumours, and a broader, 4-way classification task has been suggested instead. The argument behind this is that users in social media will not necessarily express a clear inclination towards supporting or denying a rumour, but can also be skeptical by posing questions about it or can make comments about the rumour that are

unrelated to its disputed veracity. The four categories in the extended classification scheme thus include *supporting*, *denying*, *querying* and *commenting*. In this work we set out the rumour stance classification that adopts this broader scheme. We define the rumour stance classification task as follows: we assume we have a set D of rumours R_i, each of which is composed of a collection of rumourous conversational threads. For simplicity here we refer to a rumour as the aggregate of its Twitter conversational threads, which is ultimately a collection of tweets. Each rumour has a variably sized set of tweets t_i discussing it so that $R_i = \{t_1, ..., t_{|R_i|}\}$; the task consists in determining the stance of each of the tweets t_j pertaining to a new, unseen rumour R_i as one of $Y = \{supporting, denying, querying, commenting\}$.

Moreover, within this task we propose leveraging conversation structure as one of the main features that characterise social media (Tolmie et al., 2015). So the task becomes one of classifying each tweet in a conversational thread, in the context of the thread. Twitter conversations consist of replies to each other, together forming a tree structure, as shown in the example in Figure 1. Replies can be nested in each other, so that the depth of the tree can vary. Hence, in the stance classification task applied to Twitter conversations we have rumours containing a variably sized set of conversations $R_i = \{C_1, ..., C_{|R_i|}\}$. Each of these conversations, C_j, has a varying number of tweets in it. By definition, a conversation has a source tweet (the root of the tree), $t_{j,1}$, that initiates it. The source tweet $t_{j,1}$ can receive replies by a varying number k of tweets $Replies_{t_{j,1}} = \{t_{j,1,1}, ..., t_{j,1,k}\}$, each of which can in turn receive replies by a varying number k of tweets, e.g., $Replies_{t_{j,1,1}} = \{t_{j,1,1,1}, ..., t_{j,1,1,k}\}$. Thus, we encode the tweet index as a sequence of ids of consecutive children of a preceding node, while traversing the conversation structure.

4 Dataset

We use the PHEME rumour dataset associated with eight events corresponding to breaking news stories (Zubiaga et al., 2016), which provide tweet-level annotations for stance[1]. Tweets in this dataset include tree-structured conversations, which are initiated by a tweet about a rumour (source tweet) and nested replies that further discuss the rumour circulated by the source tweet (replying tweets). Details on how the annotation was conducted through crowdsourcing can be found in Zubiaga et al. (2015).

The annotation scheme employed by the authors differs slightly from the one we need for our purposes, so we adapt it to our needs as follows. The source tweet of a conversation is originally annotated as *supporting* or *denying*, and each subsequent tweet is annotated as *agreed*, *disagreed*, *appeal for more information* (*querying*) or *commenting* as a pairwise annotation with respect to the source tweet. Instead, the labels needed for our task are *supporting*, *denying*, *querying* and *commenting*. To convert the labels, we keep the labels as *supporting* or *denying* in the case of source tweets. For the reply tweets, we keep their label as is for the tweets that are *querying* or *commenting*. To convert those tweets that agree or disagree into *supporting* or *denying*, we apply the following set of rules: (1) if a tweet agrees with a supporting source tweet, we label it *supporting*, (2) if a tweet agrees with a denying source tweet, we label it *denying*, (3) if a tweet disagrees with a supporting source tweet, we label it *denying* and (4) if a tweet disagrees with a denying tweet, we label it *supporting*. The latter enables us to infer stance with respect to the overarching rumour rather than refer to agreement with respect to the source. The resulting dataset includes 4,519 tweets, and the transformations of annotations described above only affect 24 tweets (0.53%), i.e., those where the source tweet denies a rumour, which is rare. The example in Figure 1 shows a rumour thread taken from the dataset along with our inferred annotations, as well as how we establish the depth value of each tweet in the thread.

One notable characteristic of the dataset is that the distribution of categories is skewed towards *commenting* tweets, and that this imbalance varies slightly across the eight events in the dataset (see Table 1). Given that we consider each event as a separate fold that is left out for testing, this varying imbalance makes the task more realistic and challenging. The striking imbalance towards *commenting* tweets is also indicative of the increased difficulty with respect to previous work on stance classification. Most of which performed binary classification of tweets as either supporting or denying, which as shown in our

[1]While the dataset includes data for nine events, here we use the eight events whose tweets are in English, excluding the ninth with tweets in German.

5 Experiment Design

In this section we describe the classifiers, features and evaluation measures we used in our experiments.

5.1 Classifiers

Conditional Random Fields (CRF). We use CRF as a structured classifier to model sequences observed in Twitter conversations. With CRF, we can model the conversation as a graph that will be treated as a sequence of stances, which also enables us to assess the utility of harnessing the conversational structure for stance classification. In contrast to traditionally used classifiers for this task, which choose a label for each input unit (e.g. a tweet), CRF also consider the neighbours of each unit, learning the probabilities of transitions of label pairs to be followed by each other. The input for CRF is a graph $G = (V, E)$, where in our case each of the vertices V is a tweet, and the edges E are relations of tweets replying to each other. Hence, having a data sequence X as input, CRF outputs a sequence of labels Y (Lafferty et al., 2001), where the output of each element y_i will not only depend on its features, but also on the probabilities of other labels surrounding it. The generalisable conditional distribution of CRF is shown in Equation 1 (Sutton and McCallum, 2011).

$$p(y|x) = \frac{1}{Z(x)} \prod_{a=1}^{A} \Psi_a(y_a, x_a) \tag{1}$$

where Z(x) is the normalisation constant, and Ψ_a is the set of factors in the graph G.

We use CRFs in two different settings.[2] First, we use a linear-chain CRFs (Linear CRF) to model each branch as a sequence to be input to the classifier. We also use Tree-Structured CRFs (Tree CRF) or General CRFs to model the whole, tree-structured conversation as the sequence input to the classifier. So in the first case the sequence unit is a branch and our input is a collection of branches and in the second case our sequence unit is an entire conversation, and our input is a collection of trees. An example of the distinction of dealing with branches or trees is shown in Figure 2. With this distinction we also want to experiment whether it is worthwhile building the whole tree as a more complex graph, given that users replying in one branch might not have necessarily seen and be conditioned by tweets in other branches. However, we believe that the tendency of types of replies observed in a branch might also be indicative of the distribution of types of replies in other branches, and hence useful to boost the performance of the classifier when using the tree as a whole. An important caveat of modelling a tree in branches is also that there is a need to repeat parts of the tree across branches, e.g., the source tweet will repeatedly occur as the first tweet in every branch extracted from a tree.[3]

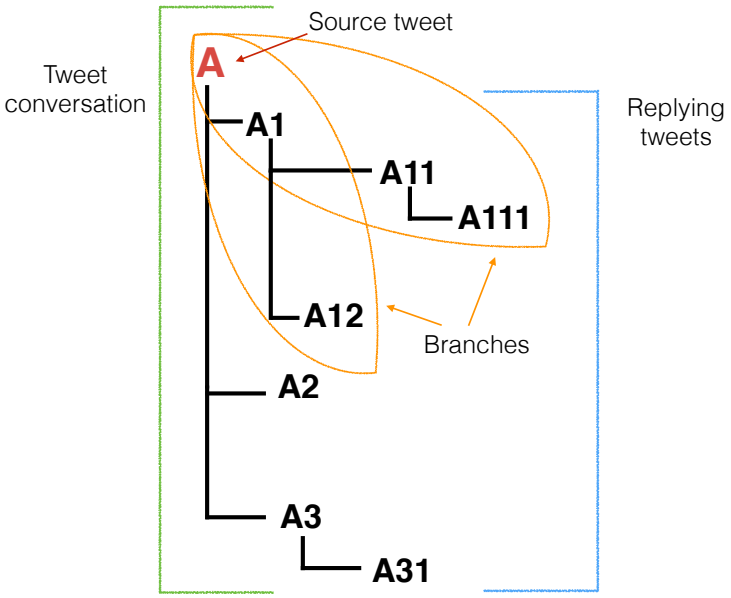

Figure 2: Example of a tree-structured conversation, with two overlapping branches highlighted.

Maximum Entropy classifier (MaxEnt). As the non-sequential equivalent of CRF, we use a Maximum Entropy (or logistic regression) classifier, which is also a conditional classifier but which operate at the tweet level, ignoring the conversational strucsture. This enables us to compare directly the extent to which treating conversations as sequences instead of having each tweet as a separate unit can boost the performance of the classifier.

Additional baselines. We also compare four more non-sequential classifiers[4]: Naive Bayes (NB), Support Vector Machines (SVM), Random Forests (RF), and Majority (i.e., a dummy classifier always labelling the most frequent class).

We experiment in an 8-fold cross-validation setting. Seven events are used for training and the remainder event is used for testing. With this, we simulate a realistic scenario where we need to use knowledge from past events to train a model that will be used to classify tweets in new events. For evaluation purposes, we aggregate the output of all eight runs as the micro-averaged evaluation across runs.

[2]We use the PyStruct to implement both variants of CRF (Müller and Behnke, 2014).

[3]Despite this also leading to having tweets repeated across branches in the test set and hence producing an output repeatedly for the same tweet with Linear CRF, this output is consistent and there is no need to aggregate different outputs.

[4]We use their implementation in the scikit-learn Python package

5.2 Features

We use four types of features to represent the tweets. Note that all of them are local features extracted from the tweet itself and independent of the rest of the conversation, hence enabling us to focus our comparison on how using the sequential structure can impact on the results.

Feature type #1: Lexicon.

- *Word Embeddings:* a vector with 300 dimensions averaging vector representations of the words in the tweet using Word2Vec (Mikolov et al., 2013). The Word2Vec model for each of the eight folds is trained from the collection of tweets pertaining to the seven events in the training set, so that the event (and the vocabulary) in the test set is unknown.
- *Part of speech (POS) tags:* a vector where each feature represents the number of occurrences of a type of POS tag in the tweet. The vector is then composed of the numbers of occurrences of different POS tags in the tweet, parsed using Twitie (Bontcheva et al., 2013).
- *Use of negation:* binary feature determining if a tweet has a negation word or not. We use a list of negation words, including: not, no, nobody, nothing, none, never, neither, nor, nowhere, hardly, scarcely, barely, don't, isn't, wasn't, shouldn't, wouldn't, couldn't, doesn't.
- *Use of swear words:* binary feature determining if 'bad' words are present in a tweet. We use a list of 458 bad words[5].

Feature type #2: Content formatting.

- *Tweet length:* the length of the tweet in number of characters.
- *Capital ratio:* the ratio of capital letters among all alphabetic characters in the tweet.
- *Word count:* the number of words in the tweet, counted as the number of space-separated tokens.

Feature type #3: Punctuation.

- *Use of question mark:* binary feature for the presence or not of question marks in the tweet.
- *Use of exclamation mark:* binary feature for the presence or not of exclamation marks in the tweet.
- *Use of period:* binary feature for the presence or not of periods in the tweet.

Feature type #4: Tweet formatting.

- *Attachment of URL:* binary feature, capturing the use or not of URLs in the tweet.
- *Attachment of picture:* binary feature that determines if the tweet has a picture attached.
- *Is source tweet:* binary feature determining if the tweet is a source tweet or is instead replying to someone else. Note that this feature can also be extracted from the tweet itself, checking if the tweet content begins with a Twitter user handle or not; there is no need to make use of the conversational structure to extract this feature.

5.3 Evaluation Measures

Given that the classes are clearly imbalanced in our case, evaluation solely based on accuracy can arguably suffice to capture competitive performance beyond the majority class. To account for the imbalance of the categories, we use both micro-averaged and macro-averaged F1 scores. Note that the micro-averaged F1 score is equivalent to the accuracy measure, while the macro-averaged F1 score complements it by measuring performance assigning the same weight to each category.

6 Results

Table 2 shows the results comparing performance of the different classifiers, both in terms of micro- and macro-F1 scores, and F1 scores by class. Due to the fact that the dataset is clearly imbalanced with a skew towards *commenting* tweets, we observe that even the majority classifier performs very well in terms of micro-averaged F1 score. In fact, the majority classifier is only slightly outperformed by other classifiers if we look at this evaluation measure. This is why we argue for an evaluation based on macro-averaged F1 score, which accounts for the ability of classifiers to produce an output that better fits to the distribution of classes. Interestingly, we observe that the conditional classifiers (i.e., MaxEnt, Linear CRF and Tree CRF) perform substantially better than the rest in terms of macro-averaged F1 score, which are the only ones to achieve a score of at least 0.4. Comparison of macro-averaged F1

[5] http://urbanoalvarez.es/blog/2008/04/04/bad-words-list/

scores of these three classifiers shows that the Tree CRF slightly outperforms the Linear CRF, while both perform significantly better than the non-sequential Maximum Entropy classifier. These results therefore do suggest that exploiting the sequential structure of conversations can lead to improvements on stance classification in rumourous Twitter conversations using the same set of local features.

When we look at the performance by class, we can observe that classifiers performing well only in terms of micro-averaged F1 have the tendency to perform well for the majority class (comments). Interestingly, CRF classifiers using conversational structure show remarkable improvements for other classes, especially supporting and querying tweets, where Tree CRF performs the best. However, all classifiers struggle to classify denials, with performance scores comparable to the other categories. We believe that one of the main reasons for this is that denials are one of the minority classes in the dataset. While querying tweets are also rare, some of the features like question marks are highly indicative of a tweet being a query, and hence they are easier to classify. Denials may in turn have significant commonalities with comments, given that the latter may also use negating words which may seem like denials. As shown in the confusion matrix for the Tree CRF in Table 3, the majority class *commenting* is being chosen in as many as 75.8% of the cases by the classifier for those tweets that are actually denials. Collection of additional denying tweets may be of help to improve performance in this class.

Classifier	Micro-F1	Macro-F1	S	D	Q	C
Majority	0.643	0.196	0.000	0.000	0.000	0.783
SVM	**0.676**	0.292	0.372	0.000	0.000	**0.796**

Table 3: Confusion matrix for Tree CRF (S: supporting, D: denying, Q: querying, C: commenting).

For comparison with the state-of-the-art stance classification approach by Lukasik et al. (2016b), we present results broken down by event in Table 4, both for their approach based on Hawkes Processes as well as our Tree CRF approach. Note that Lukasik et al. (2016b) only tested their approach on four of the events, and therefore performance scores for the rest of the events are not shown. As can be observed from the four events for which we have comparable results, the Hawkes Process performs better in terms of micro-F1, and therefore accurately classifying more instances. However, the Tree CRF performs substantially better in terms of macro-F1, which shows Tree CRF's ability to better estimate the distribution of labels in what is a highly imbalanced task and hence favouring the use of conversational structure in the classification process. We deem this a strong factor in this case as even a simple majority classifier achieves high micro-F1 scores, and the challenge lies in boosting macro-F1 scores to better balance the classification.

To better understand the effect of exploiting sequential structure, we break down performance scores by the depth of tweets. By this we want to see if the sequential classifiers are consistently performing

	Tree CRF		HP (Lukasik et al., 2016b)	
Event	Micro-F1	Macro-F1	Micro-F1	Macro-F1

Table 4: Micro- and Macro-F1 performance results broken down by event, along with a comparison with the results obtained by Lukasik et al. (2016b)'s state-of-the-art approach based on Hawkes Processes, where available.

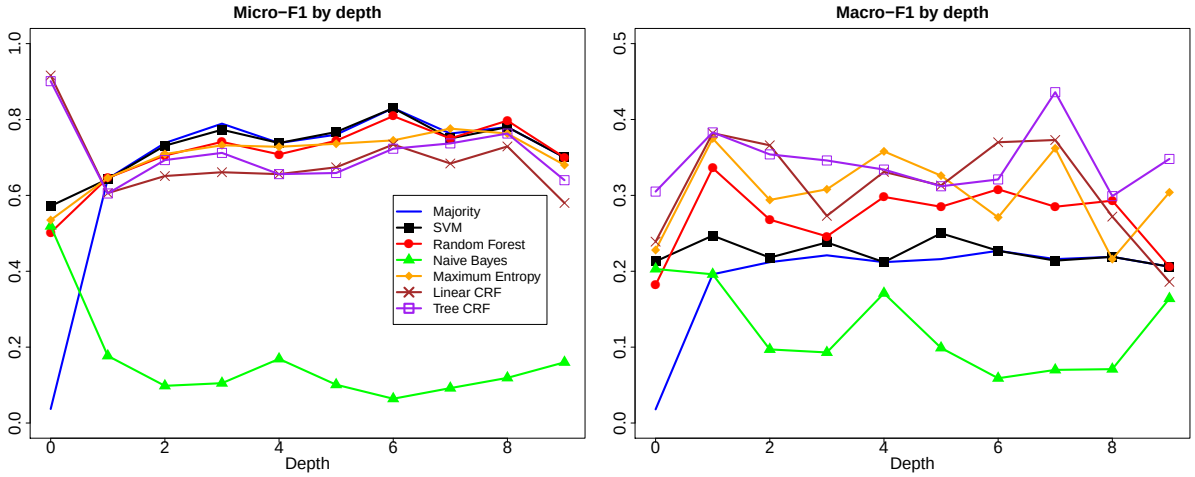

Figure 3: Micro- and macro-F1 scores by depth of tweet.

well across tweets of different depth within conversations. Figure 3 shows these results for tweets from depth 0 (source tweet) to depth 9. Further depths are omitted due to the small number of instances available. When we look at micro-averaged scores, we do not see a big performance difference across classifiers, except for the CRF classifiers performing better for source tweets; this is due to the fact that most of the source tweets tend to support a rumour, and hence sequential classifiers can learn this.

What is more interesting is to look again at the macro-averaged scores, where we see that the sequential approaches, especially the Tree CRF, consistently performs well for different levels of depth. More specifically, Tree CRF performs best in 7 out of 10 levels of depth analysed, with Linear CRF being better once (depth = 2) and Maximum Entropy being better twice (depth = 4 and 5).

7 Conclusions

We have introduced a novel way of tackling the rumour stance classification task, where a classifier has to determine if each tweet is supporting, denying, querying or commenting on a rumour's truth value. We mine the sequential structure of Twitter conversations in the form of users' replies to one another, extending existing approaches that treat each tweet as a separate unit. We have used two different sequential classifiers: a linear-chain CRF modelling tree-structured conversations broken down into branches, and a tree CRF modelling them as a graph that includes the whole tree. These classifiers have been compared with the non-sequential equivalent Maximum Entropy classifier, as well as other baseline classifiers, on eight Twitter datasets associated with breaking news.

While previous work had looked at the tweet as a single unit, we have shown that exploiting the discursive characteristics of interactions on Twitter, by considering probabilities of transitions within tree-structured conversational threads, can lead to significant improvements. Not only do we see that the linear sequence in a branch can be useful for the classifier to learn transitions, but also that having the whole picture of the tree showing the overall tendency of a conversation can further boost the performance of the classifier. Our results suggest that a tree CRF classifier outperforms all non-sequential classifiers, proving the utility of mining the conversational structure for stance classification, even when only local features are used.

To the best of our knowledge, this is the first attempt at aggregating the conversational structure of Twitter threads to produce classifications at the tweet level. Besides the utility of mining sequences from conversations for stance classification, we believe that our results will, in turn, encourage the study of sequential classifiers applied to other NLP tasks where the output for each tweet can benefit from the structure of the entire conversation, e.g., sentiment analysis and language identification.

Our plans for future work include testing additional sequential classifiers (e.g. LSTM). Moreover, while we have only tested local features for the purposes of making the experiments comparable, we also plan to test contextual features. This may also alleviate the effect of the class imbalance, producing results that are more satisfactory for minority classes, especially denials. Our approach assumes that rumours have been already identified or input by a human. An ambitious avenue for future work includes developing a rumour detection system whose output would be fed to the stance classification system.

Abstract

Sarcasm detection has been modeled as a binary document classification task, with rich features being defined manually over input documents. Traditional models employ discrete manual features to address the task, with much research effect being devoted to the design of effective feature templates. We investigate the use of neural network for tweet sarcasm detection, and compare the effects of the continuous automatic features with discrete manual features. In particular, we use a bi-directional gated recurrent neural network to capture syntactic and semantic information over tweets locally, and a pooling neural network to extract contextual features automatically from history tweets. Results show that neural features give improved accuracies for sarcasm detection, with different error distributions compared with discrete manual features.

1 Introduction

Sarcasm has received much research attention in linguistics, psychology and cognitive science (Gibbs, 1986; Kreuz and Glucksberg, 1989; Utsumi, 2000; Gibbs and Colston, 2007). Detecting sarcasm automatically is useful for opinion mining and reputation management, and hence has received growing interest from the natural language processing community (Joshi et al., 2016a). Social media such as Twitter exhibit rich sarcasm phenomena, and recent work on automatic sarcasm detection has focused on tweet data.

Tweet sarcasm detection can be modeled as a binary document classification task. Two main sources of features have been used. First, most previous work extracts rich discrete features according to the *tweet content* itself (Davidov et al., 2010; Tsur et al., 2010; González-Ibánez et al., 2011; Reyes et al., 2012; Reyes et al., 2013; Riloff et al., 2013; Ptáček et al., 2014), including lexical unigrams, bigrams, tweet sentiment, word sentiment, punctuation marks, emoticons, quotes, character ngrams and pronunciations. Some of these work uses more sophisticated features, including POS tags, dependency-based tree structures, Brown clusters and sentiment indicators, which depend on external resources. Overall, ngrams have been among the most useful features.

Second, recent work has exploited contextual tweet features for sarcasm detection (Rajadesingan et al., 2015; Bamman and Smith, 2015). Intuitively, the *history behaviors* for a tweet author can be a good indicator for sarcasm. Rajadesingan et al. (2015) exploit a behavioral approach to model sarcasm, using a set of statistical indicators extracted from both the target tweet and relevant history tweets. Bamman and Smith (2015) study the influences of tweet content features, author features, audience features and environment features, finding that contextual features are very useful for tweet sarcasm detection.

So far, most existing sarcasm detection methods in the literature leverage discrete models. While on the other hand, neural network models have gained much attention for related tasks such as sentiment analysis and opinion extraction, achieving the best results (Socher et al., 2013; dos Santos and Gatti, 2014; Vo and Zhang, 2015; Zhang et al., 2016). Success on these tasks shows potentials of neural network on sarcasm detection (Amir et al., 2016; Ghosh and Veale, 2016; Joshi et al., 2016b). There are two main advantages of using neural models. First, neural layers are used to induce features automatically,

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2449–2460, Osaka, Japan, December 11-17 2016.

making manual feature engineering unnecessary. Such neural features can capture long-range and subtle semantic patterns, which are difficult to express using discrete feature templates. Second, neural models use real-valued word embedding inputs, which are trained from large scale raw texts, and are capable of avoiding the feature sparsity problem of discrete models.

In this paper, we exploit a deep neural network for sarcasm detection, comparing its automatic features with traditional discrete models. First, we construct a baseline discrete model that exploits the most typical features in the literature, including the features on the target tweet content and the features on historical tweets of the author, achieving competitive results as compared to the previous best systems.

Second, we build a neural model, with two sub neural networks to capture tweet content and contextual information, respectively. The two-component structure closely corresponds to the two feature sources of the baseline discrete model. We model the tweet content with a gated recurrent neural network (GRNN) (Cho et al., 2014b; Cho et al., 2014a), and use a gated pooling function for feature extraction. To model the salient words from the contextual tweets, we use pooling to extract features directly.

Results on a tweet datasets show that the neural model achieves significantly better accuracies compared to the discrete baseline, demonstrating the advantage of the automatically extracted neural features in capturing global semantic information. Further analysis shows that features from history tweets are as useful to the neural model as to the discrete model. We make our source code publicly available under GPL at `https://github.com/zhangmeishan/SarcasmDetection`.

2 Related Work

Features. Sarcasm detection is typically regarded as a classification problem. Discrete models have been used and most existing research efforts have focused on finding effective features. Kreuz and Caucci (2007) studied lexical features for sarcasm detection, finding that words, such as interjections and punctuation, are effective for the task. Carvalho et al. (2009) demonstrated that oral or gestural expressions represented by emoticons and special keyboard characters are useful indicators of sarcasm. Both Kreuz and Caucci (2007) and Carvalho et al. (2009) rely on unigram lexical features for sarcasm detection. More recently, Lukin and Walker (2013) extended the idea by using n-gram features as well as lexicon-syntactic patterns.

External sources of information have been exploited to enhance sarcasm detection. Tsur et al. (2010) applied features based on semi-supervised syntactic patterns extracted from sarcastic sentences of Amazon product reviews. Davidov et al. (2010) further extracted these features from sarcastic tweets. Riloff et al. (2013) identified a main type of sarcasm, namely contrast between a positive and negative sentiment, which can be regarded as detecting sarcasm using sentiment information. There has been work that comprehensively studies the effect of various features (González-Ibánez et al., 2011; González-Ibánez et al., 2011; Joshi et al., 2015).

Recently, contextual information has been exploited for sarcasm detection (Wallace et al., 2015; Karoui et al., 2015). In particular, contextual features extracted from history tweets by the same author has shown great effectiveness for tweet sarcasm detection (Rajadesingan et al., 2015; Bamman and Smith, 2015). We consider both traditional lexical features and the contextual features from history tweets under a unified neural network framework. Our observation is consistent with prior work: both sources of features are highly effective for sarcasm detection (Rajadesingan et al., 2015; Bamman and Smith, 2015).. To our knowledge, we are among the first to investigate the effect of neural networks on this task (Amir et al., 2016; Ghosh and Veale, 2016; Joshi et al., 2016b).

Corpora. With respect to sarcasm corpora, early work relied on small-scale manual annotation. Filatova (2012) constructed a sarcasm corpus from Amazon product reviews using crowdsourcing. Davidov et al. (2010) discussed the strong influence of hashtags on sarcasm detection. Inspired by this, González-Ibánez et al. (2011) used sarcasm-related hashtags as gold labels for sarcasm, creating a tweet corpus by treating tweets without such hashtags as negative examples. Their work is similar in spirit to the work of Go et al. (2009), who constructed a tweet sentiment automatically by taking emoticons as gold sentiment labels.

The method of González-Ibánez et al. (2011) was adopted by Ptáček et al. (2014), who created a

sarcasm dataset for Czech. More recently, both Rajadesingan et al. (2015) and Bamman and Smith (2015) followed the method for building a sarcasm corpus. We take the corpus of Rajadesingan et al. (2015) for our experiments.

Neural network models. Although only very limited work has been done on using neural networks for sarcasm detection, neural models have seen increasing applications in sentiment analysis, which is a closely-related task. Different neural network architectures have been applied for sentiment analysis, including recursive auto-encoders (Socher et al., 2013), dynamic pooling networks (Kalchbrenner et al., 2014), deep belief networks (Zhou et al., 2014), deep convolutional networks (dos Santos and Gatti, 2014; Tang et al., 2015) and neural CRF (Zhang et al., 2015). This line of work gives highly competitive results, demonstrating large potentials for neural networks on sentiment analysis. One important reason is the power of neural networks in automatic feature induction, which can potentially discover subtle semantic patterns that are difficult to capture by using manual features. Sarcasm detection can benefit from such induction, and several work has already attempted for it (Amir et al., 2016; Ghosh and Veale, 2016; Joshi et al., 2016b). This motivates our work.

3 Baseline Discrete Model

We follow previous work in the literature, building a strong discrete baseline model using features from both the *target tweet* itself and its *contextual tweets*. The structure of the model is shown in Figure 1(a), which consists of two main components, modeling the target tweet and its contextual tweets, respectively. In particular, the **local component** (the left of Figure 1(a)) is used to extract features $\mathbf{f}$ from the target tweet content, and the **contextual component** (the right of Figure 1(a)) is used to extract contextual features $\mathbf{f}'$ from the history tweets of the author. Based on $\mathbf{f}$ and $\mathbf{f}'$, a logistic regression is used to obtain the output:

$$\mathbf{o} = \mathrm{softmax}\big(W_o \cdot (\mathbf{f} \oplus \mathbf{f}')\big), \tag{1}$$

where the matrix W_o is the model parameter matrix, $\mathbf{o}$ is the output two-bit sarcasm/non-sarcasm vector, and $\oplus$ denotes vector concatenation.

3.1 The Local Component

Given an input tweet $w_1, w_2 \cdots w_n$, we extract a set of sparse discrete feature vectors $\mathbf{f}_1, \mathbf{f}_2, \cdots, \mathbf{f}_n$ by instantiating a set of feature templates over each word, respectively. In particular, we follow Rajadesingan et al. (2015) and use three feature templates, including the current word w_i, the word bigram $w_{i-1}w_i$ and the word trigram $w_{i-2}w_{i-1}w_i$. The final local feature vector $\mathbf{f}$ is the sum of $\mathbf{f}_i$ from all words: $\mathbf{f} = \sum_{i=1}^{n} \mathbf{f}_i$.

3.2 The Contextual Component

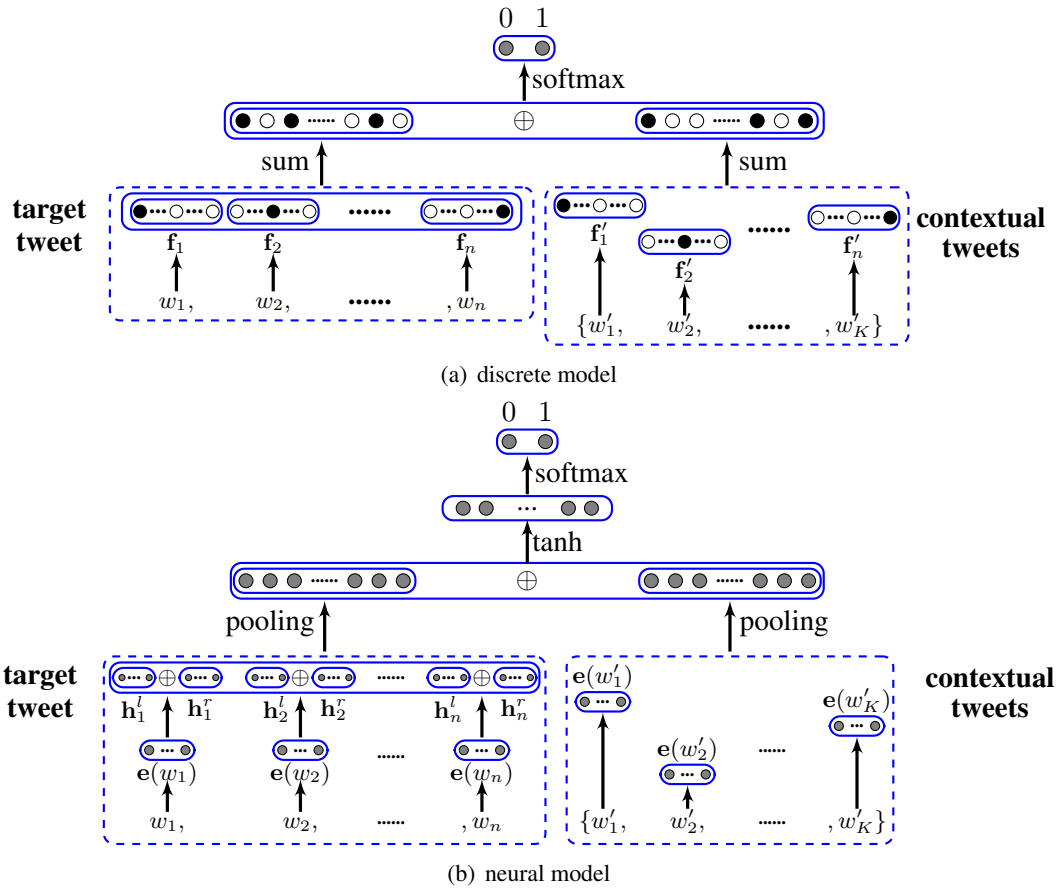
We follow Bamman and Smith (2015) for defining the features of the contextual tweets. In particular, a set of salient words are extracted from history tweets of the target tweet author, which can reflect the tendency of the author in using irony or sarcasm towards certain subjects.

First, we extract a number of most recent history tweets by using Twitter API[1], setting the maximum number of history tweets to 80.[2] The words in the history tweets are sorted by their *tf-idf* values. To estimate *tf* and *idf*, we regard the set of history tweets for a given tweet as one document, and use all the tweets in the training corpus to generate a number of additional documents. We choose a fixed-number of contextual tweet words with the highest *tf-idf* values for contextual features.

Denoting the set of words extracted from contexts as $\{\mathbf{w}'_1, \mathbf{w}'_2, \cdots, \mathbf{w}'_K\}$, where K is a hyper-parameter set manually, we use a single feature template w_i the extract a sparse feature vector $\mathbf{f}'_i$ for each word. The final contextual feature is the sum of all unigram features: $\mathbf{f}' = \sum_{i=1}^{K} \mathbf{w}'_i$. The set of baseline features, adopted from Rajadesingan et al. (2015) and Bamman and Smith (2015), are simple yet effective, giving highly competitive accuracies in our experiments.

[1] https://dev.twitter.com

[2] We use the data shared by Rajadesingan et al. (2015) directly, following their setting of history tweets.



(a) discrete model

(b) neural model

Figure 1: Discrete and neural models for tweet sarcasm detection (• denotes 1, ○ denotes 0, and • denotes a real-value feature).

4 Proposed Neural Model

In contrast to the discrete model, the neural model explores low-dimensional dense vectors as input. Figure 1(b) shows the overall structure of our proposed neural model, which has two components, corresponding to the **local** and the **contextual** components of the discrete baseline model, respectively. The two components use neural network structures to extract dense real-valued features $\mathbf{h}$ and $\mathbf{h}'$ from the local and history tweets, respectively, and we add a non-linear hidden layer to combine the neural features from the two components for classification. The output nodes can computed by:

$$\begin{aligned} \mathbf{c} &= \tanh(W_c(\mathbf{h} \oplus \mathbf{h}') + \mathbf{b}_c), \\ \mathbf{o} &= \text{softmax}(W_o\mathbf{c}), \end{aligned} \tag{2}$$

where the matrices W_c and W_o, and the vector $\mathbf{b}_c$ are model parameters.

As Figure 1 shows, the neural model is designed in such a way so that the correspondence between the model and the discrete baseline is maximized at the level of feature sources, for the convenience of direct comparison.

4.1 The Local Component

As shown on the left of Figure 1(b), we use a bi-directional gated recurrent neural network (GRNN) to model a tweet. The input layer of the network, represented by $\mathbf{x}_i$ at each position of the input tweet, is the concatenation of three consecutive word vectors, with the current word $\mathbf{w}_i$ in the center. With respect to the source of information, it is similar to the trigram feature templates of the baseline discrete model. Formally, at each word location i, the input vector is $\mathbf{x}_i = [\mathbf{e}(w_{i-1}), \mathbf{e}(w_i), \mathbf{e}(w_{i+1})]$, where $\mathbf{e}$ is a function to obtain dense embeddings for words based on a matrix E, which is a model parameter.

A recurrent neural network is used to capture sequential features automatically, hence giving semantic information over the whole input tweets. Compared with the vanilla recurrent neural network structure, gated recurrent neural networks such as long-short-term-memory (Hochreiter and Schmidhuber, 1997) apply gate structures to effectively reduce the issues of exploding and diminishing gradients (Pascanu et al., 2013; Yao et al., 2015), and therefore have been widely used as a more effective form of recurrent neural networks.

We exploit two efficient GRNNs to obtain a left-to-right ($\mathbf{h}_1^l \mathbf{h}_2^l \cdots \mathbf{h}_n^l$), and a right-to-left hidden node sequence ($\mathbf{h}_n^r \mathbf{h}_{n-1}^r \cdots \mathbf{h}_1^r$), respectively. Taking the left-to-right GRNN as an example, the hidden node vectors $\mathbf{h}_i^l$ are computed by:

$$\mathbf{h}_i^l = (\mathbf{1} - \mathbf{z}_i^l) \odot \mathbf{h}_{i-1}^l + \mathbf{z}_i^l \odot \tilde{\mathbf{h}}_i^l$$
$$\tilde{\mathbf{h}}_i^l = \tanh(W_1^l \mathbf{x}_i + U_1^l(\mathbf{r}_i^l \odot \mathbf{h}_{i-1}^l) + \mathbf{b}_1^l)$$
$$\mathbf{z}_i^l = \text{sigmoid}(W_2^l \mathbf{x}_i + U_2^l \mathbf{h}_{i-1} + \mathbf{b}_2^l)$$
$$\mathbf{r}_i^l = \text{sigmoid}(W_3^l \mathbf{x}_i + U_3^l \mathbf{h}_{i-1}^l + \mathbf{b}_3^l)$$

where the $\mathbf{z}_i^l$ and $\mathbf{r}_i^l$ are two gates, and $\odot$ denotes Hadamard product. W_1^l, U_1^l, W_2^l, U_2^l, W_3^l, U_3^l, $\mathbf{b}_1^l$, $\mathbf{b}_2^l$ and $\mathbf{b}_3^l$ are model parameters.

We use the same method to obtain $\mathbf{h}_i^r$ in the reverse direction, with the corresponding model parameters $W_1^l, U_1^l, \cdots\cdots, \mathbf{b}_3^l$ being W_1^r, U_1^r, W_2^r, U_2^r, W_3^r, U_3^r, $\mathbf{b}_1^r$, $\mathbf{b}_2^r$ and $\mathbf{b}_3^r$, respectively. After both hidden node sequences are computed, we concatenate the bi-directional hidden nodes at each position, obtaining $\mathbf{h}_1 \mathbf{h}_2 \cdots \mathbf{h}_n$ ($\mathbf{h}_i = \mathbf{h}_i^l \oplus \mathbf{h}_i^r$).

We apply a gated pooling function over the variable-length sequence $\mathbf{h}_1 \mathbf{h}_2 \cdots \mathbf{h}_n$ to project these GRNN hidden node features into a global feature vector $\mathbf{h}$. Formally, the pooling function is defined by $\mathbf{h} = \sum_{i=1}^n \alpha_i \odot \mathbf{h}_i$, where the α_i values are computed automatically by $\alpha_i \infty \exp\big(\tanh(W_g \mathbf{h}_i + \mathbf{b}_g)\big)$ with the constrain of $\sum_1^n \alpha_i = 1$, W_g and $\mathbf{b}_g$ are model parameters. Here α_is are vectors that control the bit-wise combination between the hidden vectors $h_i, i \in [1 \cdots n]$.

The gated pooling add to the degree of flexibility in the interpolation compared with max, min and average pooling techniques, which are commonly used to extract features from variable length vector sequences. For example, when all α_is are equal, the resulting pooling effect is the same as the average pooling function. This gated pooling mechanism is similar in spirit to the attention method of Bahdanau et al. (2014), but is used for each element in the operated vectors rather than the full vectors.

Note that our baseline discrete model and neural model have highly similar structures, differing mainly in the use of manual discrete features and automatic neural features. In particular, the discrete feature vector $\mathbf{f} = \sum_{i=1}^n \mathbf{f}_i$ can be regarded as being obtained by using a *sum* pooling function $\mathbf{f} = \sum_{i=1}^n \alpha_i \odot \mathbf{f}_i$, where $\alpha_i = \mathbf{1}$ ($i \in [1, n]$). Here $\mathbf{f}_i$ is a discrete feature vector with manual feature engineering. The neural model obtains $\mathbf{f}$ also by pooling, with α_i being trained automatically. Different from $\{\mathbf{f}_i\}$, the features $\{\mathbf{h}_i\}$ are obtained through automatical feature extraction via GRNN, rather than manual combination of one-hot features.

4.2 The Contextual Component

We follow the discrete baseline, using the same contextual tweet words extracted from history tweets for contextual features. Different from target tweet words, contextual tweet words are separate words without structures, and therefore it is unnecessary to use structured neural networks such as GRNNs to model them. As a result, we directly apply the gated pooling function to project their embedding vectors into a fixed-dimensional feature vector $\mathbf{h}'$.

5 Training

We use supervised learning with a training objective to minimize the cross-entropy loss over a set of training examples $(x_i, y_i)|_{i=1}^N$, plus with a l_2-regularization term,

$$L(\theta) = -\sum_{i=1}^{N} \log p_{y_i} + \frac{\lambda}{2} \parallel \theta \parallel^2,$$

where θ is the set of model parameters, and p_{y_i} is the model probability of the gold-standard output y_i, which is computed by using logistic regression over the output vector $\mathbf{o}$ in Eq (1) and (2) for the discrete and neural models, respectively.

Online AdaGrad (Duchi et al., 2011) is used to minimize the objective function for both discrete and neural models. All the matrix and vector parameters are initialized by uniform sampling in $(-0.01, 0.01)$. The initial values of the embedding matrix E can be assigned either by using the same random initialization as the other parameters, or by using word embeddings pre-trained over a large-scale tweet corpus. We obtain pre-trained tweet word embeddings using *GloVe* (Pennington et al., 2014)[3]. Embeddings are fine-tuned during training, with E belonging to model parameters.

6 Experiments

6.1 Experimental Settings

6.1.1 Data

We use the dataset of Rajadesingan et al. (2015) to conduct our experiments, collected by querying the Twitter API using the keywords #sarcasm and #not, and filtering retweets and non-English tweets automatically. In total, Rajadesingan et al. (2015) collected 9,104 tweets that are self-described as sarcasm by the authors. We stream the tweet corpus using the tweet IDs they provide.[4]

We remove the #sarcasm and #not hashtags from the tweets, assigning to them the *sarcasm* output tags for training and evaluation. General tweets that are *non-sarcastic* are also obtained using the tweet IDs shared by Rajadesingan et al. (2015). For each tweet, a set of history tweets are extracted using Twitter API, for obtaining of contextual tweet words. We remove the #sarcasm and #not hashtags of the history tweets also, in order to avoid predicting sarcasm by using explicit clues.

Our models are evaluated on a balanced and an imbalanced dataset, respectively, where the balanced dataset includes equal sarcastic and non-sarcastic tweets, and the imbalanced dataset has a sarcasm:non-sarcasm ratio of 1:4.

6.1.2 Evaluation

We perform ten-fold cross-validation experiments and exploit the overall accuracies of sarcasm detection as the major evaluation metric. We report the macro F-measures as well, considering the data imbalance. Concretely, for both sarcasm and non-sarcasm, we compute their precisions, recalls and F-measures, respectively, and then we report the averaged F-measure. To tune the model hyper-parameters, we choose 10% of the training dataset as the development corpus.

6.2 Hyper-parameters

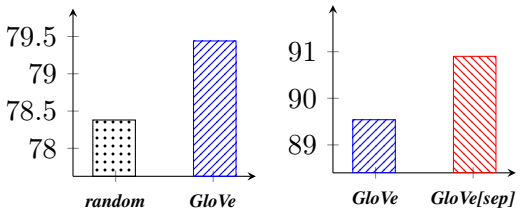
There are several important hyper-parameters in our models, and we tune their values using the development corpus. For both the discrete and neural models, we set the regularization weight $\lambda = 10^{-8}$ and the initial learning rate $\alpha = 0.01$. For the neural models, we set the size of word vectors to 100, the size of hidden vectors in GRNNs to 100, and the size of the non-linear combination layer to 50. One exception is the maximum number of history tweet words, which is 100 as default in align with Bamman and Smith (2015). We will show that the performance is still increasing when the number becomes larger in the next subsection.

6.3 Development Results

We conduct development experiments to study the effect of pre-trained word embeddings for the neural models, as well as the effect of the contextual information for both sparse and neural models. These experiments are performed on the balanced dataset.

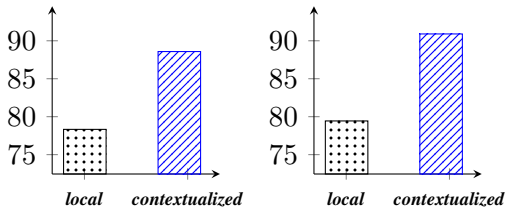
[3] http://nlp.stanford.edu/projects/glove/

[4] We are unable to obtain all the sarcastic tweets, due to modified authorization status of some tweets.



(a) local (b) contextualized

Figure 2: Influence of word representations.



(a) discrete (b) neural

Figure 3: Influence of contextual features.

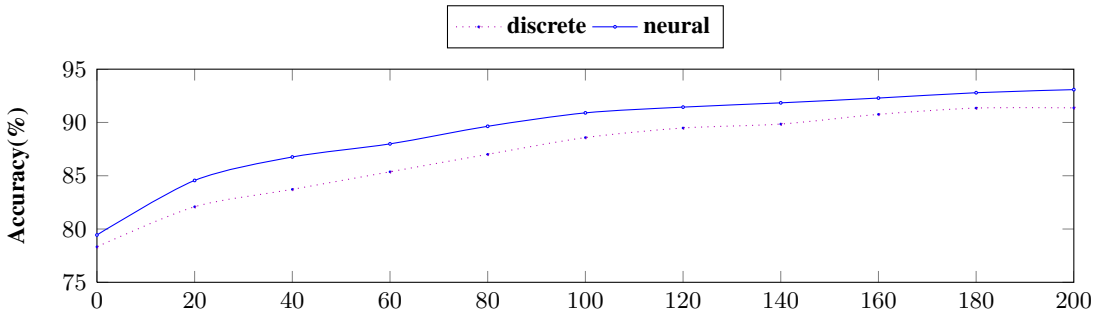


Figure 4: Developmental results with respect to different number of history tweet words.

6.3.1 Initialization of Word Embeddings

We use the neural model with only local features to evaluate the effect of different word embedding initialization methods. As shown in Figure 2(a), a better accuracy is obtained by using *GloVe* embeddings for initialization compared with random initialization. The finding is consistent with previous results in the literature on other NLP tasks, which show that pre-trained word embeddings can bring better accuracies (Collobert et al., 2011; Chen and Manning, 2014).

6.3.2 Differentiating Local and Contextual Word Embeddings

We can obtain embeddings of contextual tweet words using the same looking-up function as target tweet words, thereby giving each word a unique embedding regardless whether it comes from the target tweet to classify or its history tweets. However, the behavior of contextual tweet words should intuitively be different, because they are used as different features. An interesting research question is that whether separate embeddings lead to improved results. We investigate the question by using two embedding look-up matrices E and E', for target tweet words and contextual tweet words, respectively. The result in Figure 2(b) confirms our assumption, showing an improved accuracy by separating the two types of embeddings for each word.

Based on the above observation, we use *GloVe* embeddings for initialization in our final neural models, and use separate embedding matrices for target and contextual tweet words.

6.3.3 Effect of Contextual Features

Previous work has shown the effectiveness of contextual features for discrete sarcasm detection models (Rajadesingan et al., 2015; Bamman and Smith, 2015). Here, we study their effectiveness under both discrete and neural settings. The results are shown in Figure 3. It can be seen that contextual tweet information is highly useful under the neural setting also, which is consistent with previous work for the discrete models.

In more detail, we look at the performance with different maximum number of contextual words, in order to see the potential of contextual features. Figure 4 shows the development results, with the number range from 0 to 200, where 0 denotes the local model. As shown, the performance is consistently increasing with the increase of maximum contextual word number, although in this work we choose this

Model	Balanced		Imbalanced	
	Accuracy	F-measure	Accuracy	F-measure
Local

value by 100 to align with (Bamman and Smith, 2015).

6.4 Final Results

Table 1 shows the final results of our proposed models on both the balanced and the imbalanced datasets. The neural models show significantly better accuracies compared to the corresponding discrete baselines. Take the balanced data for example. Using only local tweet features, the neural model achieves an accuracy of 78.55%, significantly higher compared to the accuracy of 79.29% by the discrete model. Using also context tweet features, the accuracy of the neural model goes up to 90.74%, showing the strength of the history information. The F-measure values are consistent with the accuracies. These results demonstrate large advantages for the neural models on the task.

One interesting finding is that although the accuracies of imbalanced dataset are higher than those of balanced one, the micro F-measure values are on the contrary. The most possible reason could be the label bias of the imbalanced dataset, because detailed results show that the F-measures of sarcasm decrease significantly on the imbalanced dataset. According the final results, we can find both neural and contextual features can make up the F-measure gaps between balanced and imbalanced datasets, which further demonstrates the advantages of our final model.

We also compare the neural model with other sarcasm detection models in the literature. Shown in Table 1, Riloff et al. (2013) is lexicon-based model based on target tweet words only, identifying sarcasm by checking whether both positive and negative sentiment exist. *SCUBA++* shows the best results of Rajadesingan et al. (2015), using a contextualized model. Our baseline model gives higher accuracies compared to this state-of-the-art model, despite using similar features. One reason can the use of different optimization. For example, *baseline-l_1* shows the accuracy of our baseline using l_1 regularization instead of l_2, which yields variations of up to 1%. Nevertheless, the main purpose of the comparison is to show that our baseline is comparable to the best systems. Bamman and Smith (2015) report an accuracy of 75.4% on a balanced dataset, which is lower than our result. However, they performed evaluation on a different set of data, thus the results are not directly comparable.

6.5 Analysis

In order to better understand the differences between neural and manual features, we compare the discrete and neural models in more details on the test dataset. We focus on the balanced setting, and compare the contextualized models.

6.5.1 Error Characteristics

Figure 5 shows the output sarcasm probabilities of both models on each test tweet, where the x-axis represents the discrete model and the y-axis represents the neural model. The shapes + and • represent the gold-standard sarcasm and non-sarcasm labels, respectively. A probability value above 0.5 corresponds

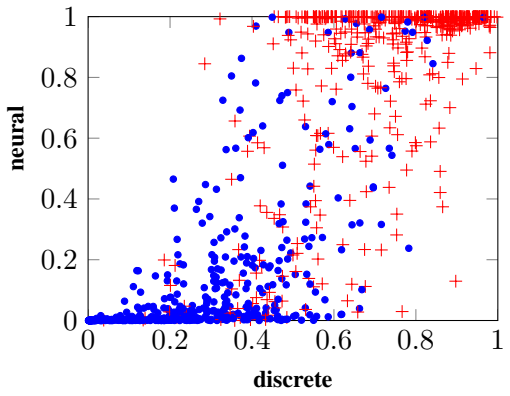

Figure 5: Error characteristic comparison, where + denotes sarcasm and • denotes non-sarcasm.

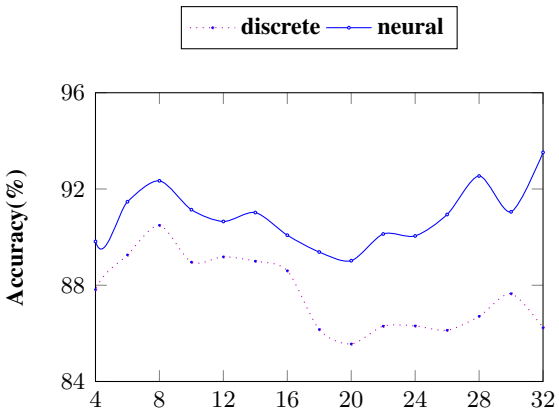

Figure 6: Accuracies against tweet length.

sarcasm	non-sarcasm
I guess finally knowing what it could have been makes me better .	so happy my brother has so many good people to help him with his move next weekend.
trying to fix my car is exactly what i wanna be doing on a saturday night.	Never go a day without telling your parents you love them

Table 2: Examples which the neural model predicted correctly but the discrete model incorrectly.

to the *sarcastic* output label. Intuitively, "+"s on the right half and "•"s on the left half of the figure show the examples that the discrete model predicts correctly, and "+"s on the top half and "•"s on the bottom half of the figure show the examples that the neural model predicts correctly.

As shown in the figure, most "+"s are in the top-right area, and most "•"s are in the bottom-left area, which indicates that the accuracies of both models are reasonably high. On the other hand, the samples are more scattered along the x-axis. This shows that the neural model is more confident in its predictions for most examples, demonstrating the discriminate power of the automatic neural features as compared with the manual discrete features.

6.5.2 Impact of Tweet Length

The GRNN neural model can potentially capture non-local syntactical and semantic information. We verify this assumption by comparing the accuracies of the neural and discrete models with respect to the tweet length. As shown in Figure 6, the neural model consistently outperforms the discrete model with respect to the tweet length. For longer tweets, the accuracies of the discrete model drops significantly, but those of the neural model remains stable.

6.5.3 Example Outputs

Table 2 shows some example sentences that the neural model predicted correctly, but the discrete model predicted incorrectly. Understanding sarcasm in the positive case requires global semantic information, which is better captured by non-local features from the recurrent neural network model. For the two cases with *non-sarcasm* gold labels, there are surface features such as "so happy", "so many" and "never", which are useful indicators of sarcasm for the discrete model. These features are local and can occur in both sarcasm and non-sarcasm tweets, thereby reducing the confidence of the discrete model (as shown in Figure 5) and can cause relatively more mistakes.

7 Conclusion

We constructed a deep neural network model for tweet sarcasm detection. Compared with traditional models with manual discrete features, the neural network model has two main advantages. First, it is free

from manual feature engineering and external resources such as POS taggers and sentiment lexicons. Second, it leverages distributed embedding inputs and recurrent neural networks to induce semantic features. The neural network model gave improved results over a state-of-the-art discrete model. In addition, we found that under the neural setting, contextual tweet features are as effective for sarcasm detection as with discrete models.

Agreement and Disagreement: Comparison of Points of View in the Political Domain

Abstract

The automated comparison of points of view between two politicians is a very challenging task, due not only to the lack of annotated resources, but also to the different dimensions participating to the definition of agreement and disagreement. In order to shed light on this complex task, we first carry out a pilot study to manually annotate the components involved in detecting agreement and disagreement. Then, based on these findings, we implement different features to capture them automatically via supervised classification. We do not focus on debates in dialogical form, but we rather consider sets of documents, in which politicians may express their position with respect to different topics in an implicit or explicit way, like during an electoral campaign. We create and make available three different datasets.

1 Introduction

When it comes to evaluate whether the statements of two persons are in agreement or not about a topic, several past works approach the problem by classifying the single statements as supporting or opposing the topic, considering the task as a variant of sentiment analysis (Somasundaran and Wiebe, 2010).

These approaches proved to be reliable in specific settings, where the goal of the statements was to express support or opposition w.r.t. the topic. However, when applied to the political domain, they often result into an oversimplified representation of the dynamics involved in the comparison of two positions. In our view, several aspects contribute to the assessment of agreement and disagreement in the political domain, requiring to be properly addressed. As an example, let us consider two excerpts uttered by Kennedy and Nixon in 1960 about the situation in *Cuba* under the *Castro regime*:

> **Kennedy:** *"There is not any doubt we had great influence in Cuba, and I think it is unfortunate that we did not use that influence more vigorously to persuade Castro to hold free, open elections, so that the people of Cuba could have made the choice."*

> **Nixon:** *"What we must remember too is that the United States has the military power - and Mr. Castro knows this - to throw him out of office tomorrow or the next day or any day that we choose."*

The two examples show that neither Nixon nor Kennedy support the Castro regime and that they both share the same negative sentiment about it in their speeches. But beside being on the same side in contrasting the regime, their points of view on it are, from a pragmatic perspective, very different: while Kennedy supports free elections, Nixon does not hesitate to remark United States military power and the possibility to remove Castro in any moment. Overall, the two positions are in disagreement. This example shows that the sentiment and the proposed solution are two relevant aspects to define a politician's attitude w.r.t. a topic, and that the contribution of these two aspects need to be better studied when comparing different points of view: while one could argue that disagreement is expressed by

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2461–2470, Osaka, Japan, December 11-17 2016.

different sentiment and different semantic content, our pilot analysis shows that the boundaries are not so clear-cut.

The main contribution of this work lies in the presentation of a first feasibility study on manually annotated data from the political domain (Section 4), where we decompose the notion of agreement / disagreement, and in the presentation of a novel system (Section 5), which takes into account the insight gained during the feasibility study. We evaluate our approach on three datasets created for this task, which we make freely available[1], and show that our approach is effective on each of them: the one created for the feasibility study presented in Section 4.1, an extended version of the same dataset, and a larger one extracted from Debatepedia presented in Section 5.2.

2 Related Work

Given the highly polarized nature of political debates, we can find in the literature many works focused on classifying political statements as supporting or opposing a debated topic. This classification can be approached in different ways, for instance by emphasizing the role of sentiment polarity in a statement, or using topic modeling to define each position.

In (Somasundaran and Wiebe, 2009; Somasundaran and Wiebe, 2010) the authors propose a way to classify stances. They gather posts on different topics from online forums, and classify the statements from these debates as in favor or against the debated issue. They use the MPQA corpus to automatically generate a lexicon of entries indicative of a positive and negative argument and add information about the use of modal verbs and sentiment-based features. A similar task is proposed in Abbott et al. (2011) to recognize disagreement in online political forums between quoted text and a given response. The goal was achieved by using word-based features (for example discourse markers) as well as meta-information. Another work investigating stance classification of online posts was presented in Anand et al. (2011): there, the authors attempt to improve the unigram baseline by adding more cognitive-motivated features such as contextual information and opinion dependencies to define the target of opinion words. The results show that the use of these features improves classification results for many topics.

Another work from Gottipati et al. (2013) proposes to learn topics and support/opposition from discussions in Debatepedia by using a model based on the probabilistic distribution of the terms over the topics and the sides of the debate. A similar work on Debatepedia has been proposed by Awadallah et al. (2012), to classify quotes as belonging to a topic and supporting or opposing it.

Other approaches to classification rely on corpus-specific features, as in Thomas et al. (2006), who detect support and opposition to legislation in congressional debates by using speech transcriptions as well as records on voting, information about the speakers and the relations among them. Other works focus on the identification of agreement and disagreement in dialogues, such as (Galley et al., 2004; Hillard et al., 2003). They classify consecutive speech transcription segments produced by different speakers as positive or negative with respect to the discussed topic by using lexical, structural, and prosodic features.

Compared to previous works, our task is different in that we perform pairwise agreement/disagreement detection between two points of view: our focus is on the relation between the two rather than the single stance. Another difference lies in the types of textual units we want to classify: we do not work on single statements but rather on longer snippets including several sentences, based on the assumption that in the political domain a person's position with respect to a topic may not be overtly expressed. Our goal is to generalise over single statements and detect agreement and disagreement based on a broader, but not necessarily explicit, textual context.

3 Task Description

In the political domain, public debates in which two opponents discuss their point of view on specific topics, usually suggested by a moderator, are just one of several occasions in which political agendas are described. If we consider an electoral campaign, for instance, candidates issue declarations, mostly in the form of speeches, in which several topics are more or less explicitly discussed, and only towards

[1] Available at `https://dh.fbk.eu/resources/agreement-disagreement`

the end of the campaign a direct confrontation between opponents takes place. While past approaches to detect direct support or opposition in dialogues (Galley et al., 2004; Hillard et al., 2003) could be appropriate to analyse such direct confrontations, they may fail to capture the complexity of other types of statements. For example, the limited length of turns in dialogues, the presence of specific emphatic expressions and the need to focus on one topic at a time all contribute to the automated detection of agreement or disagreement in direct confrontations, but this information is not necessarily present when we consider larger documents collections, containing the public declarations of a politician. This second scenario is the focus of the present work. Specifically, given two document collections containing the public declarations and speech transcriptions of two politicians, our goal is to assess whether the two agree or not on a topic. In this scenario, we cannot assume that, each time a topic is mentioned, a position is explicitly expressed, but rather that it can be understood given a set of statements related to the topic. Besides, we cannot assume that two datasets representing two politicians contain direct references or replies between the opponents on a given topic. In this complex scenario, we first define a methodology to process the document collections and extract the text passages to be compared and classified. Then, we propose an approach to classify such pairs based on supervised learning, that takes into account features capturing the relevant dimensions analysed in the pilot study.

4 Pilot Study

To investigate which dimensions are involved in the perception of agreement and disagreement in the political domain, we first perform an exploratory study by manually annotating a dataset created for the task.

4.1 1960 Presidential Campaign Dataset

We collect the transcription of discourses and official declarations issued by Nixon and Kennedy during 1960 presidential campaign from The American Presidency Project[2]. The corpus includes 881 documents[3] and more than 1,6 million tokens (around 830,000 tokens for Nixon and 815,000 tokens for Kennedy).

We define 38 topics relevant to the electoral campaign with the help of a history scholar and we represent them via a set of manually defined keywords (e.g. a topic about the Agricultural program defined as *[agricultural program, agricultural policy, farmer, farm]*, about Education *[education, school]* or about Atomic energy *[atomic energy, nuclear energy, atomic power, nuclear power]*).

For each topic, for example *Education*, we extract from the two sets of documents all sentences containing at least one of the keywords defining the topic, plus the previous and the following sentence. The decision of extending the selection to three sentences is taken in order to have a more complete portion of text about the topic. These three sentences correspond to a *text excerpt*.

For each topic, we finally pair five random excerpts from Kennedy with five random excerpts from Nixon to create our *snippets*. We used this approach because the annotation task focused on general questions that needed enough context to be answered, and single excerpts may not provide enough information for the task.

4.2 Corpus Annotation

We build 350 snippets across all the topics and ask two independent annotators to annotate them using the CrowdFlower web interface[4]. We did not open the task to the public, but we relied on trusted annotators. For each pair, the following questions are asked:

1. *Are Nixon's and Kennedy's statements about the topic in agreement, disagreement or neutral?*

2. *What is Kennedy's sentiment with respect to the topic?*

[2]The American Presidency Project, by John T. Woolley and Gerhard Peters (`http://www.presidency.ucsb.edu/1960_election.php`)

[3]These documents are freely released under the NARA public domain license.

[4]`https://www.crowdflower.com/`

3. *What is Nixon's sentiment with respect to the topic?*

4. *Are the solutions or initiatives proposed by Nixon and Kennedy similar or different?*

For each pair, we collect *i)* a judgment about the *agreement/disagreement* relation between Nixon and Kennedy on the topic (*Question 1*), *ii)* a judgment on Kennedy's and Nixon's *sentiment* w.r.t. the topic (*Question 2 and 3*) being either *Positive*, *Neutral* or *Negative* and *iii)* a judgment on the *solutions* proposed by the two candidates as *similar*, *different* or *neutral*, i.e. no solution proposed (*Question 4*). The inter-annotator agreement as provided by Crowdflower is 73% for Question 1, 69% for Question 2, 70% for Question 3, and 78% for Question 4. Crowdflower re-assigns then each snippet for which there is no agreement to one of the three categories based on a 'confidence score' (we could not obtain the exact formula used to compute this value but we assume it takes into account annotators' reliability).

4.3 Data Analysis

Based on the answers to Question 1, the dataset is composed by 203 pairs of snippets where Nixon and Kennedy agree on the topic, 97 pairs in which they disagree and 50 pairs where they neither agree nor disagree. We focus on the pairs in agreement or disagreement and further analyse the contribution of *sentiment* and *proposed solution* to the perception of agreement. Results are reported in Table 1. The analysis shows that being in agreement does not necessarily imply having the same sentiment or suggesting the same solution (no solution is suggested in most of the cases). In cases of disagreement, instead, a different sentiment and a different solution prevail.

Overall, if we cast the agreement / disagreement prediction on the basis of the sentiment, we can correctly guess 221 pairs over 350 (63.1%). Similarly, if we cast the agreement / disagreement prediction based on the fact that same or different solutions are proposed, we can correctly guess 173 pairs over 350 (49.4%). These values show that sharing the same *sentiment*, and proposing the same *solution*, *per se* are not reliable indicators of agreement.

	Same Sentiment	Same Solution
Agreement Nixon-Kennedy (203 pairs)	134/203 (66.0%)	89/203 (43.8%)
	Different Sentiment	Different Solution
Disagreement Nixon-Kennedy (97 pairs)	87/97 (89.7%)	84/97 (86.5%)

Table 1: Correspondence between agreement/disagreement and similar/different sentiment or solution.

We further analyse the direct relation between the sentiment and the semantic content (i.e. solution proposed) of the snippet pairs in the dataset with the help of Figure 1. The graph highlights that the pairs in which the two politicians share the same sentiment (on the left side) are split in half between similar and different solutions (on the right side). Instead, most of the pairs with a different sentiment (left side of the graph) end to different solutions, but only half of the pairs with different solutions (right side of the graph) derive from statements with a different sentiment.

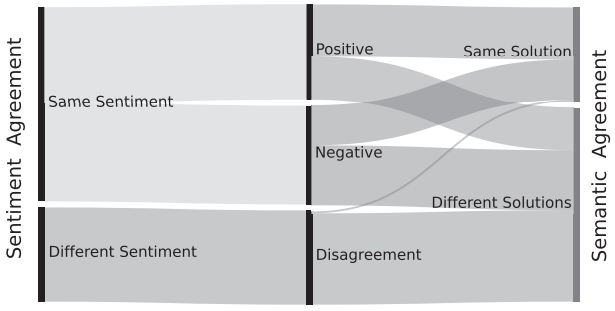

Figure 1: Relation between sentiment (annotations from Questions 2 and 3) and semantic content (annotations from Question 4) in Nixon's and Kennedy's statements.

The main findings of this pilot study can be summarised as follows: *i)* there is not a direct correspondence between the fact that Nixon and Kennedy agree on a topic and the fact that they share the same sentiment, *ii)* there is not a direct correspondence between the fact that Nixon and Kennedy agree on a topic and the fact that they propose the same initiative or solution, and *iii)* the sentiment and semantic content of the statements contribute both to defining agreement/disagreement between the two politicians. This implies that automatically classifying agreement and disagreement in this scenario needs to be addressed with appropriate features that can capture these different dimensions.

5 Experimental Setup

Based on the insight gained in the pilot study, we develop a system to automatically classify agreement and disagreement between two politicians (see Question 1 in the annotation task) trying to integrate information related to sentiment and semantic content of the statements (Questions 2-4). We classify pairs of *snippets*, one for each politician. For the task we adopt a supervised machine learning approach using LIBSVM (Chang and Lin, 2011) to train a Support Vector Machine (SVM). We evaluate our approach on the three datasets described in Section 5.2.

5.1 Features

We rely on three main categories of features. The contribution of speakers' sentiment to their agreement/disagreement is represented by a set of *sentiment-based features* (e.g. the sentiment of the statements and sentiment of the topic). To capture the differences and similarities in the proposed solutions, we use a set of *semantic features* (e.g word embeddings, cosine similarity and entailment), based on the intuition that two texts proposing the same solution are more likely to be semantically similar than two texts proposing different solutions. Finally, we add a set of *surface features* (e.g. the lexical overlap and the use of negations) that we expect to bear some information on the relation between the two snippets.

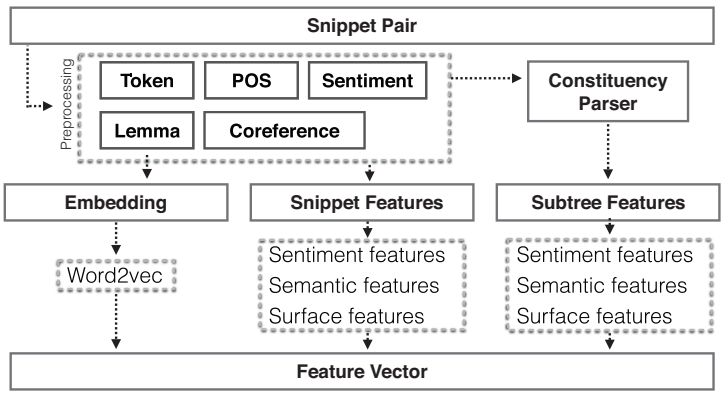

Figure 2: Features Extraction Pipeline

Figure 2 shows the pipeline we implemented for feature extraction. After preprocessing, all the features, except for word embeddings, are extracted at two different levels of granularity. In the first one, we extract the features at snippet level, which provide more information about the context in which the topic is used. In the second one, we focus only on the portion of text directly related to the topic. We use the Stanford Parser (De Marneffe et al., 2006) to extract from the sentences in the snippets all the subtrees containing the keywords representing the topic, and then we extract the features from them. With this pruning, we focus less on the context and more on the information which is directly related to the topic.

For each pair of snippets, we extract the following features:

Sentiment information: These features are inspired by previous works using sentiment information to predict a speaker's opinion on a topic (Pang and Lee, 2008; Abbasi et al., 2008). Each pair is represented by four sentiment scores, two scores for each snippet in the pair. We rely on the sentiment analysis module in the Stanford CoreNLP (Socher et al., 2013). We use a global sentiment score for each snippet (obtained by the average of the sentiment score of each sentence in it), and a score for the sentiment in

the subtrees related to the topic (obtained by the average of the sentiment score of each content word in the subtrees).

Word embeddings: Past works showed that word embeddings are an effective tool to define ideological positions in political documents (Iyyer et al., 2014). In our case, we do not focus on the sentence level, but rather on the keywords defining the topics debated in our pairs. We treat each snippet separately and we obtain two vectors for each pair: one vector representing the keywords of the topic in the first snippet and one vector for the topic in the second snippet (e.g. a vector for *Castro Regime* in Kennedy and a vector for *Castro Regime* in Nixon). The vectors are extracted using Word2vec (Mikolov et al., 2013) on each snippet (425 words on average with the topic occurring multiple times), with continuous bag-of-word algorithm, a windows size of 8 and a vector dimensionality of 50. We use this feature assuming that, when two people agree (i.e. have a similar point of view) on a topic, their respective vectors are more similar than when they are in disagreement.

Cosine similarity: In addition to the representation of the topics based on word embeddings, we use a set of features to quantify the relatedness between the way the two speakers talk about the topic. From each snippet in the pair, we extract two types of semantic vectors based on the co-occurrences (Turney et al., 2010) of topic keywords: one is computed over the entire snippet, while the other considering only the topic subtree. Co-occurrences are extracted from a window of 8 tokens and weighed using local pointwise mutual information. We then compute the cosine similarity between the vectors of the two sides of the snippet.

Entailment: The presence of entailment between the two snippets can be relevant to define if the position expressed by a speaker is accepted by the other (Cabrio and Villata, 2012). For this feature, we use the Excitement Open Platform (Magnini et al., 2014). For each pair, we use information about the entailment between the two snippets (in both the directions) and between the text in the subtrees related to the topic (in both the directions).

Lemma overlap: Past works showed that lexical overlap contributes to determining topical alignment between two texts (Somasundaran et al., 2009). Therefore, we compute lemma overlap of nouns, verbs and adjectives between two snippets. Although lexical overlap is already integrated in the textual entailment features, we believe that this information can provide useful information also in isolation.

Negation: For each snippet, we extract two features related to explicit negation cues (e.g. *not*, *don't*, *never*), adopting the list used in Councill et al. (2010). Using the parse tree of the snippets, we identify the words under the scope of a negation, and then consider as features *i)* the number of negated words in each snippet (normalized to its length) and *ii)* the percentage of the overlapping lemmas that in one snippet are under a negation. We expect that, if the same words are negated in a snippet and not in the other, this information can shed light on the relation between them.

5.2 Datasets

We evaluate our approach on three different datasets. The first is the 1960 Presidential Campaign dataset presented in the pilot study (300 snippet pairs). Given the limited number of pairs in this dataset, we create an extended version of it as follows: given a snippet pair related to a topic, we randomly replaced in each snippet two of the five excerpts belonging to it with others from the same politician, on the same topic, and with the same agreement/disagreement. By swapping random pairs of excerpts between snippets, we generated new ones and we were also able to better balance the agreement/disagreement proportion. Overall, the final dataset contains 1,400 pairs, balanced between the agreement/disagreement classes.

We further wanted to measure the impact of our approach on a larger corpus, more suitable for machine learning tasks. Therefore, we extract from Debatepedia[5] pairs of snippets compliant with the structure and the content of the two other datasets. We choose Debatepedia, an online encyclopedia of debates, because it provides statements from two opposing sides debating on well-defined, controversial topics. In particular, for each topic, Debatepedia gathers a set of relevant evidences and statements, mainly from news, that are framed as being in favour or against a specific debate question, e.g. "Is the $700 billion

[5] http://www.debatepedia.org/

bailout for the 2008 US financial crisis a good idea?" (Figure 3). In this way we have a large amount of snippets clustered into topics (e.g. individual rights, public safety, clean energy) and already structured as in agreement or not.

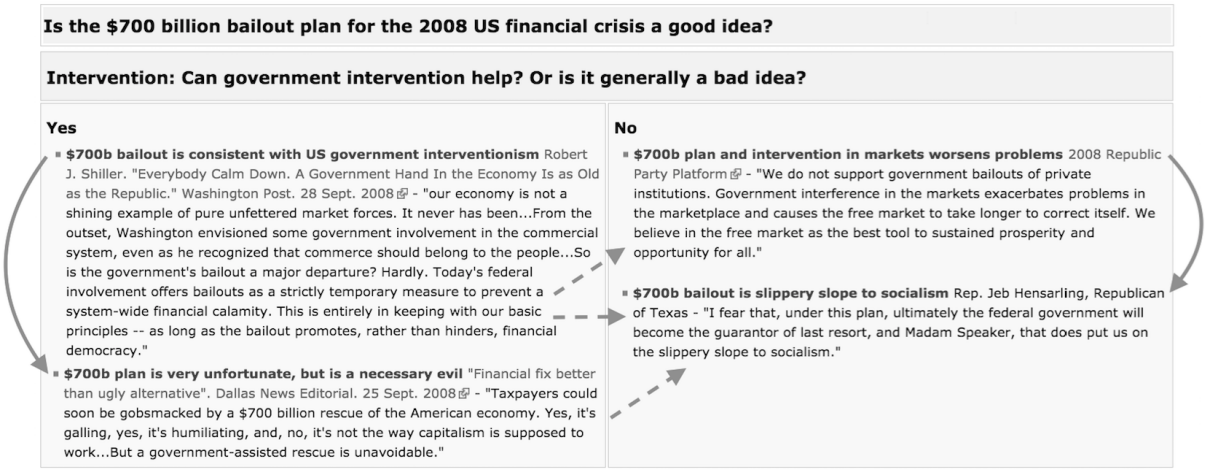

Figure 3: The Debatepedia Structure: the list of statements supporting the topic are on the left side and the list of statements opposing the topic on the right side. The solid arrows connect a pair in agreement, while the dashed lines link pairs in disagreement.

We collect from Debatepedia 646 debates for a total of 17,055 unique statements. To simulate our task, we need to organize the statements into pairs and associate each pair to a topic expressed by a keyword appearing in both statements. The pairs were created as indicated in Figure 3, by coupling two snippets being on the same side (for the agreement cases) or being on two opposite sides of the debate (for the disagreement cases).

In order to identify a keyword shared between two paired snippets, we first select only the pairs sharing at least one noun (74%). Then, we manually revised the 500 nouns most frequently overlapping, keeping only those that are not too generic and are related to the given topic of the debate. This led to a final list of 164 nouns, used as topics, for a total of 29,354 pairs. This final set of pairs, used in the classification task, is still balanced, with 14,042 pairs marked as in agreement and 15,312 in disagreement.

6 Evaluation

We report in Table 2 the results obtained on the three datasets using SVM with radial kernel (10-fold cross validation). A random baseline corresponding to the majority class is also reported. Beside evaluating the classifier performance with all features, we also analysed the contribution of single features (i.e. *negation/overlap*, *entailment*, *sentiment*, *cosine*, *word embeddings*) and their combinations to the task. Finally, we perform another evaluation, adding to the features mentioned before the outcome of the coreference resolution system in StanfordCoreNLP (Lee et al., 2011). Our intuition was that, since our snippets usually include more than one sentence, resolving pronouns and coreferential expressions may make the content more explicit, thus enabling a better agreement detection. However, results show that this information causes a slight performance drop. This can be due to coreference resolution errors rather than the feature itself, and we plan to further investigate this issue in the future.

Evaluation results confirm the findings suggested by the feasibility study: considering only sentiment-based features, or those related to semantic content is not effective as combining the two information layers (*Sent+Entailment+Embeddings+Cosine*). Surface features still have an impact on the outcome of every run, although limited.

If we compare the results obtained on the three datasets, we observe that the limited size of the 1960 Elections dataset affects classification, because some configurations yield the same performance as the random baseline. On the two other datasets, instead, the selected features are effective for classification, with a better performance achieved on the Extended 1960 dataset. This is due to the fact that all snippets

	1960 Elections	Extended 1960 Elections	Debatepedia
Used Features	Accuracy	Accuracy	Accuracy
Random Baseline	67.6%	50.0%	52.2%
Negation+Overlap	67.6%	52.7%	54.5%
Entailment	68.7%	55.7%	55.6%
Sentiment	67.6%	56.2%	54.7%
Cosine	67.6%	67.5%	53.0%
Word Embeddings	76.3%	77.5%	67.3%
Sentiment+Entailment	68.6%	60.0%	57.6%
Sent+Entailment+Embeddings	81.4%	79.7%	72.9%
Sent+Entailment+Embeddings+Cosine	81.7%	79.8%	73.1%
All features	**83.0%**	**80.1%**	**74.0%**
All features + coreference	81.6%	79.0%	73.7%

Table 2: Classification results on the 1960 Elections dataset (300 pairs), Extended 1960 Elections dataset (1,400 pairs) and Debatepedia Dataset (29,354 pairs)

are extracted from documents by Nixon and Kennedy, so that language and style are consistent across all pairs. Debatepedia, instead, relies on a wide range of sources, thus language variation is much higher.

We finally run a last experiment to test our approach on a different task, i.e. the classification of single statements as supporting or opposing a topic. We argue that, even if we chose our features with a focus on *pairwise* comparison, some of them may be effective also for single snippets. We rely again on Debatepedia, with the goal of classifying single arguments as supporting or opposing a topic. To this purpose, we remove the features strictly related to the pairwise comparison (e.g. the lemma overlap or the cosine similarity), and then classify each snippet belonging to one of the 29,354 pairs of our Debatepedia dataset via 10-fold cross-validation. Using SVM, we yield an accuracy of 87.2%. This result shows that the core set of features used to capture the point of view at snippet level are effective both to perform comparisons and to detect support or opposition given a single statement and a topic. Gottipati et al. (2013) perform the same task on Debatepedia data using a topic model-based approach, and achieve 86.0% accuracy. Although the two results are not directly comparable, since their dataset comprising 3,000 snippets is not available, we can conclude that our approach is a reliable solution also for single argument classification and can generalise well over different tasks.

7 Conclusion

In this paper, we introduced a study on the different dimensions which contribute to define agreement and disagreement between points of view in the political domain. We presented a pilot study that highlights how agreement w.r.t. a topic is derived both from the sentiment about it and the solution proposed. We used then these two dimensions, complemented by other lexical features, to train a classifier that was tested on data from the 1960 U.S Presidential Election and from Debatepedia. With this approach, we were able to correctly classify agreement and disagreement with good accuracy.

In addition to SVM, we experimented also with Convolutional Neural Networks using the TensorFlow implementation (Abadi et al., 2015), configured with 10 layers, 100 nodes and 100 iterations. So far, the performance achieved with CNN is around 20% lower than with SVM on all datasets, therefore we did not report the details in the experimental description. We plan to further investigate the motivations behind this gap, and to continue experimenting with other TensorFlow configurations.

Another research direction that we plan to pursue is the role of neutral judgments when analysing agreement and disagreement: we collected 50 neutral judgments during the pilot annotation, but we discarded them because we wanted to focus on pairwise agreement or opposition. However, in a real application scenario, it would be very important to add also this class. This extension is currently ongoing. In the future, we also plan to include the module for agreement and disagreement detection in the platform for the analysis of political speeches presented in Moretti et al. (2016).

Targeted Sentiment to Understand Student Comments

Charles Welch and **Rada Mihalcea**
University of Michigan
2260 Hayward Street
Ann Arbor, MI 48109, USA
{cfwelch,mihalcea}@umich.edu

Abstract

We address the task of targeted sentiment as a means of understanding the sentiment that students hold toward courses and instructors, as expressed by students in their comments. We introduce a new dataset consisting of student comments annotated for targeted sentiment and describe a system that can both identify the courses and instructors mentioned in student comments, as well as label the students' sentiment toward those entities. Through several comparative evaluations, we show that our system outperforms previous work on a similar task.

1 Introduction

Sentiment analysis is the computational study of people's opinions or emotions; it is a challenging problem that is increasingly being used for decision making by individuals and organizations (Pang and Lee, 2008). There is a significant body of research on sentiment analysis, addressing entire documents (Agarwal and Bhattacharyya, 2005), including blogs (Godbole et al., 2007; Annett and Kondrak, 2008) and reviews (Yi et al., 2003; Cabral and Hortacsu, 2010); sentences (Yu and Hatzivassiloglou, 2003; Nigam and Hurst, 2004) or otherwise short spans of texts such as tweets (Pak and Paroubek, 2010; Kouloumpis et al., 2011); and phrases (Wilson et al., 2005; Turney, 2002). More recent work has also addressed the task of aspect sentiment (Pontiki et al., 2015; Thet et al., 2010; Lakkaraju et al., 2014), which aims to address the sentiment toward attributes of the target entity, such as the service in a restaurant (Sauper and Barzilay, 2013), or the camera of a mobile phone (Chamlertwat et al., 2012).

In this paper we address the task of *targeted sentiment*, defined as the task of identifying the sentiment (*positive, negative*) or lack thereof (*neutral*) that a writer holds *toward* entities mentioned in a statement. Targeted sentiment has been only recently introduced as a task, to our knowledge with contributions from only two research groups that focused primarily on settings with scarce resources (Mitchell et al., 2013; Zhang et al., 2015). While previous work on data sets such as product reviews can give an accurate measure of sentiment toward products (as explicit targets of the opinions being expressed in the reviews), some corpora include additional challenges. Targeted sentiment addresses the challenge of identifying entities in running text (e.g., Twitter, student comments), and attributing separate sentiment to each mentioned entity.

In our work, we focus on an application-driven task, namely that of understanding students' sentiment towards courses and instructors as expressed in their comments. As an example, consider the statement:

(1) *I thought that natural language processing with professor Doe was a great class.*

We want to recognize the targets "natural language processing" (a course) and "Doe" (an instructor), as well as a positive sentiment toward the course, and a neutral sentiment toward the instructor. We approach targeted sentiment as a pipeline of two tasks: (1) entity extraction, which aims to identify the entities of interest (in our case, courses and instructors); and (2) entity-centered sentiment analysis, which classifies the sentiment (positive, negative, neutral) held by the student writer toward those entities.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2471–2481, Osaka, Japan, December 11-17 2016.

Section 2 overviews previous work, and shows how our work fits into the bigger picture of sentiment analysis research. Section 3 describes the data used for our experiments. Section 4.1 shows how entities are extracted from text for use in targeted sentiment analysis, and Section 4.2 describes how the sentiment held toward these entities is classified. An overall evaluation of our system and comparison with previous work are presented in Section 5, followed by a discussion and conclusions in Section 6.

2 Previous Work

Most work in sentiment analysis is done at one of three levels: document level, sentence level, and aspect level. These three levels of granularity are ordered from coarsest to finest, with the finer granularity tasks being less well studied. In general, an opinion can be represented by the following quintuple, $(e_i, a_{ij}, oo_{ijkl}, h_k, t_l)$ (Zhang and Liu, 2014). The value e_i here represents the ith entity and a_{ij} represents the aspect j of this entity. The kth holder of the opinion is represented by h_k and the time, l, that the opinion is expressed is given by t_l. Given the entity, aspect, holder, and time, one can reason about an opinion orientation oo_{ijkl}. This is usually a positive, negative, or neutral value, although occasionally a larger number of sentiment values are used (e.g., very positive, very negative).

The work most similar to ours is the open domain targeted sentiment task (Mitchell et al., 2013). Unlike Mitchell et al, we do not use an artificially balanced data set. Instead we collected all the utterances from students who talked about whichever entities they chose. While we do limit the types of entities to only classes or instructors, we do not limit the specific entities themselves and students can talk about any entities that are relevant to their previous educational experience. Our method is also somewhat different in that we do not evaluate subjectivity: all the entities are assigned a positive, negative, or neutral sentiment, and there are no entities without sentiment.

There were two follow-up papers to Mitchell et al. (Zhang et al., 2015; Zhang et al., 2016) (both from the same research group). The first of these papers worked on improving the three models used in Mitchell et al. including the pipeline, joint, and collapsed models. They show some improvements but the pipeline mode, which is most similar to ours, does not greatly differ in performance. The latter paper used different neural network models on a combination of three data sets. Two of these data sets are derived from Twitter (including Mitchell's) and the last is derived from MPQA. We do not attempt to compare to that work, but we show comparable F1 measures using simple linguistic features.

The next most closely related work to ours are the tasks of sentiment slot filling, target dependent sentiment analysis, and aspect-based sentiment analysis. Slot filling is the task of discovering information about a named entity and storing it in a knowledge source (Surdeanu and Ji, 2014). The 2013 Text Analysis Conference (TAC) had two similar tasks, which were slot filling and temporal slot filling (Surdeanu, 2013). For the slot filling task, systems had to determine the correct value for a set of slots for people and organizations. People contained slots such as "date of birth", "age", or "spouse", while organizations contained slots such as "website", "founded by", and "country of headquarters". For the task of temporal slot filling, a system must determine two time ranges. The first time range is a range in which the expressed slot-value was known to begin being a true statement and the second time is when the expressed fact is known to have ceased being true. Sentiment slot filling is the task of taking a query opinion holder and orientation and returning the set of entities that satisfy this condition. In terms of the quintuple we use to represent sentiment, these are related tasks because although slot filling and temporal slot filling are not exactly sentiment tasks, they are concerned with the entity, aspect, and time values. The sentiment slot filling task is concerned with the entity, orientation, and opinion holder.

In the task of target dependent sentiment analysis, the goal is to take a query entity and find the sentiment toward this entity in a set of tweets (Jiang et al., 2011). This is usually done with a small set of entities where the corpus is constructed by querying Twitter for tweets that contain the substring matching the entity. Jiang et al. perform this task in three steps. They first identify whether subjectivity exists, then the polarity of the sentiment toward the target, and then use a graph based method to improve classification accuracy using retweets, i.e., tweets from the same users that mention the same entities. In our task, we use a larger set of entities that have many ways of being mentioned; this makes the entity identification part of the task more difficult. We also do not have a social network structure to leverage

to improve performance.

Aspect-based sentiment analysis has been the focus of recent SemEval tasks as well as a TAC task (Ellis et al., 2014; Pontiki et al., 2014; Pontiki et al., 2015). The 2014 sentiment task was continued in 2015, and again in 2016. Researchers submitted a variety of models to evaluate the sentiment of aspects on sets of reviews for laptops, restaurants, and hotels. The highest scoring systems in the SemEval 2015 Task 12 used maximum entropy and support vector machine (SVM) models with bag of words (BoW), verb and adjective lemmas, bigrams after verbs, negation terms, punctuation, point-wise mutual information scores, part of speech tags, and other features (Li et al., 2013; Zhang and Lan, 2015). The results presented were marked as either constrained or unconstrained systems. Unconstrained systems were allowed to use data outside the training data provided, while constrained systems could not. The top two scoring models were unconstrained but the top scoring constrained system used Brown clusters in addition to other features. These are counts of how many words in the sentence belong to semantic clusters of words derived in previous work (Hamdan et al., 2015). Other entries used similar features with several entries using SVM models and a single entry that relied on an unsupervised model.

3 Data

As we are not aware of any dataset consisting of statements describing courses and instructors, and the sentiment that the writers (students) have toward them, we collected our own dataset. We extracted sentences from a Facebook student group where students describe their experience with classes in the Computer Science department at the University of Michigan, as well as from a survey run with students in the same department. The final data set consists of 1,042 utterances written by both graduates and undergraduates, describing both classes and instructors that the students had/interacted with. Table 1 shows three statement examples drawn from our dataset.

Student utterance	Annotation
I thought that introductory programming concepts was a difficult class and I did not like it.	⟨class name=introductory programming concepts, sentiment=negative⟩
Professor Williams is my favorite teacher that I've had so far.	⟨instructor name=Williams, sentiment=positive⟩
I took CS 203 last Winter. Davis was teaching and I thought the class was excellent.	⟨class name = CS 203, sentiment=positive⟩ ⟨instructor name=Davis, sentiment=neutral⟩

Table 1: Sample student utterances from our dataset along with annotations.

All the utterances were first manually annotated by one of the authors to identify courses and instructors. As often done in entity extraction methods, we identify entities using an I(nside) O(utside) B(eginning) model. For instance, given the text "I am enrolled in CS 445.", and assuming the entity to be extracted is a course name, the annotation would include the following labels "I_O am_O enrolled_O in_O CS_B 445_I.", indicating that CS is at the beginning of the course name, 445 is inside a course name, and all the other tokens are outside the course name.

Classes can be mentioned by department and class ID as in "CS 484," by ID alone as in "484," or by name as in "introduction to artificial intelligence" or "intro to AI." Instructors are mentioned by name, but could be mentioned by first, last, or first and last names. In total, the 1,042 utterances include 976 class mentions and 256 instructor mentions, for a total of 1,232 entities.

The perceived sentiment toward each entity was also manually labeled by one of the authors as either positive, negative, or neutral. When no explicit sentiment is expressed toward an entity, it is assumed to be neutral. If no sentiment is evident from a given utterance, it is assumed to be neutral. Table 1 shows the annotations for the three sample utterances from our dataset.

To calculate inter-annotator agreement for the identification of entities, a second annotator labeled 100 utterances from the data set, containing 1,263 tokens. Of these, 1,067 were mutually labeled as not being part of any entity. Of the remaining 196 tokens, 2% were not in agreement. Including all tokens, agreement was measured as 0.987 using Cohen's kappa. These two percent were two instances where

the human judges disagreed on whether or not a sequence of tokens was a course name (i.e., an entity that needed to be annotated) or simply a course description. For example, in the sentence "I believe that databases are a crucial part of computer science and 520 was interesting," while "databases" is part of the class name, one annotator decided that the word was simply a description of the content of the course and not an entity.

To calculate inter-annotator agreement for sentiment annotations, a second annotator individually labeled all the 1,232 entities. The agreement between the two annotators was measured at 77.7%, which gives a Cohen's kappa of 0.661 considered to be good agreement. Agreement was calculated as the percentage of entities for which both annotators assigned the same label. Of the annotator disagreements, 10.7% were neutral-negative disagreements, 11.2% neutral-positive disagreements, and 0.2% positive-negative.

4 Targeted Sentiment Analysis

We address this task as a pipeline of two steps. We first identify the target entities (i.e., courses and instructors), followed by a classification held by the student writer toward those entities. In the following, we describe and evaluate the method used for each step, and compare the results obtained against the state-of-the-art.

4.1 Entity Extraction

As mentioned before, we use an IOB model to identify entities in the text. We therefore apply a classification process to every token in the input text. For each token, we build a feature vector, using the following features:

Core features. These include the current word, the case and part-of-speech of the current word, the previous two words; features are also derived from the two words neighboring the current word, which are computed the same way as for the current word.

Lexicons. We record the presence/absence of words in two custom lexicons: one consisting of the professor names gathered from the University of Michigan; the second one including all the words used in the names of the classes offered in the Computer Science department at the same university. The lexicon features are generated for the current word as well as each neighboring word.

Professor titles. We use a list of titles, such as "Dr." or "Prof." to assist with the identification of professor names. The list was compiled manually, and consists of 15 tokens. A feature is generated to indicate whether a token belongs to this list or not. 38% of utterances in the corpus contain professor titles.

Sequence. Students often use a subset of the words in a class name to refer to it. The sequence feature is a binary feature that indicates whether the current word is inside a course or an instructor name sequence, where the courses and instructor names are drawn from the two lexicons described above.

Acronym. The acronym feature is another binary feature that indicates if the input token is an acronym of any class or instructor names in the lexicons. It takes the first letters of each of the words in a name and checks to see if the token matches the concatenated string of first letters for an entry in the lexicon. It subsequently checks if the removal of any number of letters, while retaining order, matches the given token. For instance, "AI" and "ITAI" both match "Introduction to Artificial Intelligence".

Nearest entity. Sometimes class or instructor names are misspelled, and for such cases lexicon features may not be effective. We create a feature that checks if the current token has an edit distance less than three to a word in a class or instructor name in the lexicons. If a match is found, the feature is set to a value of "C" (course) or "I" (instructor) respectively. If no token exists, the feature is set to "N".

As a machine learning algorithm, we use a conditional random field, as it has been previously shown to be highly effective for such entity extraction tasks (Zhang and Liu, 2014). We run a set of 67-33 train-test splits using stratified sampling. Table 2 shows the F-measure results obtained by our system, which makes use of all the features described above, for each of the four token types (B and I for courses and instructors). For comparison, we also show the results obtained with a basic setting, when only the core features are used, as well as the results obtained with a state-of-the-art entity extraction system available from the Stanford NLP group (Finkel et al., 2005), which we have retrained using our corpus.

Using our system, we see a statistically significant improvement over the core baseline for all four tokens ($p < 0.01$). We also find a statistically significant improvement over the Stanford system for I_C and B_I ($p < 0.01$) but no significant difference for the other two token types.[1]

System	B_C	I_C	B_I	I_I
Our system	0.945	0.881	0.922	0.901
Baseline (core features)	0.940*	0.849*	0.863*	0.841*
Stanford (Finkel et al., 2005)	0.944	0.848*	0.896*	0.908

Table 2: F-score figures for the identification of I and B tokens, for course (C) and instructors (I), where * indicates a that our system has a statistically significant improvement for the given token ($p < 0.01$)

To gain a better understanding of the role played by each of the features considered, we also perform feature ablation, with results for the individual feature sets shown in Table 3. We also show the base feature set for comparison.

Interestingly, while lexicon features show the greatest improvement, the titles feature does not show any improvement over the base features. It is possible that this feature ends up being subsumed by the neighboring words, included in the base features. The sequence, acronym, and nearest entity features are all based on the provided lexicons so it is not surprising that sequence and nearest entity features work well. Among them, the acronym feature appears to be less useful simply because many class names are not commonly abbreviated. The most frequently abbreviated name is "AI" for "artificial intelligence". Classes are more often referred to by a subset of the words in the class name, which is a case covered by the sequence feature. This is why we see an improvement in I tokens for classes, whereas the instructor I tokens do not show an improvement for these features. There are also fewer I instructor tokens overall in the corpus, which could make it harder to learn the importance of these features.

Since classes can be identified by an ID number (e.g., "490") or by a name (e.g. "Machine Learning") we can examine the B_C token in more detail. If we separate the B_C token into a token for class IDs and a token for class name words, we find that the improvement using the lexicon, sequence, and nearest entity features is statistically significant only for the class name words ($p < 0.01$). There is no statistically significant improvement for the ID tokens by themselves, which is not surprising given that the identification of such IDs (most of the times consisting of numbers) is an easy task.

Features	B_C	I_C	B_I	I_I
Baseline (core features)	0.940	0.849	0.863	0.841
Lexicons	0.944*	0.875*	0.915*	0.896*
Titles	0.940	0.851	0.861	0.839
Sequence	0.945*	0.871*	0.858	0.832
Acronym	0.940	0.848	0.860	0.835
Nearest entity	0.944*	0.865*	0.910*	0.895*

Table 3: Feature ablation for the identification of I and B tokens, for courses (C) and instructors (I). A feature that provides results significantly better than the base feature set is indicated with * ($p < 0.01$)

We also run an entity-based evaluation, where we use the IOB tokens to construct full class and instructor names. This is done by finding the B tokens that have the correct following sequence of I tokens. If any of the B or I tokens are missing, or are of the wrong type, the entity is not counted as correct. Table 4 shows the precision, recall, and F-score obtained by our system for the extraction of instructor and class entities, and compares our results with those obtained with the Stanford entity extraction system.

[1]Throughout this paper, we measure the statistical significance of our results by using a paired t-test with Bonferroni correction using the same 67-33 train-test splits.

	Our system			Stanford (Finkel et al., 2005)		
Set	Precision	Recall	F-score	Precision	Recall	F-score
Instructors	0.833	0.888	0.859	0.711	0.802	0.754
Classes	0.920	0.899	0.910	0.886	0.867	0.876
Both	0.900	0.897	0.900	0.845	0.853	0.849

Table 4: Precision, Recall and F-score measures for the identification of class and instructor entities

4.2 Entity-Centric Sentiment Analysis

Once the entities of interest are identified, the next step is to determine the sentiment held by the writer (student) toward those entities. This is performed as a classification task using three classes: positive, negative, and neutral. For each candidate entity, we build a feature vector using one of the following configurations:

Weighted bag-of-word. The default model is constructed using unigram counts. The first step is to extract a set of the words that exist in the training set. Using this vocabulary set, counts are constructed for every utterance. These counts are weighted based on their distance, in number of tokens, to the target entity in the statement. For each occurrence of each word, the feature is computed by $\sum_{i \in I} 1/d_{ie}$, where I is the set of occurrences of that word and d is the distance (in words) to the target entity e.

Tree weighted n-grams. A sentence is not linear in nature. A sentence contains clauses and phrases that can be grouped into a tree structure. Consider the sentence "I thought that CS 203 was going to be good, but it was awful". In this sentence "CS 203" is the target entity and we find that a positive sentiment word "good" is closer (using linear distance in number of tokens) to the entity than the negative sentiment word "awful," which represents the actual sentiment toward the entity. If we construct a constituency parse tree from this sentence, and calculate the distance as the number of hops between nodes in the tree, then the negative sentiment word is actually closer to the entity word. For each word in an utterance, we calculate this feature as the number of edges in the parse tree between that word and the target entity. For instance, for the example shown in Figure 1, the distance between "awful" and the target entity "203" is six, while the distance between "good" and "203" is eight.

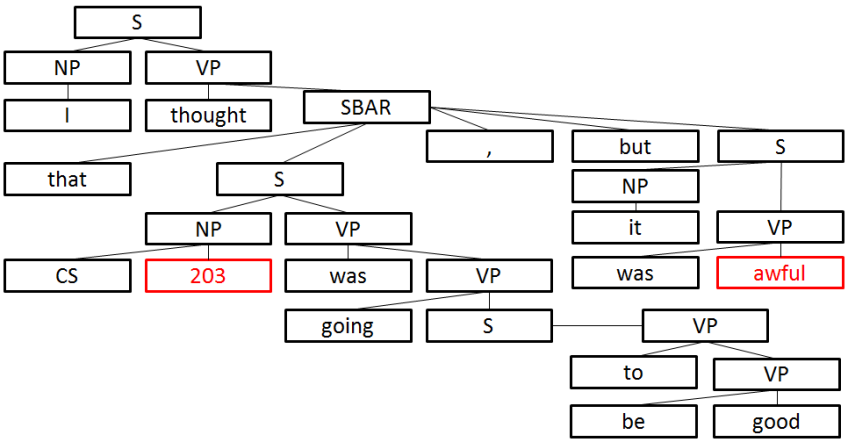

Figure 1: Example sentence, "I thought that CS 203 was going to be good, but it was awful", showing the parse tree weighting for counts using the number of node hops between a given word and the target entity.

Weighted sentiment lexicons. We also implement a feature based on the presence/absence of words from two sentiment lexicons: Bing Liu's lexicon (Hu and Liu, 2004), and the MPQA lexicon (Riloff and Wiebe, 2003) (Wilson et al., 2005). These are two of the most commonly used lexicons in recent sentiment work, and contain 6,789 and 8,222 words respectively, labeled as positive, negative, or neutral. For each word in the utterance, we now generate four features: one simply reflecting the weight of the word (calculated as described before, as a distance to the target entity), and the other three reflecting

whether the word appears as a positive, negative, or neutral word in any of the lexicons; these three latter features are again represented as weighted distance scores.

We use an SVM classifier, with a grid search for the SVM cost and gamma parameters performed using three-fold cross validation on the training set. Training and test splits contained approximately 67% and 33% of the data respectively, stratified as mentioned in Section 4.1, such that the two entity types (instructor or class) and each of the three sentiment class labels are roughly evenly spread across the train, development, and test sets.

Table 5 shows the results obtained with our sentiment analysis system. Note that all the experiments are run on the gold standard set of entities (i.e., manually annotated entities). For comparison, we also report a majority baseline, calculated as the percentage of instances in the entire data set that are neutral, as well as the inter-annotator agreement, as described in Section 3.

We also include the result obtained by using the Stanford sentiment analysis tool (Socher et al., 2013). We do not retrain this model on our own data, as this would require additional node level annotation for the parse tree of each utterance; instead, we use their sentence level sentiment analysis, which assigns an integer score of 0-4 to each sentence, ranging from "very negative" to "very positive". We assign the sentence level scores to each entity contained within that sentences. The five values can be mapped to the three values used in our data set in a number of ways, but the way that maximizes the accuracy over our entire data set maps 0 to our "negative," 1 and 2 to our "neutral," and 3 and 4 to our "positive."

Feature	Accuracy
Our system	69.5%
Majority baseline	52.8%
Stanford (Socher et al., 2013)	62.3%
Annotator agreement	77.7%

Table 5: Sentiment accuracies for our system compared to a majority baseline, the Stanford sentiment analysis tool using recursive neural tensor networks, and the inter-annotator agreement.

For a deeper analysis, Table 6 shows the results obtained by our various features.

Feature	Accuracy
Weighted bag-of-words	67.9%
Tree weighted n-grams	65.6%
Weighted sentiment lexicon	69.5%*

Table 6: Sentiment accuracies of different feature models where * indicates a feature whose difference from the default linear weighted bag-of-words is a statistically significant improvement ($p < 0.01$).

5 Overall Evaluation and Discussion

In the previous section, we described the methods used for each of the two stages of targeted sentiment analysis, along with results obtained at each stage. We now perform an overall evaluation of this task, and compare our system with previous methods for targeted sentiment analysis.

First, we evaluate the correctness of the sentiment at entity level, where an entity is marked as correct only if both the entity and the writer's sentiment toward that entity are correct. Table 7 shows the precision, recall, and F-score obtained for instructor and classes individually, and for all the entities together, assuming: (1) ground truth identification of the entities (i.e., manual annotations); and (2) automatic annotation of the entities using our system from Section 4.1.

Second, we compare the results of our system with previous work by (Mitchell et al., 2013). In that work, the authors use a dataset consisting of 2,350 English tweets containing 3,577 volitional entities, which include PERSON and ORGANIZATION entities. They evaluate the performance of the sentiment on entities by checking only the "B" token from the IOB annotation to see if the associated sentiment is

Entities	Precision	Recall	F-score
Ground Truth Instructors	0.643	0.643	0.643
Ground Truth Classes	0.710	0.710	0.710
Ground Truth Both	0.695	0.695	0.695
Extracted Instructors	0.581	0.578	0.580
Extracted Class	0.571	0.599	0.585
Extracted Both	0.573	0.600	0.586

Table 7: Micro-averaged Precision, Recall, and F-score for full targeted sentiment analysis, for both courses and instructors, using ground truth or automatically identified entities.

correct. If so, it is counted as a true positive. Note that this is less constrained than our evaluation, which also requires that the subsequent I tokens be correct.

In order to allow for a comparison between our system and theirs, we train our pipeline model on their data, by using the same ten-fold cross validation that the previous authors provided. Note that for this comparison, in the entity extraction step of our system we do not use the lexicon, professor title, acronym, sequence, or nearest entity features because of their domain specificity (these features are specifically aimed at finding sentiment toward courses and instructors, and are not expected to be useful on a dataset of general Twitter data). The results of this comparison are shown in Table 8. Mitchell et al. examine targeted sentiment with only volitional entities and do not use "neutral" as a class for targeted sentiment. For these reasons we include the second and third rows in Table 8.

Additionally, because previous work had purposefully not used certain features so that their method could be applied to low resource languages, we also show the performance of the system when we remove the part-of-speech features from our entity extraction step. Note that some of the previous work used accuracy, while other work used F-score; we therefore report both.

We also compare our system to that of (Zhang et al., 2015). Zhang et al. 2015 use a neural network model and report their F-score performance on the same corpus. They perform two evaluations, one that uses only positive/negative sentiment, and one that includes the neutral class. We find that our model is comparable when part-of-speech tags are excluded, but outperform the neural models when they are included.

Method	Accuracy	F-score
Our system	68.3%	0.687
Our system, positive/negative sentiment only	68.6%	0.664
Our system, volitional entities, positive/negative sentiment only	70.8%	0.703
Our system, no part-of-speech features	28.9%	0.393
(Mitchell et al., 2013)	30.8%	NA
(Zhang et al., 2015)	NA	0.401
(Zhang et al., 2015) positive/negative sentiment only	NA	0.279

Table 8: Accuracy and F-score for different versions of our system, as compared to previous work.

Discussion. There are a number of errors that are made by our system. Some of the errors come simply from fully or partially missing entities in the beginning of the pipeline. For instance, we found that the named entity recognition fails on some professor names, mainly because some professors use names other than those listed in the online resources that we used to generate our lexicons. A few other less common errors included recognizing first and last names as separate people, and combining class names listed after each other, e.g. "natural language processing and compilers."

Another batch of errors have correctly recognized entities, but incorrectly classified sentiment. The most common of these cases is incorrectly assigning the neutral class to an entity; the classifier may be somewhat bias toward this class given that it is assigned to 52% of entities in the corpus. Another error

involves having multiple entities in a sentence and assigning the sentiment expressed to the wrong entity. For example, in the sentence "I think that John Smith was an interesting teacher in natural language processing", positive sentiment is incorrectly assigned to "natural language processing." Another type of error comes from unresolved pronouns. In the utterance, "John Smith taught the data mining class that I took. He was an amazing teacher and I wish that he would teach machine learning," "John Smith" is classified as having neutral sentiment, rather than positive; coreference resolution could help if we reweighted the features taking into account the correct pronoun set as entity words.

6 Conclusions

In this paper, we addressed the task of targeted sentiment analysis in the context of understanding the sentiment that students hold toward courses and instructors. We introduced a new annotated dataset, collected from students at the University of Michigan, and proposed new features for the extraction of entities and the classification of the sentiment toward these entities. We performed evaluations of each of the two stages in our pipeline model, and showed that both our entity extraction method and the entity-centric sentiment analysis have performance that is competitive with the state-of-the-art. Moreover, in an overall evaluation of our pipeline, we showed that our system exceeds the performance of the two previously proposed systems for targeted sentiment analysis (Mitchell et al., 2013; Zhang et al., 2015).

Through several feature ablation analyses, we found that lexicon features play an important role in this task, and we plan to further investigate the use of such lexicons in the future, as well as that of more advanced representations of domain-specific knowledge such as knowledge-graphs.

Abstract

Sentiment analysis (SA) using code-mixed data from social media has several applications in opinion mining ranging from customer satisfaction to social campaign analysis in multilingual societies. Advances in this area are impeded by the lack of a suitable annotated dataset. We introduce a Hindi-English (Hi-En) code-mixed dataset for sentiment analysis and perform empirical analysis comparing the suitability and performance of various state-of-the-art SA methods in social media.

In this paper, we introduce learning sub-word level representations in LSTM (Subword-LSTM) architecture instead of character-level or word-level representations. This linguistic prior in our architecture enables us to learn the information about sentiment value of important morphemes. This also seems to work well in highly noisy text containing misspellings as shown in our experiments which is demonstrated in morpheme-level feature maps learned by our model. Also, we hypothesize that encoding this linguistic prior in the Subword-LSTM architecture leads to the superior performance. Our system attains accuracy 4-5% greater than traditional approaches on our dataset, and also outperforms the available system for sentiment analysis in Hi-En code-mixed text by 18%.

1 Introduction

Code Mixing is a natural phenomenon of embedding linguistic units such as phrases, words or morphemes of one language into an utterance of another (Muysken, 2000; Duran, 1994; Gysels, 1992). Code-mixing is widely observed in multilingual societies like India, which has 22 official languages most popular of which are Hindi and English. With over 375 million Indian population online, usage of Hindi has been steadily increasing on the internet.

This opens up tremendous potential for research in sentiment and opinion analysis community for studying trends, reviews, events, human behaviour as well as linguistic analysis. Most of the current research works have involved sentiment polarity detection (Feldman, 2013; Liu, 2012; Pang and Lee, 2008) where the aim is to identify whether a given sentence or document is (usually) positive, negative or neutral. Due to availability of large-scale monolingual corpora, resources and widespread use of the language, English has attracted the most attention.

Seminal work in sentiment analysis of Hindi text was done by Joshi et al. (2010) in which the authors built three step fallback model based on classification, machine translation and sentiment lexicons. They also observed that their system performed best with unigram features without stemming. Bakliwal et al. (2012) generated a sentiment lexicon for Hindi and validated the results on translated form of Amazon Product Dataset Blitzer et al. (2007). Das and Bandyopadhyay (2010) created Hindi SentiWordNet, a sentiment lexicon for Hindi.

Sentence variations
Trailer dhannnsu hai bhai
Dhannnsu trailer hai bhai
Bhai trailer dhannnsu hai
Bhai dhannnsu trailer hai

Table 1: Illustration of free structure present in code mixed text. All sentences convey the same meaning.

Word	Meaning	Appearing Variations
बहुत (bahut)	very	bahout bohut bhout bauhat bohot bahut bhaut bahot bhot
मुबारक (mubaarak)	wishes	mobarak mubarak mubark
प्यार (pyaar)	love	pyaar peyar pyara piyar pyr piyaar pyar

Table 2: Spelling variations of *romanized* words in our Hi-En code-mix dataset.

Sentiment Analysis in Code-mixed languages has recently started gaining interest owing to the rising amount of non-English speaking users. Sharma et al. (2015) segregated Hindi and English words and calculated final sentiment score by lexicon lookup in respective sentient dictionaries.

Hindi-English (Hi-En) code mixing allows ease-of-communication among speakers by providing a much wider variety of phrases and expressions. A common form of code mixing is called as *romanization* [1], which refers to the conversion of writing from a different writing system to the Roman script. But this freedom makes the task for developing NLP tools more difficult, highlighted by (Chittaranjan et al., 2014; Vyas et al., 2014; Barman et al., 2014). Initiatives have been taken by shared tasks (Sequiera et al., 2015; Solorio et al., 2014), however they do not cover the requirements for a sentiment analysis system.

Deep learning based approaches (Zhang and LeCun, 2015; Socher et al., 2013) have been demonstrated to solve various NLP tasks. We believe these can provide solution to code-mixed and romanized text from various demographics in India, as similar trends are followed in many other Indian languages too. dos Santos and Zadrozny (2014) demonstrated applicability of character models for NLP tasks like POS tagging and Named Entity Recognition (dos Santos and Guimarães, 2015). LSTMs have been observed to outperform baselines for language modelling (Kim et al., 2015) and classification (Zhou et al., 2015). In a recent work, (Bojanowski et al., 2016) proposed a skip-gram based model in which each word is represented as a bag of character n-grams. The method produced improved results for languages with large vocabularies and rare words.

The *romanized* code mixed data on social media presents additional inherent challenges such as contractions like "between" → "btwn", non-standard spellings such as "cooolll" or "bhut bdiya" and non-grammatical constructions like "sir hlp plzz naa". Hindi is phonetically typed while English (Roman script) doesn't preserve phonetics in text. Thus, along with diverse sentence construction, words in Hindi can have diverse variations when written online, which leads to large amount of tokens, as illustrated in Table 2. Meanwhile there is a lack of a suitable dataset.

Our contributions in this paper are (i) Creation, annotation and analysis of a Hi-En code-mixed dataset for the sentiment analysis, (ii) Sub-word level representations that lead to better performance of LSTM networks compared to Character level LSTMs (iii) Experimental evaluation for suitability and evaluation of performance of various state-of-the-art techniques for the SA task, (iv) A preliminary investigation of embedding linguistic priors might be encoded for SA task by char-RNN architecture and the relation of architecture with linguistic priors, leading to the superior performance on this task.

Our paper is divided into the following sections:

We begin with an introduction to Code Mixing and romanization in Section 1. We mention the issues with code-mixed data in context of Sentiment Analysis and provides an overview of existing solutions. We then discusses the process of creation of the dataset and its features in Section 2. In Section 3, we introduce Sub-word level representation and explains how they are able to model morphemes along with propagating meaningful information, thus capturing sentiment in a sentence. Then in Section 4, we explain our experimental setup, describe the performance of proposed system and compare it with baselines and other methods, proceeded by a discussion on our results.

[1] https://en.wikipedia.org/wiki/Romanization

2 Dataset

We collected user comments from public Facebook pages popular in India. We chose pages of Salman Khan, a popular Indian actor with massive fan following, and Narendra Modi, the current Prime Minister of India. The pages have 31 million and 34 million facebook user likes respectively. These pages attract large variety of users from all across India and contain lot of comments to the original posts in code-mixed representations in varied sentiment polarities. We manually pre-processed the collected data to remove the comments that were not written in roman script, were longer than 50 words, or were complete English sentences. We also removed the comments that contained more than one sentence, as each sentence might have different sentiment polarity. Then, we proceeded to manual annotation of our dataset. The comments were annotated by two annotators in a 3-level polarity scale - positive, negative or neutral. Only the comments with same polarity marked by both the annotators are considered for the experiments. They agreed on the polarity of 3879 of 4981 (77%) sentences. The Cohen's Kappa coefficient (Cohen, 1960) was found to be 0.64. We studied the reasons for misalignment and found that causes typically were due to difference in perception of sentiments by individuals, different interpretations by them and sarcastic nature of some comments which is common in social media data. The dataset contains 15% negative, 50% neutral and 35% positive comments owing to the nature of conversations in the selected pages.

The dataset exhibits some of the major issues while dealing with code-mixed data like short sentences with unclear grammatical structure. Further, *romanization* of Hindi presents an additional set of complexities due to loss of phonetics and free ordering in sentence constructions as shown in Table 1. This leads to a number of variations of how words can be written. Table 2 contains some of the words with multiple spelling variations in our dataset, which is one of the major challenges to tackle in Hi-En code-mixed data.

Dataset	Size	# Vocab	Social	CM	Sentiment
STS-Test	498	2375	✓		✓
OMD	3238	6211	✓		✓
SemEval'13	13975	35709	✓		✓
IMDB	50000	5000			✓
(Vyas et al., 2014)	381	-	✓	✓	
Ours	3879	7549	✓	✓	✓

Table 3: Comparison with other datasets.

Popular related datasets are listed in Table 3. STS, SemEval, IMDB etc. have been explored for SA tasks but they contain text in English. The dataset used by Vyas et al. (2014) contains Hi-En Code Mixed text but doesn't contain sentiment polarity. We constructed a code mixed dataset with sentiment polarity annotations, and the size is comparable with several datasets. Table 4 shows some examples of sentences from our dataset. Here, we have phrases in Hindi (source language) written in English (target) language.

Example	Approximate Meaning	Sentiment Polarity
Aisa PM naa hua hai aur naa hee hoga	Neither there has been a PM like him, nor there will be	Positive
abe kutte tere se kon baat karega	Who would talk to you, dog?	Negative
Trailer dhannnsu hai bhai	Trailer is awesome, brother.	Positive

Table 4: Examples of Hi-En Code Mixed Comments from the dataset.

Our dataset and code is freely available for download [2] to encourage further exploration in this domain.

[2] https://github.com/DrImpossible/Sub-word-LSTM

3 Learning Compositionality

Our target is to perform sentiment analysis on the above presented dataset. Most commonly used statistical approaches learn word-level feature representations. We start our exploration for suitable algorithms from models having word-based representations.

3.1 Word-level models

Word2Vec(Mikolov et al., 2013) and Word-level RNNs (Word-RNNs) (thang Luong et al., 2013) have substantially contributed to development of new representations and their applications in NLP such as in Summarization (Cao et al., 2015) and Machine Translation (Cho et al., 2014). They are theoretically sound since language consists of inherently arbitrary mappings between ideas and words. Eg: The words person(English) and insaan(Hindi) do not share any priors in their construction and neither do their constructions have any relationship with the semantic concept of a person. Hence, popular approaches consider lexical units to be independent entities. However, operating on the lexical domain draws criticism since the finite vocabulary assumption; which states that models assume language has finite vocabulary but in contrast, people actively learn & understand new words all the time.

Excitingly, our dataset seems suited to validate some of these assumptions. In our dataset, vocabulary sizes are greater than the size of the dataset as shown in Table 3. Studies on similar datasets have shown strong correlation between number of comments and size of vocabulary (Saif et al., 2013). This rules out methods like Word2Vec, N-grams or Word-RNNs which inherently assume a small vocabulary in comparison to the data size. The finite vocabulary generally used to be a good approximation for English, but is no longer valid in our scenario. Due to the high sparsity of words themselves, it is not possible to learn useful word representations. This opens avenues to learn non-lexical representations, the most widely studied being character-level representations, which is discussed in the next section.

3.2 Character-level models

Character-level RNNs (Char-RNNs) have recently become popular, contributing to various tasks like (Kim et al., 2015). They do not have the limitation of vocabulary, hence can freely learn to generate new words. This freedom, in fact, is an issue: Language is composed of lexical units made by combining letters in some specific combinations, i.e. most of the combinations of letters do not make sense. The complexity arises because the mappings between meaning and its construction from characters is arbitrary. Character models may be apriori inappropriate models of language as characters individually do not usually provide semantic information. For example, while " $King - Man + Women = Queen$" is semantically interpretable by a human, "$Cat - C + B = Bat$" lacks any linguistic basis.

But, groups of characters may serve semantic functions. This is illustrated by $Un + Holy = Unholy$ or $Cat + s = Cats$ which is semantically interpretable by a human. Since sub-word level representations can generate meaningful lexical representations and individually carry semantic weight, we believe that sub-word level representations consisting composition of characters might allow generation of new lexical structures and serve as better linguistic units than characters.

3.3 Sub-word level representations

Lexicon based approaches for the SA task (Taboada et al., 2011; Sharma et al., 2015) perform a dictionary look up to obtain an individual score for words in a given sentence and combine these scores to get the sentiment polarity of a sentence. We however want to use intermediate sub-word feature representations learned by the filters during convolution operation. Unlike traditional approaches that add sentiment scores of individual words, we propagate relevant information with LSTM and compute final sentiment of the sentence as illustrated in Figure 1.

Hypothesis: We propose that incorporating sub-word level representations into the design of our models should result in better performance. This would also serve as a test scenario for the broader hypothesis proposed by Dyer et. al. in his impressive ICLR keynote [3] - Incorporating linguistic priors in network architectures lead to better performance of models.

[3] Available at: http://videolectures.net/iclr2016_dyer_model_architecture/

Methodology: We propose a method of generating sub-word level representations through 1-D convolutions on character inputs for a given sentence. Formally, let C be the set of characters and T be an set of input sentences. The sentence $s \in T$ is made up of a sequence of characters $[c_1, ..., c_l]$ where l is length of the input.

Hence, the representation of the input s is given by the matrix $Q \in R^{d \times l}$ where d is the dimensionality of character embedding that corresponding to $[c_1, ..., c_l]$. We perform convolution of Q with a filter $H \in R^{d \times m}$ of length m after which we add a bias and apply a non-linearity to obtain a feature map $f \in R^{l-m+1}$. Thus we can get sub-word level (morpheme-like) feature map. Specifically, the i^{th} element of f is given by:

$$f[i] = g((Q[:, i : i + m - 1] * H) + b) \tag{1}$$

where $Q[:, i : i + m - 1]$ is the matrix of $(i)^{th}$ to $(i + m - 1)^{th}$ character embedding and g corresponds to ReLU non-linearity.
Finally, we pool the maximal responses from p feature representations corresponding to selecting sub-word representations as:

$$y_i = max(f[p * (i : i + p - 1)]) \tag{2}$$

Next, we need to model the relationships between these features $y^i[:]$ in order to find the overall sentiment of the sentence. This is achieved by LSTM(Graves, 2013) which is suited to learning to propagate and 'remember' useful information, finally arriving at a sentiment vector representation from the inputs. We provide f_t as an input to the memory cell at time t. We then compute values of I_t - the input gate, $\tilde{C}_t$ - the candidate value for the state of the memory cell at time t and f_t - the activation of the forget gate, which can be used to compute the information stored in memory cell at time t. With the new state of memory cell C_t, we can compute the output feature representation by:

$$O_t = \sigma(W y_t + U h_(t - 1) + V(C_t + b) \tag{3}$$

$$h_t = O_t tanh(C_t) \tag{4}$$

where W,U and V are weight matrices and b_i are biases. After l steps, h_l represents the relevant information retained from the history. That is then passed to a fully connected layer which calculates the final sentiment polarity as illustrated in the Figure 1.

Figure 2 gives schematic overview of the architecture. We perform extensive experiments to qualitatively and quantitatively validate the above claims as explained in the next section.

4 Experiments

We perform extensive evaluation of various approaches, starting with a suitability study for the nature of approaches that would be able to generalize to this data. We compare our approaches with the state-of-the-art methods which are feasible to generalize on code-mixed data and (Sharma et al., 2015), the current state-of-the-art in Hi-En code-mixed SA task.

4.1 Method Suitability

Following approaches have been used for performing SA tasks in English but do not suit mix code setting:

- Approaches involving NLP tools: RNTN (Socher et al., 2013) etc which involve generation of parse trees which are not available for code mixed text;
- Word Embedding Based Approaches: Word2Vec, Word-RNN may not provide reliable embedding in situations with small amount of highly sparse dataset.
- Surface Feature engineering based approaches: Hashtags, User Mentions, Emoticons etc. may not exist in the data.

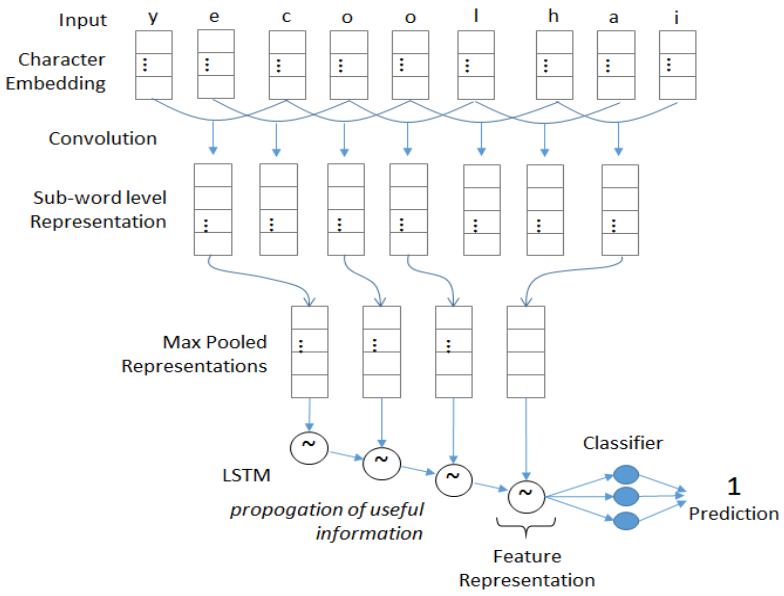

Figure 1: Illustration of the proposed methodology

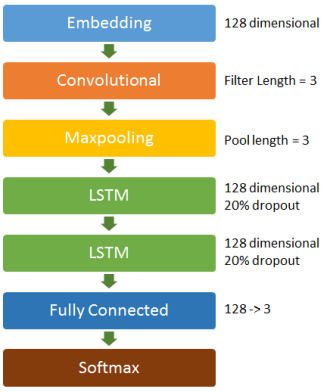

Figure 2: Schematic overview of the architecture.

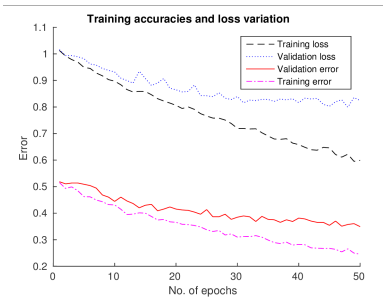

Figure 3: Training accuracy and loss variation.

4.2 Experimental Setup

Our dataset is divided into 3 splits- Training, validation and testing. We first divide the data into randomized 80-20 train test split, then further randomly divide the training data into 80-20 split to get the final training, validation and testing data.

As the problem is relatively new, we compare state of the art sentiment analysis techniques (Wang and Manning, 2012; Pang and Lee, 2008) which are generalizable to our dataset. We also compare the results with system proposed by Sharma et al. (2015) on our dataset. As their system is not available publicly, we implemented it using language identification and transliteration using the tools provided by Bhat et al. (2015) for Hi-En Code Mixed data. The polarity of thus obtained tokens is computed from SentiWordNet (Esuli and Sebastiani, 2006) and Hindi SentiWordNet (Das and Bandyopadhyay, 2010) to obtain the polarity of words, which are then voted to get final polarity of the sentence.

The architecture of the proposed system (Subword-LSTM) is described in Figure 2. We compare it with a character-level LSTM (Char-LSTM) following the same architecture without the convolutional and maxpooling layers. We use Adamax (Kingma and Ba, 2014) (a variant of Adam based on infinity norm) optimizer to train this setup in an end-to-end fashion using batch size of 128. We use very simplistic architectures because of the constraint on the size of the dataset. As the datasets in this domain expand, we would like to scale up our approach to bigger architectures. The stability of training using this architecture is illustrated in Figure 3.

Method	Reported In	Our dataset		SemEval' 13	
		Accuracy	**F1-Score**	**Accuracy**	**F1-Score**
NBSVM (Unigram)	(Wang and Manning, 2012)	59.15%	0.5335	57.89%	0.5369
NBSVM (Uni+Bigram)	(Wang and Manning, 2012)	62.5%	0.5375	51.33%	0.5566
MNB (Unigram)	(Wang and Manning, 2012)	66.75%	0.6143	58.41%	0.4689
MNB (Uni+Bigram)	(Wang and Manning, 2012)	66.36%	0.6046	58.4%	0.469
MNB (Tf-Idf)	(Wang and Manning, 2012)	63.53%	0.4783	57.82%	0.4196
SVM (Unigram)	(Pang and Lee, 2008)	57.6%	0.5232	57.6%	0.5232
SVM (Uni+Bigram)	(Pang and Lee, 2008)	52.96%	0.3773	52.9%	0.3773
Lexicon Lookup	(Sharma et al., 2015)	51.15%	0.252	N/A	N/A
Char-LSTM	Proposed	59.8%	0.511	46.6%	0.332
Subword-LSTM	Proposed	**69.7%**	**0.658**	**60.57%**	0.537

Table 5: Classification results show that the proposed system provides significant improvement over traditional and state of art method for Sentiment Analysis in Code Mixed Text

Comment/*Meaning*	**Transliterated Comment**	**Observation**
Bhai ied mubaraq *Wishes for Eid, brother*	भाई आईद मुबरक	The words ied and mubaraq are spelt differently from usual form which caused incorrect transliteration.
Aatma aur mun ki pavitrata ki jhalak hai is beti ki aawaz mei, khush raho beti *There's a glimpse of piousness of soul and mind in this girl's voice, stay happy, girl!*	आत्मा अर मुन की पवितराता की झालक है इस बेती कि आवाज़ में, खुश रहो बेती	The words aur, pavitrata and beti are written as expected, but still incorrectly transliterated.
love u sir love u soo much I'ts beautyful vedio *Love you so much sir. It's a beautiful video.*	लव उ sir लव उ सू much उर्स इ'ट beautyful vedio	love should have been identified as an English word, which expresses sentiment of the sentence.

Table 6: Output produced a by Hi-En Transliteration Tool

4.3 Observations

In the comparative study performed on our dataset, we observe that Multinomial Naive Bayes performs better than SVM(Pang and Lee, 2008) for snippets providing additional validation to this hypothesis given by Wang and Manning (2012).

We also observe that unigrams perform better than bigrams and Bag of words performs better than tf-idf in contrast to trends in English, as the approaches inducing more sparsity would yield to poorer results because our dataset is inherently very sparse. The lexicon lookup approach (Sharma et al., 2015) didn't perform well owing to the heavily misspelt words in the text, which led to incorrect transliterations as shown in Table 6.

4.4 Validation of proposed hypothesis

We obtain preliminary validation for our hypothesis that incorporating sub-word level features instead of characters would lead to better performance. Our Subword-LSTM system provides an F-score of 0.658 for our dataset, which is significantly better than Char-LSTM which provides F-score of 0.511.

Since we do not have any other dataset in Hi-En code-mixed setting of comparable to other settings, we performed cross-validation of our hypothesis on SemEval'13 Twitter Sentiment Analysis dataset. We took the raw tweets character-by-character as an input for our model from the training set of 7800 tweets and test on the SemEval'13 development set provided containing 1368 tweets. The results are summarized in Table 5. In all the cases, the text was converted to lowercase and tokenized. No extra features or heuristics were used.

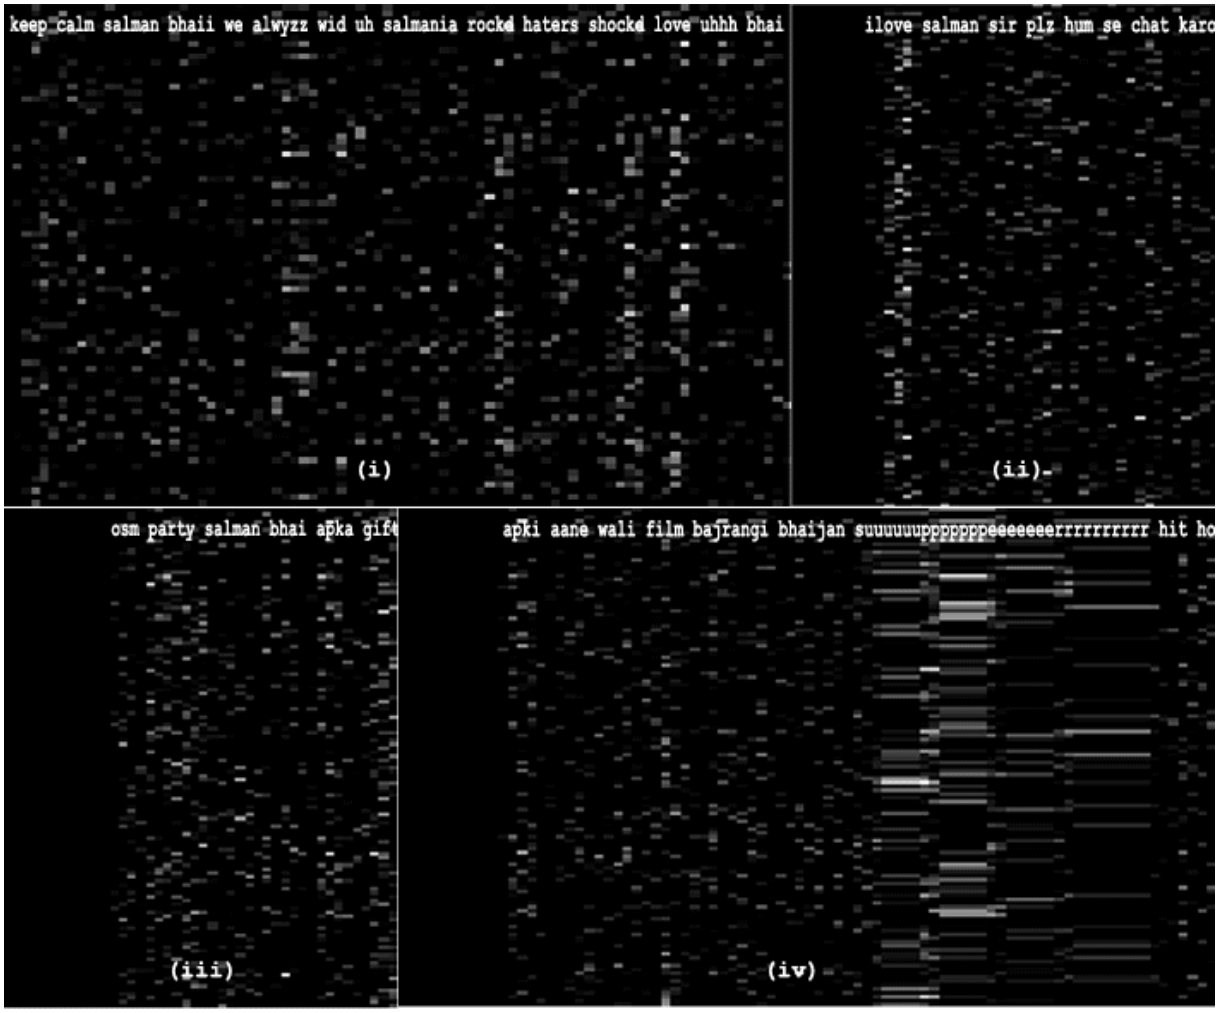

Figure 4: Visualization of the convolution layer for examples comments from the dataset show that word segments convey sentiment information despite being severely misspelt.

4.5 Visualizing character responses

Visualizations in Figure 4 shows how the proposed model is learning to identify sentiment lexicons. We see that different filters generally tend to learn mappings from different parts, interestingly showing shifting trends to the right which maybe due to LSTM picking their feature representation in future time steps. The words sections that convey sentiment polarity information are captured despite misspelling in example (i) and (ii). In example (iii), starting and ending phrases show high response which correspond to the sentiment conveying words (party and gift). The severe morpheme stretching in example (iv) also affects the sentiment polarity.

5 Conclusion

We introduce Sub-Word Long Short Term Memory model to learn sentiments in a noisy Hindi-English Code Mixed dataset. We discuss that due to the unavailability of NLP tools for Hi-En Code Mixed text and noisy nature of such data, several popular methods for Sentiment Analysis are not applicable. The solutions that involve unsupervised word representations would again fail due to sparsity in the dataset. Sub-Word LSTM interprets sentiment based on morpheme-like structures and the results thus produced are significantly better than baselines.

Further work should explore the effect of scaling of RNN and working with larger datasets on the results. In the new system, we would like to explore more deep neural network architectures that are able to capture sentiment in Code Mixed and other varieties of noisy data from the social web.

Abstract

Aspect phrase grouping is an important task in aspect-level sentiment analysis. It is a challenging problem due to polysemy and context dependency. We propose an Attention-based Deep Distance Metric Learning (ADDML) method, by considering aspect phrase representation as well as context representation. First, leveraging the characteristics of the review text, we automatically generate aspect phrase sample pairs for distant supervision. Second, we feed word embeddings of aspect phrases and their contexts into an attention-based neural network to learn feature representation of contexts. Both aspect phrase embedding and context embedding are used to learn a deep feature subspace for measure the distances between aspect phrases for K-means clustering. Experiments on four review datasets show that the proposed method outperforms state-of-the-art strong baseline methods.

1 Introduction

For aspect-level sentiment analysis (Hu and Liu, 2004; Pang and Lee, 2008), aspect identification from the corpus is a necessary step. Here *aspect* is the name of a feature of the product, while an *aspect phrase* is a word or phrase that actually appears in a sentence to indicate the aspect. Different aspect phrases can be used to describe the same aspect. For example, "picture quality" could be referred to "photo", "image" and "picture". All aspect phrases in the same group indicate the same aspect. In this paper, we assume that all aspect phrases have been identified by using existing methods (Jin et al., 2009; Kobayashi et al., 2007; Kim and Hovy, 2006), and focus on grouping domain synonymous aspect phrases.

Most existing work employed unsupervised methods, exploiting lexical similarity from semantic dictionary as well as context environments (Zhao et al., 2014; Zhai et al., 2011a; Guo et al., 2009). The context for an aspect phrase is formed by aggregating related sentences that mention the same aspect phrase. Thereafter, aspect phrase and context environment are represented using bag-of-word (BoW) models separately, and integrated into a unified learning framework.

One limitation of the existing methods is that they do not model the interaction between aspect phrases and their contexts explicitly. For example, in the review "the picture is clear, bright and sharp and the sound is good", the words "clear", "bright" and "sharp" are related to the aspect phrase "picture", while the word "good" is related to the aspect phrase "sound". By the traditional model, these words are not differentiated when they are taken for the context, thereby causing noise in the grouping of the two aspect phrases.

To address this issue, we propose a novel neural network structure that automatically learns the relative importance of each context word with respect to a target/aspect phrase, by leveraging an attention model (Luong et al., 2015; Rush et al., 2015; Ling et al., 2015). As shown in Figure 1, given a sentence that contains an aspect phrase, we use a neural network to find a vector representation of the aspect phrase and its context. For the grouping of a certain aspect phrase, we concatenate all the occurrences of the aspect phrase in a corpus to find its vector form. Thus, the problem of aspect phrase grouping is transformed into a clustering problem in the resulting vector space. Different from traditional methods, which leverage

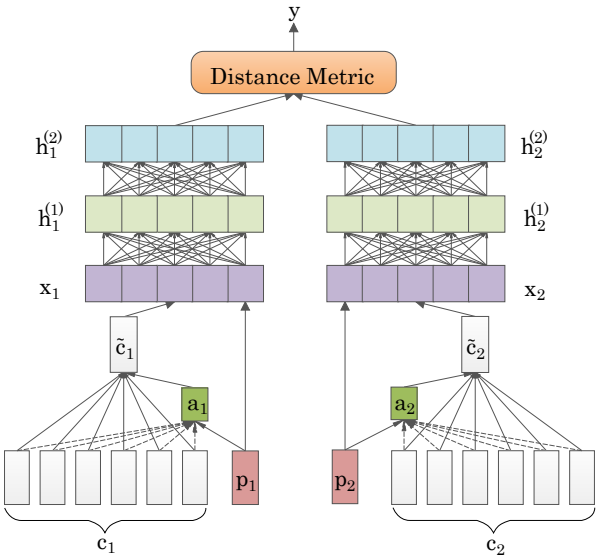

Figure 1: Architecture of the proposed method. For a given pair of aspect phrases p_1 and p_2, with their contexts c_1 and c_2 respectively, two vectors x_1 and x_2 are obtained via attention-based semantic combination, and then mapped into the same feature subspace as $h_1^{(2)}$ and $h_2^{(2)}$.

a bag-of-word feature space, our vector space considers not only words, but also semantic similarities between aspect phrases and contexts (Xu et al., 2015).

One challenge to the success of our method is the finding of a proper training algorithm for the neural network model. Inspired by word embedding training methods (Collobert et al., 2011; Mikolov et al., 2013), we take a negative sampling approach. In particular, we take pairs of sentences that contain the same aspect phrase as positive training examples, and pairs of sentences that contain incompatible aspect phrase as negative training examples, maximizing a score margin between positive and negative examples. Here two aspect phrases are incompatible if the distance based on a semantic lexicon is large (Faruqui et al., 2015; Yu and Dredze, 2014).

To find a better vector space representation, we add two nonlinear transformation layers, as shown in $h^{(1)}$ and $h^{(2)}$ in Figure 1. This method is similar to the Mahalanobis distance metric learning for face verification (Hu et al., 2014). Model training is performed by back-propagation over all neural nodes. With such vector space being learned, direct K-means clustering can be used to group aspect phrases.

Results on a standard benchmark show that our neural network significantly outperforms traditional models. The average results on 4 domains reached 0.51 (Purity) and 1.74 (Entropy), better than the previous best result (0.43 in Purity and 2.02 in Entropy).

2 Method

Our proposed model addresses two main problems: (1) to express fine-grained semantic information with a fixed length vector, which can naturally combine aspect phrases and their contexts, and (2) to provide nonlinear transformations to learn a feature subspace, under which the distance between each intra-group aspect phrase pair is smaller than that between each inter-group pair. We discuss an attention-based semantic composition model in Section 2.1, and then describe a Multi-Layer Perceptron (MLP)-based nonlinear transformation model in Section 2.2, which are designed for (1) and (2), respectively.

2.1 Attention-Based Semantic Composition

The goal of the model is to learn the semantic representation of the context of each aspect phrase. For our task, the same context is frequently shared by more than one aspect phrases. For example, in the sentence: "the **picture** is clear and sharp and the **sound** is good.", two different aspect phrases "picture" and "sound" are mentioned. We use an attention-based neural semantic composition model to consider

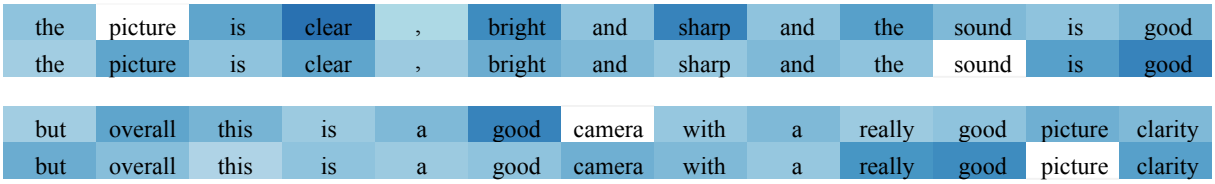

Figure 2: Visualization of weighted context by our attention model. There is a context which contains two aspect phrases (white background), where the weight of each word is taken from the developing dataset. For different aspect phrases, the words in the same context have different weights. Different background represent different weights, bigger weights corresponding to deeper background.

contextual words based on their weight scores with respect to each aspect phrase. In particular, given each word vector e_i, which is projected into a word embedding matrix $L_w \in \mathbb{R}^{d \times |V|}$, where d is the dimension of word vector and $|V|$ is the size of word vocabulary. All of e_i can be randomly initialized from a uniform distribution, and then updated during the back propagation training procedure. Alternatively, another way is using pre-trained vectors as initialization, which is learnt from text corpus with embedding learning algorithms. In our experiment, we adopt the latter strategy. Let $c = \{e_i | e_i \in R^{l \times 1}\}_{i=1,2,...,n}$ denote the set of n input words in context, where l is the dimension of the original context segment. We employ a linear layer to combine the original context vector c and attentional weight a to produce an attentional context representation as:

$$\tilde{c} = f_w(c, a), \tag{1}$$

where f_w is a weighted average function. The idea is to give different weights for different words in the context when deriving the context vector $\tilde{c}$. The weight $a \in \mathbb{R}^{n \times 1}$ is a variable-length attention vector, whose size is equal to the number of words in the context. Its value is computed as follows:

$$a(e_i) = \frac{\exp(score(e_i, p))}{\sum_{i'} \exp(score(e_{i'}, p))}, \tag{2}$$

where $score(e_i, p) = W_a^T [e_i; p]$ and $W_a \in \mathbb{R}^{(2*d) \times 1}$ is a model parameter to learn. Although the length of context is variable, our model uses a fixed-length W_a parameter to weight the importance of each word e_i for its corresponding aspect phrase p. This results in a fixed length vector form for each aspect phrase in a variable-size context.

2.2 MLP-Based Nonlinear Transformation

After obtaining the attention-based context $\tilde{c}$, we employ a MLP-based nonlinear transformation to learn a feature subspace for final aspect phrase grouping. Although $\tilde{c}$ is a weighted context according to the aspect phrase, the aspect phrase p itself is still a necessary source of information for grouping. Therefore, we concatenate $\tilde{c}$ and p to produce a vector x as the input to MLP.

Our model is based on a variant of the Mahalanobis distance metric learning method (Hu et al., 2014). The problem is formulated as follows. Given a training set $X = \{x_i | x_i \in R^{(2*d) \times 1}\}_{i=1,2,...,m}$, where x_i is the ith training sample and m is the size of training set. The method aims to seek a linear transformation W, under which the distance between any two samples x_i and x_j can be computed as:

$$d_w(x_i, x_j) = \|Wx_i - Wx_j\|_2 \tag{3}$$

where W is an alternative of the covariance matrix M in Mahalanobis distance. $\|A\|_2$ represents the $L2$ norm of the matrix A. M can be decomposed by:

$$M = W^T W, \tag{4}$$

Further, Equation (3) can be rewritten as

$$\begin{aligned} d_w(x_i, x_j) &= \|Wx_i - Wx_j\|_2 \\ &= \sqrt{(x_i - x_j)^T W^T W (x_i - x_j)} \\ &= \sqrt{(x_i - x_j)^T M (x_i - x_j)} \end{aligned} \tag{5}$$

Equation (5) is the typical form of Mahalanobis distance between x_i and x_j. Therefore, Equation (3) is both the Euclidean distance of two samples in the linear transformed space, and the Mahalanobis distance in the original space. The transformation Wx can be replaced with a generalized function g. When g is a nonlinear function, we obtain the nonlinear transformation form of Mahalanobis distance. Following Hu et al. (2014), we use the squared Euclidean distance in our model:

$$d_g^2(x_i, x_j) = \|g(x_i) - g(x_j)\|_2^2 \tag{6}$$

As shown in Figure 1, we use hierarchical nonlinear mappings to project the samples to a feature subspace. Assume that there are M layers in the designed network, and $k^{(m)}$ units in the mth layer, where $m = 1, 2, ..., M$. For a given aspect phrase sample x, the output of the first layer is computed as

$$h^{(1)} = f_a(W^{(1)}x + b^{(1)}) \in \mathbb{R}^{k^{(2)}}, \tag{7}$$

where the weight matrix $W^{(1)} \in \mathbb{R}^{k^{(2)} \times k^{(1)}}$ can be seen as a linear projection transformation, $b^{(1)} \in \mathbb{R}^{k^{(2)}}$ is a bias vector, and $f_a : \mathbb{R} \mapsto \mathbb{R}$ is a nonlinear activation function.

Subsequently, the output of the first layer $h^{(1)}$ is used as the input of the second layer. In the same way, the output of the second layer is

$$h^{(2)} = f_a(W^{(2)}h^{(1)} + b^{(2)}) \in \mathbb{R}^{k^{(3)}}, \tag{8}$$

where $W^{(2)} \in \mathbb{R}^{k^{(3)} \times k^{(2)}}$, $b^{(2)} \in \mathbb{R}^{k^{(3)}}$ and f_a are the projection matrix, a bias and a nonlinear activation function of the second layer, respectively.

Finally, the output of the topmost layer is calculated as follows:

$$h^{(M)} = f_a(W^{(M)}h^{(M-1)} + b^{(M)}) \in \mathbb{R}^L, \tag{9}$$

where L is the dimension of the output vector.

Given a pair of aspect phrase samples x_i and x_j, let $g(x_i) = h_i^{(M)}$ and $g(x_j) = h_j^{(M)}$. The function g represents a hierarchical nonlinear transformation, in which the aspect phrase sample pair is passed through the M-layer deep network and mapped into a feature subspace. By using Equation (6), we can measure the distance between the sample pair in the new feature subspace.

2.3 K-means Clustering

With a given corpus, we first employ the parallel deep neural network to learn the semantic representation $h^{(M)}$, and then utilize the K-means algorithm to perform clustering of $h^{(M)}$. During training, we sample aspect phrase pairs using the sentence as context. During testing, we concatenate all the sentences that mention the aspect phrase for clustering the aspect phrase.

2.4 Model Training

The ultimate goal of our model is to make the distance metric effective for grouping aspect phrase samples. To achieve this, we use a large-margin framework to restrict the distance, as proposed by Mignon and Jurie (2012). In particular, sample pairs containing the same aspect phrase are used as positive instances and sample pairs with incompatible aspect phrase are used as negative instances.

We exploit lexical similarity to obtain incompatible aspect phrases, which have low similarity in semantic lexicon. In particular, we choose WordNet as the semantic lexicon. Two aspect phrase are incompatible when the WordNet similarity between them is smaller than a threshold η. And the WordNet similarity is calculated by Equation (12)

$$Res(w_1, w_2) = IC(LCS(w_1, w_2)) \tag{10}$$

$$IC(w) = -logP(w) \tag{11}$$

$$Jcn(w_1, w_2) = \frac{1}{IC(w_1) + IC(w_2) - 2 \times Res(w_1, w_2)} \tag{12}$$

where LCS (lease common subsumer) is the most specific concept that is a shared ancestor of the two concepts represented by the words (Pedersen, 2010). $P(w)$ is the probability of the concept word w. In our experiments, the threshold is set to 0.85.

Traditional methods (Zhai et al., 2010; Zhai et al., 2011b) exploit lexical knowledge to provide soft constraint for clustering aspect phrases. They assume that the aspect phrases that have high similarity in semantic lexicon, are likely to belong to the same group. In this cause, our method uses a similar assumption.

For obtaining the training data, we apply an extra sample pair generation process. The generated sample aspect phrase pairs are fed into left and right sub neural network of Figure 1, respectively. Specifically, each training sentence is utilized with its labelled aspect phrase as a gold sample. Then, we combine each aspect phrase and its related sentences to form training sample set. For example, given an aspect phrase p_1 and a sentence set $S^1 = \{s_1^1, s_2^1, ..., s_m^1\}$, in which there are m sentences that mention p_1, we can construct m samples $\{p_1 \cup s_1^1, p_1 \cup s_2^1, ..., p_1 \cup s_m^1\}$. The group label of the sample is the same as its original aspect phrase, e.g. when p_1 belongs to group 1, then all of $p_1 \cup s_i^1$ have the group label 1.

Assuming that there are n selected aspect phrases, the number of positive sample pairs candidates is $\binom{n}{2}$. A negative sample pair is formed by randomly selecting incompatible aspect phrases and their contexts. For balancing the training set, we obtain the same number of negative sample pairs.

In the training objective, the distance $d_g^2(x_i, x_j)$ of positive instances ($l_{ij} = 1$) is less than a small threshold t_1 and that of negative instance ($l_{ij} = -1$) is higher than a large threshold t_2, where the label l_{ij} denotes the similarity or dissimilarity between a sample pair x_i and x_j, and $t_2 > t_1$. Let $t > 1$, $t_1 = t - 1$ and $t_2 = t + 1$. This constraint can be formulated as follows:

$$l_{ij}(t - d_g^2(x_i, x_j)) > 1, \tag{13}$$

Equation (13) enforces the margin between $d_g^2(x_i, x_j)$.

During the training phase, each aspect phrase pair must satisfy the constraint in Equation (13). Let $\omega = 1 - l_{ij}(t - d_g^2(x_i, x_j))$, we minimize the objective function:

$$J = \frac{1}{2} \sum_{i,j} \sigma(\omega) + \frac{\lambda}{2} \sum_{m=1}^{M} (\left\| W^{(m)} \right\|_F^2 + \left\| b^{(m)} \right\|_2^2) \tag{14}$$

where $\sigma(\omega) = \frac{1}{\beta} \log(1 + \exp(\beta\omega))$ is the generalized logistic loss function (Mignon and Jurie, 2012), which is a smooth approximation of the hinge loss $E(z) = \max(0, z)$. β is the sharpness parameter, λ is a regularization parameter and $\|W\|_F^2$ represents the Frobenius norm of matrix W.

The minimization problem in Equation (14) is solved using a stochastic sub-gradient descent scheme. We train the network using back-propagation. We set the dimension of word vectors as 200, the output length of MLP as 50. The parameters of the linear layer are initialized using normalized initialization (Glorot and Yoshua, 2010). We train a three-layer MLP and employ dropout with 50% rate to the hidden layer. We choose $tanh$ as the activation function. The threshold t, the regularization parameter λ and learning rate μ are empirical set as 3, 0.002 and 0.03 for all experiments, respectively.

3 Experiments

3.1 Data Preparation

We employ the datasets of Xiong and Ji (2015) to evaluate our proposed approach. The datasets are based on *Customer Review Datasets* (CRD) (Hu and Liu, 2004), including four different domains: digital camera (DC), DVD player, MP3 player (MP3) and cell phone (PHONE). We take 3 different random splits of datasets (30% train, 50% test, and 20% development). The statistics are described in Table 1.

	DC	DVD	MP3	PHONE
#Sentences	330	247	581	231
#Aspect Phrases	141	109	183	102
#Aspects	14	10	10	12
#Pairs	19163	11211	64945	8855

Table 1: Statistics of the review corpus. # donotes the size

3.2 Pre-trained Word Vectors

We use *Glove*[1] tools to train word embeddings, and the training parameters are set by following Pennington et al. (2014). Because of the review corpus is too small for learning word embeddings, we use *Amazon Product Review Data* (Jindal and Liu, 2008) as one auxiliary training corpus.

3.3 Evaluation Metrics

Since the problem of aspect phrase grouping is a clustering task, two common measures for clustering are used to its evaluate performance (Zhai et al., 2010) : *Purity* and *Entropy*.

Purity is the percentage of correct clusters that contain only data from the gold-standard partition. A large Purity reflects a better model.

Entropy looks at how various groups of data are distributed within each cluster. A smaller Entropy reflects a better model.

3.4 Baseline Methods and Settings

The proposed ADDML method is compared with a number of methods, which include (1) the state-of-the-art methods, (2) baseline neural methods.

In the first category[2], all methods except Kmeans and CC-Kmeans exploit labelled data, which is generated using sharing word constraint and lexical similarities based on WordNet[3]:

Kmeans. The most popular clustering algorithm based on distributional similarity with *cosine* as similarity measure and BoW as feature representation.

DF-LDA. A combination of Dirichlet Forest Prior and LDA model, in which it can encode domain knowledge (the label) into the prior on topic-word multinomials (Andrzejewski et al., 2009)[4]. The code is available in author's website[5].

L-EM. A state-of-the-art semi-supervised method for clustering aspect phrases (Zhai et al., 2011a). It employed lexical knowledge to provide a initialization for EM. We implemented this method ourselves.

CC-Kmeans. It is proposed by Xiong and Ji (2015), it encodes the capacity limitation as constraint and proposes a capacity constrained K-means to cluster aspect phrases. We use the code from the author[6].

[1] http://nlp.stanford.edu/projects/glove/

[2] Because we use sample pairs but not cluster label for training, it is not possible to train a supervised classifier for testing.

[3] The generation of labelled data follows Zhai et al. (2011a).

[4] There are other LDA based methods for this task, such Constrained LDA (Zhai et al., 2010). Although Constrained LDA used two domains data form CRD dataset as core corpus, they actually crawled many other camera and phone reviews. So we are unable to compare with them by directly using their published results. Since DF-LDA is more effectiveness and suitable for our smaller datasets, we use DF-LDA as the representative of the LDA-based methods.

[5] http://pages.cs.wisc.edu/~andrzeje/research/df_lda.html

[6] https://github.com/pdsujnow/cc-kmeans

The word embedding composite methods employ different composite strategies to form the sample vector, respectively. The clustering method is Kmeans with cosine distance in which word embedding is used as feature vector.

AVG/MIN/MAX+MLP use the average/minimum/maximum value of all the context word vectors in each dimension as the context vector $\tilde{c}$, respectively, and then, concatenates aspect phrase p and $\tilde{c}$ to form the sample vector.

AP only uses aspect phrase (AP) vector to cluster aspect phrases.

Since all the methods based on Kmeans depend on the random initiation, we use the average results of 10 runs as the final result. For L-EM, we use the same parameter settings with the original paper.

Table 2: Comparison of Purity and Entropy with baselines. Our model is ADDML.

We present and compare the results of ADDML and the 8 baseline methods based on 4 domains. The results are shown in Table 2, where **avg** represents the average result of the 4 domains. The results are separated into two groups according to categories of the baseline methods. Our approach outperforms baseline methods on the average result of all domains. In addition, we make the following observations:

- From the first group, we can see that L-EM and CC-Kmeans perform better than the other methods. The methods that exploit external knowledge and constraint can achieve better performance. However, the proposed ADDML method outperforms all baselines by using weighted contexts as well as distance metric learning.

- From the second group, all methods employ word embeddings to represent word semantic and text composition semantic. Yet these methods achieve uneven results due to different semantic composition strategies. The neural bag-of-word AVG method performs better than the others in the overall result, in which it averages the semantics of each word in the context. The average operation is a commonly used approach in many neural methods, such as CNN (Convolution Neural Network), and achieves better performance. However, it still falls behind our ADDML method according to its task-independent characteristic.

3.6 Discussion

Case study We manually examined a number of samples, which can be successfully grouped by ADDML but not the baselines. For example, two aspect phrases "*photo quality*" and "*quality*" belong to group "*picture*" and "*build quality*", respectively. Most of the baselines incorrectly clustered them into the same group, while ADDML correctly grouped them. There are two main reasons: (1) the two aspect phrase themselves have similar semantics characteristic and share words, (2) reviewers commonly used similar words to express their opinion. ADDML can learn an exact vector representation that are context sensitive, while the baseline methods can not distinguish similar contexts. Figure 2 shows some example results of attention values.

	Purity						Entropy

Table 3: The result of different module combinations.

Module Analysis ADDML has three modules: attention-based semantic composition module (atn), MLP-based nonlinear transformation module (mlp) and metric learning (ml). For studying the contribution of each module, we introduce a general convolution neural network (cnn) as an alternative to atn. cnn is a state-of-the-art neural network method for modelling semantic representation of sentence (Kalchbrenner et al., 2014; Tang et al., 2015), which extracts N-gram features by convolution operations.

Table 3 reports the results of different module combinations. We use AP, which only uses aspect phrase vector for clustering, as a reference. The symbol ↑ denotes average percentage improvement than AP in 4 domains. By considering context, $cnn + ml$ and $atn + ml$ achieved better results than AP, which only uses aspect phrase embeddings. After adding nonlinear transformation module, $cnn + mlp + ml$ and $atn + mlp + ml$ further improve the performance. Under the same condition, atn is superior to cnn for our task.

Naturally, aspect phrases in some domains, such as MP3, may have fixed meanings. As a result, an aspect phrase and its context have less correlation under the grouping task in these domains. Therefore, AP achieves a little better result than the other methods except for ADDML. Overall, atn solves the context representation and $mlp + ml$ provides a better metric learning ability for our model.

Similarity Threshold Different similarity thresholds η results in different negative sample pairs, and have a certain impact on performance of our model. For obtaining a better threshold, we performed experiments on developing data with different similarity value. Figure 3 presents the result on DC dataset. The performance slowly decrease with the growth of threshold, which is in line with intuitively understanding. For obtaining enough negative samples, we chosen 0.3 as the similarity threshold.

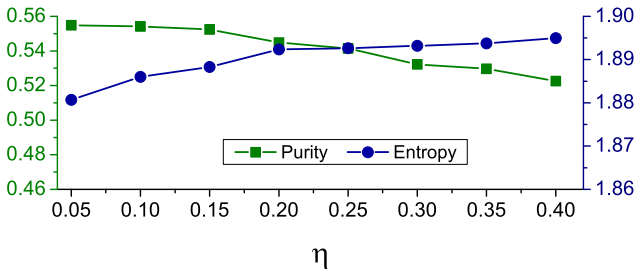

Figure 3: Influence of the similarity threshold η

4 Related Work

Our work is related to aspect-level sentiment analysis, metric learning, and deep learning.

For **aspect-level sentiment analysis**, there are many methods on clustering aspect phrases. Some topic-model-based approaches jointly extract aspect phrases and group them at the same time (Chen et al., 2013; Moghaddam and Ester, 2012; Lu et al., 2011; Jo and Oh, 2011; Zhao et al., 2010; Lin and He, 2009). Those methods tend to discover coarse-grained and grouped aspect phrases, but not specific opinionated aspect phrase themselves. In addition, Zhai et al. (2011a) showed that they did not perform well even considering pre-existing knowledge. Some other work focuses on grouping aspect phrases. Guo et al. (2009) grouped aspect phrases using multi-level LaSA, which exploits the virtual

context documents and semantic structure of aspect phrase. Zhai et al. (2010) used an EM-based semi-supervised learning method for clustering aspect phrases, in which the lexical knowledge is used to provide better initialization for EM. Zhao et al. (2014) proposed a framework of Posterior Regularization to cluster aspect phrases, which formalizes sentiment distribution consistency as a soft constraint. This method requests special semi-structured reviews to estimate the sentiment distribution. In contrast to these methods, we provide a Siamese neural network to learning feature representation through distance supervising.

Metric learning algorithms have been successfully applied to address the problem of face verification (Ding et al., 2015; Yi et al., 2014; Cai et al., 2012; Hu et al., 2014). A common objective of these methods is to learn a better distance metric so that the distance between a positive pair is smaller than the distance between a negative pair. However, these methods not perform nonlinear transformation. Hu et al. (2014) employed a MLP-based nonlinear transformation, but its input is the given image descriptor, which can be directly concatenated to form feature vectors. In this paper, we adapt this method to the aspect phrase grouping task, and provide an extra attention-based semantic composite model to obtain feature vectors based on word vectors of aspect phrase and its context.

Our work is related to **word embedding** and **deep learning**. Prior research (Collobert and Weston, 2008; Mnih and Hinton, 2007; Mikolov et al., 2013; Tang et al., 2014; Ren et al., 2016b) presented different models to improve the performance of word embedding training, and our training is inspried by negative sampling. Deep learning methods (Kalchbrenner et al., 2014; Kim, 2014; Socher et al., 2013; Vo and Zhang, 2015; Zhang et al., 2015; Zhang et al., 2016; Ren et al., 2016a) have been applied to many tasks related to sentiment analysis. In this paper, we explore attention (Luong et al., 2015; Rush et al., 2015; Ling et al., 2015) with a MLP network to tackle the aspect phrase grouping problem.

5 Conclusion

We studied distance metric learning for aspect phrase grouping, exploring a novel deep neural network framework. By leveraging semantic relations between aspect phrase and their contexts, our approach give better performance to strong baselines which achieve the best results in standard benchmark. Our method can be applied to other NLP applications, such as short text clustering and sentence similarity measures.

Abstract

WebQuestions and *SimpleQuestions* are two benchmark data-sets commonly used in recent knowledge-based question answering (KBQA) work. Most questions in them are 'simple' questions which can be answered based on a single relation in the knowledge base. Such data-sets lack the capability of evaluating KBQA systems on complicated questions. Motivated by this issue, we release a new data-set, namely *ComplexQuestions*[1], aiming to measure the quality of KBQA systems on 'multi-constraint' questions which require multiple knowledge base relations to get the answer. Beside, we propose a novel systematic KBQA approach to solve multi-constraint questions. Compared to state-of-the-art methods, our approach not only obtains comparable results on the two existing benchmark data-sets, but also achieves significant improvements on the *ComplexQuestions*.

1 Introduction

Knowledge-based question answering is a task that aims to answer natural language questions based on existing knowledge bases (KB). In the last decades, large scale knowledge bases, such as Freebase (Bollacker et al., 2008), have been constructed. Based on Freebase, two benchmark data-sets, *WebQuestions* (Berant et al., 2013) and *SimpleQuestions* (Bordes et al., 2015) are constructed and used in most of KBQA work (Berant and Liang, 2014; Bordes et al., 2014a; Fader et al., 2014; Yang et al., 2014; Bao et al., 2014; Reddy et al., 2014; Dong et al., 2015; Yih et al., 2015).

However, about 85% of questions (Yao, 2015) of *WebQuestions* and all questions in *SimpleQuestions* are 'simple' questions, where a 'simple' question denotes that it can be answered based on a single KB relation. For example in Figure 1, "Which films star by Forest Whitaker" is a simple question that can be answered by the KB triples like ⟨Forest Whitaker,acted_films,?⟩ with a single KB relation acted_films. This leads to the fact that such data-sets cannot measure the capability of KBQA systems on 'multi-constraint' questions, where 'multi-constraint' means a question containing multiple semantic constraints expressed with different expressions to restrict the answer set. To answer a multi-constraint question, we have to base on multiple KB relations. For example in Figure 1, "Which films star by Forest Whitaker and are directed by Mark Rydell" is a multi-constraint question with a constraint "directed by Mark Rydell", which requires multiple

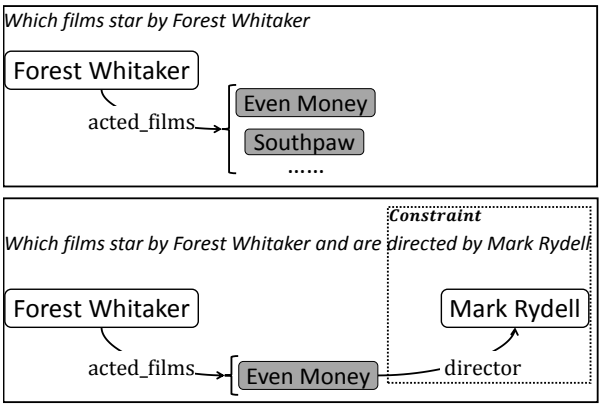

Figure 1: Simple and multi-constraint questions.

This work was finished while the author was visiting Microsoft Research Asia.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2503–2514, Osaka, Japan, December 11-17 2016.

Constraint Category	Example	Percentage
Multi-Entity	which films star by **Forest Whitaker** and are directed by **Mark Rydell**?	30.6%
Type	which **city** did Bill Clinton born?	38.8%
Explicit Temporal	who is the governor of Kentucky **2012**?	10.4%
Implicit Temporal	who is the us president **when the Civil War started**?	3.5%
Ordinal	what is the **second longest** river in China?	5.1%
Aggregation	**how many** children does bill gates have?	1.2%

Table 1: Constraint categories, examples, and distributions over a set of web queries. Note, a multi-constraint question may belong to not only one constraint category. And there are still other relatively low frequency type of complex questions existing which we don't take consideration in this work. So the sum of the Percentage for these constraints are not guaranteed to be 1.

KB triples ⟨`Forest Whitaker,acted_films,Even Money`⟩ and ⟨`Even Money,director,Mark Rydell`⟩ with two KB relations `acted_films` and `director` to get the exact answer set.

Motivated by this issue, this work contributes to QA research in the following two aspects: (1) We propose a novel systematic KBQA approach to solve multi-constraint questions by translating a **mul**ti-**c**onstraint **q**uestion (MulCQ) to a **mul**ti-**c**onstraint query **g**raph (MulCG); (2) A new QA data-set, namely *ComplexQuestions*, is released, aiming to measure the quality of KBQA systems on multi-constraint questions. Compared to state-of-the-art approaches, our method obtains comparable results on the existing benchmark data-sets *WebQuestions* and *SimpleQuestions*. Furthermore, we achieve significant improvement on the newly created *ComplexQuestions* data-set.

2 Multi-Constraint Question

2.1 Constraint Classification

A MulCQ is defined as a question which requires multiple KB relations or special operations to get the answer. Based on web query analysis, we classify constraints into 6 categories as follows:

(1) *Multi-entity constraint*. A question in this category denotes that multiple entities occur in it, which restrict the answer. For example, "Forest Whitaker" and "Mark Rydell" are two entity constraints in the first question in Table 1.

(2) *Type constraint*. A question in this category denotes that its answer should follow a type, which is explicitly mentioned by the question. For example, the answer to the second question in Table 1 should be a "city" name, instead of locations with other types such as country, town, etc.

(3) *Explicit temporal constraint*. A question in this category denotes that it contains explicit temporal expressions, such as "2012" in the third question in Table 1. Such questions are very common in web queries, which means handling them well will bring about significant improvements.

(4) *Implicit temporal constraint*. A question in this category denotes that it contains implicit temporal expressions. For example, "when the Civil War started" denotes an implicit temporal constraint in the fourth question in Table 1. We should transform it into an explicit temporal constraint before answering the question. Such constraints are usually expressed by subordinate clauses.

(5) *Ordinal constraint*. A question in this category denotes that its answer should be selected from a ranked set, based on ordinal numbers or superlative phrases as ranking criteria. For example, "second longest" in the fifth question in Table 1 denotes that the answer should be the second item in the ranked Chinese river set, based on their lengths.

(6) *Aggregation constraint*. A question in this category denotes that it asks for the number of a set, which often starts with phrases "how many" or contains "number of", "count of", etc.

2.2 Question Selection

We perform the following steps to select suitable multi-constraint question candidates for human annotators to label, based on Freebase.

Firstly, a three month (2015.1.1-2015.4.1) query log from a practical search engine is used as the raw

Operation	Trigger	Description
$Equal(y_0, y_1)$	N/A	Return `True` if y_0 is equal to y_1, otherwise `False`
$<(y_0, y_1)$	"after" or "later then"	Return `True` if y_0 is smaller than y_0, otherwise `False`
$>(y_0, y_1)$	"before" or "earlier then"	Return `True` if y_0 is larger than y_0, otherwise `False`
`MaxAtN`(x, n)	Maximize superlatives in WordNet	Rank items of x in descending order, return the n^{th} one
`MinAtN`(x, n)	Minimize superlatives in WordNet	Rank items of x in ascending order, return the n^{th} one
`Count`(x)	"how many", "count of" or "number of"	Return the number of entity set x.

Table 2: Functional predicates defined in this work.

query set, which contains 20,999,951 distinct 5W1H questions[2] that satisfy the following two rules: (i) each query should not contain pronouns (e.g., 'you', 'my', etc.), as questions with such words are usually non-factual questions, and (ii) each query's length is between 7 and 20, as short queries seldom contain multi-constraints, and long queries are usually difficult to answer. Then, we further sample 10 percent of questions, and use an entity linking method (Yang and Chang, 2015) to detect entities. If no entity can be detected from a query, we simply remove it. Next, both *WebQuestions* and *SimpleQuestions* are used to extract a set of words, without considering stop words and entity words. If a query does not contain any word in this word set, we simply remove it. This is intuitive, as *WebQuestions* and *SimpleQuestions* are our training data, and we only consider queries that can be covered by the training data as query candidates. Last, we classify the remaining queries based on the following rules:

(1) If a question contains at least two non-overlap entities, then it belongs in the Multi-Entity category;

(2) If a question contains a type phrase that comes from Freebase, then it belongs in the Type category;

(3) If a question contains a time expression detected by an Named Entity Recognizer (NER) (Finkel et al., 2005), then it belongs in the Explicit Temporal category;

(4) If a question contains keywords "when", "before", "after" and "during" in the middle, then it belongs in the Implicit Temporal category;

(5) If a question contains ordinal number or superlative phrase from WordNet (Miller, 1995), then it belongs in the Ordinal category;

(6) If a question starts with "how many", or includes "number of" or "count of", then it belongs in the Aggregation category.

Note, a multi-constraint question may contain multiple types of constraints. We show constraint types, examples, and distributions in Table 1. Ten thousand questions from the above 6 categories are selected, according to their distributions. By manually labeling these questions according to Freebase, we obtain 878 multi-constraint question answer pairs.

2.3 Question Annotation

We release the *ComplexQuestions* data-set, which consists of 2100 multi-constraint question answer pairs coming from 3 sources:

(1) 596 QA pairs selected from *WebQuestions* training set, and 326 from the test set,

(2) 300 QA pairs released by (Yin et al., 2015),

(3) 878 manually labeled QA pairs based on Section 2.2.

We then split it into two parts: a training set containing 1300 QA pairs and a test set including 800 QA pairs[3].

3 Definition

3.1 Knowledge base

$\mathcal{K}$ denotes a knowledge base[4] (KB) that stores a set of facts. Each fact $t \in \mathcal{K}$ is a triple $\langle s, p, o \rangle$, where p represents a predicate (e.g., `birthday`), and s, o (e.g., `BarackObama`, `1961`) represent an entity or a value,

[2] 5W1H questions are ones the start with "what", "where", "when", "who", "which" or "how".

[3] We put QA pairs from the training (testing) set of *WebQuestions* still in the training (testing) set of *ComplexQuestions*, and the same for the test part.

[4] In this work, we use Freebase, which is a large knowledge base with more than 46 million entities and 2.6 billion facts. In Freebase setting, CVT, namely *compound value type* is a special entity category, which is not a real world entity, but is used to collect multiple fields of an event.

which are the subject and object of t.

3.2 Multi-Constraint Query Graph

Before introducing multi-constraint query graph (MulCG), we first define four basic elements:

Vertex There are two types of vertices: constant vertex (rectangle) and variable vertex (circle). A constant vertex represents a grounded KB entity or a value, such as `Barack Obama` or `1961`. A variable vertex represents ungrounded entities or unknown values.

Edge There are two types of edges: relational edge and functional edge. A relational edge represents a predicate in the KB, such as `birthday`. A functional edge represents a functional predicate of a truth, such as $<$ in the truth $\langle$`2000`, $<$, `2001`$\rangle$. Functional predicates are defined in Table 2.

Basic Query Graph A basic query graph is defined as a triple $\langle v_s, p, v_o \rangle$, where v_s denotes a constant vertex as the subject that occurs in a given question, v_o (shaded circle) denotes a variable vertex as hidden answers of the question, p denotes the 'path' that links v_s and v_o by one or two edges [5] (e.g., `officials-holder`).

Constraint A constraint is defined as a triple $\langle v_s, r, v_o \rangle$, where v_s is a constant vertex, v_o is a variable vertex, r is a functional edge, and after instantiation based on a knowledge base, all instantiated entities from v_o should satisfy the predicate of r with regard to v_s.

MulCG A MulCG is constructed based on a basic query graph $\mathcal{B}$ of a question and an ordered constraint sequence $\mathcal{C} = \{\mathcal{C}_1, ..., \mathcal{C}_N\}$ by the following operations: (1) Treat the basic query graph $\mathcal{B}$ of the given question as $\mathcal{G}_0$; (2) Iteratively add $\mathcal{C}_i$ to $\mathcal{G}_{i-1}$ to generate $\mathcal{G}_i$, by linking the variable vertex of $\mathcal{C}_i$ to a vertex of $\mathcal{G}_{i-1}$ with some possible path, or directly merge them as one variable vertex. (3) Output $\mathcal{G}_N$.

Given a MulCG of a question, we can execute it based on the KB by instantiating all variable vertices according to the constraints in order. Specifically, we start from the constant vertex in the basic query graph and instantiate all variable vertices according to the constraints in order. During this procedure, each instantiated paired entities connected by an edge should satisfy the predicate of the edge based on $\mathcal{K}$ and commonsense knowledge.

Figure 2 shows one possible MulCG for the given question. $\mathcal{B}$ is a basic query graph with a constant vertex `United States`, variable vertices y_0 and x, and two edges `officials` and `holder`. $\{\mathcal{C}_1, \mathcal{C}_2, \mathcal{C}_3\}$ is an ordered constraint sequence detected based on the question, where $\mathcal{C}_1 = \langle$`President`, `Equal`, $y_1\rangle$, $\mathcal{C}_2 = \langle$`2000`, $<$, $y_2\rangle$, $\mathcal{C}_3 = \langle$`1`, `MaxAtN`, $y_2\rangle$. By adding $\mathcal{C}_1, \mathcal{C}_2, \mathcal{C}_3$ in order, we can construct the MulCG in Figure 2. Note, different constraint order can result in different MulCGs. We will introduce how to generate a MulCG in Section 4.

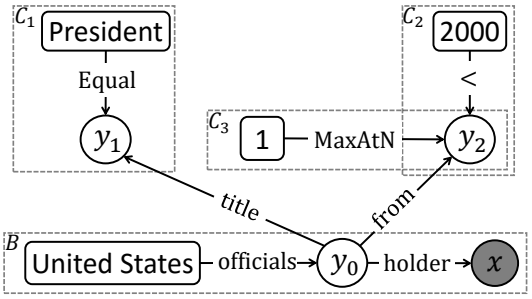

Figure 2: MulCG for question "Who was the first president of United States after 2000?"

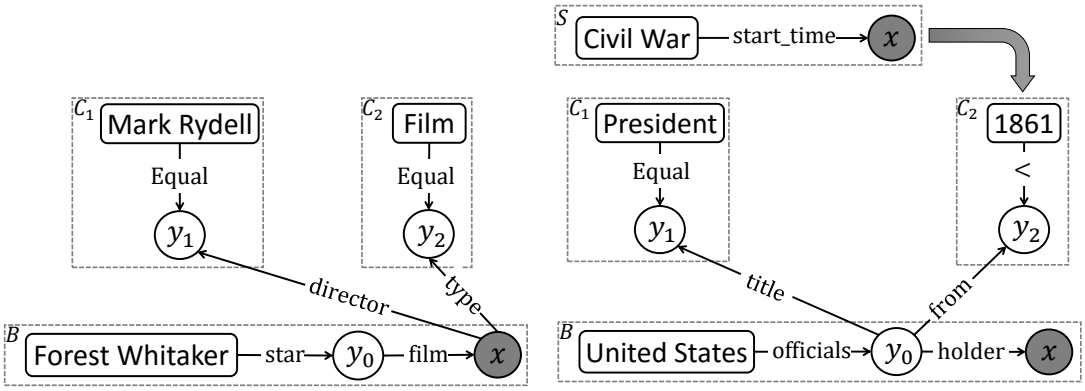
Compared to the stage graph in Yih et al. (2015), our MulCG has the following two differences: (1) Entity constraints can be added beyond single KB fact, while stage graph only considers entities that connect to the CVT node of a single KB fact as constraints. (2) Non-entity constraints are defined and handled in a systematic way, while stage graph only considers limited non-entity constraints, i.e., type and gender.

4 Our Approach

Problem Formalization Given a MulCQ $\mathcal{Q}$ and a KB $\mathcal{K}$, the question is parsed into a set of MulCGs $\mathcal{H}(\mathcal{Q})$. For each MulCG $\mathcal{G} \in \mathcal{H}(\mathcal{Q})$, a feature vector $\mathcal{F}(\mathcal{Q}, \mathcal{G})$ is extracted and the one with the highest

[5] If p contains two edges, then the vertex between must represent a CVT entity in KB. We call an edge or two edges with a CVT variable vertex 'path' in this work.



(a) MulCG with entity and type constraint for question "Which films star by Forest Whitaker and are directed by "Who was U.S. president after the Civil War started". Mark Rydell".

Figure 3: MulCGs examples for different type of constraints.

ranking score is selected. Finally, by executing the MulCG, we get the answers $\mathcal{A}$.

4.1 Basic Query Graph Generation

We use the entity linking approach proposed by (Yang and Chang, 2015) to detect entities mentioned by the given question. For each detected entity s, we treat it as a subject constant vertex. Based on the KB, for each unique KB 'path' from s, where a KB 'path' means one hop predicate p_0 or two hop predicates p_1-p_2[6], we construct a basic query graph $\langle s, p_0, x\rangle$ or $\langle s, p_1\text{-}y_{cvt}\text{-}p_2, x\rangle$. y_{cvt} and x are variable vertices, and x denotes the answer. For example, the basic query graph $\mathcal{B}$ in Figure 2 can be represented as $\langle$`United States`, `officials`-y_0-`holder`, $x\rangle$.

To measure the quality of each basic query graph constructed, we leverage a convolutional neural network (CNN)-based model that is similar to (Gao et al., 2015; Shen et al., 2014b; Shen et al., 2014a; Yih et al., 2015) to calculate the similarity between question and the path of the basic query graph. We will describe the training resource in Section 4.4.

4.2 Constraint Detection and Binding

Basic query graph is fit for single relation questions (Yih et al., 2014; Bordes et al., 2015), but not suffices to express a question with multiple constraints, such as the question in Figure 2. Hence, we propose to use constraints to restrict the answer set by adding them into the basic query graph.Adding a constraint contains two steps: *Constraint Detection* and *Constraint Binding*. We explain how to add each of the six kinds of constraints respectively in the following parts.

Entity Constraint Entity constraint is designed to understand entities and relations which are often expressed by noun phrases and verb phrases. A constraint with an entity as its constant vertex is an entity constraint. For instance, Figure 3(a) is a question with multiple entities such as "Forest Whitaker" and "Mark Rydell". After the basic query graph $\mathcal{G}_0 = \mathcal{B}$ is generated, we detect a constraint $\mathcal{C}_1 = \langle$`Mark Rydell`, `Equal`, $y_1\rangle$ and bind it to $\mathcal{G}_0$ by an edge `director`. Generally, the two steps to add an entity constraint are as follows: (1) *Constraint Detection*: For a detected entity $e \in \mathcal{E}$ (e.g., `Mark Rydell`), we construct a constraint $\mathcal{C}_i = \langle e$, `Equal`, $y_i\rangle$ (e.g., $\langle$`Mark Rydell`, `Equal`, $y_1\rangle$); (2) *Constraint Binding*: Given a MulCG $\mathcal{G}_{i-1}$ (e.g., $\mathcal{B}$), and a detected constraint $\mathcal{C}_i$ (e.g., $\langle$`Mark Rydell`, `Equal`, $y_1\rangle$), we try to bind $\mathcal{C}_i$ to $\mathcal{G}_{i-1}$ by linking the variable vertex of $\mathcal{C}_i$ (e.g., y_1 of $\mathcal{C}_1$) to a vertex of $\mathcal{G}_{i-1}$ (e.g., x of $\mathcal{B}$) by a possible path p (e.g., `director`). To measure the similarity between the path p (e.g., `director`) and the 'context pattern'[7] (e.g., "directed by e1") of constraint $\mathcal{C}_i$, we adopt a convolutional neural network (CNN) model which is described in Section 4.4.

[6] A KB 'path' containing two hop predicates means the entity between the two predicates is a CVT entity in the KB.
[7] A 'context pattern' is a 2-word context with the entity mention replaced by a slot "*e1*"

Note, a constraint can be linked to any vertex in the basic query graph. For example, the constraint $\mathcal{C}_1$ in Figure 2 is binding to a variable vertex y_0. When a constraint is binding to a constant vertex, then it is usually used for entity disambiguation.

Type Constraint Answer type is often explicitly expressed by nouns in questions. For instance, "film" is the answer type of the question in Figure 3(a), which denotes a type constraint. (1) *Constraint Detection*: Different from an entity constraint, we detect an answer type with simple but efficient rules as Yao and Durme (2014) for the question. For each KB type[8], we construct a type constraint (e.g., $\mathcal{C}_2 = \langle \texttt{Film}, \texttt{Equal}, y_2 \rangle$); (2) *Constraint Binding*: A type constraint is only added to the variable vertex which denotes the answers with a specific edge `type`.

Explicit Temporal Constraint Temporal constraint is designed to understand temporal expressions, which are often expressed by numericals, prepositional phrases or clauses. An explicit time expression, such as "after 2000" in the question in Figure 2 indicates a temporal constraint $\mathcal{C}_2$. Through linking the vertex y_0 to y_2 with a predicate `from`, functional constraint $\mathcal{C}_2 = \langle \texttt{2000}, <, y_2 \rangle$ selects the subset of the grounded entities for y_0 whose taking office time is later than `2000`. Generally, the two steps to add an explicit temporal constraint are as follows: (1) *Constraint Detection*: We use Stanford NER (Finkel et al., 2005) to detect a time phrase. If a time t (e.g., `2000`) is detected, and a functional operation r (e.g., $<$) is triggered by a lexicon which is partially listed in Table 2, we then construct a constraint $\mathcal{C}_i = \langle t, r, y_i \rangle$ (e.g., $\mathcal{C}_2 = \langle \texttt{2000}, <, y_2 \rangle$); (2) *Constraint Binding*: If an explicit temporal constraint $\mathcal{C}_i$ (e.g., $\mathcal{C}_2$) is detected, then we execute $\mathcal{G}_{i-1}$ (e.g., $\mathcal{B}$ with $\mathcal{C}_1$) on the KB. If there is a KB path p from grounded entities of the linking vertex (e.g., y_0) in $\mathcal{G}_{i-1}$ satisfying the restriction that p's object KB type is `Date_Time`, then the temporal constraint $\mathcal{C}_i$ is bound to $\mathcal{G}_{i-1}$ by an edge denoting p.

Implicit Temporal Constraint Time expressions such as the clause "after the Civil War started" in the question in Figure 3(b) can also trigger a temporal constraint, but it is expressed with an implicit temporal adverbial clause. (1) *Constraint Detection*: A NER can not detect this kind of implicit temporal expressions, so the dependency information is adopted to detect temporal clause starting with predefined keywords[9]. We first use our system to answer the clause to get an explicit time (e.g., by a MulCG $\mathcal{S}$ to get `1861`), then the detection falls into the same procedure as an explicit temporal constraint; (2) *Constraint Binding*: It is same as an explicit temporal constraint.

Ordinal Constraint An ordinal constraint aims to understand the numerals and superlative forms of adjectives or adverbs. For example, the question in Figure 2 contains an expression "first" which denotes that an ordinal constraint $\mathcal{C}_3$ should be added to graph $\mathcal{G}_2$ ($\mathcal{B}$ with constraints $\mathcal{C}_1$ and $\mathcal{C}_2$). After executing $\mathcal{G}_2$, we rank the grounded values of vertex y_2 and pick up the 1^{st} one by functional operation `MaxAtN`. Generally, two steps are adopted to add an ordinal constraint: (1) *Constraint Detection*: We use a manually collected ordinal number list and superlative vocabulary from WordNet (Miller, 1995) to detect an ordinal number n (e.g., 1) and a functional operation *op* (e.g., `MaxAtN` or `MinAtN`) to construct an ordinal constraint $\mathcal{C}_i = \langle n, op, y_i \rangle$; (2) *Constraint Binding*: If an edge p (e.g., from) linking a vertex of $\mathcal{G}_{i-1}$ (e.g., y_0 of $\mathcal{G}_2$) to the variable vertex of a constraint $\mathcal{C}_i$ (e.g., y_2[10] of $\mathcal{C}_3$) satisfies the restriction that the object entity of the predicate of p is a numerical or time value, and the word embedding similarity between the superlative word and the binding path's last word is the largest, then $\mathcal{C}_i$ is bound to $\mathcal{G}_{i-1}$ with edge p (e.g., $\mathcal{C}_3$ is bound to $\mathcal{G}_2$ with `from`).

Aggregation Constraint An aggregation constraint is added when the question starts with phrase "how many", or contains "number of", "count of". For instance, the phrase "how many" in the question "how many children does bill gates have" trigger an aggregation constraint. We treat it specially by counting the number of the grounded entities of the answer vertex.

4.3 Search Space Generation

[8] A KB type is the type of an entity in the KB, such as `People`, `Film`. We extract entire KB types from Freebase.

[9] Such as "when","before","after","during",etc.

[10] Note, since the linking edges for $\mathcal{C}_2$ and $\mathcal{C}_3$ are both `from`, we bind $\mathcal{C}_3$ with $\mathcal{G}_2$ by merging y_3 and y_2 as y_2.

Given a MulCG $\mathcal{Q}$, Algorithm 1 explains how to generate the search space $\mathcal{H}(\mathcal{Q})$. Firstly, we set $\mathcal{H}(\mathcal{Q})$ and a temp set $\mathcal{T}$ empty. A set of entities $\mathcal{E}$ are detected by entity linking component which takes $\mathcal{Q}$ as input. Secondly, for each entity $e \in \mathcal{E}$, we generate all possible basic query graphs $\mathcal{G}_b$ based on the knowledge base $\mathcal{K}$. Each basic query graph $g_b \in G_b$ is added into both $\mathcal{T}$ and $\mathcal{H}(\mathcal{Q})$. Then, for each basic query graph $g_b \in \mathcal{T}$, based on $\mathcal{Q}, \mathcal{E}, \mathcal{K}$, a set of constraints $\mathcal{C}$ are detected through constraint detection component. Function $Permutation(\mathcal{C})$ returns all possible index sequences of permutations of $\mathcal{C}$. For each index sequence $\mathcal{I} \in Permutation(\mathcal{C})$, constraints are bound recurrently. For each constraint $\mathcal{C}_{\mathcal{I}_i}$, we try to bind $\mathcal{C}_{\mathcal{I}_i}$ into a temporary MulCG g_c. Finally, a set of MulCG candidates $\mathcal{H}(\mathcal{Q})$ is generated.

Algorithm 1: MulCG Generation

$\mathcal{H}(\mathcal{Q}) = \emptyset$;
$\mathcal{T} = \emptyset$;
$\mathcal{E} = EntityLinking(\mathcal{Q})$;
foreach $s \in \mathcal{E}$ **do**
  $\mathcal{G}_b = BasicQueryGraphGenration(s, \mathcal{K})$;
  foreach $g_b \in \mathcal{G}_b$ **do**
    insert g_b to $\mathcal{T}$;
    insert g_b to $\mathcal{H}(\mathcal{Q})$;
  end
end
foreach $g_b \in \mathcal{T}$ **do**
  $\mathcal{C} = ConstraintDetection(g_b, \mathcal{E}, \mathcal{Q}, \mathcal{K})$;
  foreach $\mathcal{I} \in Permutation(\mathcal{C})$ **do**
    $g_c = g_b$;
    for $i = 0$ *to* $|\mathcal{I}| - 1$ **do**
      $g_c = ConstraintBinding(g_c, \mathcal{C}_{\mathcal{I}_i})$;
    end
    insert g_c to $\mathcal{H}(\mathcal{Q})$;
  end
end
return $\mathcal{H}(\mathcal{Q})$.

4.4 Features and Ranking

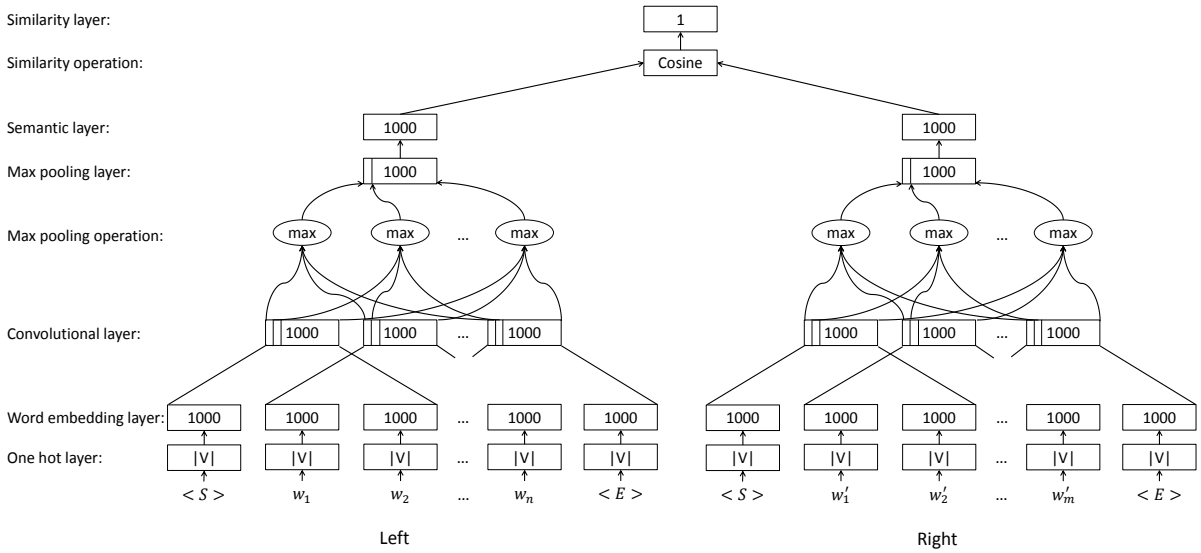


Figure 4: Siamese Convolutional Neural Network

In this work, we propose using Siamese convolutional neural networks (CNN) in Figure 4 to calculate the similarity of two sequences. The model consists of two neural networks taking two sequences as input and maps both of them to k-dimensional vectors. Similar models, such as CDSSM (Shen et al., 2014b; Gao et al., 2015) has been proved for web search. Besides, Yih et al. (2015) use similar frameworks for semantic parsing and question answering. This continuous space representation approach has shown better results compared to lexical matching approaches (e.g., word-alignment models).

Specifically, for two sequences $\mathcal{S}_l = (w_1, w_2, ..., w_n)$ and $\mathcal{S}_r = (w_1^{'}, w_2^{'}, ..., w_m^{'})$, we add "$\langle S \rangle$" and "$\langle E \rangle$" to the head and tail of them respectively to form an input $\mathcal{S}_l^{'}$ and $\mathcal{S}_r^{'}$ of the network. Firstly, a word hashing layer is adopted to hash a word $w \in \mathcal{S}_l$ (or $\mathcal{S}_r$) to a one-hot vector $\mathcal{H}_h = OneHot(w, \mathcal{V})$ based on the vocabulary $\mathcal{V}$. Then by looking up the word embedding table $\mathcal{W}_e$, each word w is embedded into a k-dimensional vector $\mathcal{H}_e = LookUp(\mathcal{H}_h, \mathcal{W}_e)$. A convolutional matrix $\mathcal{W}_c$ is used to project the embedding of words within a context window of 3 words to a local contextual feature vector, and a max pooling layer follows which extracts the most salient local features to get a fix length global feature

vector. With a multi-layer perceptron (MLP) to map the max pooling layer to a semantic layer, we get $\mathcal{H}_l$ and $\mathcal{H}_r$ as the distributed representation of the left and right side. Finally, the semantic similarity is computed as $cosine(\mathcal{H}_l, \mathcal{H}_r)$. To conclude, this model can be defined as $Sim(\mathcal{S}_l, \mathcal{S}_r)$.

Based on the CNN model described above, we design four features in Table 3 for the basic query graph, and four types of features for each kind of constraints, namely indicating features $\mathcal{I}_{s/t/e/i/o/a}$, count features $\mathcal{N}_{s/t/e/i/o/a}$, constraint detection features $\mathcal{V}_{s/t/e/i/o/a}$ and constraint binding features $\mathcal{P}_{s/t/e/i/o/a}$.

Given a MulCQ $\mathcal{Q}$ and a MulCG candidate $\mathcal{G}_i \in \mathcal{H}(\mathcal{Q})$, $\mathcal{F}_k(\mathcal{Q}, \mathcal{G}_i)$ represents the k^{th} feature of $\langle \mathcal{Q}, \mathcal{G}_i \rangle$. A liner scoring function is adopted to calculate the reward score of each $\langle \mathcal{Q}, \mathcal{G}_i \rangle$ as $Score(\mathcal{Q}, \mathcal{G}_i) = \sum_k \lambda_k \cdot \mathcal{F}_k(\mathcal{Q}, \mathcal{G}_i)$. A learning to rank method lambda-rank (Burges, 2010) is used to learn the each feature weight λ_k.

Features	Description
Basic Query Graph	$\mathcal{S}_{ent}$: Entity linking score ('EntityLinking') $\mathcal{S}_{pc}$: CNN score between question pattern and path ('PatChain') $\mathcal{S}_{qep}$: CNN score between question and entity+path ('QuesEP') $\mathcal{S}_{cw}$: CNN score between question and path, where the model is trained on ClueWeb ('ClueWeb')
Constraint	$\mathcal{I}_{s/t/e/i/o/a}$: **I**ndicating features for each kind of constraints, each value is 1 or 0 $\mathcal{N}_{s/t/e/i/o/a}$: **N**umber of each kind of constraints, each value is a positive integer $\mathcal{V}_s$: Sum of entity linking scores for constant **V**ertex in each entity constraint. $\mathcal{V}_t$: Sum of CNN scores between answer type and KB type of the constant **V**ertex in each type constraint $\mathcal{V}_i$: Sum of reward scores of temporal clause for constant **V**ertex in each implicit temporal constraint $\mathcal{P}_s$: Sum of CNN scores between context pattern and binding **P**ath for each entity constraint $\mathcal{P}_o$: Sum of embedding similarities between superlative phrase and binding **P**ath for each ordinal constraint

Table 3: Features and their description.

5 Experiment

We introduce experiment part on these aspects. We first introduce the settings of our experiments, especially the three data sets containing question/answer (QA) pairs. On these data sets, the results of our method are given, and based on the results we analyze drawbacks.

5.1 Set Up

System Components We use the entire Freebase dump which is same as Berant et al. (2013) and host it with Virtuoso engine[11]. Besides, an entity linker (Yang and Chang, 2015), the Stanford NER (Finkel et al., 2005), and an in-house implementation of shift-reduce dependency parser (Zhang and Nivre, 2011) with Stanford dependency (De Marneffe et al., 2006) which is used in detecting temporal clause are adopted in this work.

Data Sets We evaluate our approach on three data sets.

(i) *ComplexQuestions* (CompQ): It is a new data set which includes 2100 QA pairs released by this work with the details in Section 2.

(ii) *WebQuestions* (WebQ): It contains 3778 QA pairs on training set and 2032 on test set which is released by Berant et al. (2013). The questions are collected from query log and the answers are manually labeled based on Freebase.

(iii) *SimpleQuestions* (SimpQ): Each question in *SimpleQuestions* is written by a human with reference to a knowledge base triple.

CNN Training Data To train a CNN model, we first use our system S_0 to enumerate all possible basic query graphs for each question, and pick up the ones with the F_1 score larger then 0. We then get a set of question-path pairs to train the initial CNN models. Then we use these CNN models to train a system S_1. Given S_1, we use it to answer each question to get all MulCGs and pick up the ones with the F_1 score larger then 0.5. Finally we get a set of question-path pairs as our CNN training data.

METHOD	SETTING	CNN TRAINING SOURCE			TEST (Average F_1)

	√	-	√	-	-	52.36
	√	√	√	-	37.42	52.35
	√	√	√	√	37.69	54.30
This Work	-	√	-	-	30.31	-
	-	-	√	-	-	50.98
	-	√	√	-	31.58	51.69
	-	√	√	√	31.42	54.20
	√	√	-	-	40.94	-
	√	-	√	-	-	52.43
	√	√	√	-	41.75	52.49
	√	√	√	√	**42.33**	**54.36**

Table 4: Average F_1 score on **CompQ-Test** and **WebQ-Test** which stand for the test sets of *ComplexQuestions* and *WebQuestions* respectively. **CompQ-Train**, **WebQ-Train** stand for the training sets of *ComplexQuestions* and *WebQuestions* respectively, and **SimpQ** represents the *SimpleQuestions*. **Constraint** means whether to add constraints or not.

5.2 Results and Analysis

We re-implement STAGG method (Yih et al., 2015) as our baseline. STAGG method considers some constraints, such as entity constraint on CVT vertex, type constraint and ordinal constraint triggered by "first" and "oldest". To evaluate our method compared to the baseline on different settings, we design experiments shown in Table 4. The results show that our method outperforms the baseline on the test set of *ComplexQuestions* and have comparable result on the test set of *WebQuestions*.

Specifically, the **Constraint** column in Table 4 indicates using constraints or not. Through these settings, we can see how important the constraints are for answering multi-constraint questions. Besides, $\mathcal{S}_{pc}$ and $\mathcal{S}_{qep}$ are in-domain features that the CNN models they relay on vary from the training data. So we train different CNN models for $\mathcal{S}_{pc}$ and $\mathcal{S}_{qep}$ on different combinations of training resource. By these settings, we can know how does the amount of CNN training data effect on the results.

5.2.1 Results on *ComplexQuestions*

Table 4 shows that, when using the same CNN training sources, our method outperforms the STAGG method about 4.35 ± 0.30 points (40.94-36.89, 41.75-37.42 and 42.33-37.69) on *ComplexQuestions*. This result indicates that our systematic constraint solving method is more suitable for answering questions with multiple constraints than the baseline. Besides, adding constraints can bring about 10.54 ± 0.37 points' (40.94-30.31, 41.75-31.58 and 42.33-31.42) gain on *ComplexQuestions* which tells that constraints as an important feature can help to bring a significant improvement for multi-constraint questions. Since the training set of *ComplexQuestions* contains a relative small size of QA pairs (1300), we add *WebQuestions* and *SimpleQuestions* to enlarge the CNN training data. So another improvement is gained from adding new CNN training resource. STAGG achieves a 0.8 points' gain, our method improves with 1.39 and 1.11 points with or without constraint respectively.

5.2.2 Results on *WebQuestions* and *SimpleQuestions*

We also evaluate our method on the test set *WebQuestions*. From Table 4 we can see that, our method has comparable results with STAGG by comparing 52.43 to 52.36[12], 52.49 to 52.35, and 54.36 to 54.30. This indicates that adding constraints can get a small improvement on the *WebQuestions* because most of the questions in the *WebQuestions* are simple questions, each of which can be solved by a single KB relation. So adding more CNN training resource bring about 1.93 (54.36-52.43) point improvement for our method. Table 5 also shows the results of recent work on *WebQuestions*, and this work outperforms the others.

[11] http://virtuoso.openlinksw.com/

[12] We get a similar result with Yih (2015)'s 52.50 F_1 score.

Besides, the result also shows that our system performs stable, which not only works well on multi-constraint questions, but also simple questions. To further prove the stability of our system, we also test on the test set of *SimpleQuestions*, by using a dictionary based entity linker, our method achieves 72.78 on accuracy. This is because all the *SimpleQuestions* are single relation questions.

6 Related Work and Discussion

Knowledge-based question answering (KBQA) works with lexical features (Yao, 2015) or convolutional neural network features (Yih et al., 2015) already achieve good results on single relation questions. *WebQuestions* (Berant et al., 2013) and *SimpleQuestions* (Bordes et al., 2015) are two data sets for KBQA task. Based on our analysis, more than 84% and almost all questions in *WebQuestions* and *SimpleQuestions* are single relation questions.

Method	**Average F_1**
(Berant et al., 2013)	35.70
(Bordes et al., 2014b)	29.70
(Yao and Durme, 2014)	33.00
(Bao et al., 2014)	37.50
(Berant and Liang, 2014)	39.90
(Yang et al., 2014)	41.30
(Wang et al., 2014)	45.30
(Bordes et al., 2015)	39.90
(Yao, 2015)	44.30
(Berant and Liang, 2015)	49.70
(Yih et al., 2015)	52.50
(Reddy et al., 2016)	50.30
(Xu et al., 2016)	53.30
This work	**54.36**

Table 5: QA result on **WebQ**.

Previous KBQA work (Yao and Durme, 2014; Bordes et al., 2014a; Yang et al., 2014; Fader et al., 2014; Reddy et al., 2014; Dong et al., 2015; Bordes et al., 2015) testing on these two data sets do not solve multiple constraints systematically. Different methods such as specific *bridging* operator (Berant et al., 2013), semantic template $p.(p1.e1 \sqcap p2.e2)$ (Berant and Liang, 2014) are used to treat questions with multiple entities specially. Yih et al. (2015) have already done some work to handle questions with constraints, such as considering entity constraints on CVT vertice or ordinal constraints triggered by "first" or "oldest". But these methods haven't specifically evaluated their KBQA systems or presented solutions to multi-constraint questions in a systematic manner.

We propose a novel method to answer questions with multi-constraints by multiple-constraint query graphs. By evaluating it on the *ComplexQuestions* released by this work, we find our method works well on multi-constraint questions.

7 Conclusion

We release a QA data-set *ComplexQuestions* which contains multi-constraint questions, and propose a novel systematic KBQA method using multi-constraint query graph to answer multi-constraint questions. Experiments show that, compared to state-of-the-art approaches, our method obtains comparable results on the existing benchmark data-sets *WebQuestions* and *SimpleQuestions*. Furthermore, we achieve significant improvement on the newly created *ComplexQuestions* data-set. Besides, we put learning the matching between constraint expressions and semantic constraints from massive data in future work.

Abstract

Community question answering (cQA) websites are focused on users who query questions onto an online forum, expecting for other users to provide them answers or suggestions. Unlike other social media, the length of the posted queries has no limits and queries tend to be multi-sentence elaborations combining context, actual questions, and irrelevant information. We approach the problem of question ranking: given a user's new question, to retrieve those previously-posted questions which could be equivalent, or highly relevant. This could prevent the posting of nearly-duplicate questions and provide the user with instantaneous answers. For the first time in cQA, we address the selection of relevant text —both at sentence- and at constituent-level— for parse-tree-based representations. Our supervised models for text selection boost the performance of a tree kernel-based machine learning model, allowing it to overtake the current state of the art on a recently released cQA evaluation framework.

1 Introduction

Community-driven question-and-answering (cQA) sites are popular forums in which users ask and answer questions on diverse topics. The freedom in these websites, and the diversity of their users, promote massive participation, resulting in large amounts of texts in the form of both questions and answers.

All the steps in the assembly line of these highly-collaborative sites —from the question posting up to the seek for sensitive answers among those triggered by the question—, pose interesting natural language processing (NLP) challenges. When a user posts a query question, a model can search for previously-posted equivalent or relevant questions which might address the user's information need at once. Once a number of comments have been posted intending to answer a question, another model can select the most appropriate one, or at least rank them on the basis of their quality. The same technology can be applied to discard inappropriate or diverting answers. When a website has accumulated a significant amount of posts, a model can be implemented to look for near-duplicates or related questions and answers.

Different approaches have been proposed to address these tasks. Here we focus on the first of them: question re-ranking in cQA. That is, given a query question q and a pool of previously-posted questions D, rank the questions in D according to their relevance against q. This problem has attracted the attention of a manifold of research works which rely on the use of standard lexical similarity metrics, semantic representations, machine-translation models, tree kernels, or neural networks, to mention just some examples of representations and models. Nevertheless, those approaches neglect one of the inherent facets of cQA sites: opposed to other social media, users are free to post potentially ill-formed texts of anarchic lengths. They may include multiple sentences with courtesy chunks, potentially-redundant elaborations, or off-topic fragments. In this paper, we address the problem of selecting the most relevant text chunks in the questions in order to build a better representation of the texts to be fed into the machine learning machinery. We propose supervised and unsupervised models that operate both at sentence and at chunk level (using constituency parse trees) and apply them on top of a state-of-the-art tree-kernel-based classification model. To the best of our knowledge, this is the first time that this problem is addressed. Our

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers,
pages 2515–2525, Osaka, Japan, December 11-17 2016.

results on a recently-released cQA corpus show that, by carefully selecting both sentences and words, the performance of the ranking model can be significantly improved (in the range of more than two MAP points), also improving the current best model on the evaluation framework we used.

The rest of our contribution is distributed as follows. Section 2 overviews the literature addressing different problems in cQA, paying special attention to question ranking. Section 3 describes the machine learning strategy to rank questions upon which we build our main contribution: the proposal of two models to select the most relevant —noise-less— text fragments to represent the questions, described in Section 4. Section 5 describes our experimental settings and discusses the obtained results. Finally, Section 6 draws conclusions and sketches some of our current efforts.

2 Related Work

Community question answering poses various challenges: answer and question ranking, and question de-duplication are three examples. We now review the related literature with focus on question ranking.

One of the first approaches to answer ranking relied completely on the website's metadata (Jeon et al., 2006), such as an author's reputation and click counts. Agichtein et al. (2008) explored a graph-based model of contributors relationships together with both content- and usage-based features. These approaches depend heavily on the forum's meta-data and social features. Still, as Surdeanu et al. (2008) stress, relying on this kind of data causes the model portability to be difficult; a drawback that disappears when focusing on the content of the questions and answers only. Therefore, our model is based on textual content only. Some of the most recent proposals aim at classifying whole threads of answers (Joty et al., 2015; Zhou et al., 2015) rather than each answer in isolation.

Question ranking can be approached from different fronts. Cao et al. (2008) approached it as a recommendation task: given a query question, recommend questions that could be interesting or relevant, regardless of whether they convey the same information request. They tackle this problem by comparing representations based on topic terms graphs; i.e., by judging topic similarity. In a follow up paper, Duan et al. (2008) searched for equivalent questions by considering the question's focus as well. Zhou et al. (2011) dodged the lexical gap between two questions by assessing their similarity on the basis of a (monolingual) phrase-based translation model (Koehn et al., 2003). They considered the (pre-filtered) contents of the question–answer pairs as their "parallel" corpus to learn the translation model from. Jeon et al. (2005b) had used monolingual translation as well. Given a large repository of question and answer threads, they looked for highly-similar threads (Jeon et al., 2005a). Similar answers are likely to address similar questions! The questions in the so-generated pairs compose their "parallel" corpus. Wang et al. (2009) computed their similarity function on the syntactic-tree representations of the questions. The more substructures the trees have in common, the more similar their associated questions are. A different approach using topic modeling for question retrieval was introduced by Ji et al. (2012) and Zhang et al. (2014). Here, the authors use LDA topic modeling to learn the latent semantic topics that generate question/answer pairs and use the learned topics distribution to retrieve similar historical questions.

The recent boom in neural network approaches has also impacted question retrieval. dos Santos et al. (2015) applied convolutional neural networks to retrieve semantically-equivalent questions' subjects. When dealing with whole questions —subject and (generally long) body—, they had to aggregate a bag-of-words neural network to boost the model's performance. They suggested that the performance of state-of-the-art models for semantic paraphrasing assessment on short texts (e.g., (Filice et al., 2015b)) cannot be applied straightforwardly to whole questions in cQA. For the first time, we address such problem in this paper.

The two editions of the SemEval Task 3 on cQA (Nakov et al., 2015; Nakov et al., 2016) have triggered a manifold of approaches. The datasets they released include manual crowd-sourced annotation rather than forum-inferred judgments. The 2015 edition focused on answer retrieval. The first performing system (Tran et al., 2015) applied machine translation in a similar fashion as Jeon et al. (2005b) and Zhou et al. (2011), together with topic models, embeddings, and similarities. Both the first and the second runners (Hou et al., 2015; Nicosia et al., 2015) applied supervised models with lexical, syntactic and meta-data features. The 2016 edition included a question retrieval challenge as well. We take ad-

vantage of the evaluation framework developed for this task. The top-three participants opted for SVMs as learning models. The top-ranked (Franco-Salvador et al., 2016) used SVM^{rank} (Joachims, 2006), the first (Barrón-Cedeño et al., 2016) and second (Filice et al., 2016) runners up used KeLP (Filice et al., 2015a) to combine various kernels. Another difference between these models is in the amount of knowledge they use. Franco-Salvador et al. (2016) rely heavily on distributed representations and semantic information sources, such as Babelnet and Framenet. Both Barrón-Cedeño et al. (2016) and Filice et al. (2016) use lexical similarities and tree kernels on parse trees. No statistically-significant differences were observed in the performance of these three systems.

To the best of our knowledge, so far the only other work exploring text selection to improve cQA systems is that of Romeo et al. (2016). In that paper, we do sentence selection and pruning on the basis of attention weights, computed with neural networks.

3 Base Model to Rank Questions

In this section we describe a state-of-the-art technique to assess question–question similarity in question ranking. This is the core of our ranking approach and the base on which we test our text selection models (cf. Section 4). We apply a learning-to-rank approach (Liu, 2009) to produce the ranking of forum questions. Related questions in cQA sites are usually spotted and labeled as such by the users themselves. This can be directly projected into a training dataset with binary annotations: *Relevant* vs. *Irrelevant* and a perfect ranking puts all the *Relevant* questions on top of all the *Irrelevant* ones, regardless of the order within both subsets (Cao et al., 2008; dos Santos et al., 2015; Jeon et al., 2005b). We adopt the same architecture as the recently-proposed, most successful, models on this kind of setting (Franco-Salvador et al., 2016; Barrón-Cedeño et al., 2016; Filice et al., 2016). We apply a kernel approach to solve a binary classification problem, $f : Q \times D \rightarrow \{Relevant, Irrelevant\}$, and sort the forum questions $d \in D$ according to their classification score against q: $f(q, d)$.

We opt for a tree kernel applied to parse-tree representations (Moschitti, 2006b; Sun et al., 2011), as it performs well in ranking both passages (Severyn and Moschitti, 2012) and questions (Barrón-Cedeño et al., 2016; Da San Martino et al., 2016; Filice et al., 2016). Additionally, the nodes of the parse trees of the pairs (q, d) are marked with a REL tag when there is at least a lexical match between the phrases of the questions (c.f. (Filice et al., 2015b) for details). The approach for dealing with a pair of trees, is to compose kernels on single trees $K^T(x_1, x_2)$:

$$K((q_i, d_i), (q_j, d_j)) = K^T(t(q_i, d_i)), t(q_j, d_j))) + K^T(t(d_i, q_i)), t(d_j, q_j))), \quad (1)$$

where d_i and d_j are the i^{th} and j^{th} retrieved questions and $t(x, y)$ extracts the syntactic tree from the text x, enriching it with REL tags computed with respect to y. Note that $t(x, y)$ is not symmetric: $t(y, x)$ would return the tree related to y enriched with REL tags. Specifically we apply a partial tree kernel (PTK) as the base kernel K^T, which counts the number of shared subtrees between x_1 and x_2 (Moschitti, 2006a).

4 Text Selection for Parse-Tree Representations

We complement our classifier with twenty-two similarities $sim(q, d)$ computed on lemmatized versions of the texts, which are described in Table 1. The inverse of the Google-generated position of d (included in the corpus) is included as well. We plug the similarities on an RBF kernel and combine it linearly with the tree kernel as they boost the performance of the tree kernels (Da San Martino et al., 2016).

Questions in cQA websites tend to be composed of multiple sentences (c.f. Figure 1) and to include noisy or irrelevant fragments. We apply the same trick as Filice et al. (2016) to feed our tree kernel with pairs of single trees: we hang together the constituency parse trees of all the sentences in q (d) from an additional root node. Still, tree kernels are expensive and sensitive to noise, thus it is difficult for them to deal with multi-sentence noisy text. In order to tackle these issues in the questions' texts, we designed two general strategies which operate either at sentence or at word level. Our objective is twofold: we want to represent our questions with the shortest —most informative— text fragments and at the same time discard noise, such as acknowledgments or unnecessary elaborations.

Metric		Details
String similarity		
Greedy string tiling	(Wise, 1996)	Considering a minimum matching length of 3.
Longest common subsequence	(Allison and Dix, 1986)	Both standard and normalized by the first string.
Longest common substring	(Gusfield, 1997)	Based on generalized suffix trees.
Lexical similarity		
Jaccard coefficient	(Jaccard, 1901)	Over stopworded $[1, \ldots, 4]$-grams.
Word containment	(Lyon et al., 2001)	Over stopworded $[1, \ldots, 2]$-grams.
Cosine		Over stopworded $[1, \ldots, 4]$-grams.
		Over $[1, \ldots, 4]$-grams.
		Over $[1, \ldots, 3]$-grams of part of speech.
Syntactic similarity		
PTK	(Moschitti, 2006a)	Similarity between shallow syntactic trees.

Table 1: Overview of similarity metrics.

4.1 Learning to Select Sentences

This selection strategy occurs before the parse trees of the questions are built. The output of this process is a selected number of sentences from q and d, composed on the basis of sentence-pair rankings. Algorithm 1 sketches our strategy. Firstly, we combine all the possible pairs of sentences between questions q and d. Secondly, we compute a similarity function φ for each pair and rank the pairs accordingly. Thirdly, we identify the k pairs of sentences with the highest similarities. Finally, we discard those sentences from q and d which have not been included within the top-k pairs. Our rationale implies a number of constraints. The sentences that result from the process are in the same order as in the original questions; not in the order of the sentence ranking. This is because we want to preserve the discourse structure of the text. Sentences are promiscuous: they can be linked to different sentences from the other question. If a sentence is part of more than one of the top-k pairs, it is not duplicated in the output. Finally, the input question may go unaltered on either side. The similarity function φ is the key factor for this model and we experimented with two learning strategies:

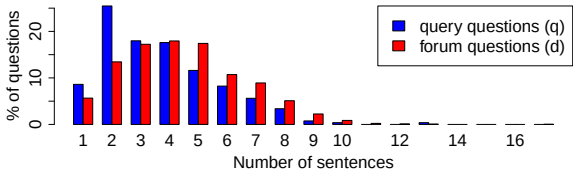

Figure 1: Distribution of question lengths in terms of sentences for query (q) and forum (d) questions.

Our unsupervised model is based on the cosine similarity over TF×IDF-weighted vector representations of the sentences in q and d.

Our supervised model is based on a binary SVM classifier, using the same similarity functions as in Section 3, over and RBF kernel. We add information in terms of features on the position of the sentence within the question: the inverse of the position, whether the sentence appears in position 1, between positions 2 and 4 (inclusive), or after position 4. We take 4 as threshold because it is the mode of the number of sentences in the questions of the corpus (mean=4.38). Our prediction function is $c(p_q, p_d) \in \{Relevant, Irrelevant\}$. The class labels are borrowed from those at question level.

We took good care of not misusing the development and test data. In the unsupervised model, we compute the document-frequency statistics on sentences from the training set only. In the supervised model, the scores for the training set are estimated by 5-fold cross validation. On dev and test, the used document frequencies are those from the training set and the scores are computed with the model trained on the training partition.

4.2 Learning to Select Constituents in Tree Kernel Spaces

Our strategy for selecting text at token level is to operate directly on the parse trees and prune those branches which are associated with less important or noisy text fragments. We use a supervised approach based on kernel methods to determine such fragments. A few facts on kernel methods need to be recalled to better understand our approach. After training a kernel method, using a kernel function $K()$, on the

Input :
q the query question
d the forum question
k the maximum number of pairs to return
Output:
q' q, after selecting the best sentences; $len(q') \leq len(q)$
d' d, after selecting the best sentences; $len(d') \leq len(d)$

$P \leftarrow sent(q) \times sent(d)$ // All the possible sentence pairs between q and d
for $p \in P$ **do**
  $score_p = \varphi(p_q, p_d)$ // Compute the similarity between the sentences
end
$P \leftarrow rank(P, score_P)$ // Rank the pairs in P in terms of the similarities
$P \leftarrow trim(P, k)$ // Select (at most) the top-k pairs in P
$q' \leftarrow q \cap P_q$ // Remove from q all the sentences not in P
$d' \leftarrow d \cap P_d$ // Remove from d all the sentences not in P
return q', d'

Algorithm 1: Sentence-level selection.

problem sketched in Section 3, the solution of the dual optimization problem is expressed as a linear combination of a subset of the training examples: $M = \{(\alpha_i, (q_i, d_i))\}$, where the (q_i, d_i) are training examples and α_i are the coefficients of the combination. The classification of a new example is obtained as the sign of the score function $f()$:

$$f\left(q, d\right) = \sum_{1 \leq i \leq |M|} \alpha_i K\left((q, d), (q_i, d_i)\right), \tag{2}$$

where $|M|$ is the number of support vectors, i.e., the number of elements of the set M. The higher the absolute value of the score of an example, the more confident the learning algorithm is in classifying it. We exploit such property of the kernel methods to devise a strategy to determine the importance $w(n)$ of a node. Let n be a node of a tree t, $\overset{n}{\triangle}$ is the proper sub-tree rooted at n, i.e., the tree composed of n and all its descendants in t. We use the score of $\overset{n}{\triangle}$ with respect to M to assess the importance of n:

$$w(n) = \begin{cases} \sum_{1 \leq i \leq |M|} \alpha_i K^T(\overset{n}{\triangle}, q_i) & \text{if } n \in q, q \in Q \\ \sum_{1 \leq i \leq |M|} \alpha_i K^T(\overset{n}{\triangle}, d_i) & \text{if } n \in d, d \in D. \end{cases} \tag{3}$$

In order to be consistent, only the parse trees of $q_i \in Q$ will be used to compute $w(n)$, if n belongs to a question in Q for each pair $(q_i, d_i) \in M$. Conversely if n belongs to a question in D only the parse trees of $d_i \in D$ will be used. Note that, by grouping and caching the scores computations as in (Aiolli et al., 2011, eq. (4)), the worst-case complexity of Eq. (3) for all the nodes is the same as the complexity of predicting the class of the pair (q, d).

Now we can proceed to prune a tree on the basis of the $w(n)$ importance estimated by model M for each of its nodes and a user-defined threshold. We prune a leaf node n if $-h < w(n) < h$. If n is not a leaf, then it is removed if all its children are going to be removed. Note that the threshold h determines the number of pruned nodes. Our algorithm has a constraint: REL-tagged nodes are never pruned, regardless of their estimated importance. This is because a REL tag indicates that q and d share a common leaf in $\overset{n}{\triangle}$, which conveys useful information for paraphrasing (Filice et al., 2015b).

5 Experiments

We perform three different experiments. Firstly, we evaluate the performance of our supervised sentence-level classifier and select the best of them for the next experiment. Secondly, we analyze the impact of the supervised and unsupervised sentence selectors in the performance of our overall question ranking model. Thirdly, we evaluate the impact of our tree-pruning strategy in the performance of our overall

Class	train	dev	test	overall
Relevant	1,083	214	233	1,530
Irrelevant	1,586	286	467	2,339
Total	2,669	500	700	3,869

Table 2: Class distribution in the training, development, and test partitions of the cQA-2016 corpus.

Model	Acc	P	R	F_1	MAP	AvgRec	MRR
sim	65.88	44.44	14.29	21.62	60.15	85.39	64.22
$sim + pos_{lin}$	68.24	53.85	25.00	34.15	61.13	85.79	64.22
$sim + pos_{RBF}$	71.76	59.09	46.43	52.00	62.84	86.95	66.67

question ranking model. As discussed in Section 3, we use binary SVMs to generate the rankings, combining a tree kernel for the parse trees and an RBF kernel for the rest of features.

5.1 Setup

We run our experiments on the SemEval 2016 Task 3 on Community Question Answering evaluation framework (Nakov et al., 2016), which uses the cQA-2016 corpus in which each item includes a query question linked to ten potentially-relevant candidate questions. Table 2 shows the class distribution. We stick to the retrieval problem formulation of the task: a perfect model should rank relevant documents on top of the irrelevant ones. Our evaluation is based on mean average precision, average recall, and mean-reciprocal rank. This allows for a direct comparison against Task 3's official ones.

5.2 Impact of Sentence Selection in Question Ranking

We first evaluate our sentence ranking model in isolation, before assessing its impact on the question ranker. We trained a sentence level classifier, on the training partition of the corpus, as defined in Section 4.1 —considering the question-level annotations as gold standard. However, the latter choice introduces a lot of false positives as sentences in relevant questions may be unrelated. Thus, for correctly evaluating the sentence classifier, we used labels obtained by crowdsourcing. We selected sentence pairs to be annotated from the development set according to a few constraints. The (q, d) pairs we extract the sentences from must include at least five sentences in d. Each selected sentence must include at least 3 content words and 3 stop-words. This resulted in 125 sentences for this small control experiment. We submitted HIT's composed of 15 sentence pairs to CrowdFlower.[1] Annotators had to decide if two sentences "expressed the same information". Each item was annotated by 3 contributors, with an agreement of 0.83. 21% of the sentence pairs resulted as positive.

Table 3 shows the performance of different configurations of the sentence-level classifier, trained on the training partition and tested on the Crowdflower-annotated data. The task is the same as at question level: ranking, but we include accuracy, precision, recall, and F_1-measure to get a clear picture. Similarity measures constantly perform better on RBF kernels and, as observed, positional features do as well. The performance boost caused by the positional features is more evident in terms of F_1 and recall. These values might be perceived as relatively low, but let us keep in mind that many (unrelated) sentences in the training set inherit incorrect labels from the label of their question. Given these figures, we select the model with both similarities and position features on an RBF kernel to select sentences for the question ranker. Our unsupervised model does not require any evaluation nor tuning.

Now we look at the impact of our sentence selection model in the question ranker. Figure 2 shows the performance of the ranker as a function of the number of sentences. In our supervised model sim+pos$_{RBF}$, the x-axis refers to the number of pairs considered after the SVM-generated ranking. In our unsupervised model TF$\times$IDF, the x-axis stands for the number of sentences that represent q and d in the ranking model. We also display the behavior when the sentences are added in the natural order, which could be considered as a sentence-selection baseline. The constant line "SemEval baseline" corresponds to the competition baseline (Nakov et al., 2016). The upper constant line in Figure 2b corresponds to the winner of the SemEval competition (Franco-Salvador et al., 2016).

(a) On the development set.

(b) On the test set.

Figure 2: Evolution of MAP for various sentence-selection strategies. The point marked as *All* on the x axis —where the curves converge— corresponds to the values obtained when using all the sentences.

It is worth observing that all our models depart relatively low performance values when considering one single sentence: MAP $\simeq$ 68.12 on development and 70.40 on test. Nevertheless, the natural order one stops improving at 3 sentences and it never goes over the base system, which considers the full texts. This is not the case for our selection models: already from 3 (and 4) sentences they improve over the full-text system. On the development set the supervised model reaches a MAP of 76.01 with five sentences and the unsupervised reaches 75.40 with eight sentences. The SVM supervised model is also the best on test, even when considering less sentences (Figure 2b). Again, the best performance is obtained by the supervised model. Although, TF$\times$IDF has a peak with 3 sentences, adding more pairs results in a quick performance decrease. Therefore, the supervised sentence classifier is more stable and thus preferable. In summary, our sentence pre-selection manages to identify those sentences which are more relevant to assess the similarity between two questions and produce a better ranking. Overall, the supervised model performs better than the unsupervised one and the best configurations improve over the SemEval best system. We select the best performing model on development —the SVM on sim+pos$_{RBF}$— and list its corresponding performance in Table 4, for comparison with the best pruning model and the rest of systems.

5.3 Impact of Constituency Tree Selection on Question Reranking

We experimented with two models for generating the weights $w()$ to prune the nodes: (*i*) an SVM with the kernels described in Section 3 (*model 1*); (*ii*) the same SVM trained on the training set after applying the sentence selection described in section 4.1 (*model 2*).

We first performed a 5-fold cross validation on the training set to select a pruning threshold. For each cross validation split into train/test, we first perform learning on train to get weigths using *model 1*, then we prune both train and test partitions and finally we apply the "Base Model" described in section 3 to assess its performance. In order to have more clues on the behavior of our technique, once learning has been performed on a training partition, we predict on the development and test sets as well. Figure 3 reports the results. Considering the curve related to the prediction on the split of the training set, pruning more than 35% of the nodes also increases MAP, with a peak of 69.41 when 75% of the nodes are

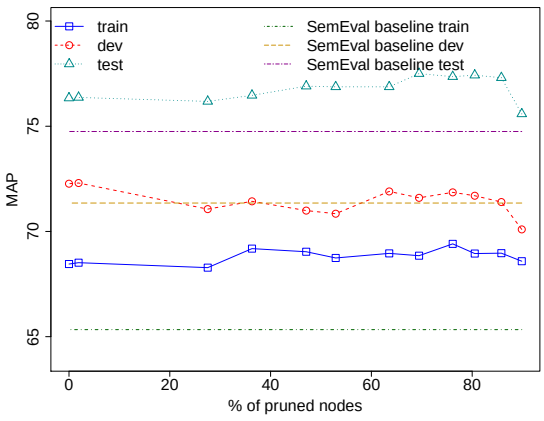

Figure 3: Cross validation for the pruning *model 1*. Each training fold is tested on the remaining part of the training set, the development and test sets.

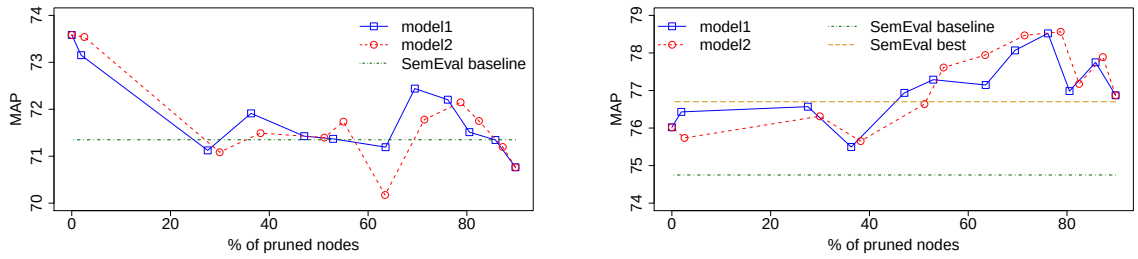
Model	selection	Acc	P	R	F_1	MAP	AvgRec	MRR
Sentence *sim+pos*	6 sent	78.43	67.98	66.52	67.25	75.09	90.35	82.7
Pruning *model 2*	75% nodes pruned	80.57	69.96	72.96	71.43	**78.56**	91.39	85.12
Full text	-	78.71	68.58	66.52	67.54	76.02	90.70	84.64
SemEval Baseline	-	-	-	-	-	74.75	88.30	83.79
SemEval Best	-	76.57	63.53	69.53	66.39	76.70	90.31	83.02

Table 4: Performance of selected models on test.



(a) On the development set.

(b) On the test set.

Figure 4: MAP of base model with respect to the percentage of nodes pruned. Pruning performed with *model 1* and *model 2*.

pruned ($+0.958$ with respect to not applying pruning). The results on the development set do not show any increase in MAP. This may be due to annotation differences between the training/test and development partitions. At the same time the decrease is not significant. The behavior on the test set is similar to the one on the training set, although the peak is around 70% of nodes pruned this time (MAP=77.5, $+1.16$ w.r.t not applying pruning).

We performed further experiments by using all the training set for computing the weights $w()$ and, after pruning, for learning the "Base Model". This time we used the two models, *model 1* and *model 2*. Figure 4 shows the results on the development and test sets. Note that both on development and test sets there is not much difference between performing the pruning with *model 1* or *model 2*. The two plots show a similar pattern to the corresponding curves in Figure 3: on development there is no improvement, although there is a peak around 70% of nodes pruned, while on the test there is a notable improvement, the peak being MAP=78.56 ($+2.5$). Once again, our models manage to improve over SemEval's best (Franco-Salvador et al., 2016), even if it does not rely on any external knowledge. Note that the peak coincides with the threshold that we would select on cross validation on the training set, i.e. 75% of nodes pruned. We performed a student paired t-test (significance level 0.05) to check whether the MAP differences are statistically significant. It turns out that the best value on test allows us to have a statistically significant improvement with respect to the baseline.

The reduction of the size of the trees due to pruning, reduces significantly the running time, both in the learning and prediction phases. For example, the best model prunes 75% of the nodes, which translates into a reduction of the learning time of 12.7 times, from 134.51 to 10.53 minutes; the time for computing the predictions decreases from 15.14 to 9.22 minutes (1.64 times less).

Table 4 summarizes the results obtained with the different models. The tree kernel model itself, denoted as "Full text" in the table, improves over the SemEval baseline. Our best sentence selection model on development results in a worst performance on test. As aforementioned, it is not robust enough. Still it allows the pruning *model 2* system to improve by 1.86 MAP points the SemEval's best presented system.

6 Conclusions

Establishing question–question similarity for question ranking is of great importance in real-world community question answering tasks. While tree kernels are a key component of many state-of-the-art systems for question–question similarity, they are negatively affected by noisy and uninformative texts,

which are common for forum questions posted by web users. In this paper we studied the problem of selecting the most significant sentences and parse tree fragments from the question's text. For this purpose, we used unsupervised and supervised methods, exploiting standard cosine similarity models and we modeled supervised classifiers for learning effective sentence selection and tree fragments.

Our results on the recently-released SemEval 2016 cQA corpus show that supervised models can greatly improve the quality of text selection, thus reducing the size of the parse trees. An immediate consequence of this fact is that the prediction is faster (in our experiments prediction up to 50% and training more than 12 times), without any significant loss in MAP performance. In fact, it turns out that in most cases the structures removed might contain misleading information for the learning algorithm, therefore the MAP increased on the test set. Our proposed model outperforms the top systems submitted to the SemEval 2016 task on community Question Answering.

In the future, we would like to experiment with more advanced selection techniques, which have been shown successful in traditional text summarization; for instance, by using discourse structure.

Abstract

Nowadays, neural networks play an important role in the task of relation classification. In this paper, we propose a novel attention-based convolutional neural network architecture for this task. Our model makes full use of word embedding, part-of-speech tag embedding and position embedding information. Word level attention mechanism is able to better determine which parts of the sentence are most influential with respect to the two entities of interest. This architecture enables learning some important features from task-specific labeled data, forgoing the need for external knowledge such as explicit dependency structures. Experiments on the SemEval-2010 Task 8 benchmark dataset show that our model achieves better performances than several state-of-the-art neural network models and can achieve a competitive performance just with minimal feature engineering.

1 Introduction

Classifying the relation between two entities in a given context is an important task in natural language processing (NLP). Take the following sentence as an example:

Jewelry and other smaller $\langle e_1 \rangle$ *valuables* $\langle /e_1 \rangle$ *were locked in a* $\langle e_2 \rangle$ *safe* $\langle /e_2 \rangle$ *or a closet with a dead-bolt.*

Here, the marked entities "valuables" and "safe" are of the relation "Content-Container(e1; e2)".

Relation classification plays a key role in various NLP applications, and has become a hot research topic in recent years. Various machine learning based relation classification methods have been proposed for the task, based on either human-designed features (Kambhatla, 2004; Suchanek et al., 2006), or kernels (Kambhatla, 2004; Suchanek et al., 2006). Some researchers also employed the existing known facts to label the text corpora via distant supervision (Mintz et al., 2009; Riedel et al., 2010; Hoffmann et al., 2011; Takamatsu et al., 2012).

All of these approaches are effective because they leverage a large body of linguistic knowledge. However, these methods may suffer from two limitations. First, the extracted features or elaborately designed kernels are often derived from the output of pre-existing NLP systems, which leads to the propagation of the errors in the existing tools and hinders the performance of such systems (Bach and Badaskar, 2007). Second, the methods mentioned above do not scale well during relation extraction, which makes it very hard to engineer effective task-specific features and learn parameters.

Recently, neural network models have been increasingly focused on for their ability to minimize the effort in feature engineering of NLP tasks (Collobert et al., 2011; Zheng et al., 2013; Pei et al., 2014). Moreover, some researchers have also paid attention to feature learning of neural networks in the field of relation extraction. (Socher et al., 2012) introduced a recursive neural network model to learn compositional vector representations for phrases and sentences of arbitrary syntactic types and length. (Zeng et al., 2014; Xu et al., 2015b) utilized convolutional neural networks (CNNs) for relation classification. (Xu et al., 2015c) applied long short term memory (LSTM)-based recurrent neural networks (RNNs) along the shortest dependency path.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2526–2536, Osaka, Japan, December 11-17 2016.

We have noticed that these neural models are all designed as the way that all words are equally important in the sentence, and contribute equally to the representation of the sentence meaning. However, various situations have shown that it is not always the case. For example,

"The $\langle e_1 \rangle$ *women* $\langle /e_1 \rangle$ *that caused the* $\langle e_2 \rangle$ *accident* $\langle /e_2 \rangle$ *was on the cell phone and ran thru the intersection without pausing on the median."*, where the type of relation is "Cause-Effect(e2,e1)".

Obviously, not all words contribute equally to the representation of the semantic relation. In this sentence, "caused" is of particular significance in determining the relation "Cause-Effect", but "phone" is less correlated with the semantic of the relation of "Cause-Effect". So how to identify critical cues which determine the primary semantic information is an important task.

If the relevance of words with respect to the target entities is effectively captured, we can find critical words which determine the semantic information. Hence, we propose to introduce the attention mechanism into a convolution neural network (CNN) to extract the words that are important to the meaning of the sentence and aggregate the representation of those informative words to form a sentence vector. The key contributions of our approach are as follows:

1. We propose a novel convolution neural network architecture that encodes the text segment to its semantic representation. Compared to existing neural relation extraction models, our model can make full use of the word embedding, part-of-speech tag embedding and position embedding.

2. Our convolution neural network architecture relies on the word level attention mechanism to choose important information for the semantic representation of the relation. This makes it possible to detect more subtle cues despite the heterogeneous structure of the input sentences, enabling it to automatically learn which parts are relevant to the given class.

3. Experiments on the SemEval-2010 Task 8 benchmark dataset show that our model achieves better performance with an F1 score of 85.9% than previous neural network models, and can achieve a competitive performance with an F1 score of 84.3% just with minimal feature engineering.

2 Related Works

A variety of learning paradigms have been applied to relation extraction. As mentioned earlier, supervised methods have shown to perform well in this task. In the supervised paradigm, relation classification is considered as a multi-classification problem, and researchers concentrate on extracting complex features, either feature-based or kernel-based. (Kambhatla, 2004; Suchanek et al., 2006) converted the classification clues (such as sequences and parse trees) into feature vectors. Various kernels, such as the convolution tree kernel (Qian et al., 2008), subsequence kernel (Mooney and Bunescu, 2005) and dependency tree kernel (Bunescu and Mooney, 2005), have been proposed to solve the relation classification problem. (Plank and Moschitti, 2013) introduced semantic information into kernel methods in addition to considering structural information only. However, the reliance on manual annotation, which is expensive to produce and thus limited in quantity has provided the impetus for distant-supervision (Mintz et al., 2009; Riedel et al., 2010; Hoffmann et al., 2011; Takamatsu et al., 2012).

With the recent revival of interest in deep neural networks, many researchers have concentrated on using deep networks to learn features. In NLP, such methods are primarily based on learning a distributed representation for each word, which is also called a word embedding (Turian et al., 2010). (Socher et al., 2012) presented a recursive neural network (RNN) for relation classification to learn vectors in the syntactic tree path connecting two nominals to determine their semantic relationship. (Hashimoto et al., 2013) also employed a neural relation extraction model allowing for the explicit weighting of important phrases for the target task. (Zeng et al., 2014) exploited a convolutional deep neural network to extract lexical and sentence level features. These two levels of features were concatenated to form the final feature vector. (Ebrahimi and Dou, 2015) rebuilt an RNN on the dependency path between two marked entities. (Xu et al., 2015b) used the convolutional network and proposed a ranking loss function with data cleaning. (Xu et al., 2015c) leveraged heterogeneous information along the shortest dependency path between two entities. (Xu et al., 2016) proposed a data augmentation method by leveraging the directionality of relations.

Another line of research is the attention mechanism for deep learning. (Bahdanau et al., 2014) pro-

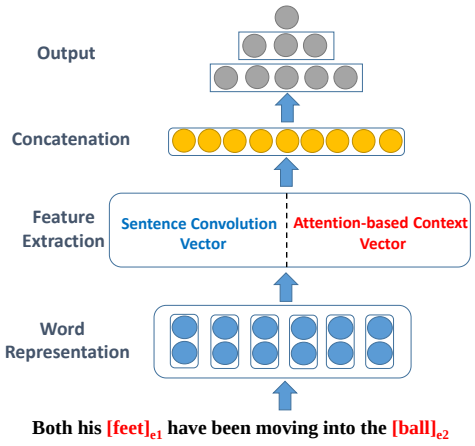

Figure 1: Architecture of the attention-based convolution neural network.

posed the attention mechanism in machine translation task, which is also the first use of it in natural language processing. This attention mechanism is used to select the reference words in the original language for words in the foreign language before translation. (Xu et al., 2015a) used the attention mechanism in image caption generation to select the relevant image regions when generating words in the captions. Further uses of the attention mechanism included paraphrase identification (Yin et al., 2015), document classification (Yang et al., 2016), parsing (Vinyals et al., 2015), natural language question answering (Sukhbaatar et al., 2015; Kumar et al., 2015; Hermann et al., 2015) and image question answering (Lin et al., 2015). (Wang et al., 2016) introduced attention mechanism into relation classification which relied on two levels of attention for pattern extraction. In this paper, we will explore the word level attention mechanism in order to discover better patterns in heterogeneous contexts for the relation classification task.

3 Methodology

Given a set of sentences $x_1, x_2, ...x_n$ and two corresponding entities, our model measures the probability of each relation r. The architecture of our proposed method is shown in Figure 1. Here, feature extraction is the main component, which is composed of sentence convolution and attention-based context selection. After feature extraction, two kinds of vectors – the sentence convolution vector and the attention-based context vector, are generated for semantic relation classification.

- **Sentence Convolution**: Given a sentence and two target entities, a convolutional neutral network (CNN) is used to construct a distributed representation of the sentence.
- **Attention-based Context Selection**: We use word-level attention to select relevant words with respect to the target entities.

3.1 Sentence Convolution

3.1.1 Input of Model

Word Embeddings. Figure 2 shows the architecture of our convolution neural network. In the word representation layer, each input word token is transformed into a vector by looking up word embeddings. (Collobert et al., 2011) reported that word embeddings learned from significant amounts of unlabeled data are far more satisfactory than the randomly initialized embeddings. Although it usually takes a long time to train the word embeddings, there are many freely available trained word embeddings. A comparison of the available word embeddings is beyond the scope of this paper. Our experiments directly utilize the embeddings trained by the CBOW model on 100 billion words of Google News (Mikolov et al., 2013).

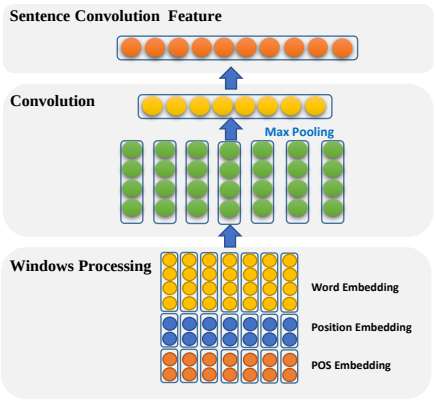

Figure 2: Architecture of convolution neural network.

Position Embeddings. In the task of relation extraction, the words close to the target entities are usually more informative in determining the relation between entities. Similar to (Zeng et al., 2014), we use position embeddings specified by entity pairs. It can help the CNN to keep track of how close each word is to the head or the tail entity, which is defined as the combination of the relative distances from the current word to the head or the tail entity. For example,

"The $\langle e_1 \rangle$ *game* $\langle /e_1 \rangle$ *was sealed in the original* $\langle e_2 \rangle$ *packing* $\langle /e_2 \rangle$ *unopened and untouched."*

In this sentence, the relative distance from the word "sealed" to the head entity "game" is 2 and the tail entity "packing" is -4. According to the above rule, we can obtain the relative distance from every word in the above sentence to each entity. We first create two relative distance files of entity e_1 and entity e_2. Then, we use the CBOW model to pretrain position embeddings on two relative distance files respectively (Mikolov et al., 2013). The dimension of position embedding is set 5.

Part-of-speech tag Embeddings. Our word embeddings are obtained from the Google News corpus, which is slightly different to the relation classification corpus. We deal with this problem by allying each input word with its POS tag to improve the robustness. In our experiment, we only take into use a coarse-grained POS category, containing 15 different tags. We use the Stanford CoreNLP Toolkit to obtain the part-of-speech tagging (Manning et al., 2014) . Then we pretrain the embeddings by the CBOW model on the taggings, and the dimension of part-of-speech tag embedding is set 10.

Finally, we concatenate the word embedding, position embedding, and part-of-speech tag embedding of each word and denote it as a vector of sequence $w = [WF, pF, POSF]$.

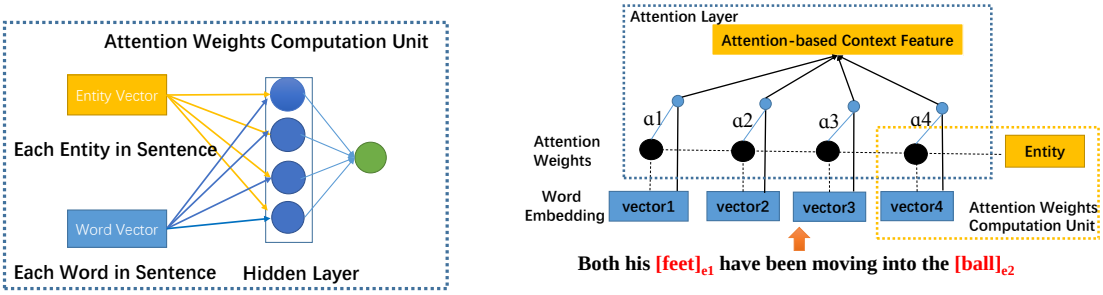
3.1.2 Convolution, Max-pooling and Non-linear Layers

In relation extraction, one of the main challenges is that, the length of the sentences is variable and important information can appear anywhere. Hence, we should merge all local features and perform relation prediction globally. Here, we use a convolutional layer to merge all these features. The convolutional layer first extracts local features with a sliding window of length l over the sentence. We assume that the length of the sliding window l is 3. Then, it combines all local features via a max-pooling operation to obtain a fixed-sized vector for the input sentence. Since the window may be outside of the sentence boundaries when it slides near the boundary, we set special padding tokens for the sentence. It means that we regard all out-of-range input vectors w_i ($i < 1$ or $i > m$) as zero vector.

Let $x_i \in R^k$ be the k-dimensional input vector corresponding to the ith word in the sentence. A sentence of length n (padded where necessary) is represented as:

$$x_{1:n} = x_1 \oplus x_2 \oplus x_3 \oplus ... \oplus x_n \tag{1}$$

where $\oplus$ is the concatenation operator. Let $x_{i:i+j}$ refer to the concatenation of words $x_i, x_{i+1}, ..., x_{i+j}$. A convolution operation involves a filter $w \in R^{hk}$, which is applied to a window of h words to produce a new feature. For example, a feature c_i is generated from a window of words $x_{i:i+h-1}$ by



(a) Attention weights computation unit.

(b) Attention layer network.

Figure 3: Architecture of attention layer network.

$$c_i = f(w \cdot x_{i:i+h-1}) \tag{2}$$

Here f is a non-linear function such as the hyperbolic tangent. This filter is applied to each possible window of words in the sentence $\{x_{1:h}, x_{2:h+1}, ..., x_{n-h+1:n}\}$ to produce a feature map:

$$\mathbf{c} = [c_1, c_2, ..., c_{n-h+1}] \tag{3}$$

with $c \in R^{n-h+1}$. We then apply a max-overtime pooling operation over the feature map and take the maximum value $\hat{c} = max\{\boldsymbol{c}\}$ as the feature. The idea is to capture the most important feature – one with the highest value – for each feature map. This pooling scheme naturally deals with variable sentence lengths.

3.2 Attention-based Context Selection

Our attention model is applied to a rather different kind of scenario, which consist of heterogeneous objects, namely a sentence and two entities. So we seek to give our model the capability to determine which parts of the sentence are most influential with respect to the two entities of interest. For instance,

"That coupled with the $\langle e_1 \rangle$ *death* $\langle /e_1 \rangle$ *and destruction caused by the* $\langle e_2 \rangle$ *storm* $\langle /e_2 \rangle$ *was a very traumatic experience for these residents."*.

Here, the type of relation is "Cause-Effect(e2,e1)".

In this sentence, the non-entity word "caused" is of particular significance in determining the relation "Cause-Effect". Fortunately, we can exploit the fact that there is a salient connection between "caused" and "death". We introduce a word attention mechanism to quantitatively model such contextual relevance of words with respect to the target entities.

In order to calculate the weight of each word in the sentence, we need to feed each word in the sentence and each entity to a multilayer perceptron (MLP). The network structure of the attention weight computation is shown in Figure 3 (a).

Assume that each sentence contains T words. w_{it} with $t \in [1, T]$ represents the words in the ith sentence. e_{ij} with $j \in [1, 2]$ represents the jth entity in the ith sentence. We concatenate the representation of entity e_{ij} and the representation of word w_{it} to get a new representation of word t, i.e., $h_{it}^j = [w_{it}, e_{ij}]$. u_{it}^j quantifies the degree of relevance of the tth word with respect to the jth entity in the ith sentence. This relevance scoring function is computed by the MLP network between the respective embeddings of the word w_{it} and the entity e_{ij}. We named the degree of relevance as the word attention weight, namely, u_{it}^j. The calculation procedure of u_{it}^j is as follows:

$$h_{it}^j = [w_{it}, e_{ij}] \tag{4}$$

$$u_{it}^j = W_a[\tanh(W_{we}h_{it}^j + b_{we})] + b_a \tag{5}$$

The output of the attention MLP network is u_{it}^{j}. Now we can get a normalized importance weight α_{it}^{j} through a softmax function.

$$\alpha_{it}^{j} = \frac{\exp(u_{it}^{j})}{\sum_{t} \exp(u_{it}^{j})} \tag{6}$$

The architecture of our proposed attention layer is shown in Figure 3 (b). After that, we compute the sentence context vector s_{ij} about entity j as a weighted sum of the word in the sentence i based on the weights as follows:

$$s_{ij} = \sum_{t} \alpha_{it}^{j} w_{it} \tag{7}$$

The context vector s_{ij} can be seen as a high level representation of a fixed query "what is the informative word" over the words. The weight of attention MLP network is randomly initialized and jointly learned during the training process.

3.3 MLP Layer

At last, we can obtain the output of three networks, which includes the result of convolution network, and the sentence context vectors of the two entities. We then concatenate all three output vectors into a fixed-length feature vector.

The fixed length feature vector is fed to a multi-layer perceptron (MLP), which is shown in Figure 1. More specifically, first, the vector obtained is fed into a full connection hidden layer to get a more abstractive representation, and then, this abstractive representation is connected to the output layer. For the task of classification, the outputs are the probabilities of different classes, which is computed by a softmax function after the fully-connected layer. We name the entire architecture of our model **Attention-CNN**.

3.4 Model Training

The relation classification model proposed here using attention-based convolutional neural network could be stated as a parameter vector θ. To obtain the conditional probability $p(i|x, \theta)$, we apply a softmax operation over all relation types:

$$p(i|x, \theta) = \frac{e^{o_i}}{\sum_{k=1}^{n} e^{o_k}} \tag{8}$$

Given all the T training examples $(x^{(i)}; y^{(i)})$, we can then write down the log likelihood of the parameters as follows:

$$\mathcal{J}(\theta) = \sum_{i=1}^{T} \log p(y^{i}|x^{i}, \theta) \tag{9}$$

To compute the network parameter of θ, we maximize the log likelihood $\mathcal{J}$ using stochastic gradient descent (SGD). θ are randomly initialized. We implement the back-propagation algorithm and apply the following update rule:

$$\theta \leftarrow \theta + \lambda \frac{\partial \log p(y|x, \theta)}{\partial \theta} \tag{10}$$

Minibatch size	32
Word embedding size	300
Word Position Embedding size	5
Part-of-speech tag Embeddings	10
Word Window size	3
Convolution size	100
Learning rate	0.02

Table 1: Hyperparameters of our model

4 Experiments

4.1 Dataset and Evaluation Metrics

We evaluated our model on the SemEval-2010 Task 8 dataset, which is an established benchmark for relation classification (Hendrickx et al., 2009). The dataset contains 8000 sentences for training, and 2717 for testing. We split 1000 samples out of the training set for validation.

The dataset distinguishes 10 relations, and the former 9 relations are directed, whereas the "Other" class is undirected. In our experiments, We do not distinguish the direction of the relationship. To compare our results with those obtained in previous studies, we adopt the macro-averaged F1-score in our following experiments.

4.2 Parameter Settings

In this section, we experimentally study the effects of different kinds of parameters in our proposed method: Word embedding size, Word Position Embedding size, Word Window size, Convolution size, Learning rate, and Minibatch size. For the initialization of the word embeddings used in our model, we use the publicly available word2vec vectors that were trained on 100 billion words from Google News. Words not present in the set of pre-trained words are initialized randomly. The other parameters are initialized by randomly sampling from the uniform distribution in [-0.1,0.1].

Model	Feature Sets	F_1
SVM	POS, stemming, syntactic pattern, WordNet	78.8
RNN	-	74.8
	+POS, NER, WordNet	77.6
MVRNN	-	82.4
	+POS, NER, WordNet	82.4
CNN	-	78.9
(Zeng et al., 2014)	+WordNet, words around nominals	82.7
FCM	depedency parsing, NER	83.0
CR-CNN	+WordNet, words around nominals	83.7
SDP-LSTM	POS, WordNet, grammar relation	83.7
	-	**84.3**
Attention-CNN	+WordNet, words around nominals	**85.9**

Table 2: Comparison of the proposed method with existing methods in the SemEval-2010 Task 8 dataset.

For other hyperparameters of our proposed model, we take those hyperparameters that achieved the best performance on the development set. The final hyper-parameters are shown in Table 1.

4.3 Results of Comparison Experiments

To evaluate the performance of our automatically learned features, we select six approaches as competitors to be compared with our method.

Table 2 summarizes the performances of our model, SVM (Hendrickx et al., 2009), RNN, MV-RNN (Socher et al., 2012), CNN (Zeng et al., 2014), FCM (Gormley et al., 2015), CR-CNN (Xu et al., 2015b), and SDP-LSTM (Xu et al., 2015c). All of the above models adopt word embedding as representation except SVM. For fair comparison among the different model, we also add two types of lexical features, WordNet hypernyms and words around nominals, as part of the fixed length feature vector to the MLP layer.

We can observe in Table 2 that, Attention-CNN, without extra lexical features such as WordNet and words around nominals, still outperforms previously reported best systems of CR-CNN and SDP-LSTM with F1 of 83.7%, though both of which have taken extra lexical features into account. It shows that our method can learn a robust and effective relation representation. When added with the same lexical features, our Attention-CNN model obtains the result of 85.9%, significantly better than CR-CNN and

SDP-LSTM. In general, richer feature sets lead to better performance. Such neural models as RNN, MVRNN, CR-CNN and SDP-LSTM can automatically learn valuable features, and all of these models heavily depend on the result of the syntactic parsing. However, the error of syntactic parsing will inevitably inhibit the ability of these methods to learn high quality features.

Similarly, Attention-CNN, CNN, and CR-CNN all apply convolution neural network to the extraction of sentence features, but we can see from Table 2 that Attention-CNN yield a better performance of 84.3%, compared with CNN and CR-CNN. One of the reason is that the input of the three models are different. Our model uses word embeddings, position embeddings, part-of-speech embeddings as input. CNN also leverages position embeddings and lexical features. CR-CNN makes use of heterogeneous information along the shortest dependency path between two entities. Our experiments verify that the part-of-speech embeddings used by us contain rich semantic information. On the other hand, our proposed Attention-CNN model can still yield higher F1 without prior NLP knowledge. The reason should be due to that word level attention mechanism is able to better choose which parts of the sentence are more discriminative with respect to the two entities of interest.

Feature Sets	F_1
WF	74.5
+pF	80.7
+POSF	82.6
+WA	84.3
+WA+(Lexical Feature)	85.9

Table 3: Score obtained for various sets of features on the test set. The bottom portion of the table shows the best combination of all the features.

4.4 Effect of Different Feature Component

Our network model primarily contains four sets of features, "Word Embeddings (WF)","Position Embeddings (pF)","Part-of-speech tag Embeddings (POSF)", and "Word Attention (WA)". We performed ablation tests on the four sets of features in Table 3 to determine which type of features contributed the most. From the results we can observe that our learned position embedding features are effective for relation classification. The F1-score is improved remarkably when position embedding features are added. POS tagging embeddings are comparatively more informative, which can boost the F1 by 1.9%. The system achieves approximately 2.3% improvements when adding Word Attention. When all features are combined, we achieve the best result of 85.9%.

4.5 Visualization of Attention

In order to validate whether our model is able to select informative words in a sentence or not, we visualize the word attention layers in Figure 4 for several data from test sets.

Every line in Figure 4 shows a sentence. The size of a word denotes the importance of it. We normalize the word weight to make sure that only important words are emphasized. Given the following sentence as an example,

"The burst has been caused by water hammer pressure."

we can find that the word "caused" was assigned the highest attention score, while words such as "burst" and "pressure" also are important. This makes sense in light of the ground-truth labeling as a "Cause-Effect" relationship. Additionally, we observe that words like "The", "has" and "by" have low attention scores. These are indeed rather irrelevant with respect to the "Component-Whole" relationship.

5 Conclusion

In this paper, we propose an attention-based convolutional neural network architecture for semantic relation extraction. Here, the convolutional neural network architecture is used to extract the features

Relation	Representation of Word Attention Weight
Instrument-Agency	The author of a keygen uses a disassembler to look at the raw assembly code
Message-Topic	The Pulitzer Committee issues an official citation explaining the reasons for the award
Cause-Effect	The burst has been caused by water hammer pressure
Instrument-Agency	Even commercial networks have moved into high-definition broadcast
Component-Whole	The girl showed a photo of apple tree blossom on a fruit tree in the Central Valley
Member-Collection	They tried an assault of their own an hour later, with two columns of sixteen tanks backed by a battalion of Panzer grenadiers

Figure 4: Visualization of Attention.

of the sentence. Our model can make full use of word embedding, part-of-speech tag embedding and position embedding information. Meanwhile, word level attention mechanism is able to better determine which parts of the sentence are most influential with respect to the two entities of interest. Experiments on the SemEval-2010 Task 8 benchmark dataset show that our model achieves better performances than several state-of-the-art systems.

In the future, we will focus on exploring better neural network structure about feature extraction in relation extraction. Meanwhile, because end-to-end relation extraction is also an important problem, we will seek better methods for completing entity and relation extraction jointly.

Abstract

This paper proposes a novel context-aware joint entity and word-level relation extraction approach through semantic composition of words, introducing a Table Filling Multi-Task Recurrent Neural Network (TF-MTRNN) model that reduces the entity recognition and relation classification tasks to a table-filling problem and models their interdependencies. The proposed neural network architecture is capable of modeling multiple relation instances without knowing the corresponding relation arguments in a sentence. The experimental results show that a simple approach of piggybacking candidate entities to model the label dependencies from relations to entities improves performance.

We present state-of-the-art results with improvements of 2.0% and 2.7% for entity recognition and relation classification, respectively on CoNLL04 dataset.

1 Introduction

Relation classification is defined as the task of predicting the semantic relation between the annotated pairs of nominals (also known as relation arguments). These annotations, for example named entity pairs participating in a relation are often difficult to obtain. Traditional methods are often based on a pipeline of two separate subtasks: Entity Recognition (ER[1]) and Relation Classification (RC), to first detect the named entities and then performing relation classification on the detected entity mentions, therefore ignoring the underlying interdependencies and propagating errors from the entity recognition to relation classification. The two subtasks together are known as End-to-End relation extraction.

Relation classification is treated as a sentence-level multi-class classification problem, which often assume a single relation instance in the sentence. It is often assumed that entity recognition affects the relation classification, but it is not affected by relation classification. Here, we reason with experimental evidences that the latter is not true. For example, in Figure 1, relation *Work_For* exists between *PER* and *ORG* entities, *ORGBased_in* between *ORG* and *LOC*, while *Located_In* between *LOC* and *LOC* entities. Inversely, for a given word with associated relation(s), the candidate entity types can be detected. For example, in Figure 2, for a given relation, say *Located_in*, the candidate entity pair is (*LOC*, *LOC*). Therefore, the two tasks are interdependent and optimising a single network for ER and RC to model the interdependencies in the candidate entity pairs and corresponding relations is achieved via the proposed joint modeling of subtasks and a simple piggybacking approach.

Joint learning approaches (Roth and Yih, 2004; Kate and Mooney, 2010) built joint models upon complex multiple individual models for the subtasks. (Miwa and Sasaki, 2014) proposed a joint entity and relation extraction approach using a history-based structured learning with a table representation; however, they explicitly incorporate entity-relation label interdependencies, use complex features and search heuristics to fill table. In addition, their state-of-the-art method is structured prediction and not based on neural network frameworks. However, *deep learning* methods such as recurrent and convolutional neural networks (Zeng et al., 2014; Zhang and Wang, 2015; Nguyen and Grishman, 2015) treat relation

Table 1: Entity-Relation Table for the example in Figure 1. Demonstrates the word-level relation classification via a Table-Filling problem. The symbol (⊥) indicates *no_relation* word pair. Relations are defined on the words, instead of entities. The diagonal entries have the entity types and ⊥ relations to the words itself, while the off-diagonal entries are the relation types.

classification as a sentence-level multi-class classification, and rely on the relation arguments provided in the sentence. Therefore, they are incapable in handling multiple relation instances in a sentence and can not detect corresponding entity mention pairs participating in the relation detected.

We tackle the limitations of joint and deep learning methods to detect entities and relations. The contributions of this paper are as follows:

1. We propose a novel Table Filling Multi-task Recurrent Neural Network to jointly model entity recognition and relation classification tasks via a unified multi-task recurrent neural network. We detect both entity mention pairs and the corresponding relations in a single framework with an entity-relation table representation. It alleviates the need of search heuristics and explicit entity and relation label dependencies in joint entity and relation learning. As far as we know, it is the first attempt to jointly model the interdependencies in entity and relation extraction tasks via multi-task recurrent neural networks.

   We present a word-level instead sentence-level relation learning via word-pair compositions utilising their contexts via Context-aware RNN framework. Our approach has significant advantage over state-of-the-art methods such as CNN and RNN for relation classification, since we do not need the marked nominals and can model multiple relation instances in a sentence.

2. Having named-entity labels is very informative for finding the relation type between them, and vice versa having the relation type between words eases problem of named-entity tagging. Therefore, a simple approach to piggyback candidate named entities for words (derived from the associated relation type(s) for each word) to model label dependencies improves the performance of our system. In addition, the sequential learning approach in the proposed network learns entity and relation label dependencies via sharing model parameters and representations, instead modeling them explicitly.

3. Our approach outperforms the state-of-the-art method by 2.0% and 2.7% for entity recognition and relation classification, respectively on CoNLL04 dataset.

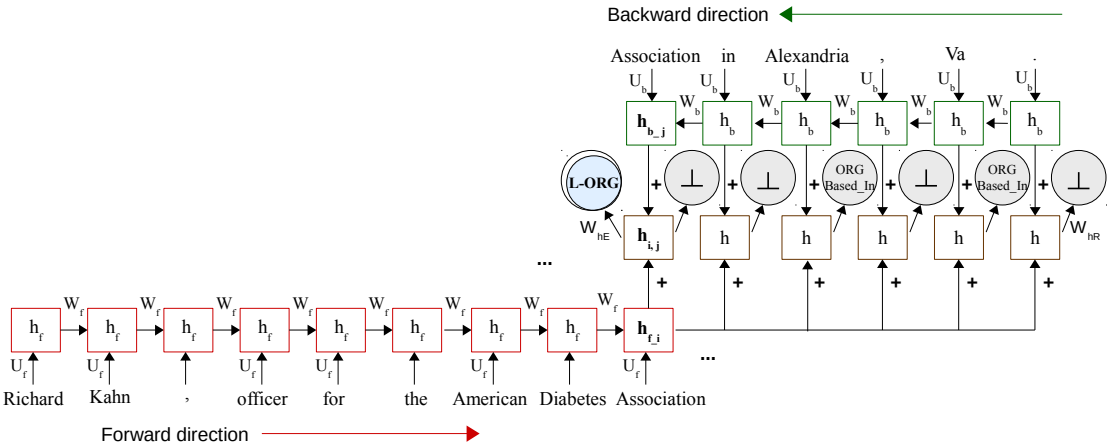

Figure 3: The Table Filling Multi-Task Recurrent Neural Network (TF-MTRNN) for joint entity and word-level relation extraction. Overlapping circle: Entity labels; Single circle: Relation label. In the above illustration, the word *Association* at $t = i$ (where; $t = 0, ..., i, ..., N$) from forward network is combined with each of the remaining words in the sequence (Figure 1), obtained from backward network at each time step, $j = i, ..., N$. Similarly, perform all possible word pair compositions to obtain Table 1. *ORGBased_In* relation in each word-pairs: (*Association*, *Alexandria*) and (*Association*, *Va*).

2 Methodology

2.1 Entity-Relation Table

As the backbone of our model we adopt the table structure proposed by Miwa and Sasaki (2014), shown in Table 1. This structure allows an elegant formalization of joint entity and relation extraction because both entity and relation labels are defined as instances of binary relations between words w_i and w_j in the sentence. An entity label is such a binary relationship for $i = j$, i.e., a cell on the diagonal. A relation label is such a binary relationship for $i \neq j$, i.e., an off-diagonal cell. To eliminate redundancy, we stipulate that the correct label for the pair (w_i, w_j) is relation label r if and only if $i \neq j$, w_i is the last word of a named entity e_i, w_j is the last word of a named entity e_j and $r(e_i, e_j)$ is true.[2] We introduce the special symbol $\perp$ for "no_relation", i.e., no relation holds between two words.

Apart from the fact that it provides a common framework for entity and relation labels, another advantage of the table structure is that modeling multiple relations per sentence comes for free. It simply corresponds to several (more than one) off-diagonal cells being labeled with the corresponding relations.

2.2 The Table Filling Multi-Task RNN Model

Formally, our task for a sentence of length n is to label $n(n+1)/2$ cells. The challenge is that the labeling decisions are highly interdependent. We take a deep learning approach since deep learning models have recently had success in modeling complex dependencies in NLP. More specifically, we apply recurrent neural networks (RNNs) (Elman, 1990; Jordan, 1986; Werbos, 1990) due to their success on complex NLP tasks like machine translation and reasoning.

To apply RNNs, we order the cells of the table into a sequence as indicated in Figure 4 and label – or "fill" – the cells one by one in the order of the sequence. We call this approach *table filling*.

More specifically, we use a bidirectional architecture (Vu et al., 2016b), a forward RNN and a backward RNN, to fill each cell (i, j) as shown in Figure 3. The forward RNN provides a representation of the history $w_1, \ldots, w_i$. The backward network provides a representation of the following context $w_j, \ldots, w_{|s|}$. The figure shows how the named entity tag for "Association" is computed. The forward RNN is shown as the sequence at the bottom. h_{f_i} is the representation of the history and h_{b_j} is the representation of the following context. Both are fed into $h_{i,j}$ which then predicts the label L-ORG. In this case, $i = j$. The prediction of a relation label is similar, except that in that case $i \neq j$.

[2]Relation types (excluding $\perp$) exist only in the word pairs with entity types: (L-*, L-*), (L-*, U-*), (U-*, L-*) or (U-*, U-*), where * indicates any entity type encoded in BILOU (Begin, Inside, Last, Outside, Unit) scheme.

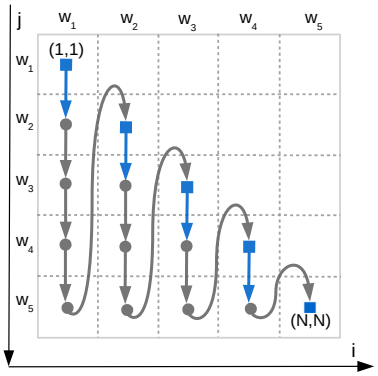

Figure 4: Table Filling/Decoding Order. Filled squares in blue represent both entity and relation label assignments, while filled circles in gray represent only relation label assignments, analogous to entries in Table 1. (i, j) is the cell index in the table, where i and j are the word indices in the sequence.

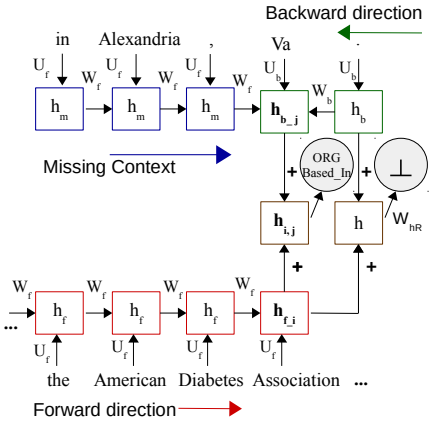

Figure 5: The context-aware TF-MTRNN model. (...) indicates the remaining word pair compositions (Table 1).

Our proposed RNN based framework jointly models the entity and relation extraction tasks to learn the correlations between them, by sharing the model parameters and representations. As illustrated in Figure 3, we use two separate output nodes and weight matrices each for entity and relation classification. An entity label is assigned to a word, while a relation is assigned to a word pair; therefore, EE is performed only when the same words from forward and backward networks are composed.

Dynamics of the proposed TF-MTRNN architecture (Figure 3) are given below:

$$\begin{aligned} s_{R_{i,j\in i:N}} &= g(W_{hR}h_{i,j}); \qquad s_{E_{i,j=i}} = g(W_{hE}h_{i,j}); \qquad h_{i,j} = h_{f_i} + h_{b_j} \\ h_{f_i} &= f(U_f w_i + W_f h_{f_{i-1}}); \qquad h_{b_j} = f(U_b w_j + W_b h_{b_{j+1}}) \end{aligned} \tag{1}$$

where i and j are the time-steps of forward and backward networks, respectively. ith word in the sequence is combined with every jth word, where $j = i, ..., N$ (i.e. combined with itself and the following words in the sequence). N is the total number of words in the sequence. For a given sequence, $s_{R_{i,j}}$ and $s_{E_{i,j}}$ represent the output scores of relation and entity recognition for ith and jth word from forward and backward networks, respectively. Observe that EE is performed on the combined hidden representation $h_{i,j}$, computed from the composition of representations of the same word from forward and backward networks, therefore $i = j$ and resembling the diagonal entries for entities in Table 1. h_{f_i} and h_{b_j} are hidden representations of forward and backward networks, respectively. W_{hR} and W_{hE} are weights between hidden layers ($h_{i,j}$) and the output units of relation and entity, respectively. f and g are activation and loss functions. Applying $argmax$ to $s_{R_{i,j\in i:N}}$ and $s_{E_{i,j=i}}$ gives corresponding table entries for relations and entities, in Table 1 and Figure 4.

2.3 Context-aware TF-MTRNN model

In Figure 3, we observe that when hidden representations for the words *Association* and *Va* are combined, the middle context i.e. all words in the sequence occurring between the word pair in composition are missed. Therefore, we introduce a third direction in the network (Figure 5) with missing context (i.e. *in Alexandria ,*) to accumulate the full context in combined hidden vectors ($h_{i,j}$).

Dynamics of the context-aware TF-MTRNN is similar to Eq. 1, except h_{b_j}, in Figure 5:

$$\begin{aligned} h_{b_j} &= f(U_b w_j + W_b h_{b_{j+1}} + U_f h_{m_{t=T}}) \\ h_{b_{j+1}} &= f(U_b w_{j+1} + W_b h_{b_{j+2}}); \qquad h_{m_t} = f(U_f w_t + W_f h_{m_{t-1}}) \end{aligned} \tag{2}$$

where h_{b_j} is the hidden representation in backward network obtained from the combination of jth word and contexts from backward network and from missing direction, $t = (i + 1, ..., T = j - 1)$, where i and j are the time-steps for forward and backward networks, respectively. $h_{m_{t=i}}$ is initialized with zeros similar to forward and backward networks. There is no missing context when $i = 0$ and $j = 0$ i.e. w_t is NULL and therefore, we introduce an artificial word *PADDING* and use its embedding to initialise w_t.

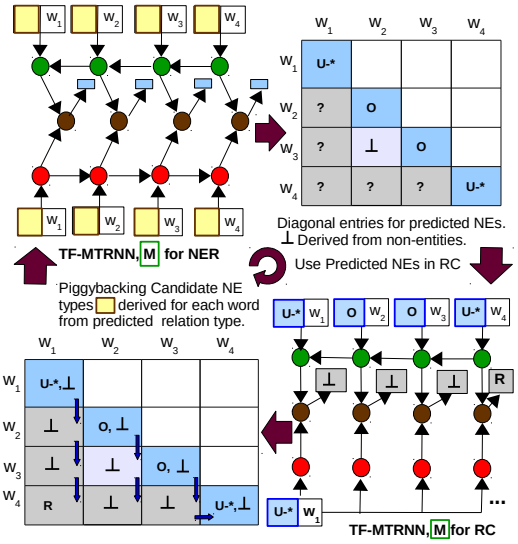

Figure 6: End-to-End Relation Extraction by jointly modeling entity and relation in a unified Multi-task RNN framework, M (TF-MTRNN) and filling an Entity-Relation table. Figure 8: State Machine driven Multi-task Learning. ER:Entity Recognition; RC:Relation Classification; lr:learning rate; $ER - ValidBestF1$:Best entity recognition F_1 score on validation set.

2.4 Piggybacking for Entity-Relation Label Dependencies

Having named-entity labels is very informative for finding the relation type between them, and vice versa having the relation type between words eases problem of named-entity tagging. We model these label interdependencies during the end-to-end relation extraction in Figure 6, where the input vector at time step, t is given by -

$$input_t = \{C_{RE}, E_{ER}, W_{emb}\} \tag{3}$$

where C_{RE} is the count vector to model relation to entity dependencies, E_{ER} is the one-hot vector for predicted entities to model entity to relation dependencies and W_{emb} is the word embedding vector. Therefore, the input vector at each time step, t is the concatenation of these three vectors.

To model *entity to relation* dependency, the TF-MTRNN model, M for NER (Figure 6) first computes entity types, which are represented by diagonal entries of entity-relation table. Each predicted entity type E_{ER} (filled blue-color boxes) is concatenated with its corresponding word embedding vector W_{emb} and then input to the same model, M for relation classification.

To model *relation to entity* dependency, we derive a list of possible candidate entity tags for each word participating in a relation(s), except for $\perp$ relation type. Each word associated with a relation type(s) is determined from relation classification (RC) step (Figure 6). Figure 7 illustrates the entity type count vector for each word of the given sentence (Figure 1). For example, the word *Alexandria* participates in the relation types: *ORGBased_In* and *Located_In*. Possible entity types are {*U-ORG*, *L-ORG*, *U-LOC*, *L-LOC*} for *ORGBased_In*, while {*U-LOC*, *L-LOC*} for *Located_In*. We then compute a count vector C_{RE} from these possible entity types. Therefore, *U-LOC* and *L-LOC* each with occurrence 2, while *U-ORG* and *L-ORG* each with occurrence 1 (Figure 7). The candidate entity types as count vector (filled-yellow color box) for each word is piggybacked to model, M for entity learning by concatenating it with corresponding word embedding vector W_{emb}. This simple approach of piggybacking the count vectors of candidate entities enables learning label dependencies from *relation to entity* in order to improve entity extraction. In addition, multi-tasking by sharing parameters and adapting shared embeddings within a unified network enables learning label interdependencies.

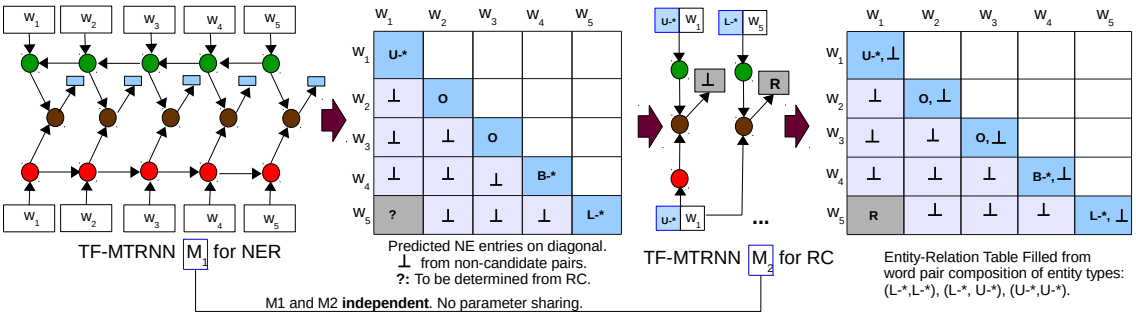

Figure 9: Pipeline Approach in End-to-End Relation Extraction.

2.5 Ranking Bi-directional Recurrent Neural Network (R-biRNN)

Ranking loss has been used in neural architectures (dos Santos et al., 2015) and (Vu et al., 2016b) to handle *artificial* classes. In our experiments, for a given sentence x with class label y^+, the competitive class c^- is chosen the one with the highest score among all competitive classes during SGD step. The basic principle is to learn to maximize the distance between the true label y^+ and the best competitive label c^- for a given data point x. We use the ranking loss to handle the two artificial classes i.e. 'O' and $\perp$ in entity and relation types, respectively. The ranking objective function is defined as-

$$L = \log(1 + \exp(\gamma(m^+ - s_\theta(x)_{y^+}))) + \log(1 + \exp(\gamma(m^- + s_\theta(x)_{c^-})));$$
$$c^- = \arg \max_{c \epsilon C; c \neq y^+} s_\theta(x)_c \tag{4}$$

where $s_\theta(x)_{y^+}$ and $s_\theta(x)_{c^-}$ are the scores for positive y^+ and the most competitive c^- classes. γ controls the penalization of the prediction errors while hyperparameters m^+ and m^- are the margins for the true and competitive classes. We set $\gamma = 2, m^+ = 2.5, m^- = 0.5$, following (Vu et al., 2016b).

The unified architecture (Figure 3) can be viewed as being comprised of two individual models, each for NER and RE (Figure 6). We illustrate that the R-biRNN (Figure 12 in Appendix A) is integrated in TF-MTRNN (Figure 3) and therefore, the unified model leverages R-biRNN (Vu et al., 2016b) effectiveness for entity extraction, where the full context information is availed from the forward and backward network at each input word vector along with the ranking loss at each output node. Figure 12 corresponds to the diagonal entries for named entities in Table 1 and enables entity-entity label dependencies (Miwa and Sasaki, 2014) via sequential learning.

3 Model Training

3.1 End-to-End Relation Extraction

In CoNLL04, more than 99% of the whole word pairs lie in the no_relation class. Therefore, named-entity candidates are required to choose the candidate word pairs in relation learning. In Figure 6 and Figure 9, we demonstrate the joint and pipeline approach for end-to-end relation extraction.

In Figure 6, the candidate relation pairs are chosen by filtering out the non-entities pairs. Therefore, in entity-relation table, we insert 'no_relation' label for the non-entities pairs and RC is not performed. Note that a word pair is chosen for RC in which at least one word is an entity. It allows the model M to correct itself at NER by piggybacking candidate named entities (Figure 7). In addition, it reduces a significant number of non-relation word pairs and does not create a bias towards the no_relation class. However, in Figure 9, the two independent models, M_1 and M_2 are trained for NER and RC, respectively. In pipeline approach, the only relation candidates are word pairs with (U-*, U-*),(L-*, L-*) or (U-*, L-*) entity types. Therefore, only w_1 and w_5 from word sequence are composed in M_2 for RC subtask.

Figure 11: T-SNE view of the semantic entity-relation space for the combined hidden representations of each word pair composition. Relations: (0:*LIVEIN*, 1:*ORGBASEDIN*, 2:*LOCATEDIN*, 3:*WORKFOR*, 4:*KILL*, 5:*NORELATION*). Entity-pair and relation denoted by E1-RELATION-E2 and/or count in [0-5]. 5: misclassified entity-pairs.

3.2 Word Representation and Features

Each word is represented by concatenation of pre-trained 50-dimensional word embeddings[3] (Turian et al., 2010) with N-gram, part-of-speech (POS), capital feature (CF: all-capitalized; initial-capitalized) and piggybacked entity vectors (Section 2.4). The word embeddings are shared across entity and relation extraction tasks and are adapted by updating them during training. We use 7-gram $(w_{t-3}w_{t-2}w_{t-1}w_tw_{t+1}w_{t+2}w_{t+3})$ obtained by concatenating corresponding word embeddings.

3.3 State Machine driven Multi-tasking

Multi-task training is performed via switching across multiple tasks in a block of training steps. However, we perform switches between ER and RC subtasks based on the performance of each task on the common validation set and update learning rate only when task is switched from RC to ER (Figure 8). ER is the task to start for multi-tasking and ER/RC is switched in the following training step, when their $ValidF1$ score is not better than $BestValidF1$ score of previous steps on the validation set.

4 Evaluation and Analysis

4.1 Dataset and Experimental Setup

We use CoNLL04[4] corpus of Roth and Yih (2004). Entity and relation types are shown in Figure 2. There are 1441 sentences with at least one relation. We randomly split these into training (1153 sentences) and test (288 sentences), similar to Miwa and Sasaki (2014). We release this train-test split at `https://github.com/pgcool/TF-MTRNN/tree/master/data/CoNLL04`. We introduce the pseudo-label $\perp$ "no_relation" for word pairs with no relation.

To tune hyperparameters, we split (80-20%) the training set (1153 sentences) into $train$ and validation (dev) sets. All final models are trained on $train$+dev. Our evaluation measure is F_1 on entities and relations. An entity is marked correct if NE boundaries and entity type[5] are correct. A relation for a word pair is marked correct if the NE boundaries and relation type are correct. However, in separate approach, a relation for a word pair is marked correct if the relation type is correct.

[3] with a special token PADDING. Also, used when there is no missing context.

Table 2: State-of-the-art comparison for EE and RE on CoNLL04 dataset.

4.2 Results

Figure 10 shows results for NER[6] and RE. All models use n-grams for $n = 7$ (Section 3.2). Embedding dimensionality is 50. The notation "+" (e.g., +POS) at the beginning of a line indicates that the model of this line is the same as the model on the previous line except that one more model element (e.g., POS) is added. The separate NER model performs NER only. The separate RE model performs RE only, without access to NER results. The pipeline RE model takes the results of the separate NER model and then performs RE. The joint model is trained jointly on NER and RE. For compactness, we show the results of *two different models* (an NER model and an RE model) in the separate part of the table; in contrast, results for a *single model* – evaluated on both NER and RE – are shown in the joint part.

We make the following observations based on Figure 10. (i) All of our proposed model elements (POS, CF, CTX, piggybacking, ensemble) improve performance, in particular CTX and piggybacking provide large improvements. (ii) Not surprisingly, the pipeline RE model that has access to NER classifications performs better than the separate RE model. (iii) The joint model performs better than separate and pipeline models, demonstrating that joint training and decoding is advantageous for joint NER and RE. (iv) Majority voting[7] (ensemble) results in a particularly large jump in performance and in the overall best performing system; F_1 is .936 for NER and .721 for RE, respectively.

4.3 Comparison with Other Systems

Our end-to-end relation extraction system outperform the state-of-the-art results. We compare the entity and relation extraction performance of our model with other systems (Roth and Yih, 2007; Kate and Mooney, 2010; Miwa and Sasaki, 2014). (Roth and Yih, 2007) performed 5-fold cross validation on the complete corpus (1441 sentences), while (Miwa and Sasaki, 2014) performed 5-cross validation on the data set, obtained after splitting the corpus. We report our results on the test set from random split (80-20%) of the corpus, similar to (Miwa and Sasaki, 2014). Since, the standard splits were not available, we cannot directly compare the results, but our proposed model shows an improvement of 2.0% and 2.7% in F_1 scores for entity and relation extraction tasks, respectively (Table 2).

[6]Our NER model reports 86.80% F1 score, comparable to 86.67% from (Lample et al., 2016) on CoNLL03 shared task using the standard NER evaluation script with strict multi-word entity evaluation, and adapted for BILOU encoding.

[7]Randomly pick one of the most frequent classes, in case of a tie

4.4 Word pair Compositions (T-SNE)

Using t-SNE (der Maaten and Hinton, 2008), we visualize the hidden representations obtained on the composition of hidden vectors of every two words (word pair) in the sentence via TF-MTRNN model. In Figure 11, we show all data points i.e. word pair compositions, leading to natural relations (except $\perp$ denoted by 5). We observe that the entity mention pairs with common relation types form clusters corresponding to each relation in the semantic entity-relation space. We observe that the relation clusters with common entity type lie close to each other, for example, *KILL* has (*PER*, *PER*) entity pairs, which is close to relation cluster *LIVEIN* and *WORKFOR*, in which one of the entities i.e. *PER* is common. While, *KILL* relation cluster is at a distance from *LOCATEDIN* cluster, since they have no common entity.

4.5 Hyperparamter Settings

We use stochastic gradient descent with L2 regularization with a weight of .0001. The initial learning rate for entity and relation extraction is .05 with hidden layer size 200. The learning rate update and task switching is driven by the state machine (Figure 8). Models are trained for 40 iterations performing stochastic gradient descent. We initialize the recurrent weight matrix to be identity and biases to be zero. We use Capped Rectified Linear units (CappedReLu) and ranking loss with default parameters (section 2.5). The entity vectors C_{RE} and E_{ER} are initialized with zero when NER is performed for the first time in entity and relation extraction loop (Figure 6). The models are implemented in Theano (Bergstra et al., 2010; Bastien et al., 2012).

5 Related Work

Recurrent and convolutional neural networks (Zeng et al., 2014; Nguyen and Grishman, 2015; Zhang and Wang, 2015; Vu et al., 2016a) have delivered competitive performance for sentence-level relation classification. Socher et al. (2012) and Zhang and Wang (2015) proposed recurrent/recursive type neural networks to construct sentence representations based on dependency parse trees. However, these sentence-level state-of-the-art methods do not model the interdependencies of entity and relation, do not handle multiple relation instances in a sentence and therefore, can not detect entity mention pairs for the sentence-level relations. Our approach is a joint entity and word-level relation extraction capable to model multiple relation instances, without knowing nominal pairs.

Existing systems (Roth and Yih, 2004; Kate and Mooney, 2010; Miwa and Sasaki, 2014) are complex feature-based models for joint entity and relation extraction. The most related work to our method is (Miwa and Sasaki, 2014); however they employ complex search heuristics (Goldberg and Elhadad, 2010; Stoyanov and Eisner, 2012) to fill the entity-relation table based on structured prediction method. They explicitly model the label dependencies and their joint approach is not based on neural networks. Multi-task learning (Caruana, 1998) via neural networks (Zhang and Yeung, 2012; Seltzer and Droppo, 2013; Dong et al., 2015; Li and J, 2014; Collobert and Weston, 2008) have been used to model relationships among the correlated tasks. Therefore, we present a unified neural network based multi-task framework to model the entity-relation table for end-to-end relation extraction.

6 Conclusion

We proposed TF-MTRNN, a novel architecture that jointly models entity and relation extraction, and showed how an entity-relation table is mapped to a neural network framework that learns label interdependencies. We introduced word-level relation classification through composition of words; this is advantageous in modeling multiple relation instances without knowing the corresponding entity mentions in a sentence. We also introduced context-awareness in RNN network to incorporate missing information, and investigated piggybacking approach to model entity-relation label interdependencies.

Experimental results show that TF-MTRNN outperforms state-of-the-art method for both entity and relation extraction tasks.

Abstract

Parallel sentence representations are important for bilingual and cross-lingual tasks in natural language processing. In this paper, we explore a bilingual autoencoder approach to model parallel sentences. We extract sentence-level global descriptors (e.g. *min*, *max*) from word embeddings, and construct two monolingual autoencoders over these descriptors on the source and target language. In order to tightly connect the two autoencoders with bilingual correspondences, we force them to share the same decoding parameters and minimize a corpus-level semantic distance between the two languages. Being optimized towards a joint objective function of reconstruction and semantic errors, our bilingual antoencoder is able to learn continuous-valued latent representations for parallel sentences. Experiments on both intrinsic and extrinsic evaluations on statistical machine translation tasks show that our autoencoder achieves substantial improvements over the baselines.

1 Introduction

Neural sentence modeling that learns continuous-valued vector representations for sentences in a low-dimensional latent semantic space, has recently attracted considerable interests in the field of nature language processing (NLP). A variety of models have been proposed (Collobert and Weston, 2008; Socher et al., 2011; Mikolov et al., 2011; Hermann and Blunsom, 2013; Kalchbrenner and Blunsom, 2013; Kalchbrenner et al., 2014; Kim, 2014; Ma et al., 2015; Tai et al., 2015; Zhang et al., 2015a). Most of these models, however, focus on monolingual cases where sentences from a single language are modeled. They do not explore semantic correspondences among parallel sentences. On account of this, monolingual neural sentence models are not naturally fit for bilingual or cross-lingual NLP tasks, such as machine translation, cross-lingual classification and information retrieval.

In order to induce sentence representations in a bilingual rather than monolingual semantic space, researchers have proposed a few approaches, following efforts of bilingual word embeddings (Klementiev et al., 2012; Zou et al., 2013). These studies either explore *recursive/recurrent* neural networks (Zhang et al., 2014; Su et al., 2015) or *bag-of-words* based neural networks (Yih et al., 2011; Chandar et al., 2014; Lauly et al., 2014; Hermann and Blunsom, 2014; Zhou et al., 2015) to learn bilingual sentence representations. The former recursively compose sentences from the bottom up, taking into account bilingual constraints from word alignments. Due to the complexity, they are not easy to be scalable. Additionally, they also suffer from errors and noises of word alignments. In contrast, the latter are relatively simple and scalable. However, they often heavily rely on only one descriptor of the bag-of-words embeddings (e.g. the *avg* representation) and hence are weak in capturing fine-grained complex linguistic phenomena. Therefore we believe that modeling parallel sentences still remains a serious challenge.

Inspired by works on multimodal autoencoders (Ngiam et al., 2011; Wang et al., 2014; Feng et al., 2014; Feng et al., 2015), we explore a novel bilingual autoencoder to model parallel sentences, which is able to incorporate global semantic information into sentence representations. The overall architecture

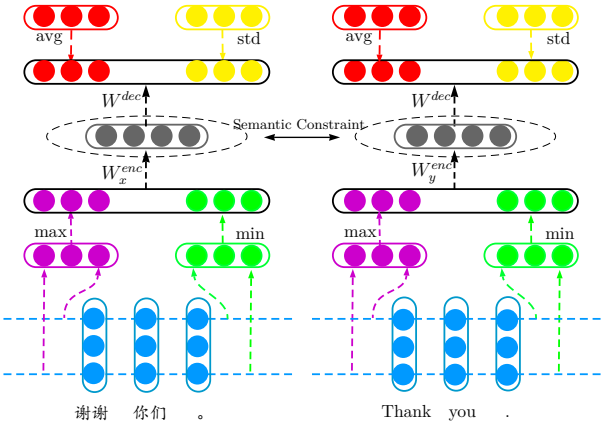

Figure 1: The architecture of our bilingual autoencoder visualized with a parallel sentence pair. Word embeddings are represented in blue color, while the *avg*, *std*, *min* and *max* descriptors are indicated in red, yellow, green and purple colors, respectively. Specifically, we use gray color to denote the hidden layer. The subscripts x and y indicate the source and target language respectively, and the superscripts enc and dec indicate the encoding and decoding process. Each dash line with its corresponding color depicts the information related with that specific descriptor, and the black ellipse around the hidden layer means that the bilingual semantic constraint is built at the corpus rather than sentence level.

is illustrated in Figure 1.[1] It is fast and scalable as we do not use complex recursiveness or recurrence. Comparing with conventional bag-of-words based autoencoders, our model explores several complementary sentence-level statistical descriptors, i.e., *min* (minimum), *max* (maximum), and *avg* (average), *std* (standard deviation) computed over all word vectors, to capture high-level global features. These descriptors alleviate the weakness of conventional bag-of-words representations in feature extraction and their insensitiveness to semantic constraints between sentences. The proposed autoencoder further encodes global descriptors (e.g., *min*, *max*) into hidden representations, and then decodes them into the other descriptors (e.g., *avg*, *std*). In order to capture bilingual correspondences, we force our autoencoder to share the decoding parameters across two languages (i.e., the same W^{dec} in Figure 1), and further optimize the parameters with respect to a corpus-level semantic constraints between the source and target language. This architecture tightly connects two monolingual autoencoders and bridges the gaps between the source and target semantic spaces.

To evaluate the effectiveness of our proposed bilingual autoencoder, we conduct both intrinsic and extrinsic evaluations on statistical machine translation (SMT) tasks. The intrinsic evaluation measures the capability of our model in semantic similarity calculation, while the extrinsic evaluation examines whether our model can be used to improve machine translation quality. Results on the NIST 2006 and 2008 datasets show that our autoencoder can significantly outperform the baseline methods. The main contributions of our work lie in the following three aspects:

- The proposed autoencoder learns bilingual representations for parallel sentences using global descriptors. To the best of our knowledge, this architecture has never been investigated before.
- We incorporate the corpus- rather than sentence-level semantic constraint into sentence embeddings, and share the decoding parameters to further bridge the semantic spaces of two different languages.
- Our model does not rely on word alignments. It is scalable, simple yet effective.

2 Related Work

Previous studies that are related to our work can be roughly divided into three groups: neural sentence modeling, multimodal autoencoders and bilingual autoencoders. We will briefly describe them in this

[1]For illustration, we set the dimensionality of word embedding to 3. Besides, we also omit the dash lines from word embeddings to *avg* and *std* descriptors. Without loss of generality, throughout this paper we assume the input and target to be *min*, *max* and *avg*, *std* respectively.

section and highlight the differences of our work from them.

neural sentence modeling (NSM): NSM is able to provide distributed sentence representations for many NLP tasks. One natural approach to NSM is to produce sentence representations from word embeddings with recursive or recurrent neural networks via composition (Socher et al., 2011; Mikolov et al., 2011; Hermann and Blunsom, 2013). To preserve sequence information over time, Tai et al. (2015) further incorporate LSTMs into tree-structured recursive networks. Unlike these composition-based methods, convolutional neural models utilize convolution layers to explicitly capture task-specific n-grams (Collobert and Weston, 2008; Kalchbrenner et al., 2014; Kim, 2014; Ma et al., 2015; Zhang et al., 2015a). Kalchbrenner and Blunsom (2013) combine convolutional and recurrent neural networks to model discourse representations. Different from these monolingual studies, our model aims at generating bilingual sentence representations. Furthermore we use autoencoders instead of recursive or recurrent neural networks. The descriptors in our model can be considered as a shallow convolution layer over an entire sentence (Zhang et al., 2015a).

multimodal autoencoders: Sentence modeling is performed only on text modality. However, information from different modalities might be complementary to each other. Motivated by this, Ngiam et al. (2011) develop deep multimodal autoencoders based on restricted Boltzmann machines (RBM) to jointly learn features over audio and video modalities. Instead of RBM, Wang et al. (2014) exploit stacked autoencoders for multimodal retrieval, and Feng et al. (2014) propose correspondence autoencoders for cross-modal retrieval. Feng et al. (2015) further investigate the utilization of deep correspondence RBM for cross-modal retrieval.

bilingual autoencoders: As a special case of multimodal autoencoders where each language is viewed as a modality, bilingual autoencoders have drawn attention in recent years. Based on recursive autoencoders, Zhang et al. (2014) incorporate phrase-level bilingual constraints into phrase representation learning. Along this line, Su et al. (2015) further exploit bilingual subphrase correspondences via word alignments for learning bilingual phrase structures and representations. Dissimilarly, Zhou et al. (2015) employ denoising autoencoders to learn bilingual embeddings. Lauly et al. (2014) directly perform encoding and decoding between source and target sentences based on bag-of-words representations. Chandar et al. (2014) exploit joint reconstruction and cross-lingual correlations on bilingual autoencoders. Unlike these models, our model builds autoencoders on global descriptors extracted from word embeddings, and incorporates bilingual semantics via corpus-level bilingual constraints into the hidden layer.

Our work is similar to the work of Zhang et al. (2015b) in that we both aim at modeling parallel sentences under the semantic constraints. The difference lies on the following two aspects: 1) they employ a chunk-based convolutional neural network to model sentences, while we use a much simpler autoencoder network; and 2) they impose the bilingual constraint strictly on the sentence level. Instead, we explore a much more relax constraints on the corpus level. As Chandar et al. (2014)'s bilingual autoencoder is most closely related to ours, we use their autoencoder as our baseline and describe it with more details in the next section.

3 Bilingual Bag-of-Words Autoencoder

The Bilingual Bag-of-Words Autoencoder (BBoWAE) (Chandar et al., 2014) builds two separate feed-forward autoencoders based on bag-of-words representations. The two autoencoders are jointly reconstructed with cross-lingual correlations. Figure 2 shows the overall architecture. Given a parallel sentence pair $(\mathbf{x}, \mathbf{y})$, BBoWAE model first generates corresponding bag-of-words based sentence representations, and then encodes them into the hidden layer:

$$a(\mathbf{x}) = c + W^{\mathcal{X}} v(\mathbf{x}),\ \phi(\mathbf{x}) = h(a(\mathbf{x})); \quad a(\mathbf{y}) = c + W^{\mathcal{Y}} v(\mathbf{y}),\ \phi(\mathbf{y}) = h(a(\mathbf{y})) \tag{1}$$

where $v(\cdot)$ converts sentence into a fixed-size but sparse binary vector, $W^{\mathcal{X}}$ and $W^{\mathcal{Y}}$ implicitly represent language specific word embeddings, c is the bias term shared by both autoencoders and $h(\cdot)$ is an element-wise non-linear function.

Upon these hidden layers, BBowAE model further performs a reconstruction of the original sentence

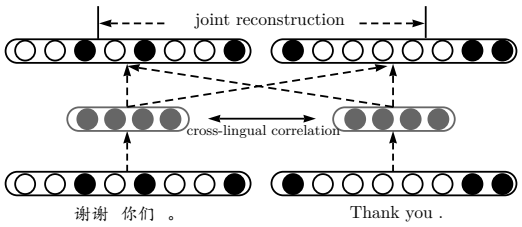

Figure 2: The architecture of BBoWAE model. We use black and white colors to indicate 1 and 0 respectively, which form the bag-of-words representation of a sentence. Notice that the gray nodes are real-valued.

in both languages:

$$\hat{v}(\mathbf{x})_{\mathbf{x}} = h(W^{\mathcal{X}^T}\phi(\mathbf{x}) + b^{\mathcal{X}}), \hat{v}(\mathbf{y})_{\mathbf{x}} = h(W^{\mathcal{Y}^T}\phi(\mathbf{x}) + b^{\mathcal{Y}}) \tag{2}$$

$$\hat{v}(\mathbf{x})_{\mathbf{y}} = h(W^{\mathcal{X}^T}\phi(\mathbf{y}) + b^{\mathcal{X}}), \hat{v}(\mathbf{y})_{\mathbf{y}} = h(W^{\mathcal{Y}^T}\phi(\mathbf{y}) + b^{\mathcal{Y}}) \tag{3}$$

where $b^{\mathcal{X}}$ and $b^{\mathcal{Y}}$ are bias terms, $h(\cdot)$ here is the sigmoid non-linearity and $\hat{v}(\mathbf{x})_{\mathbf{y}}$ denotes the reconstructed representation of $v(\mathbf{x})$ from $v(\mathbf{y})$. The other three reconstructed vectors are similarly defined.

To favour more meaningful bilingual representations, BBoWAE incorporates a cross-lingual correlation error and different reconstruction errors into the objective function:

$$\ell(\mathbf{x},\mathbf{y}) + \ell(\mathbf{y},\mathbf{x}) + \ell(\mathbf{x},\mathbf{x}) + \ell(\mathbf{y},\mathbf{y}) + \beta\ell([\mathbf{x},\mathbf{y}],[\mathbf{x},\mathbf{y}]) - \lambda cor(a(\mathbf{x}), a(\mathbf{y})) \tag{4}$$

where β, λ are hyperparameters, and $[\mathbf{x},\mathbf{y}]$ represents the concatenation of the two sentences. Each loss function $\ell(\cdot)$ is the cross-entropy error between the original bag-of-words representation $v(\cdot)$ and reconstructed representation $\hat{v}(\cdot)$. (e.g. $v(\mathbf{y})$ vs. $\hat{v}(\mathbf{y})_{\mathbf{x}}$).

The term $\ell([\mathbf{x},\mathbf{y}],[\mathbf{x},\mathbf{y}])$ is the joint reconstruction term, where the two sentences are simultaneously presented as input and reconstructed; and the term $cor(a(\mathbf{x}), a(\mathbf{y}))$ is the sum of scalar correlations between $a(\mathbf{x})$ and $a(\mathbf{y})$ across all dimensions. To obtain a stochastic estimate of the correlation, small mini-batches are used during training.

Notice that the sentence representation $a(\mathbf{x})$/$a(\mathbf{y})$ is actually the *sum* of bag-of-words embeddings. Although BBoWAE is effective in learning bilingual word embeddings, it is weak in modeling parallel sentences due to the well known insufficiency of the sum representations. We instead resort to multiple global descriptors over word embeddings and further explore more suitable bilingual constraints.

4 Bilingual Autoencoder with Global Descriptors

We describe our model in two phases: autoencoder with global descriptors and bilingual semantic constraints. The former constitutes the basic structure for modeling monolingual sentences, while the latter explores bilingual constraints to connect the two autoencoders. After the description of the architecture, we present details for parameter inference.

4.1 Autoencoder with Global Descriptors

Our autoencoder is built upon distributed word embeddings, where each word in vocabulary V corresponds to a d-dimensional dense, real-valued vector, and all word vectors are stacked into a word embedding matrix $L \in \mathbb{R}^{d\times|V|}$, where $|V|$ is the vocabulary size.

Given an ordered list of n words in a sentence, we retrieve the i-th word representation from L with its corresponding vocabulary index I_i: $e(x_i) = L_{:,I_i} \in \mathbb{R}^d$. All word vectors in the sentence $\mathbf{x}$ produce the following output matrix: $M = (e(x_1), e(x_2), \ldots, e(x_n)) \in \mathbb{R}^{d\times n}$. From this matrix M, we investigate four sentence-level statistical descriptors: *min*, *max*, *avg* and *std* in each row r as follows:

$$g_r^{min} = \min(M_{r,1:n}), g_r^{max} = \max(M_{r,1:n}), g_r^{avg} = \frac{1}{n}\sum_{i=1}^{n} M_{r,i}, g_r^{std} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(M_{r,i} - g_r^{avg})^2} \tag{5}$$

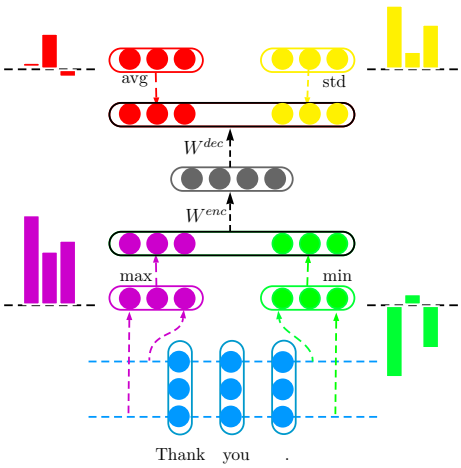

Figure 3: Monolingual autoencoder with global descriptors. The colored histogram on each corner indicates the corresponding descriptor for a toy example. Notice that the black dash line in each histogram represents the value 0.

Figure 3 illustrates the distribution of each descriptor for a toy example[2], from which we can find that these descriptors represent different aspects of the same sentence and are complementary to each other.

After obtaining these global descriptors, we select some of them as our encoding input (e.g. *min*, *max*), and leave the others as our decoding target (e.g. *std*, *avg*). Note that the neural network built on these descriptors is an autoencoder since the input and output layer in the network represent the same sentence.[3] Additionally, this autoencoder can naturally handle variable-length sentences (Notice that $g \in \mathbb{R}^d$). In particular, we concatenate the input descriptors into one vector, and encode it into the hidden layer shown as gray nodes in Figure 3:

$$hid = f(W^{enc}[g^{max}; g^{min}] + b^{enc}) \tag{6}$$

where $W^{enc} \in \mathbb{R}^{m \times 2d}$ and $b^{enc} \in \mathbb{R}^m$ are the encoding parameters. $hid \in \mathbb{R}^m$ is the sentence representation, and $f(\cdot)$ is an element-wise activation function such as $tanh(\cdot)$, which is used for all activation functions in our model. To prevent the hidden layer from being very small, we normalize all output vectors of the hidden layer to have a unit length, $hid = \frac{hid}{\|hid\|}$.

Upon the hidden layer, we stack a decoding layer to *reconstruct* the other descriptors:

$$out = f(W^{dec} hid + b^{dec}) \tag{7}$$

where $W^{dec} \in \mathbb{R}^{m \times 2d}$ and $b^{dec} \in \mathbb{R}^{2d}$ are the decoding parameters.

To integrate the information contained in different descriptors into sentence embedding learning, we train our autoencoder to minimize the following Euclidean distance error with respect to the target descriptors $[g^{avg}; g^{std}]$:

$$E_{ae}(\mathbf{x}) = \frac{1}{2}\|[g^{avg}; g^{std}] - out\|^2 \tag{8}$$

4.2 Bilingual Semantic Constraints

In order to incorporate bilingual correspondences between the source and target sentences into the above-mentioned autoencoder, we employ two kinds of bilingual constraints.

The first bilingual constraint is to share decoding parameters across the two autoencoders, that is, using the same W^{dec} and b^{dec} for them. This ensures that the relations between sentence representations (in the hidden layer) and target descriptors (in the output layer) are consistent across the source and target language. In this way, bilingual information is propagated from one language to the other language

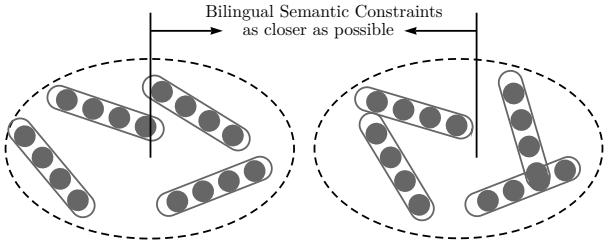

Figure 4: Corpus-level bilingual semantic constraints. The left and right dashed ellipses indicate bilingual semantic spaces.

through these parameters.

The second bilingual constraint is that the center of bilingual spaces should be as close as possible. Therefore we minimize a corpus-level semantic distance defined as follows:

$$E_{sem}(\mathcal{C}) = \sum_{k=1}^{\lceil N/B \rceil} \frac{1}{2} \| \frac{1}{B} \sum_{i=1}^{B} \mathbf{x}_{k,i} - \frac{1}{B} \sum_{i=1}^{B} \mathbf{y}_{k,i} \|^2 \tag{9}$$

where $\mathcal{C}$ represents the entire parallel corpus, which has N parallel sentences with a batch size of B.

Figure 4 shows this constraint, where we try to shorten the distance between the centers of the source and target language spaces. Different from previous works (Zhang et al., 2014; Chandar et al., 2014; Su et al., 2015), we define this distance at the corpus rather than sentence level. The reasons for this are twofold: 1) The potential equivalent translations for a source sentence could be many, and 2) the number of non-equivalent translations for one sentence must be enormous. Therefore, defining the semantic distance at the sentence level would be too strict, and may bring in noises to our model. In contrast, our corpus-level constraint is much more relax and general. Notice that if we set $B = 1$, this constraint goes back to sentence level; If we set $B \to \infty$, it becomes a constraint upon the whole training corpus. Intuitively, B controls the strictness of the semantic constraints.

4.3 Parameter Inference

There are two kinds of errors involved in the overall objective function: the *autoencoder error* in Eq. (8) and the *semantic error* in Eq. (9). Given the training corpus $\mathcal{C}$, the joint training objective is:

$$J(\mathcal{C}) = \frac{\alpha}{N} \sum_{i=1}^{N} (E_{ae}(\mathbf{x}_i) + E_{ae}(\mathbf{y}_i)) + (1-\alpha) E_{sem}(\mathcal{C}) + R(\theta) \tag{10}$$

α is a balance factor, $\theta = \{L_{\mathbf{x}}, L_{\mathbf{y}}, W^{enc}_{\mathbf{x}}, W^{enc}_{\mathbf{y}}, W^{dec}\}$, and $R(\theta)$ is the regularization term: $R(\theta) = \frac{\lambda_L}{2}\|\theta_L\|^2 + \frac{\lambda_W}{2}\|\theta_W\|^2$. For regularization, we divide θ into two sets: θ_L for $(L_{\mathbf{x}}, L_{\mathbf{y}})$ and θ_W for $(W^{enc}_{\mathbf{x}}, W^{enc}_{\mathbf{y}}, W^{dec})$. Accordingly, λ_L and λ_W are the corresponding coefficients.

We employ the toolkit Word2Vec (Mikolov et al., 2013) to pretrain word embeddings for each language on the corresponding part of $\mathcal{C}$, and randomly initialize the other parameters using normal distribution ($\mu = 0, \sigma = 0.01$). To optimize these parameters, we apply the L-BFGS algorithm to the gradient of Eq. (10).

5 Sentence Representation and Semantic Similarity

Given a parallel sentence pair $(\mathbf{x}, \mathbf{y})$, our model will generate sentence representations $(hid_{\mathbf{x}}, hid_{\mathbf{y}})$ with the trained parameters θ^*. Different from Eq. (6) that only uses the input descriptors to calculate the hidden layer, we use both the input and target descriptors to compute the final hidden representation

[2]We sampled the word embeddings uniformly from -1 to 1. Finally, we obtained *Thank*:$(0.95, 0.64, -0.23)$, *you*:$(-0.82, 0.54, 0.72)$ and .:$(-0.12, 0.10, -0.52)$ respectively for illustration.

[3]Therefore, the *autoencoder* in this paper is an extension of the conventional autoencoder.

of $\mathbf{x}$ or $\mathbf{y}$ as these descriptors provide different and complementary views of a sentence. The final hidden representations of the sentence $\mathbf{x}$ and $\mathbf{y}$ are defined as follows:

$$hid_{\mathbf{x}} = f(W_{\mathbf{x}}^{enc,*}[g_{\mathbf{x}}^{min}; g_{\mathbf{x}}^{max}] + W^{dec,*^T}[g_{\mathbf{x}}^{avg}; g_{\mathbf{x}}^{std}] + b^{enc}) \tag{11}$$

$$hid_{\mathbf{y}} = f(W_{\mathbf{y}}^{enc,*}[g_{\mathbf{y}}^{min}; g_{\mathbf{y}}^{max}] + W^{dec,*^T}[g_{\mathbf{y}}^{avg}; g_{\mathbf{y}}^{std}] + b^{enc}) \tag{12}$$

The corresponding semantic similarity is measured by the Euclidean distance between the two hidden representations:

$$Sim(\mathbf{x}, \mathbf{y}) = \frac{1}{2}\|hid_{\mathbf{x}} - hid_{\mathbf{y}}\|^2 \tag{13}$$

The smaller $Sim(\cdot, \cdot)$ is, the more semantically similar the parallel sentence pair is. All the following intrinsic and extrinsic evaluations are based on this similarity measurement.

6 Experiments

In this section, we carried out a series of experiments to validate the effectiveness of our proposed bilingual autoencoders on NIST Chinese-English translation tasks using large-scale bilingual training data. In particular, we investigated 1) whether our model is able to distinguish parallel sentence pairs from nonparallel sentences, and 2) whether our model can improve machine translation quality.

6.1 Setup

Our translation decoder is a state-of-the-art hierarchical phrased-based SMT system (Chiang, 2007). The bilingual training data is the combination of LDC2003E14, LDC2004T07, LDC2005T06, LDC2005T10 and LDC2004T08 (Hong Kong Hansards/Laws/News), which contains 2.9M sentence pairs with 80.9M Chinese words and 86.4M English words. We used a 4-gram language model which was trained on the Xinhua section of the English Gigaword corpus (306M words) using the SRILM[4] toolkit (Stolcke, 2002) with modified Kneser-Ney smoothing.

In addition to the baseline decoder, we also compared our bilingual autoencoder against the abovementioned BBoWAE model (Chandar et al., 2014). To train this model, we used the same bilingual corpus and their open source code[5] with the same hyperparameters as they used. We employed the objective in Eq. (4) except for the correlation term as an entropy-based semantic similarity measure.[6]

Since our model is general in terms of input and target descriptors, we investigated two variants of the proposed bilingual autoencoder: 1) *min* and *max* as the input descriptors, while *avg* and *std* as the target descriptors (MM2AS); and 2) the opposite direction (AS2MM). Throughout all experiments, we set $B = 100$, $\alpha = 0.100$, $\lambda_L = 10^{-6}$, $\lambda_W = 10^{-3}$ and $m = 2d$. With respect to the dimensionality of word embeddings, we tried four different dimensions from 25 to 100 with an increment of 25 each time.

We used the NIST evaluation set of MT05 as our development set, and sets of MT06/MT08 as the test sets. Case-insensitive NIST BLEU (Papineni et al., 2002) was used to measure translation performance. We used minimum error rate training (MERT) (Och, 2003) to optimize the feature weights. In order to alleviate the instability of MERT, we followed Clark et al. (2011) to run MERT three times and report average BLEU scores over the three runs for all our MT experiments.

6.2 Intrinsic Evaluation: Semantic Analysis

The first group of experiments aims at analyzing the ability of our model in distinguishing parallel sequences from nonparallel sequences, at both the phrase and sentence level. For convenience, we used MM2AS model and set $d = 25$ in all the following experiments.

[4]http://www.speech.sri.com/projects/srilm/download.html

[5]http://www.sarathchandar.in/crl.html

[6]We make this choice due to the following two reasons: 1) the correlation term is meaningless for a single sentence pair; 2) the combined reconstruction errors in Eq. (4) provide a balanced and comprehensive similarity measure as they calculate cross entropies of $\mathbf{x}$ to $\mathbf{x}$, $\mathbf{y}$ to $\mathbf{y}$, $\mathbf{x}$ to $\mathbf{y}$, $\mathbf{y}$ to $\mathbf{x}$ and $[\mathbf{x}, \mathbf{y}]$ to $[\mathbf{x}, \mathbf{y}]$.

Source Phrase	Target Candidates
充满 激情	imbued with passions full of passion full of excitement
宾至如归 的 感觉	feeling of being at home feel at home feel welcomed
促进 可 持续 发展	promotion of sustainable development promote sustainable development promote sustained growth

Table 1: Source phrases in our phrase table with their top-3 target translations selected by our model.

System	MT06	MT08	Avg
BBoWAE	77.73	74.57	76.15
Our Model	87.18	85.85	**86.52**

Table 2: Accuracy on recognizing parallel sentence pairs.

6.2.1 Analysis on Phrasal Semantic Similarities

To have a deep look into what our model measures similarities of bilingual phrases, we show some examples from our scored phrase table in Table 1. For each variable-length source phrase, we extract the top-3 target candidates according to their semantic similarity scores calculated in Eq. (13).

Take the source phrase " 宾至如归 的 感觉" as an example, our model succeeds in distinguishing the most semantically equivalent translation "*feeling of being at home*" from the less equivalent translation "*feel welcomed*". Although the candidate "*feel at home*" has almost the same meaning, this candidate is a verb phrase which is not consistent with the noun phrase at the source side from the perspective of syntax. This indicates that the proposed bilingual model is able to capture some semantic and syntactic properties of bilingual sequences.

6.2.2 Evaluation on Sentential Semantic Similarities

To testify the ability of our model at the sentence level, we further collected source sentences and their reference translations from the test sets MT06/MT08 as our parallel sentence pairs. We randomly sampled l target sentences from the target vocabulary based on reference translations and combined sampled target sentences and their corresponding source sentences as nonparallel sentence pairs.[7]

For both our model and BBoWAE model, we test whether the model can assign a higher similarity score to a parallel sentence pair than a sampled nonparallel sentence pair. We employ accuracy as our evaluation metric, and conducted 5 evaluations, for each of which we sampled 3 different target sentences for each source sentence. The final average results are shown in Table 2. We find that our model significantly outperforms BBoWAE model by an absolute improvement of 10%. This demonstrates that our model can learn better semantic representations for parallel sentences than BBoWAE does.

6.3 Extrinsic Evaluation: Machine Translation

The second group of experiments were carried out to study the effectiveness of our model in calculating semantic similarities for SMT task: *decoding with phrasal semantic similarities*. This needs to measure the semantic similarity between a source sequence and its translation candidate according to Eq. (13).

In addition to the conventional four translation probabilities (phrase translation probabilities and lexical weights in both directions), we incorporate the phrasal semantic similarities as an additional feature into our baseline SMT system.

Table 3 summarizes the results, from which we observe that:

1) Our model can significantly improve translation quality on all testsets for any dimensions. Particularly, AS2MM model obtains the best result 28.08 when $d = 100$, which outperforms Baseline and BBoWAE model by up to 1.46 and 1.1 BLEU points respectively.

[7]The length of a sampled sentence is uniformly sampled from 1 to the length of the corresponding reference sentence.

System	d	MT06	MT08	Avg
Baseline	-	30.04	23.19	26.62
BBoWAE	40	30.52	23.43	26.98
MM2AS	25	31.11↑	23.90↑	27.51
	50	31.42⇑	24.19⇑	27.81
	75	31.18↑	23.98↑	27.58
	100	31.11↑	23.91↑	27.51
AS2MM	25	31.29⇑	24.34⇑	27.82
	50	31.10↑	24.06⇑	27.58
	75	31.17↑	23.92↑	27.55
	100	31.64⇑	24.51⇑	28.08

Table 3: Experiment results for different dimensions with phrasal semantic similarities on the test sets. **Avg** = average BLEU scores on the test sets. ⇑/↑:significantly better than BBoWAE ($p < 0.01/0.05$, respectively).

2) The BBoWAE model, designed for learning bilingual word embeddings, is not good at modeling high-level and long sequence representations. The translation result of this model is 26.98, only 0.36 points higher than the Baseline. Additionally, as one major difference between BBoWAE and our model is the corpus-level semantic constraints, this result further demonstrates the superiority of this constraint.

3) It's interesting that the overall result of AS2MM model is slightly better than that of MM2AS model (27.76 vs. 27.60 on average). The reason may be that when back-propagating autoencoder errors onto the hidden and input layer, AS2MM model is easier and more straightforward than MM2AS.

7 Conclusion and Future Work

In this paper, we have presented a simple yet effective and scalable bilingual autoencoder for parallel sentence modeling. We incorporate global descriptors and corpus-level semantic constraints into bilingual sentence representations. Experiment results show that our approach achieves substantial improvements against the baseline models.

For the future work, we would like to explore more variants of our bilingual autoencoder, e.g. taking the *avg*, *max* as inputs and the *std*, *min* as targets. Besides, we will further enhance our autoencoder with semantic and deeper descriptors and verify our model on other bilingual or cross-lingual tasks, such as cross-lingual sentiment classification.

Abstract

In this paper we combine two strands of machine translation (MT) research: automatic post-editing (APE) and multi-engine (system combination) MT. APE systems learn a target-language-side second stage MT system from the data produced by human corrected output of a first stage MT system, to improve the output of the first stage MT in what is essentially a *sequential* MT system combination architecture. At the same time, there is a rich research literature on *parallel* MT system combination where the same input is fed to multiple engines and the best output is selected or smaller sections of the outputs are combined to obtain improved translation output. In the paper we show that parallel system combination in the APE stage of a sequential MT-APE combination yields substantial translation improvements both measured in terms of automatic evaluation metrics as well as in terms of productivity improvements measured in a post-editing experiment. We also show that system combination on the level of APE alignments yields further improvements. Overall our APE system yields a statistically significant improvement of 5.9% relative BLEU over a strong baseline (English–Italian Google MT) and 21.76% productivity increase in a human post-editing experiment with professional translators.

1 Introduction

The term Post-Editing (PE) is defined as the correction performed by humans over the translation produced by an MT system (Veale and Way, 1997). It is often understood as the process of improving a translation provided by an MT system with the minimum amount of manual effort (TAUS Report, 2010). While MT is often not perfect, post-editing MT can yield productivity gains as post-editing MT output may require less effort compared to translating the same input manually from scratch. MT outputs are often post-edited by professional translators and the use of MT has become an important part of the translation workflow. A number of studies confirm that post-editing MT output can improve translators' performance in terms of productivity and it may positively impact on translation quality and consistency (Guerberof, 2009; Plitt and Masselot, 2010; Zampieri and Vela, 2014). The wide use of MT in modern translation workflows in the localization industry, in turn, has resulted in substantial quantities of PE data which can be used to develop APE systems.

APE (Knight and Chander, 1994) has been proposed as an automatic method for improving raw MT output, before performing actual human post-editing on it. The approach is based on collecting human corrected output of a first stage MT system and using this to train a system to correct errors produced by the MT system, possibly resulting in a productivity increase in the translation process. The advantage of APE relies on its capability to adapt to any black-box MT engine; i.e., upon availability of post-edited data, no incremental training or full re-training of the MT system is required to improve the overall translation quality of the first stage MT system that was involved in the post-edition data collection. APE assumes the availability of source texts (S_{ip}), corresponding MT output (T_{mt}) and the human post-edited (T_{pe}) version of T_{mt}, and APE systems can be modelled as an MT system between $S_{ip}\_T_{mt}$ (i.e., a joint representation of S_{ip} and T_{mt}) and T_{pe}. However, statistical APE (SAPE) systems can also be built

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2559–2570, Osaka, Japan, December 11-17 2016.

without the availability of S_{ip} using only sufficient amounts of parallel "target-side" T_{mt}–T_{pe} text within the statistical MT (SMT) framework.

Usually APE tasks focus on systematic errors made by MT systems - the most frequent ones being incorrect lexical choices, incorrect word ordering, incorrect insertion or deletion of a word. The system presented in this paper explores the use of system combination in APE. System combination in MT has been studied extensively (Matusov et al., 2006; Du et al., 2009; Pal et al., 2014), except in the context of APE. Here we use system combination architectures on three different levels: (i) sequential combination between first-stage system and APE, (ii) parallel combination of alignment systems at the level of the APE and (iii) parallel combination of APE MT systems (including the first stage MT system). More precisely, our approach makes use of a hybrid implementation of multiple alignment combination within phrase-based SAPE (PB-SAPE) and hierarchical PB-SAPE (HPB-SAPE) and a system combination framework (a multi-engine pipeline) – that combines the best translations from the enhanced PB-SAPE, HPB-SAPE and the raw MT output. The model takes T_{mt} as input and provides T_{pe} as output. As we also use the output of the original first stage MT system in some combination experiments, our set-up indirectly also uses S_{ip} information. System combination and hybrid word alignment strategies are commonly used in MT, however to the best of our knowledge the work presented in this paper is the first approach to APE that uses system combination and hybrid word alignment methods within the APE engine. System combination has been found to be a very useful technique in MT where translation hypotheses from multiple MT engines are available. Motivated by the success of system combination in MT, we applied system combination in APE. Similarly, the use of multiple word alignments has been shown to improve MT results (Pal et al., 2013). For our APE, alignments have to be produced on "monolingual" target-side data (T_{mt} and T_{pe}). A particular focus of our paper is to explore the performance of hybrid alignments based on combinations of statistical and edit-distance based aligners in this "monolingual" setting.

The remainder of the paper is organized as follows. Section 2 gives an overview of the related work. Section 3 describes the components of our SAPE system. Section 4 outlines the data and data preprocessing and the experimental setup. Section 5 presents the results of automatic and human evaluation, followed by conclusions and avenues for further research in Section 6.

2 Related Research

APE approaches cover a wide methodological range. Simard et al. (2007a) and Simard et al. (2007b) applied phrase-based SMT (PB-SMT) for post-editing that handles the repetitive nature of errors typically made by rule-based MT (RBMT) systems. The APE system was trained on the output of the rule-based system as the source language and reference human translations as the target language. This APE system was able to correct systematic errors produced by the RBMT system and reduce the post-editing effort. The approach achieved large improvements in performance not only over the baseline rule-based system but also over a similar PB-SMT used in a standalone mode. Denkowski (2015) proposed a method for real time integration of post-edited MT output into the translation model. He extracted a grammar for each input sentence and applied it to the model. Rosa et al. (2012) and Mareček et al. (2011) applied a rule-based approach to APE of English–Czech MT outputs on the morphological level. They used 20 hand-written rules based on the most frequent errors encountered in translation. The method efficiently corrects morpho-syntactic categories of a word such as number, case, gender, person as well as dependency labels. The inclusion of source-language information in APE is also useful to improve the APE performance (Béchara et al., 2011). To overcome data sparsity issues, Chatterjee et al. (2015) proposed a pipeline where the best language model and pruned phrase table are selected through task-specific dense features. Recently, a bidirectional recurrent neural network model of APE using T_{mt}–T_{pe} was proposed by Pal et al. (2016) which consists of an encoder that encodes the MT output into a fixed-length vector from which a decoder provides a post-edited (PE) translation. They reported statistically significant improvement over a strong first stage MT system baseline.

Various automatic or semi-automatic post-processing techniques to implement corrections of repetitive errors have been developed, although often the overall resulting MT output after APE still needs to be

post-edited by humans in order to produce publishable quality translation (Roturier, 2009; TAUS/CNGL Report, 2010). Even though MT and APE output often need human PE, it is often faster and cheaper to post-edit MT and APE output than to perform human translation from scratch.

System combination is a technology where multiple translation outputs from potentially very different MT systems are combined. System combination includes (i) hypothesis selection (Rosti et al., 2007a; Hildebrand and Vogel, 2010), (ii) confusion network based decoding (Matusov et al., 2006; Rosti et al., 2007b) and (iii) model combination (DeNero and Macherey, 2011). The confusion networks are built using backbone selection using either multiple hypotheses as backbones (Leusch and Ney, 2010) or a single backbone (Rosti et al., 2007b; Du et al., 2009) using TER (Snover et al., 2006) or BLEU (Papineni et al., 2002). These alignment metrics select the hypothesis that agrees most with the other hypotheses on average. System combination can improve translation quality significantly which motivated us to apply the strategy for the APE task.

Some of the research mentioned above studied the impacts of various factors and methods in APE on productivity gains. However, those studies were not conducted to observe PE effort in commercial environments. The focus of our study is twofold - to examine how existing word alignment techniques and a system combination framework can be intelligently used to improve monolingual APE, and whether the improvements in APE measured in terms of automatic evaluation metrics translate to measurable productivity gains in human post-editing in commercial translation workflows.

3 System Description

Our APE system consists of four basic components: (i) a target side mono-lingual hybrid word alignment model based on a number of alignment approaches, (ii) PB-SAPE, (iii) HPB-SAPE, and (iv) a system combination module (also including the first stage MT system). The SAPE systems are trained monolingually with Italian T_{mt} generated by Google Translate (GT) and the manually post-edited translations T_{pe}.

3.1 A Hybrid Word Alignment Model for Target Side APE

Previous research in MT demonstrates that a combination of information coming from multiple alignment models can improve translation quality. This can be achieved in different ways, e.g., by combining exactly two bidirectional alignments (Och, 2003; Koehn et al., 2003; DeNero and Macherey, 2011), combining an arbitrary number of alignments (Tu et al., 2012; Pal et al., 2013), by constructing weighted alignment matrices over 1-best alignments from multiple alignments generated by different models (Liu et al., 2009; Tu et al., 2011) etc. Below we apply an alignment combination model to APE.

Our hybrid word alignment method combines word alignments produced by three different statistical word alignment methods: (i) GIZA++ (Och and Ney, 2003) word alignment with grow-diag-final-and (GDFA) heuristic (Koehn, 2010), (ii) Berkeley word alignment (Liang et al., 2006), and (iii) Sym-Giza++ (Junczys-Dowmunt and Szał, 2012) word alignment, as well as two different edit distance based word aligners based on TER (Translation Edit Rate) (Snover et al., 2006) and METEOR (Lavie and Agarwal, 2007). We follow Pal et al. (2013) in combining word alignment tables, however, we additionally use 3-word consistent phrases to generate more alignment links (cf. Section 3.1.3). We integrate the word alignment obtained with this hybrid model into our PB-SAPE (Pal et al., 2015) and HPB-SAPE (Pal, 2015) models.

3.1.1 Statistical Word Alignment

GIZA++ is a statistical word alignment tool which implements IBM models 1–5, an HMM alignment model, as well as the IBM-6 model for covering many to many alignments. The Berkeley word aligner uses an extension of Cross Expectation Maximization and is jointly trained with HMM models. Sym-Giza++ is a modification of GIZA++ . It modifies the counting phase of each model of Giza++ allowing for updating the symmetrisized models between the iterations of the original training algorithm. Sym-Giza++ computes symmetric word alignment models with the capability of taking advantage of multi-processor systems.

3.1.2 Edit Distance-Based Word Alignment

We use two different kinds of edit distance based word aligners where alignments are based on edit distance style MT evaluation metrics – METEOR and TER.

METEOR Alignment: METEOR is an automatic MT evaluation metric which provides an alignment between a translation hypothesis H (i.e., MT output) and a reference translation R (in this case the PE translation). Given a pair of strings such as H and R to be compared the alignment is a mapping between words in H and R, which is built incrementally by the three sequences of word-mapping modules: (i) **Exact:** maps if the words are exactly the same (ii) **Porter stem:** maps if they are the same after stemming (iii) **WN synonymy:** maps if they are synonyms in WordNet. If multiple alignments exist, METEOR selects the alignment for which the word order in the two strings is most similar (i.e. having the fewest number of crossing alignment links). The final alignment is produced as the union of all stage alignments (e.g. Exact, Porter Stem and WN synonymy).

TER Alignment: TER is an edit distance based automatic MT evaluation metric that measures the ratio between the number of edit operations that are required to turn a H into R to the total number of words in R. The allowable edit operations include insertion (I), substitution (S), deletion (D) and phrase shifts (Sh). As a byproduct of finding the minimum edit distance, it produces an alignment between the hypothesis and the reference. In the monolingual SAPE task, we make use of TER alignment as a potential alignment between T_{mt} and T_{pe}. The TER alignment between a T_{pe} and T_{mt} is illustrated in Figure 1. Where, the vertical bar '|' represents a match and *I*, *D* and *S* represent the three post-editing operations – insertion, deletion and substitution, respectively.

TL_{mt}:	w_1	w_2	w_3	ϵ	w_4	w_5	w_6	w_7	w_8	w_9
	|	D	S	I	|	|	S	|	|	|
TL_{pe}:	$\bar{w}_1$	ϵ	$\bar{w}_2$	$\bar{w}_3$	$\bar{w}_8$	$\bar{w}_4$	$\bar{w}_5$	$\bar{w}_6$	$\bar{w}_7$	$\bar{w}_9$

Figure 1: TER based monolingual word alignment

3.1.3 Producing Additional Alignments for Edit-Distance Based Alignment

To generate additional alignment points between parallel sentence pairs, we perform phrase extraction (Koehn et al., 2003)[1] between T_{mt} and T_{pe}. We extract all phrase pairs, T_{mt} phrase (e) and T_{pe} phrase ($\bar{e}$), that are continuous and consistent with the edit distance based monolingual alignments. This phrase extraction process is performed individually for both TER and METEOR based alignments. A phrase pair $(e, \bar{e})$ is consistent with alignment a if Equation 1 is satisfied.

$$(\forall w_i \in e : (w_i, x) \in a \wedge x \in \bar{e}) \wedge \ (\forall \bar{w}_i \in \bar{e} : (y, \bar{w}_i) \in a \wedge y \in e) \tag{1}$$

Unaligned words in a phrase pair are aligned to all the phrase internal words in the other language. Figure 2 depicts the process of generating additional alignments where the solid links represent edit distance based alignments and the dashed links represent the newly established alignments. The newly established alignment points are added to the corresponding (i.e, TER or METEOR) alignment matrix.

3.2 Hybridization

Our method follows the following heuristic. We consider either of the alignments generated by GIZA++ with grow-diag-final-and heuristic (Koehn, 2010) (a_1), Berkeley aligner (a_2), or SymGiza++ (a_3) as the standard alignment since edit distance based TER (a_4) and METEOR (a_5) fail to align many words in the monolingual Italian MT–PE parallel sentences. From the five alignments a_1–a_5, we compute the alignment combination as follows.

[1]For this task, we use 3-words phrases.

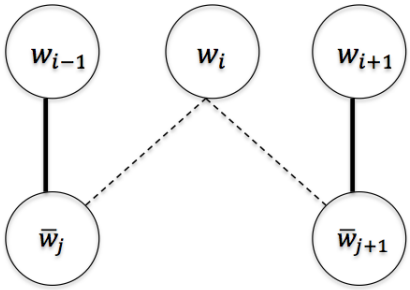

Figure 2: Producing additional alignments (w_i–$\bar{w}_j$, w_i–$\bar{w}_{j+1}$)

- **Step 1:** Choose a standard alignment[2] (S_a) from a_1, a_2 or a_3.
- **Step 2:** Produce a combined alignment $S_c = S_a \cup (a_2 \cap a_3)$, if a_1 is considered as S_a.
- **Step 3:** Delete all the alignment points $a_{ij} \in S_c$ such that $\exists a_{ik} \in a_4 \cup a_5$ where $j \neq k$.
- **Step 4:** Update S_c as $S_c = S_c \cup a_4 \cup a_5$.

3.3 System Combination for APE

Our system combination framework selects the best hypothesis translation from multiple hypotheses produced by different systems. In order to apply the system combination framework on the translations produced by our SAPE systems and the baseline MT system (Google Translate) we implemented the Minimum Bayes Risk (MBR) coupled with the Confusion Network (MBRCN) framework as described in (Du et al., 2009). The MBR decoder (Kumar and Byrne, 2004) selects for each sentence the best system output from the three outputs by minimizing BLEU (Papineni et al., 2002) loss. This output is known as the backbone. A confusion network (Matusov et al., 2006) is built from the backbone while the remaining hypotheses are aligned against the backbone using the edit-distance based alignment methods (cf. Section 3.1.2). The features used to score each arc in the confusion network (CN) are word posterior probability, target language model and length penalties. Minimum Error Rate Training (MERT) (Och, 2003) is applied to tune the CN weights. In our experiments, both APE hypotheses – PB-SAPE and HPB-SAPE, and the baseline Google Translate (GT) output are passed on to the system combination framework which produces the final system output (SC-APE).

4 Experiments

4.1 Data

The post-edition dataset for training the APE systems was developed in the MateCat[3] project. The data consist of 312K parallel sentences of Europarl and client data. The parallel data contains Italian translations (T_{mt}) produced by Google Translate from English as the source language and the corresponding post-edited Italian translations (T_{pe}) produced by professional translators. The parallel data were cleaned and processed by using a preprocessing module (see Section 4.2). After cleaning, we obtained a sentence-aligned MT–PE parallel corpus containing 213,795 sentence pairs. We randomly extracted 1,000 sentences each for the development set and test set from the parallel corpus and treated the remaining data (211,795) as the training set. The language model was built on the Italian Europarl corpus along with the PE side of the training set. The entire monolingual Italian corpus consists of 49,483,285 words.

4.2 Corpus Cleaning and Preprocessing

The MateCat corpus contains some non-Italian as well as non-English words and sentences. Therefore, we applied a language identifier (Shuyo, 2010) on both bilingual English–Italian MT output and MT

[2]Empirically best preforming aligner among the individual aligners (a_1, a_2 or a_3), is considered as S_a.
[3]https://www.matecat.com/

output–PE (Italian) parallel data. We discarded those sentence pairs from the bilingual training data which are considered as belonging to a different language or contain segment(s) in a different language. The same method was also applied to the monolingual Italian data. Next, the parallel corpus was further cleaned using the Gale-Church filtering method described in Tan and Pal (2014). We sorted the entire parallel training corpus based on sentence length and removed duplicates. We applied tokenization and punctuation normalization using the Moses scripts.

4.3 Experimental Settings

In our APE experiments we first integrated the hybrid word alignment model (cf. Section 3.1) into the SAPE engines modelled with PB-SMT (Koehn et al., 2003) and hierarchical PB-SMT (HPB-SMT) (Chiang, 2005). For building our statistical APE system, we used maximum phrase length of 7 and a 5-gram language model trained using KenLM (Heafield, 2011). Model parameters were tuned using MERT (Och, 2003) on the held-out development set.

5 Evaluation

During evaluation we take into consideration the output produced by all the three APE systems: PB-SAPE with hybrid word alignment, HPB-SAPE with hybrid word alignment and the system combination system (SC-APE) which also includes the output from the first stage system Google MT. As a baseline APE system we use a PB-SAPE system with GIZA++ alignment. The evaluation was carried out in two ways: (i) automatic evaluation and (ii) human evaluation of the 1,000 testset sentences automatically post-edited by our SAPE systems. Out of the 1,000 testset sentences, the output of the system combination based final post-editing system (SC-APE) were different from the raw Google Translate translation output for 198 sentences, i.e. only 19.8% of the GT translations are post-edited by the SC-APE system, the remaining sentences are not affected by APE. The entire testset is evaluated with automatic evaluation metrics while only the 198 sentences are subjected to human evaluation.

5.1 Automatic Evaluation

We evaluated the systems using three well known automatic MT evaluation metrics: BLEU, METEOR and TER. We also performed sentence level BLEU evaluation. Table 1 provides a comparison in terms of sentence level BLEU evaluation of the individual APE systems. Based on sentence level BLEU scores, the evaluation results presented in Table 1 show that 159 out of the 198 translations provided by the SC-APE are of better quality than the GT output. However, for the rest (39) of the translations, the GT output is of better quality than the APE output. This may be partly due to the fact that the human post-edited reference translations are biased towards GT output. However, manual analysis revealed that some of these 39 translations are indeed worse than the GT output. Overall, PB-SAPE, HPB-SAPE and SC-SAPE provide gains in terms of translation quality in 0.9%, 3.7% and 12% of the cases, respectively, as measured by S-BLEU. APE quality increases with the integration of the hybrid word alignment (HWA) model (cf. Section 3.2) into the different APE systems (cf. Table 2).

Systems	APE	GT	Tie	% Gain	% Loss
PB-SAPE	65	56	879	6.5%	5.6%
HPB-SAPE	91	54	855	9.1%	5.4%
SC-APE	159	39	802	15.9%	3.9%

Table 1: Automatic evaluation using Sentence-BLEU over 1,000 testset sentences.

Table 2 provides a comparison between the baseline PB-SAPE based on GIZA++ word alignment, PB-SAPE and HPB-SAPE based on hybrid word alignment (HWA), SC-APE and GT. The comparison is carried out in terms of BLEU, METEOR and TER scores. A general trend can be observed across all metrics. Baseline PB-SAPE system fail to improve over GT, while HWA based PB-SAPE, HPB-SAPE and SC-APE improve the translation quality over GT according to all metrics. Among the HWA based three APE systems, SC-APE performs best followed by HPB-SAPE and PB-SAPE in all metrics.

The SC-APE system provides 5.9%, 11% and 2.4% relative improvements over GT in BLEU, TER and METEOR, respectively, and all these improvements are statistically significant ($p < 0.01$). The HPB-SAPE system also provides promising improvements (4.2%, 7.3% and 1.2% in BLEU, TER and METEOR, respectively) over GT while PB-SAPE system yields in modest improvements.

Metric	PB-SAPE (Baseline)	PB-SAPE (HWA)	HPB-SAPE (HWA)	SC-APE	GT (First-Stage MT)
BLEU	59.90	62.70	63.87	**64.90**	61.26
TER	33.52	29.92	28.67	**27.52**	30.94
METEOR	69.54	73.31	73.63	**74.54**	72.73

Table 2: Automatic evaluation of the systems over 1,000 testset sentences.

5.2 Human Evaluation

The human evaluation process was carried out with 4 professional translators by introducing a polling system. The polling system provides every voter with three choices, two of which correspond to two different translation options for every source English segment. Translators act as voters and make a choice between the SC-APE output and the GT first-stage translation, based on whichever translation option looks better to them. Translators were also provided with a third option called *uncertain* (U), applicable whenever they are uncertain about which translation is better, i.e. when they deem both the GT and APE translations to be of equal quality (including equally unusable).

Table 3 shows the results of the polling scheme (human evaluation) of the raw GT output compared to the final automatic post-editing (SC-APE) output. The values in the table represent how many translations were chosen by each translator for individual systems. The polling based evaluation was carried out with 145 (of the 198) sentences. We discarded sentences containing less than six words either in source sentences or in the translations. We conducted the voting process serially to avoid any conflict between the translators. Table 3 shows that translators preferred APE output over the raw MT output. Translators did not have any knowledge about which translations are from which system as the two translation options were presented to them in random order. The winning APE system received on average 49.3% votes compared to 17% votes received by the GT system, while 33.7% votes were neutral as the translators were undecided for those sentences.

The SC-APE system received a total of 280 votes and it received votes from at least one translator for 105 unique segments, while GT received 112 total votes for 61 unique segments and 188 votes were received for 94 unique segments for the *uncertain* category. After detailed analysis we found that all 4 translators agreed on 27 APE translations, 6 GT translation and 9 neutral cases among the 145 sentences.

Translators	APE	GT	U
T1	91	22	32
T2	57	17	71
T3	72	37	36
T4	65	23	58
Average	71.5	24.7	49.2

Table 3: Outcome of polling with four expert translators for 145 sentences.

For the 145 sentences, we measured pairwise inter-annotator agreements between the translators by computing Cohen's κ coefficient (Cohen, 1960). Table 4 shows the inter-annotator agreements. The κ coefficients ranged from 0.141 (between T1 and T2) to 0.54 (between T2 and T4). The overall κ coefficient was 0.330. According to (Landis and Koch, 1977) this correlation coefficient can be interpreted as fair.

Cohen's κ	T1	T2	T3	T4
T1	-	0.141	0.424	0.398
T2	0.141	-	0.232	0.540
T3	0.424	0.232	-	0.248
T4	0.398	0.540	0.248	-

Table 4: Inter-annotator agreement between the translators.

5.3 Time and Productivity Gain Analysis

In order to investigate the performance of the APE system in terms of time and productivity gains, a completely new set of test data was distributed among the four translators. The new test data consists of real-life client segments. SC-APE and GT translations are presented separately to the translators within their daily usage interface (MateCat). Table 5 shows the statistics of how much time on average each individual translator took for the post-editing task. Table 5 also shows the average number of words (per minute, hour) post-edited by each translator. We calculated productivity gain by comparing column 2 (SC-APE) and 3 (GT) in Table 5. Table 5 shows that, SC-APE improves the productivity of the translators in general. Among the 4 translators, SAPE resulted in improved productivity for 3 translators (T1, T2 and T3), while for one translator (T4) it seems to result in productivity loss. If we look at the seconds/word, words/minute, and words/hour measures on the GT data for the 4 translators, it is easily noticeable that T1 is the most efficient post-editor, followed by T2, T4 and T3. However, when the translators work on the SAPE output, T2 is found to be the most productive while T4 is found to be the least productive. The productivity changes vary from 46.6% to -40%, which indicates that the utility of SAPE also varies from person to person. However, even taking into account the decrease in productivity of T4, average productivity increases 12.96% with SAPE. One thing to be noted here is that the productivity loss of T4 perhaps should not be considered for evaluation. We spoke to T4 after the evaluation and found that the translator was not solely concentrating on the post-editing job, switching among different jobs.

	SC-APE			**GT**				
	secs /word	**words /min**	**words /hour**	**secs /word**	**words /min**	**words /hour**	**Gain /hour**	**% Gain**
T1	2.81	21	1260	2.92	20	1200	60	5.0
T2	2.7	22	1320	3.88	15	900	420	46.6
T3	4.82	12	720	6.75	9	540	180	33.3
T4	9.80	6	360	5.84	10	600	-240	-40.0

Table 5: Post editing statistics over GT and SC-APE.

We also conducted a detailed evaluation of the post-editing carried out by the four translators. The results are reported in Table 6. Column 2 (fine grained evaluation score) in Table 6 shows the average of scores assigned to each translator by MateCat based on 5 criteria: tag issues (mismatches, white spaces), translation errors (mistranslation, additions/omissions), terminology and translation consistency, language quality (grammar, punctuation, spelling) and style (readability, consistent style and tone). MateCat also classifies each translator to one of the 4 performance levels[4] – excellent (3), acceptable (2), poor (1) and fail (0), for each of the above mentioned 5 criteria. Column 3 (weight based on quality) shows the sum of the scores indicating performance levels for the 5 criteria. By multiplying the values in column 2 and column 3, we arrive at the final assessment score assigned to each translator.

By weighting the percentage gain (cf. last column in Table 5) with the final assessment scores (cf. last column in Table 6), as in Equation 2, we obtain an average productivity increase of 21.76%. Even

6 Conclusions and Future Work

The use of a single statistical aligner in our PB-SMT based baseline APE fails to improve over raw Google MT output; instead it degrades the performance, as was also reported by (Béchara et al., 2011). This motivated us to use alignment combination models including both statistical and edit-distance based methods in our hybrid word alignment model for APE. By improving word alignment, the APE system automatically acquires better lexical associations and already the "hybrid alignment-based" PB-SAPE system shows improvements over the Google MT baseline. The reason for using a hierarchical phrase extraction model for APE is that it makes the model sensitive to syntactic structures. Moreover, HPB-SAPE captures global reordering by SCFG, helping to correct word order errors to some extent. Integration of our hybrid word alignment into the APE model resulted in both PB-SAPE (S_1) and HPB-SAPE (S_2) producing better translations than GT. System combination based APE (SC-APE) of S_1, S_2 and GT provided further statistically significant improvements over raw MT output. We performed statistical significance testing between GT, S_1, S_2 and SC-APE. S_1 provides statistically significant ($0.01 < p < 0.04$) improvements over GT across all metrics. Similarly S_2 yields statistically significant ($p < 0.01$) improvements over both GT and S_1 in all metrics. Our SC-APE system performs best and results in statistically significant ($p < 0.01$) improvements over all other systems across all metrics. In future, we will try bootstrapping strategies for further tuning the model and add more sophisticated features beyond the lexical level. The future study will also include a comparison of our system performance with Neural APE (Pal et al., 2016). We will also carry out experiments on different datasets including the WMT APE datasets.

Measuring the Effect of Conversational Aspects on Machine Translation Quality

Abstract

Research in statistical machine translation (SMT) is largely driven by formal translation tasks, while translating informal text is much more challenging. In this paper we focus on SMT for the informal genre of dialogues, which has rarely been addressed to date. Concretely, we investigate the effect of dialogue acts, speakers, gender, and text register on SMT quality when translating fictional dialogues. We first create and release a corpus of multilingual movie dialogues annotated with these four dialogue-specific aspects. When measuring translation performance for each of these variables, we find that BLEU fluctuations between their categories are often significantly larger than randomly expected. Following this finding, we hypothesize and show that SMT of fictional dialogues benefits from adaptation towards dialogue acts and registers. Finally, we find that male speakers are harder to translate and use more vulgar language than female speakers, and that vulgarity is often not preserved during translation.

1 Introduction

Research in statistical machine translation (SMT) has mostly been driven by formal translation tasks. These are, however, not representative for the abundance of informal data emerging on the Internet, for which state-of-the-art SMT systems perform markedly worse (van der Wees et al., 2015a). Recent years have therefore shown an increasing effort in improving SMT for informal text, for example by normalizing noisy text to more formal text (Bertoldi et al., 2010; Banerjee et al., 2012; Ling et al., 2013a), or by enhancing formal training data with user-generated data (Banerjee et al., 2011; Jehl et al., 2012; Ling et al., 2013b).

In this paper we focus on SMT for dialogues, an informal genre that involves, by definition, multiple speakers, and is thus noticeably different from formal text (Fernández, 2014). Formal text is typically written by a single writer with a clear intention (e.g., informing or persuading), and moreover has been editorially controlled according to standards of language use. In dialogues, on the other hand, different *speakers* have different intentions and language use, affected, for example, by their *gender*. Such variations are reflected by *register*, a term referring to socio-situational language variation (Lee, 2001), and *dialogue acts*, functional actions such as questions or answers (Bunt, 1979).

While these and other dialogue-specific aspects have been analyzed in dialogue research (Schlangen, 2005; Fernández, 2014), their impact on SMT has hardly been studied. A likely explanation is the lack of adequate evaluation data, i.e., parallel conversations annotated with dialogue-specific variabels. In this paper, we take a first step towards investigating the effect of dialogue acts, speakers, gender, and register on SMT performance by measuring their respective impact on annotated dialogues from movie subtitles.

Since movie dialogues are fictional, we can only consider them as an approximation of real face-to-face conversation. However, several corpus-based studies have shown that, while movie dialogues differ from natural spoken dialogues in terms of spontaneity—they exhibit fewer incomplete utterances, hesitations, and repetitions—, they do not differ to a great extent in terms of linguistic features and main

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2571–2581, Osaka, Japan, December 11-17 2016.

messages (Forchini, 2009; Forchini, 2012; Dose, 2013). In fact, movie dialogues approximate real face-to-face conversation more than for example SMS and chat, in which media constraints influence the flow of a conversation (Whittaker, 2003; Brennan and Lockridge, 2006). Finally, Danescu-Niculescu-Mizil and Lee (2011) have shown that certain psycholinguistic and gender-specific aspects of language are also observed in fictional dialogues, indicating that conclusions drawn from experiments on fictional dialogues generalize at least partially to real spoken conversations.

The structure and contributions of this paper are as follows: First, in Section 2 we annotate multilingual movie dialogues with four dialogue-specific variables; dialogue acts, speakers, gender, and register level, and we release these annotated corpora. In Section 3 we describe our approach to measure how SMT quality is affected by each of the four dialogue-specific aspects. Next, in Section 4 we use our annotated benchmarks to show that (i) performance fluctuations among the studied dialogue dimensions are larger than randomly expected, (ii) male speakers are harder to translate than female speakers and use more vulgar language, and (iii) vulgarity is often not preserved during translation. Finally, in Section 5 we investigate and confirm the hypothesis that SMT of fictional dialogues benefits from adaptation towards various dialogue acts and registers, indicating that apart from domain adaptation, adaptation to other variables should be considered to improve SMT quality for fictional, and potentially real, dialogues.

2 Corpus construction and annotation

To measure the effect of dialogue acts, speakers, gender, and register on SMT performance we need a multilingual dialogue corpus in which utterances are annotated with each of these dialogue aspects. Unfortunately, existing corpora are limited to the English language (Janin et al., 2003; McCowan et al., 2005; Danescu-Niculescu-Mizil and Lee, 2011; Banchs, 2012; Walker et al., 2012) or contain only some of the required annotations (Wang et al., 2016). We therefore first automatically annotate multilingual movie dialogues with the above dialogue dimensions for five language pairs: Arabic-English, Chinese-English, Dutch-English, German-English, and Spanish-English.

For this annotation process we build on two main resources: (i) the OpenSubtitles corpus (Lison and Tiedemann, 2016), containing non-professionally translated subtitles, collected from `www.opensubtitles.org` and cross-lingually aligned using time information, bilingual lexicons, and cognates (Tiedemann, 2008); and (ii) the Internet Movie Script Database (IMSDb)[1], containing English movie scripts with speakers, utterances, and context (e.g., change of scenes). Using these and a number of additional resources we create our annotated corpora as follows:

1. First we collect **speaker-utterance pairs** from IMSDb scripts, based on their respective indentation sizes. We then use the Champollion sentence aligner (Ma, 2006) monolingually to align English subtitles to the English script, and follow the OpenSubtitles alignment links to align foreign subtitles to the English subtitles-script bitext. Finally, we discard the script text from the resulting 'tritext', yielding multilingual speaker-annotated dialogue corpora. Table 1a shows statistics on the average number of speakers and main characters (i.e., speakers with at least 20 utterances) per movie.

2. We learn each speaker's **gender** based on their name's occurrence in a number of online name databases and a list of gender-revealing tags such as 'aunt', 'boy', or 'grandma'. Annotations are available for ∼58% of the utterances, and the average female-to-male ratio is 1:1.7, see Table 1b.

3. We heuristically detect the **dialogue act** of each source-language utterance, considering *questions*, *exclamations* and *declaratives*. Distributions of these dialogue acts differ between language pairs, see Table 1c, but make up on average 28%, 9%, and 63% of the corpora, respectively.

4. We define a **register** label, based on the fraction of colloquial and vulgar expressions in an utterance, according to meta-information from an online dictionary[2]. We consider three register levels: *vulgar*, *colloquial*, and *neutral*, comprising circa 10%, 68%, and 22% of the corpora, respectively. Distribution statistics per language pair are shown in Table 1d.

Post-processing and annotation quality. The above described alignment and annotation process is done fully automatically, making it prone to errors. We therefore increase the alignment and annotation quality of our corpus by taking a number of measures: First, *before* running the Champollion aligner, we remove context information such as '[moaning]', '[clapping]' or '[chuckles]', which is most prevalent in, but not limited to, subtitles created for hearing-impaired people. In addition, we remove subtitle-specific tokens indicating continuation of a sentence on the next screen or switches in speaker turns, yielding more fluent and less fragmented utterances.

Next, *after* running the alignment process, we favor high-quality alignments by selecting only movies or movie versions (OpenSubtitles typically contains several alternative versions for a single movie (Tiedemann, 2016)) that meet the following criteria; (i) sentence lengths between both language pairs are sufficiently close, (ii) the number of sentences for which ambiguous speakers have been aligned does not exceed a given threshold, (iii) the letter distribution is sufficiently similar to the average distribution of the language. By enforcing these quality standards, we respectively reduce the number of OpenSubtitles alignment errors, Champollion alignment errors, and OCR errors. Finally, we remove utterances with ambiguous speaker labels as these are caused by erroneous Champollion alignments.

Despite efforts to improve alignment quality, our corpus still contains some incorrect alignments. To quantify these, and to verify the correctness of the automatic annotations, we manually inspect randomly selected fragments across different language pairs and movies. Based on evaluation of a sample of 120 utterances, we estimate a final alignment accuracy of 92.5%. In addition, Table 2 shows confusion matrices for manual versus automatic annotation of gender, dialogue acts, and register for the 120 selected utterances. With the overall annotation agreement per variable ranging from 85% to 97.5%, we find that our automatic annotation strategies are very accurate. Disagreement between manual and automatic annotations occurs mostly for speakers labeled with unknown gender, and between the register levels colloquial and neutral, indicating that these categories can benefit from more advanced annotation methods. For example, to better distinguish colloquial and neutral register levels, one could exploit sentence length or language model perplexity.

Soll ich dir einen Cappuccino holen?	Shall I go and get you a cappuccino? You know, ease the pain a bit.	Martin, M, coll., question
Ja. Lieber nur einen halben. Mehr kann ich mir nicht leisten.	Yeah. Better make it a half. All I can afford.	William, M, coll., declarative
Logisch. Demi-Cappu. Kommt sofort.	Get your logic. Demi-cappu coming right up.	Martin, M, coll., declarative

Table 3: Example dialogue from Notting Hill; a) original sentences in the OpenSubtitles corpus, where // indicates a sentence boundary in many-to-one or one-to-many alignments, and b) final annotated utterances generated in our annotation pipeline, annotated with speaker (William, Martin), gender (M=male, F=female), register level (neutral, colloquial, vulgar) and dialogue act (declarative, exclamation, question). Note that sentences pairs from the original corpus are often merged in the Champollion alignment process, and that erroneous OpenSubtitles alignments are not corrected.

Table 3 shows an example dialogue with annotations and its original form in the OpenSubtitles corpus. Note that our annotated corpora differ from OpenSubtitles since only actual dialogues are included (i.e., no context), many erroneously aligned sentence pairs have been removed, and utterances are longer and less fragmented. The latter is a result of the Champollion alignment process. Since sentences in the IMSDb scripts are typically longer than those in OpenSubtitles, Champollion regularly enforces one-to-many alignments. Following the OpenSubtitles-internal alignment links then yields a large number of many-to-many alignments in which subtitles get merged into longer utterances.

Finally, table 4a lists the statistics of the benchmarks which we use in this paper and make available for download[3]. While the remainder of this paper uses the annotated fictional dialogues to analyze the impact of dialogue-specific aspects on SMT, we believe that our data set may also help to advance dialogue research—today largely confined to the English language—in a multilingual scenario.

3 Measuring dialogue effects on SMT

In this section we measure the effect of dialogue dimensions on SMT performance of fictional dialogues. To this end, we quantify BLEU (Papineni et al., 2002) fluctuations between differences in dialogue acts, speakers, gender, and register, and we determine whether the observed fluctuations are larger than randomly expected.

Table 4: Specifications of parallel training and evaluation data. Training data consists of OpenSubtitles corpora, evaluation data consists of speaker-annotated dialogues.

3.1 Basic experimental setup

We run our experiments using an in-house phrase-based SMT system similar to Moses (Koehn et al., 2007), with features including lexicalized reordering, linear distortion with limit 5, and lexical weighting. Our systems are trained on 59M–171M tokens (depending on the language pair, see Table 4b) of unannotated OpenSubtitles corpora. We use Kneser-Ney smoothed 5-gram language models (500M–1.7B tokens, depending on the language pair) that linearly interpolate OpenSubtitles with various LDC and WMT corpora using weights optimized on a held-out set of OpenSubtitles data. Systems are tuned using pairwise ranking optimization (PRO) (Hopkins and May, 2011) on a different held-out OpenSubtitles set. The resulting systems are thus at all levels adapted to the movie dialogues translation task rather than the general domain.

3.2 Approximate randomization testing

When translating dialogues, we naturally observe *some* BLEU variations across categories such as different dialogue acts or speakers. An important question is whether the observed differences are to be expected (the null hypothesis), or whether they are indicators that one category is truly harder to translate than another (the alternative hypothesis). We test this hypothesis with an approximate randomization approach (Edgington, 1969; Noreen, 1989).

While approximate randomization (also known as approximate permutation) is often used to compare the mean and variance of *two* groups, it can be adapted to our setting with multiple categories. To this end, we compute BLEU for each of the categories in a dialogue variable (e.g., vulgar, colloquial, and neutral utterances for the dialogue variable of register level). Next, we randomly permute category labels over utterances, following the original distribution of utterances per category, and we recompute BLEU for the randomized labels.

As our test statistic of interest, we define and measure the *mean absolute BLEU difference*, which captures BLEU fluctuations between categories:

$$\text{MBD} = \frac{2}{|S|^2 - |S|} \sum_{i=1}^{|S|} \sum_{j=i+1}^{|S|} \mid \text{BLEU}_i - \text{BLEU}_j \mid \quad (1)$$

Here S is the set of categories for a given dialogue variable (e.g., $S_{\text{register}} = \{\text{vulgar, colloquial, neutral}\}$), and BLEU_i the BLEU score for category i. Each pair of categories (i, j) is compared exactly once in terms of BLEU scores. Note that MBD is a specific instance of *mean absolute difference* (MD) or *Gini mean absolute difference* (GMD), a measure of statistical dispersion which has shown to be superior to other common statistical dispersion measures such as variance, standard deviation and interquartile range (Yitzhaki, 2003).

Next, we compute the p-value by counting how often (in a total of 1,000 permutations) we observe an MBD value that is at least as extreme as the one observed for the real categories. If for a given dialogue variable $p \leq 0.05$ or $p \leq 0.01$, we conclude that this variable has a weakly or strongly significant impact on SMT quality, respectively.

For dialogue acts, gender and register we permute labels over the entire benchmark. For speakers we only permute labels within each movie since inter-movie variations in BLEU are affected by many other factors (e.g., script writers, translators, movie genre) which distract from the impact of speakers. In addition, when computing speaker-specific BLEU, we only include main characters (i.e., speakers with at least 20 utterances) to avoid BLEU's instability on small documents .

Table 5: BLEU for dialogue acts, speakers, gender, and register, translated using baseline SMT trained and tuned on OpenSubtitles corpora. MBD: mean absolute BLEU difference, see Equation (1), all statistically significant at $p \leq 0.01$ (▲). ssMBD: percentage of movies with statistically significant speaker-MBD at $p \leq 0.05$.

4 Results

In this section we discuss the observed BLEU fluctuations (see Table 5) for our four dialogue variables of interest, guided by Spanish-to-English and English-to-German examples in Table 6, to which we provide pointers (EX#) in the text.

4.1 The effect of dialogue acts on SMT quality

As shown in Table 5a, there are substantial performance fluctuations between dialogue acts for all language pairs. However, there is no consistent pattern between different languages. For instance, we observe punctuation errors (EX1) for ES↔EN, and verb drop (EX2) and wrong word order (EX3) for EN→DE. This makes it particularly interesting to further investigate how dialogue acts can be exploited to improve translation quality of (fictional) dialogues. Improving SMT for the dialogue acts under consideration resembles cross-lingual question answering (Tiedemann, 2009). However, when considering finer dialogue act granularities, it may be profitable to exploit context information, which is not used in our current SMT setup.

4.2 The effect of speakers on SMT quality

In Table 5b we report the percentage of movies per language pair for which the observed MBD is statistically significant at $p \leq 0.05$, which is 18.6% on average. Since there are too many speakers to report individual BLEU scores, we randomly select 100 German-English movies, and compute for each of these ΔMBD as the difference between MBD for real speakers and the average MBD for randomized labels:

$$\Delta\text{MBD} = \text{MBD}_{real} - \overline{\text{MBD}}_{random} \quad (2)$$

Figure 1 shows that inter-speaker BLEU fluctuations among real speakers are often larger than inter-speaker BLEU fluctuations among randomized speaker tags. These findings suggest that, while domain adaptation is an established task in SMT, conversational SMT may benefit—at least for the fraction of movies with statistically significant speaker differences—from a fine-grained adaptation at the speaker

Annotations	ES source	ES→EN SMT output	EN reference
S1, M, neutral, declarative	se acabaron los días de olvidar, han empezado los de recordar.	the days are over, have begun to forget them to remember.	the days of forgetting are over. the days of remembering have begun.
S2, F, colloquial, question	¿sabes qué pareces cuando hablas así?	you know what you look like when you talk like that?	know when you go on what you sound like?
S1, M, vulgar, declarative	un *j***do*(EX4) hombre sensato.	a sensible man.(EX6)	i sound like a sensible *f***ing* man.
S2, F, colloquial, excl.	un pato. ¡cuac, cuac!	a duck. [quack, quack!(EX1)	you sound like a duck. quack, quack

Annotations	EN source	EN→DE SMT output	DE reference

Table 6: Censored ES→EN (top) and EN→DE (bottom) translation examples of an annotated dialogue, originating from Pulp Fiction and involving two speakers: Pumpkin (S1, M=male) and Honeybunny (S2, F=female). Examples of phenomena marked with (EX#) are discussed in Sections 4.1–4.4.

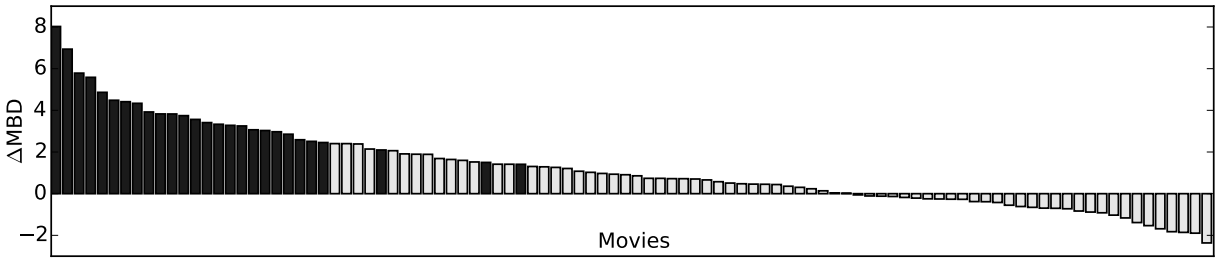

Figure 1: ΔMBD (see Section 4.2) for 100 randomly selected German-English benchmark movies. Black bars indicate movies with statistical significant positive ΔMBD at $p \leq 0.05$.

level, as proven successful in speech recognition research (Shinoda, 2011), and related to recent work on personalizing machine translation (Mirkin et al., 2015; Mirkin and Meunier, 2015).

Finally, since our analysis is carried out on fictional dialogues, it may be worth investigating to what extent BLEU scores fluctuate between actors or script writers rather than only characters, however this requires additional annotation.

4.3 The effect of gender on SMT quality

Table 5c shows that BLEU scores per gender follow a similar pattern in all language pairs. Male speakers are significantly harder to translate than female speakers, despite the fact that male speakers are likely better represented in the parallel OpenSubtitles data, based on the male-to-female ratio in our evaluation sets. However, we find that female utterances are better covered by the language model, with perplexity values on average 8% higher for males than females. This finding is consistent with recent work by Wang et al. (2016), who show that SMT can benefit from gender-adapted language models but do not provide gender-specific BLEU scores. Gender differences in movie dialogues have also been reported by Danescu-Niculescu-Mizil and Lee (2011), who show that characters adapt their language easier to females than to males.

However, we have to be careful drawing conclusions about the impact of gender on real spoken dialogues from our observations on fictional dialogues. Since the vast majority of movie scripts are written by men (Lauzen, 2016), our findings reflect differences between language of male and female characters as perceived by male writers. The observed BLEU differences might therefore be based on stereotypes rather than real gender differences. On the other hand, a tremendously large body of work has studied gender and language or discourse (Tannen, 1994; Wodak, 1997; Holmes and Meyerhoff, 2008, among others), indicating that these concepts are closely intertwined. To the best of our knowledge, our work is the first to study the impact of gender on SMT, albeit for scripted dialogues, and we believe that meta-information about a speaker's gender is also a potential source to customize SMT for real dialogues.

4.4 The effect of register on SMT quality

The results per register (Table 5d) show that SMT quality is worst for vulgar utterances and generally best for neutral sentences. While consistent with previous findings that informal language is hard to translate (van der Wees et al., 2015a), this observation cannot solely be attributed to poor model coverage, since colloquial and vulgar language are well-covered in our OpenSubtitles-trained systems.

When manually inspecting human translations for vulgar expressions, we find that these vary from literal (EX4) to very nuanced (EX5) translations, yielding inconsistent SMT output. We also observe that vulgarity is often not preserved in (both human and machine) translation (EX6): A comparison of vulgarity scores shows that, while vulgarity sometimes increases, the number of vulgar utterances in the SMT output is on average 35% lower than in the reference set.

Finally, since poor SMT quality is observed for both male characters and vulgar language, we hypothesize that the two might co-occur. Indeed, the average vulgarity scores for males are 64% higher than for females, which may in part explain the observed SMT quality between genders.

5 Preliminary adaptation towards dialogue variables

We observed that BLEU scores significantly fluctuate between differences along dialogue dimensions. This finding suggests that SMT for fictional dialogues may benefit from adaptation towards different categories along these dimensions. To verify this hypothesis we run a number of adaptation experiments, in which we adapt our baseline SMT systems towards different dialogue acts and different registers—two dialogue aspects which can be computed straightforwardly for the unannotated training corpora.

We adapt our systems at two levels: First, we create category-specific language models by interpolating our general movie dialogue language model with a language model trained on only the most relevant subset of the bitext's target side. We determine relevant sentences by applying the same annotation guidelines that were used for annotation of the benchmarks (Section 2). Second, we tune our systems on held-out sets selected according to the same criteria, thus comprising category-specific data.

We run adaptation experiments for the language pairs with the largest observed MBD; Dutch-English, English-Spanish, and Arabic-English for dialogue acts, and German-English, English-German, and Dutch-English for register. Note that the aim of our adaptation experiments is to verify whether SMT performance can benefit from a simple adaptation approach at the fine-grained level of different dialogue-specific aspects, rather than presenting a novel SMT adaptation approach.

The results of our adaptation experiments are shown in Table 7. The first observation we can make is that the adapted systems result in substantially lower mean absolute BLEU differences (MBD) for both dialogue dimensions—dialogue act and register level—for all language pairs except Arabic-English. This means that most of the adapted systems generate translations of more uniform quality with a lower degree of fluctuation in BLEU. Further, the BLEU scores for the individual categories of both dialogue dimensions show that the lower MBD scores are due to statistically significant improvements for most of the dialogue acts and registers. The only case where our simple adaptation method causes a statistically significant drop in BLEU is for the translation of questions from Dutch into English. Vulgar and colloquial language profit particularly well from language model adaptation, while results for question and exclamation marks are more variable between language pairs. Finally, we would like to emphasize that we do not claim that the simple adaption method used here constitutes the best adaptation approach

	MBD		Questions			Exclamations			Declaratives		
Language pair	Base.	Adapt.	Base.	Adapt.	Diff.	Base.	Adapt.	Diff.	Base.	Adapt.	Diff.

Table 7: Results of adaptation experiments. Top: adaptation towards dialogue acts for the 3 language pairs with the largest mean absolute BLEU difference (MBD, see Equation (1)) between dialogue acts. Bottom: adaptation towards registers for the 3 language pairs with the largest MBD between register levels. Statistical significance against the baseline at $p \leq 0.05$ ($\triangle$/$\triangledown$) and $p \leq 0.01$ ($\blacktriangle$/$\blacktriangledown$) is measured using approximate randomization (Riezler and Maxwell, 2005).

for dialogue-specific phenomena, but rather that already a simple adaptation approach can benefit from our dialogue-specific annotations.

6 Conclusions and implications

While SMT research has mostly been driven by formal translation tasks, very little work has been reported on SMT for informal genres such as dialogues, a genre that differs substantially from formal text and thus poses different translation challenges. Following the previous finding that genre and topic affect SMT differently (van der Wees et al., 2015b), we have in this paper analyzed the impact of dialogue-specific aspects in SMT for fictional dialogues. We created and released a movie-dialogue benchmark in which utterances are annotated with dialogue acts, speakers, gender, and register, and we studied the effect of these four variables on SMT performance.

Our analysis shows that BLEU fluctuations for all variables are often significantly larger than randomly expected. When looking at specific dialogue aspects, we found that the register level has a significant impact on translation quality, with translations of vulgar utterances being of substantially lower quality than neutral or even colloquial utterances for all language pairs under consideration. Similarly we found large variations in translation quality between different dialogue acts, although we did not detect a consistent pattern between different languages; e.g., questions can be more difficult to translate than exclamations for one language pair, while the reverse is true for another language pair.

These findings suggest that conversational SMT may benefit from adaptation at fine-grained levels. We tested and confirmed this hypothesis in a series of simple adaptation experiments.

Finally, we found that male speakers are harder to translate and use more vulgar language than female speakers, and that vulgarity is often not preserved during translation. While our analyses are carried out on fictional dialogues, we believe that our findings generalize at least partially to other types of dialogues, and are thus valuable for advancing conversational SMT.

Acknowledgements

This research was funded in part by the Netherlands Organization for Scientific Research (NWO) under project number 639.022.213. We thank Raquel Fernández for sharing valuable insights from dialogue research, Tobias Schnabel for providing feedback on the approximate randomization approach, and the anonymous reviewers for their thoughtful comments.

Enriching Phrase Tables for Statistical Machine Translation Using Mixed Embeddings

Peyman Passban, Qun Liu and Andy Way
ADAPT Centre
School of Computing

firstname.lastname@adaptcentre.ie

Abstract

The phrase table is considered to be the main bilingual resource for the phrase-based statistical machine translation (PBSMT) model. During translation, a source sentence is decomposed into several phrases. The best match of each source phrase is selected among several target-side counterparts within the phrase table, and processed by the decoder to generate a sentence-level translation. The best match is chosen according to several factors, including a set of bilingual features. PBSMT engines by default provide four probability scores in phrase tables which are considered as the main set of bilingual features. Our goal is to enrich that set of features, as a better feature set should yield better translations. We propose new scores generated by a Convolutional Neural Network (CNN) which indicate the semantic relatedness of phrase pairs. We evaluate our model in different experimental settings with different language pairs. We observe significant improvements when the proposed features are incorporated into the PBSMT pipeline.

1 Introduction

PBSMT models sentence-level translation with a phrase-based setting in which sentences are decomposed into different phrases (Koehn et al., 2007; Koehn, 2009). At each step, for a given source phrase the best candidate among the target phrases is selected as its translation. Phrasal translations are combined together to produce the sentence-level translation. This is a high-level view of PBSMT and there are many other processes involved in the main pipeline. Different bilingual and monolingual features are taken into account to make the final translation as adequate and fluent as possible. In this paper we only focus on the phrase-pairing process and try to enrich that part. The standard baseline bilingual features in the PBSMT pipeline by default are: the phrase translation probability $\phi(e|f)$, inverse phrase translation probability $\phi(f|e)$, lexical weighting $lex(e|f)$ and inverse lexical weighting $lex(f|e)$. These scores are computed based on the co-occurrence of phrase pairs in training corpora and do not indicate any other information about phrases, their relation or context. Our goal in this research is to extend this set of features by incorporating semantic information of phrase pairs.

Word embeddings are numerical representations of words which preserve semantic and syntactic information about words themselves and their context (Huang et al., 2012; Luong et al., 2013; Mikolov et al., 2013a; Mikolov et al., 2013b). They also preserve information about word order. These types of contextual, syntactic and semantic information can be quite useful for machine translation (MT), but being by its very nature a bilingual application, it requires bilingual (cross-lingual) information. Accordingly, we need methods to train bilingual embeddings via which we can access syntactic and semantic information about the source side as well as the target.

Several papers have explored the training of bilingual embeddings (Mikolov et al., 2013b; Zou et al., 2013; Cho et al., 2014; Gouws et al., 2015; Passban et al., 2015a; Zhao et al., 2015; Passban et al., 2016) with different architectures for different tasks such as MT and document classification. In our work we also try to follow the same research line. We propose a multi-plane data structure and a CNN to train

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2582–2591, Osaka, Japan, December 11-17 2016.

mixed embeddings. Using the proposed data structure, source and target words are linked together, so we call our embeddings mixed. Our model is a bilingual extension to well-known embedding models (Mikolov et al., 2013a; Pennington et al., 2014) with a quite different architecture which is fine-tuned for MT tasks.

The reminder of the paper is structured as follows. In Section 2 we briefly review some similar models which train bilingual embeddings. Section 3 discusses our neural model and how we incorporate results from our model into the PBSMT pipeline. Section 4 explains the results from several experiments to show the impact of the proposed model. Finally, Section 5 concludes the paper with some avenues for future work.

2 Background

One of the most successful neural models proposed for training word embeddings is *Word2Vec* (Mikolov et al., 2013a). In such models words are encoded into an n-dimensional feature space and represented by numerical vectors called embeddings. Embeddings are able to preserve different types of information about words. *Word2Vec* trains word-level embeddings. Le and Mikolov (2014) proposed a new architecture which is an extension to *Word2Vec* which scales up the model to train document-level (phrase, sentence and any chunk of text) embeddings. Although these models are very useful for natural language processing (NLP) tasks, they only provide monolingual information which is not adequate for cross-lingual NLP, MT, multilingual text classification etc. Therefore, some models have been proposed in this regard.

A sample of training bilingual embeddings was proposed in Mikolov et al. (2013b) and Zhao et al. (2015). They separately project words of source and target languages into embeddings, then try to find a transformation function to map the source embedding space into the target space. The transformation function was approximated using a small set of word pairs. This approach allows the construction of a word-level translation engine with a very large amount of monolingual data and only a small number of bilingual word pairs. The cross-lingual transformation mechanism enables the engine to search for translations for OOV (out-of-vocabulary) words by consulting a monolingual index which contains words that were not observed in the parallel training data. This is a word-level translation/transformation but clearly MT is more than a word-level process. To go beyond and train document-level bilingual embeddings several models have been proposed and applied to MT and document classification tasks (Zou et al., 2013; Cho et al., 2014; Gouws et al., 2015; Passban et al., 2016). These models have different architectures which we try to address in the next sections.

3 Proposed Model

The proposed pipeline can be briefly explained in five steps: a) A PBSMT engine is trained and tuned on a bilingual parallel corpus. b) By use of the same training corpus, mixed embeddings are trained by our CNN. c) The proposed CNN takes a pair of translationally equivalent source and target sentences (s, t) and tries to link related words from both sides. d) Input words are mixed through a multi-plane data structure and a specific convolution function. e) At the end of training, we wish to have embeddings which preserve different types of monolingual and bilingual information. f) Finally, we use mixed embeddings to enrich the bilingual feature set of the phrase table. Sections 3.1 and 3.2 explain the training method and the way we use word embeddings in the PBSMT pipeline, respectively.

3.1 Training Mixed Embeddings

Generally, to train word embeddings a neural network processes an input sequence of words at each pass. One word is randomly selected (w_p) from the input sequence which is considered as the sequence label and expected to be predicted at the output layer. This architecture is known as the CBOW (Continuous-Bag-Of-Words) model (Mikolov et al., 2013a) and all other embedding models can be viewed as variations of this model. The goal of such a process is to use context words (preceding and following words around w_p) to predict w_p. With this technique, word embeddings are informed about contextual information and word order. Moreover, since they are trained in a shared space, they are connected to each other.

In the forward pass, embeddings for context words are combined to make the prediction. Each neural network has a loss function which penalizes wrong predictions. Error values are computed based on the loss function and back-propagated to the network. Network parameters are updated with respect to error values as word embeddings comprise part of those parameters, they are updated at each pass. For more information about embedding learning, see Goldberg and Levy (2014).

In existing embedding models the input data structure is a matrix and the setting is monolingual. Each column in the matrix includes an embedding (which is a vector) for one of context words. In our model we expand the input matrix to a 2-plane tensor (each plane is a matrix) in order to change the monolingual setting into a bilingual version. Training instances in our setting are a pair of translationally equivalent source and target sentences. The first and second planes include embeddings for source and target words, respectively. In embedding models w_p is not included in the input matrix. Similarly we do not have w_p in our input tensor. We randomly select a word either from the source or target side of (s, t) as w_p and remove all information about it and its translation(s)[1] from the input tensor. What remains after removing w_p and its translation(s) are 'context words'. Embeddings for source context words are placed in the first plane by the order of their appearance in s. Then the counterpart/translation of each column in the first plane is retrieved (among target-side embeddings) according to the alignment function, and placed in the same column in the second plane.

The example below clarifies the structure of the input tensor. For *s="I will ask him to come immediately ."* with a Farsi[2] translation *t="mn āz āū xvāhm xvāst ke fūrn byāyd ."*, the word alignment provided by a PBSMT engine is $a(s, t)$ = [0-0, 1-3, 2-4, 3-1, 3-2, 4-7, 5-6, 6-7, 7-6, 8-8] which is illustrated in Figure 1.

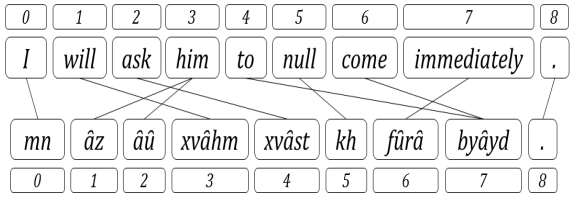

Figure 1: Word alignments provided by a PBSMT engine for a given (s, t) example. *'him'* is selected as w_p so *'him'* and its translations are excluded from the input tensor.

$a(.)$ is an alignment function which generates a list of i-j tuples. i indicates the position of a source word w_i^s within s and j is the position of the translation of w_i^s within t (namely w_j^t). If *'him'* is randomly selected as w_p, *'him'* and its translations (*'āz'* and *'āu'*) are all removed from the input tensor, and embeddings for the rest of the words are loaded into the input tensor according to i-j tuples. Embeddings for source words except *'him'* are sequentially placed in the first plane. For the second plane, each column c includes the embedding for the translation of a source word located in the c-th column of the first plane. If the embedding of each word is referred to by $\mathcal{E}$, the order of source and target embeddings in the first and second planes is as follows:

$$p_1 = [\mathcal{E}(w_0^s), \mathcal{E}(w_1^s), \mathcal{E}(w_2^s), \mathcal{E}(w_4^s), \mathcal{E}(w_5^s), \mathcal{E}(w_6^s), \mathcal{E}(w_7^s), \mathcal{E}(w_8^s)]$$

$$p_2 = [\mathcal{E}(w_0^t), \mathcal{E}(w_3^t), \mathcal{E}(w_4^t), \mathcal{E}(w_7^t), \mathcal{E}(w_5^t), \mathcal{E}(w_7^t), \mathcal{E}(w_6^t), \mathcal{E}(w_8^t)]$$

.

Our CNN takes the 2-plane tensor as its input and combines its planes through a specific convolution function. The new multi-plane convolution function is a simple extension of the standard convolution function which is formulated as in (1). It takes a multi-plane data structure (in our case, 2-plane) and

[1]Sometimes the alignment function assigns more than one target word to a given source word.

[2]We used the DIN transliteration standard to show the Farsi alphabets: `https://en.wikipedia.org/wiki/Persian_alphabet`.

generates another data structure with one or more planes:

$$\mathcal{M}_{p,i,j} = \sum_{l=1}^{|P|} \sum_{w=1}^{w_{\mathcal{F}}} \sum_{h=1}^{h_{\mathcal{F}}} \mathcal{F}_{p,l,w,h} \times \mathcal{I}_{l,(i-1)+w,(j-1)+h} \quad (1)$$

where $\mathcal{I}$, $\mathcal{M}$ and $\mathcal{F}$ are the input, output and filter,[3] respectively. $\mathcal{M}$, is the results of the fusion process (mixing embeddings) should have one to many planes which are referred to by the p subscript. Each plane in $\mathcal{M}$ is a matrix and its values are accessible by the (i, j) coordinates, i.e. $\mathcal{M}_{p,i,j}$ shows the value of the i-th row and the j-th column in the p-th plane. l is the plane index and $|P|$ shows the number of input planes. In our setting both $\mathcal{I}$ and $\mathcal{F}$ are 2-plane tensors so $|P| = 2$. $w_{\mathcal{F}}$ and $h_{\mathcal{F}}$ are the width and height of each plane in the filter. Finally the (w, h) tuple shows the coordinates of each plane in the filter $\mathcal{F}$. The first subscript of filter (p) indicates to which plane in $\mathcal{M}$ the filter belongs.

3.1.1 Network Architecture

The first layer of our architecture is a lookup table which includes word embeddings. The lookup table can be viewed as a matrix of weights whose values are updated during training. For each training sample (s, t), w_p is selected. Embeddings for context words are retrieved from the lookup table and placed within the input tensor, based on the alignment function. Through the multi-plane convolution, planes are convolved together. In our setting, the output of convolution is a matrix ($\mathcal{M}$). Based on Equation (1) for multi-plane convolution, it is possible to map the 2-plane input to a new structure with one to many planes, however we generate a structure with only one plane (a matrix). According to experimental results structures with more than one plane provide slightly better results but considerably delay the training phase. The new generated matrix contains information about source and target words, their order and relation. After multi-plane convolution we apply *max-pooling* to select the strongest features in 2×2 windows. We reshape the matrix to a vector and apply non-linearity by a *Rectifier* function. To prevent over-fitting, we place a *Dropout* layer (Srivastava et al., 2014) with $p = 0.4$ after *Rectifier*. The output of the *Dropout* layer is a vector which is passed to a *Softmax* layer.

Using the *Softmax* layer we try to predict the right class of the input which should be w_p. *Softmax* is a scalar function which maps its input to a value in the range [0,1], which is interpreted as the probability of predicting w_p given the input. In our network, similar to most embedding-training models, the objective is to maximize the log probability of w_p given the context, as in (2):

$$\frac{1}{n} \sum_{j=1}^{n} \log p(w_p | C_{2p}) \quad (2)$$

where C_{2p} is the context information represented by the 2-plane data structure. The network was trained using stochastic gradient descent and back-propagation (Rumelhart et al., 1988). All parameters of the model are randomly initialized over a uniform distribution in the range [-0.1,0.1]. Filter, weights, bias values and embeddings are all network parameters which are tuned during training. Our embedding size is 100 in all experiments. The network architecture is illustrated in Figure 2.

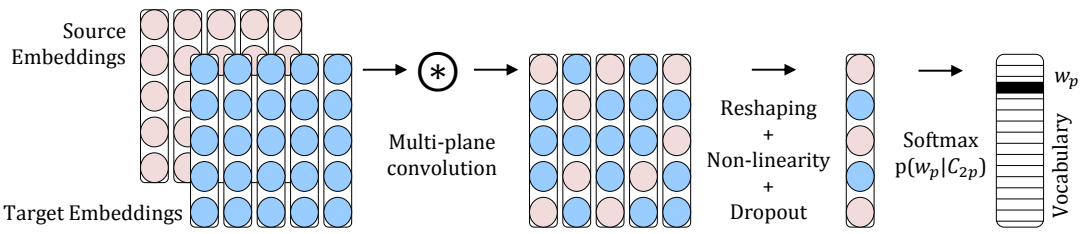

Figure 2: Network Architecture.

[3] *'Filter'* is referred to as *'Kernel'* in the literature.

3.2 Using Mixed Embeddings in the SMT Pipeline

After training we have mixed/bilingual word embeddings. Since we link/align equivalent words, those which are each other's translation are expected to have close embeddings. In the phrase table, parallel phrase pairs are stored, with their relevance being indicated by four default probabilities. We add two new scores to those probabilities.

As the first proposed score, for a given pair of source and target phrases, we retrieve embeddings for all source words and compute the average of those embeddings which gives us $\overline{v}_s$. Embeddings are numerical vectors, so we can easily compute the average of several vectors which produces another vector with the same dimensionality. We do the same for the target phrase, namely we retrieve embeddings for all target words and compute the average which provides $\overline{v}_t$. Using the Cosine similarity, we compute the distance between $\overline{v}_s$ and $\overline{v}_t$ and map the value to the range [0,1]. This new number is the first score we define to enrich the bilingual feature set.

As the second score, for each phrase pair we compute $score_2(s_p, t_p)$ by the computation explained in (3):

$$score_2(s_p, t_p) = \prod_{i=1}^{|s_p|} \frac{1}{|\{\alpha_i\}|} \sum_{i \in \{\alpha_i\}} \mathbf{C}(w_i^{s_p}, \alpha(w_i^{s_p})) \tag{3}$$

where $\alpha(.)$ is a word-level alignment function for the phrase pair (s_p, t_p), $\{\alpha_i\}$ is the set of target positions aligned to $w_i^{s_p}$ and $\mathbf{C}$ is the value of the Cosine distance mapped to the range [0,1]. For each phrase pair in the phrase table, we add these two new scores as the additional bilingual features and tune the PBSMT engine using both previous and new features.

4 Experimental Results

To show the impact of the proposed scores we perform several experiments. In the first experiment we evaluate the model on the English–French (En–Fr) pair. Results are reported in Table 1.

System	**En→Fr**			**Fr→En**		
	200K	500k	1M	200k	500k	1M
Baseline	34.4	35.2	35.7	33.8	34.5	35.4
Extended	35.5	36.0	36.0	35.1	35.2	35.5
Improvement	**+1.1**	**+0.8**	**+0.3**	**+1.3**	**+0.7**	+0.1

Table 1: Experimental results on the En–Fr pair. The numbers indicate the BLEU scores. The bold-faced scores indicate improvements are statistically significant according to paired bootstrap re-sampling with $p = 0.05$.

BLEU (Papineni et al., 2002) is used as the evaluation metric. We trained 3 baseline systems over datasets of 200K, 500K and 1 million (1M) parallel sentences. As the test set we use a corpus of 1.5K parallel sentences and the validation set includes 2K parallel sentences. All sentences are randomly selected from the En–Fr part of the Europarl (Koehn, 2005) collection. In our models we use 5-gram language models trained using the IRSTLM toolkit (Stolcke, 2002) and we tune models via MERT (Och, 2003). The extended systems those which include new scores within their phrase tables. In the extended systems we keep everything unchanged. only adding two new scores to the phrase table and the re-tune the PBSMT engine. The bold-faced scores indicate improvements are statistically significant according to paired bootstrap re-sampling with $p = 0.05$ (Koehn, 2004).

As Table 1 shows, adding new features considerably boosts the PBSMT model, especially for small-size datasets. For example, the BLEU score reported for the En→Fr system trained on the 500K dataset is 35.2, while a better performance (35.5) is achievable on the smaller 200K dataset in the presence of the new features. Usually as the size of the phrase table grows, the impact of such models attenuate, as large(r) phrase tables are rich enough to cover different cases and do not need to be enriched. Accordingly, such models are more suitable for small/medium-size datasets or low-resource languages. Other

similar models (Gao et al., 2013; Zou et al., 2013) were also evaluated on datasets with almost 500K parallel sentences and reported similar improvements.

4.1 Discussion

In this section we try to address different issues about the proposed model to analyse it from different perspectives. First we wish to discuss the advantages of the proposed architecture. We use a convolutional model to mix source and target words. We believe that the convolutional module enables the network to generate high-quality embeddings. To show the impact of this module we train a simple baseline using *Word2Vec*.

For the baseline model, we prepare a mixed training corpus, so that for each training sentence in the corpus, some words (up to 40% of whole words) are randomly selected and substituted with their translations. For example, to train mixed embeddings for their use in the En→Fr PSMT engine, some English words are randomly replaced with their French translations, and then the *Word2Vec* model is used to train mixed embeddings. For the Fr→En model we do the same and manipulate the French training corpus. In this model, instead of combining words via the NN we explicitly mix them in the training corpus so the context window for each w_p includes words from both sides. To train this model we used the *CBOW* setting (Mikolov et al., 2013a) with a context window of 10 words. For the En→Fr and Fr→En directions the new *Word2Vec*-based model performs with BLEU scores of 34.2 and 34.1, respectively. The new model degrades the En→Fr baseline engine (see the 200K-baseline model in Table 1) by -0.2 BLEU points and the improvement provided for the Fr→En engine is only +0.3. In the new model words are explicitly mixed together but the final result is not satisfactory. Therefore, the simple combination of words is not enough to boost the PBSMT engine and words should be processed efficiently.

The *Word2Vec*-based model is a simple baseline to show the impact of the proposed CNN but we wish to compare our model to other state-of-the-art and more powerful models. Unfortunately, datasets and source-code for the models by Gao et al. (2013) and Zou et al. (2013) (which are the most related works to ours) are not available so we cannot directly compare ours to those models. Gao et al. (2013) also uses an in-house translation decoder which makes the comparison even harder. Recently, Passban et al. (2016) proposed a feed-forward architecture to train bilingual phrase embeddings. The idea behind their model is similar to that of Devlin et al. (2014). They performed their evaluation on Farsi (Fa) which is a low-resource and morphologically rich language. Clearly, this model is an appropriate alternative to be compared to our CNN which can (partly) show the advantages/disadvantages of the proposed CNN compared to the feed-forward architecture. In Passban et al. (2016), the network concatenates phrase-level embeddings of source and target phrases to predict w_p, and error values are back-propagated to word and phrase embeddings. After training, the model provides bilingual phrase- and word-level embeddings. They use the similarity between parallel phrases as a new feature function (which is refered to as *sp2tp* in their paper). Using the same dataset and experimental setting, we compare the CNN to that model. The En–Fa model is trained using the TEP++ corpus (Passban et al., 2015b) which is a collection of ∼600K parallel sentences. The test, validation and training sets include 1K, 2K and 500K sentences, respectively. Results for this experiment are illustrated in Table 2. We tried to compare our CNN to a feed-forward architecture on the same task and same dataset. As the table shows, the proposed CNN performs better than a similar feed-forward architecture.

System	**En→Fa**	**Fa→En**
Baseline	21.03	29.21
Passban et al. (2016)	21.46 (+0.43)	29.71 (+0.50)
Our model	21.58 (**+0.55**)	29.93 (**+0.72**)

Table 2: Experimental results on the En–Fa pair.

In addition to quantitative evaluations, we look at the output of our engines to confirm that the proposed

pipeline affects the translation process in a particular way. Some examples are provided in Table 3. Based on our analysis, the new features positively affect word selection. Extended translations include better words than baseline translations. Furthermore, translations provided by the extended models have better grammatical structures. They are also semantically close(r) to the reference translations. The second and fourth examples are a clear indication to these issues. For the fourth example, in spite of a very low BLEU score the translation provided by the extended engine is a perfect translation.

System	Translation	sBLEU
	Example 1 (En)	
Reference	i would like to return to the matter of the embargo to conclude .	100
Baseline	i would like to revisit (to) the issue of the embargo in conclusion .	27.58
Extended	i would like to return to the issue of the embargo to conclude .	78.25
	Example 2 (En)	
Reference	subject to these remarks , we will support the main thrust of the fourçans report . however , we have to criticise the commission ' s economic report for lacking vision .	100
Baseline	it is on these observations that we shall broadly the (main thrust) fourçans report (. however) we must also consider the economic report from the commission (' s) a certain lack(ing) of breath .	7.39
Extended	it is under these comments that we will approve in its broad outlines the fourçans report by UNK however , (we) the commission ' s economic report a certain lack(ing) of breath .	22.37
	Example 3 (Fr)	
Translation	furthermore , the european union will always be open to all europeans who accept its values .	-
Reference	par ailleurs , l ' union européenne sera toujours ouverte à tous les européens qui acceptent ses valeurs .	100
Baseline	en outre , l ' union européenne devra toujours être ouverte à tous ces européens qui acceptent de ses valeurs .	33.46
Extended	en outre , l ' union européenne sera toujours ouverte à tous les européens qui acceptent de ses valeurs .	74.83
	Example 4 (Fa)	
Translation	anyway your collection will have its emerald star back in .	-
Reference	به هرحال آن ستاره سبز به کلکسیون آکواریوم تو برمیگردد .	100
Baseline	به هرحال (آن) مجموعه جا دوستان آنها زمردین میارم .	13.74
Extended	به هرحال آن مجموعه سبز به کلکسیون آکواریوم (تو) میاید .	26.48

Table 3: Translation results from different models. Differences between reference and candidate translations are underlined and missing translations are shown within parentheses. sBLEU indicates the sentence-level BLEU score.

Finally, we asked native French and Farsi speakers to evaluate our results from the perspectives of fluency and adequacy. We prepared a list of 100 sentences, randomly selected from translations of the 200k-baseline and extended models (see Table 1). Evaluators marked each translation's fluency and adequacy with scores in the range of 1 to 5. Fluency and adequacy scales are defined in Table 4a and results obtained from this experiment are reported in Table 4b.

As Table 4 shows, the proposed model positively affects both the fluency and adequacy of translations. To discuss this experiment with more details we report exact numbers for the Farsi evaluation which are shown in Figure 3. Each translation is marked with two scores. Clearly, there are 100 fluency and 100

	Fluency	Adequacy
1	incomprehensible	none
2	disfluent	little meaning
3	non-native	much meaning
4	good	most meaning
5	flawless	all meaning

(a) Fluency and adequacy scales.

	Fluency		Adequacy	
	Base	Ext	Base	Ext
En→Fr	2.96	**3.03**	3.05	**3.22**
En→Fa	2.43	**2.63**	3.10	**3.43**

(b) Average fluency and adequacy scores for 100 translations. Base and Ext show the baseline and extended systems.

Table 4: Human evaluation results on 100 French (Fr) and Farsi (Fa) translations.

adequacy scores for each evaluation set (Table 4b reports the average of these 100 scores). Results can be interpreted from different perspectives, some of which we briefly mention below. For the baseline model, the fluency rate of 38% of translations is 3, but this percentage is raised to 45% in the extended model. 27% of the baseline translations are disfluent but in the extended model this is reduced to 19%. For the adequacy feature the condition is even better. Translations which could not properly convey the meaning are changed to translations which are more acceptable for our evaluators. Figure 3 illustrates these changes and shows how our model improves both fluency and adequacy of translations. The number of bad translations is reduced in the extended model and correspondingly, the number of high-quality translations is increased.

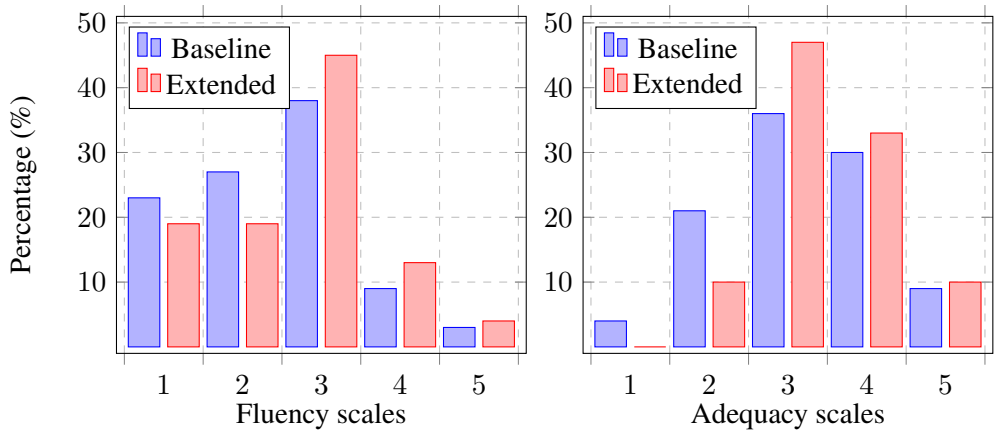

Figure 3: Human evaluation results on En→Fa translation.

5 Conclusion

We proposed a new CNN to train bilingual embeddings and incorporated our embeddings in the PBSMT pipeline. We showed that our embeddings provide useful information. Our model and other similar models are more suitable for medium-size datasets and low-resource languages. We evaluated our model on English, French and Farsi and were able to obtain significant improvements for all of them. Boosting the Farsi engine is a valuable achievement for us, as Farsi is a low-resource and morphologically rich language which makes the translation process hard for any PBSMT engine. We also performed human evaluations, whose results confirmed the impact of our model.

The proposed CNN has a good potential for handling complex structures. For our future work we wish to extend the input tensor with several layers to process richer source-side information. Each word in the proposed architecture could be accompanied with extra information such as morphological and syntactic information.

Abstract

We introduce a novel task *Anecdote Recognition and Recommendation*. An anecdote is a story with a point revealing account of an individual person. Recommending proper anecdotes can be used as evidence to support argumentative writing or as a clue for further reading.

We represent an anecdote as a structured tuple — $< person, story, implication >$. Anecdote recognition runs on archived argumentative essays. We extract narratives containing events of a person as the anecdote story. More importantly, we uncover the anecdote implication, which reveals the meaning and topic of an anecdote. Our approach depends on discourse role identification. Discourse roles such as *thesis*, *main ideas* and *support* help us locate stories and their implications in essays. The experiments show that informative and interpretable anecdotes can be recognized. These anecdotes are used for anecdote recommendation. The anecdote recommender can recommend proper anecdotes in response to given topics. The anecdote implications contribute most for bridging user interested topics and relevant anecdotes.

1 Introduction

Building technical tools to assist learning and writing is of great significance and challenging. While a number of tools have been developed for giving feedback on spelling (Bangert-Drowns, 1993), grammar patterns (Yen et al., 2015) and organization (Burstein et al., 2003b), little exists to provide support during planning and composition process. During the process, an automated system, that can effectively collect topic oriented evidence and reading materials, will greatly reduce the cognitive load.

This paper introduces the ***anecdote recognition and recommendation*** task. An anecdote is a story with a point revealing account of an individual person or an incident. We aim to recognize anecdotes from texts and recommend anecdotes according to given topics. The recommended anecdotes can be used as evidence to support argumentative writing.

The argumentative essay is a genre of writing that requires the writer to investigate a topic and establish a position in a concise manner. In addition to create good claims, the quality of argument is greatly affected by the effectiveness of evidence. Finding relevant evidence is not easy, since it heavily depends on long-term accumulation of materials (from reading and observation) and the ability to retrieve and figure out right ones from memory. This process brings in great challenges for both novice and more sophisticated writers. Anecdotal evidence is one of the most commonly used evidence types (Hornikx, 2005). For a given claim, a system that can provide relevant anecdotes would help writers find good evidence and potentially improve the organization and the quality of essays. Recommending anecdotes can be the first step to recommend all types of evidence.

Recognizing anecdotes is related to previous work that extracts story-like elements from text. For example, Chambers and Jurafsky (2008) propose an unsupervised approach to extract narrative event chains from newswire text. A narrative event chain is a set of narrative events that share a common participant. However, extracting stories only is not sufficient. Suppose that we are writing an essay about *the value of life*, how can a system understand which stories are related to this topic? The stories are

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2592–2602, Osaka, Japan, December 11-17 2016.

Field	Content
Person	Steve Jobs
Story	Steve Jobs changed the digital world. He devoted his life to the digital revolution.
Implication	The value of life is to change the world.

Table 1: An extracted anecdote. The story is a narrative consisting of human-centric events and the implication is an automatically extracted text span, from which we can infer the meaning of Jobs's story.

	Topic: The value of life
Rank	Recommended Anecdotes
1	**Person**: Steve Jobs **Story**: Steve Jobs changed the digital world. Steve Jobs devoted his life to the digital revolution. **Implication**: The value of life is to change the world.
3	**Person**: Bruno **Story**: Bruno, who was burned to death, was a martyr of modern science. **Implication**: The value of life depends on its donation rather than its duration.
2	**Person**:Helen Keller **Story**:Helen Keller is known for her efforts in learning and her arduous work for the disabled. **Implication**: The life means fighting against the fate.

Table 2: An example of anecdote recommendation. Anecdotes are ranked according to the given topic.

objective facts, but the writing goals are subjective. The semantic relatedness between them are less direct as discussed in (Rinott et al., 2015). To close this gap, we have to figure out the meanings or intents that these stories want to express.

Considering the above issues, **we define an anecdote as a structured tuple, including *person*, *story* and *implication***. The *story* describes the factual information about the story of specific persons. The *implication* indicates the meanings and significance of the story. We recognize anecdotes from essays and re-use the anecdotes to assist future argumentative writing.

Our approach is based on discourse role identification, which automatically recognizes discourse roles such as the *thesis*, *main ideas*, *support* and *conclusion* in argumentative essays. These discourse roles are closely associated with the anecdote stories and implications.

To recognize anecdote stories, we propose a human-centric approach. The narratives containing events related to a shared person and playing a discourse role as *support* are extracted as an anecdote story. To recognize anecdote implications, we assume that the stance expressed by authors of essays implies the implications of anecdotes. Therefore, we choose the *thesis*, *main ideas* and *conclusion* that the stories support as their implications.

Table 3 presents an example of the extracted anecdotes. Our method can recognize in an essay that one implication of the story that *Steve Jobs changed the digital world* is that *the value of life is to change the world*, because they are identified as the discourse roles *support* and *main idea* respectively and the former supports the latter.

In this way, we recognize anecdotes from archived essays and store them to build an anecdote database. Based on this database, we can recommend anecdotes in response to user queries, which represent their interested topics. Table 2 shows an example of the results of anecdote recommendation. The suggestive anecdotes provide representative persons and brief descriptions of their stories related to the given topic. The recommendations would motivate uses to choose proper ones as evidence.

To summarize, we make the following contributions in this paper:

- We introduce the anecdote recognition and recommendation task. We explicitly define the structure of anecdotes and automatically extract factual anecdote stories and anecdote implications based on discourse role identification. The structured anecdotes are readable, interpretable and searchable. They can be recommended as potential evidence to support argumentative writing.

- Human evaluation demonstrates that accurately extracting anecdotes is indeed feasible. Moreover, the results in anecdote recommendation show that the recommended anecdotes have good relevance and usefulness. Anecdote implications contribute most for bridging anecdotes and user intent.

2 Related Work

2.1 Writing Assistance

There have been many tools providing technical support for assisting and evaluating writing at lexical and discourse levels (Bangert-Drowns, 1993; Burstein et al., 2003a; Yen et al., 2015) or based on collaboration (Noël and Robert, 2004; Nebeling et al., 2016). This paper extends existing work and proposes to recognize and recommend anecdotes for assisting argumentative writing. Our work is related to work on quote recommendation (Tan et al., 2015) and citation recommendation (He et al., 2010). But the focuses and techniques are quite different. To the best of our knowledge, our work is the first to recommend structured factual evidence to support argumentative writing.

2.2 Argumentation Mining

Argumentation mining aims to identify the components and their relationships in argumentation (Stab and Gurevych, 2014; Peldszus and Stede, 2015; Abbas and Sawamura, 2012; Lippi and Torroni, 2015; Feng and Hirst, 2011). Similar work focuses on identifying discourse roles in student essays and scientific abstracts (Burstein et al., 2003b; Guo et al., 2010). Our work focuses on recognizing anecdotes based on discourse role identification in student essays. Moreover, we are also interested in the association between roles, such as factual evidence and the arguments they support.

Our work is close to (Rinott et al., 2015), which aims to recommend evidence according to given claims. The main differences include: (1) In (Rinott et al., 2015), the system runs over dedicated manually labeled data. Instead, our approach automates all aspects of anecdote extraction and recommendation based on information extraction and discourse role identification. (2) Our approach explicitly defines and recognizes the implications of the anecdotal stories. This makes the stories more understandable and closes the semantic relatedness gap between the stories and user interested topics. (3) We focus on a specific application scenario: anecdote recommendation for argumentative writing.

2.3 Narrative Modeling

We extract anecdote stories by extracting human centric events. Story extraction is a kind of narrative modeling. A story is usually viewed as a sequence of events (Chambers and Jurafsky, 2008) based on information extraction (Etzioni et al., 2011). Much work has been done for extracting facts and events from various resources (Banko et al., 2007; Ritter et al., 2012; Bamman and Smith, 2015; Bamman et al., 2014). Similar techniques have been used in educational applications. For example, factual information in argumentative essays has be exploited for essay scoring (Klebanov and Higgins, 2012).

Our work differs from existing work in two folds: (1) We combine event extraction and discourse role identification for extracting anecdote stories. (2) We also uncover the implications of these stories in order to close the gap between objective facts and subjective human intent.

3 Data and Task

3.1 Data

The task we propose is recognizing and recommending anecdotes for assisting argumentative writing. We focus on dealing with argumentative essays, because there exist rich evidence used by the authors to support their claims. We aim to extract anecdotes from archived essays and use them as suggestions to users who are planning to write on similar topics. The users can use the recommended anecdotes as evidence directly, or view them as a clue to find more materials.

In order to recognize anecdotes that are likely to be used for supporting writing, we collect data from an online essay collection, LELE KeTang.[1] This collection contains different types of student essays such as *argumentative essays* and *narrative essays*. The types can be read through the tags of essays. We collected 16618 argumentative essays written by students from senior high school and above in Chinese.

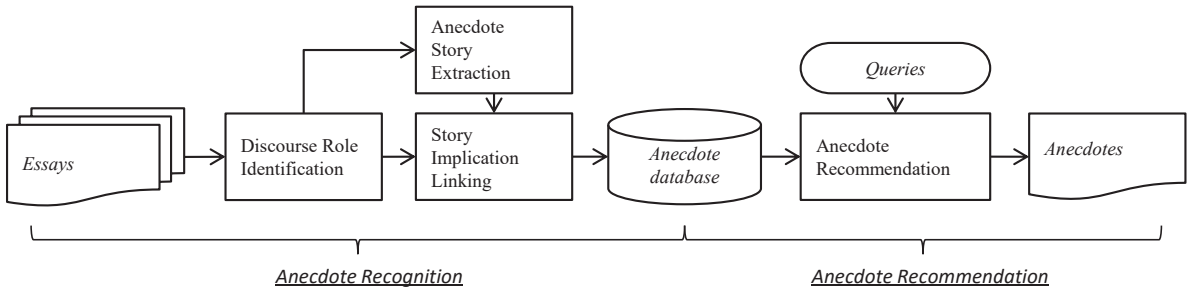

Figure 1: The framework of Anecdote Recognition and its application on Anecdote Recommendation.

3.2 Task Overview

We formally define an anecdote as a structured tuple, $< person, story, implication >$, in order to make it readable, interpretable and searchable.

An anecdote story is a concise summary of the factual events of a certain person. We view anecdote story recognition as a human-centric event extraction task. An anecdote story consists of a set of narratives describing the events of the persons.

The anecdote implication of an anecdote implies the meaning and topic of the anecdote story. We call it *implication* because the meanings or topics of the anecdote are hard to be read directly from the story itself, since the story is usually a factual description. Therefore, we have to infer the implication by means of extra information and strategies. The functions of anecdote implication should include: (1) It interprets the factual information and demonstrates how others take stance on the facts; (2) It closes the gap between objective facts and subjective writing goals to make anecdotes searchable by topics.

The general architecture of our approach is shown in Figure 1. The anecdote recognition module recognizes anecdotes from essays and stores them in a database. Anecdote stories and implications are extracted based on discourse role identification. The anecdote recommendation as an application can recommend anecdotes according to user queries.

Role	**Definition**
Introduction	introduces the background and/or grabs readers' attention
Thesis	states the main claim on the issue for which the author is arguing
Main idea	asserts ideas or aspects that are related to the thesis
Support	provides evidence to explain or support the thesis and the main ideas
Conclusion	concludes the whole essay
Other	doesn't fit into the above elements or makes no meaningful contribution

Table 3: Definitions of discourse roles.

4 Anecdote Recognition

Anecdote recognition is to extract stories and their implications from a given essay. We realize it based on discourse role identification. *Discourse roles* represent the contributions that sentences can make to text organization. Table 3 lists the discourse roles we use, which are inspired by (Burstein et al., 2003b). Our motivation is that the stories and implications relate to different discourse roles in an argumentative essay. Stories are mainly used as evidence to support the *thesis* and *main ideas* proposed by the writer. Therefore, the *thesis* and *main ideas* could be viewed as the implications of the stories in the same essay. We use the *thesis*, the *main idea* and the *conclusion* sentences as implication candidates. The reason we distinguish these roles is because they control different ranges of an essay. The *thesis* and the *conclusion* set up the main tune and conclude the whole essay, while the *main ideas* mainly control the local zones.

According to our motivation, anecdote recognition is divided into three steps: discourse role identification, story extraction and story-implication linking. Before anecdote extraction, an essay text is preprocessed by a pipeline of components including word segmentation, POS tagging, named entity

tagging, dependency parsing and semantic role labeling with HIT-LTP (Che et al., 2010). Also, we use pairs of quotations to locate quotes and view each quote as a whole.

4.1 Discourse Role Identification

We identify discourse roles based on a linear-chain Conditional Random Field (CRF) model (Lafferty et al., 2001) in order to capture the correlations among sequential predictions. The features for each sentence are mainly inspired by the previous work (Burstein et al., 2003b; Stab and Gurevych, 2014):

- **Position features** We use the relative position (beginning, middle, end) of the sentence in its paragraph and its paragraph in the essay, and the number of the sentence in the document as features.
- **Indicator features** We use manually collected cue words/phrases like *in my opinion*, *first of all* and *in conclusion* as indicators. Boolean features are designed for them.
- **Lexical features** We construct boolean features for connectives and modal verbs (such as *should*). We don't use unigrams and bigrams as features because they are sparse on a small dataset.
- **Structural features** We use the number of words, the number of clauses in the sentence and the number of sentences in the same paragraph and the ending punctuation as structural features.
- **Human and quote features** Boolean features are designed respectively to indicate whether the sentence contains human mentions, first person pronouns, third person pronouns and quotes.
- **Thesis word features** Two boolean features are used to indicate whether the sentence contains the words in essay title and the automatic extracted thesis words.

The motivation of thesis word features is that the words that reveal the thesis of an essay would help distinguish *thesis*, *main idea* and *conclusion* sentences from others. We only consider nouns, verbs and adjectives as candidate thesis words. The words in essay titles are used as thesis words. In addition, we attempt to extract thesis words automatically. We observe that the words that distribute globally in an essay tend to indicate the topic of the essay. Therefore, we rank words according to the number of paragraphs a word occurs and view the top ranked words as thesis words.

The model is learned on an annotated dataset that would be introduced in §6.1. The learned model would be used to predict the discourse roles in new essays. These identified discourse roles provide supporting information for anecdote story and implication extraction.

4.2 Story Extraction

We propose a human-centric approach to recognize anecdote stories, since anecdotes usually center around certain persons. Story extraction is conducted in two steps: recognizing human mentions, and extracting narrative events related to human mentions.

Recognizing human mentions A human mention is an observed textual reference to an individual or a group of people. Our approach considers person names, human noun phrases (NPs) and third-person pronouns. The person names are identified according to the POS tagging results provided by HIT-LTP. Human NPs refer to non-specific persons like *soldiers*. We build a dictionary containing human NPs which have a definition as HUMAN and a POS as NOUN in the common-sense knowledge base HowNet (Dong and Dong, 2006). Strings that match entries in this dictionary are marked as human NPs.

Many references to persons are in the form of pronouns. Since we have marked person names and human NPs, the pronouns should choose antecedents from them. We implement a rule-based approach considering the gender and number compatibility, syntactic roles and distance constraints. Unresolved pronouns are discarded.

Narrative event extraction Similar to (Chambers and Jurafsky, 2008), we assume that a story consists of a chain of events involving the same person. For each human mention, we extract all sentences containing it or its references. Then we conduct semantic role labeling on these sentences and extract the <agent, predicate, recipient > tuples as events. If the agent field contains the human mention, the tuple

would be retained. Since the stories have to be shown, we keep the sentences containing the retained tuples as the anecdote story candidates.

Notice that sentences that contain human mentions might be not a part of a story. Consider the following two sentences:

sentence 1 *Steve Jobs devoted his life to the digital world and designed a series of revolutionary products.*

sentence 2 *What we learn from Steve Jobs' story is that we should try our best to pursue our dreams.*

We can see that sentence 2 actually expresses an opinion rather than facts. To resolve this, we only retain the candidates with the discourse role *support* as the anecdote story.

4.3 Story Implication Linking

By now, we have extracted a set of anecdote stories. As mentioned earlier, we consider the sentences with discourse roles *thesis*, *main idea* and *conclusion* sentences as the potential implications of the stories. We have to link the stories and implications together.

We assign *thesis* and *conclusion* sentences to every anecdote story in the same essay as parts of their implications, since they cover the whole essay. The *main ideas* argument from multiple aspects. Therefore, we should link main ideas to nearby stories.

To deal with it, we train a story-idea classifier to determine whether a story and a main idea should be linked. For simplicity, we merge adjacent main idea sentences within the same paragraph as a main idea block. We derive features for every pair of a story and a main idea block. The features include (1) Paragraph distance, which is the difference between their paragraph numbers; (2) The number of shared words; (3) Connectives, since some of which like *therefore* are key indicators of the linking relation; (4) Whether they share human mentions or their references.

We train a logistic regression classifier on manually labeled story-idea pairs. For the story in a positive pair, we choose the nearest but unlinked main idea block (if there is one) to form a negative pair. During prediction, for each extracted story, we apply the classifier to determine whether it should be linked to the closest main idea blocks before and after it within 2 paragraphs. If the prediction is positive, the corresponding main idea blocks are used as part of the anecdote implication.

After story-implication linking, we get a set of <*person, story, implication*> tuples as anecdotes. By accumulating anecdotes from all available essays, we construct an anecdote database.

5 Anecdote Recommendation

Anecdote recommendation is an application of anecdote recognition. Once writers decide the main topic to address, they would attempt to find evidence to support their claims. Anecdote recommendation aims to recommend anecdotes as suggestions according to user interested topics.

The task can be described as follows: with the anecdote database C available, given a query q, the recommender returns a subset of anecdotes E, which are ranked top by a ranking model. The ranking depends on the relatedness measurement between the anecdotes and the queries.

Relatedness measurement We are interested to study which information—the anecdote story or the anecdote implication—contributes more for measuring the true relevance. Therefore, we focus on comparing the following strategies for ranking anecdotes:

- **Query-Story (QS)**. Rank based on the relatedness between the anecdote story and the query.
- **Query-Implication (QI)**. Rank based on the relatedness between the anecdote implication and the query.

To compute the semantic relatedness between the query and a text, we compare the BM25 that is a term-matching based ranking model (Robertson and Zaragoza, 2009) and a word embedding based approach (WE) — We use the average word embedding to represent a text. We are interested to see whether word embedding based approach can alleviate the semantic gap problem.

Learning to Rank Based on the above relatedness measurements, we get four ranking functions: QS-BM25, QI-BM25 and QS-WE, QI-WE. We adopt the learning to rank framework to integrate them. We

use linear ranking functions and transform the ranking problem into a two-class classification problem (Herbrich et al., 1999; Joachims, 2002). For each query, given two comparable instances whose feature vectors and labels are (x_i, y_i) and (x_j, y_j), we transform it into $(x', y') = (x_i - x_j, sign(y_i - y_j))$. After transformation, we use the SVM classifier with linear kernel to learn a ranking function.

The learned weights of some ranking functions might be negative. Since all signals should contribute positively to the final ranking, a constant is added to each weight to make sure all the weights are positive.

Training Data We build the training data based on *pseudo queries*. For an anecdote, its pseudo query is the title of the essay, from which the anecdote is extracted. It is reasonable to assume that essay titles can be used to simulate writers' search intent. We consider binary relevance labels: *relevant* and *irrelevant*. Given an essay title as a pseudo query, the anecdotes that are extracted from essays with the same title are viewed as relevant, while randomly sampled anecdotes are labeled as irrelevant to the pseudo query. In this way, we can build a training data without any manual labor.

6 Evaluation

6.1 Evaluating Discourse Role Identification

Data Two annotators manually labeled 200 student essays with discourse roles at sentence level according to a set of initial guidelines. The percentage agreement between annotators is 0.84. They discussed to reach new standards and then reviewed all annotations together. The distribution of the six discourse roles is unbalanced. The *support* discourse role accounts for 52% of all sentences, while the *introduction, thesis, main idea* and *conclusion* sentences account for 9%, 5%, 18% and 9% respectively.

Evaluation settings We conducted experiments on the corpus using 5-fold cross-validation. The precision (P), recall (R) and F_1 score are reported.

Discourse role	P	R	F_1
Introduction	73.1	74.6	73.8
Thesis	66.7	61.1	63.7
Main idea	69.0	60.9	64.6
Support	83.2	86.4	84.8
Conclusion	81.8	84.5	83.2

Table 4: Performance on identifying five discourse roles.

Results The experimental results on the corpus are shown in Table 4. We can see that our method can recognize *support* sentences well. In contrast, the *thesis* and *main ideas* are identified with moderate performance. By analyzing the errors, we found that many errors are related to the boundaries of *thesis* sentences. Some errors come from distinguishing *introduction* and *thesis*. In some cases, *introduction* sentences also involve thesis related words, although they don't explicitly make a claim, while some essays make claims at the beginning without placing any introduction. Some other errors come from incorrectly distinguishing *thesis* and *main ideas*. When there are multiple *thesis* sentences in an essay, the ones that appear later might be identified as *main idea* incorrectly. In addition, due to the imbalanced data, more sentences tend to be classified into the majority class.

6.2 The Anecdote Database

Our anecdote recognizer ran on the dataset introduced in §3 to construct an anecdote database. The database contains 26060 anecdotes, involving 9762 persons.

Data and evaluation settings We randomly sampled 200 anecdotes and asked two raters, who are students from the department of Literature, to evaluate the quality of the anecdotes. The anecdote story and implication were shown to the raters. The evaluation is based on the criteria below by judging story and implication jointly. Here is a description of the criteria:

Good	The story is understandable and complete. The implication can interpret the story.
Poor Story	The story is hard to be understood. The implication is unable to be judged.
Poor Implication	The story is understandable and complete. The implication can't interpret the story.

	Good (%)	Poor Story(%)	Poor Implication(%)
Rater1	61	22	17
Rater2	62	25	13

Table 5: The manual evaluation results by two raters.

Results Table 9 shows the evaluation results by two raters. We can see that more than 60% of the anecdotes in average are judged as *good*. This means that the anecdote stories and the corresponding implications can be effectively extracted and paired together. About 23% of the extracted anecdotes are judged as *poor story*. Most of these errors are caused by incorrectly recognized user names and the failure of pronoun resolution. 15% of the extracted anecdotes are judged as *poor implication*.

We manually labeled the story-idea pairs in 50 essays. The story-idea classifier can achieve an accuracy of 87% by cross-validation. We observe that the stories and their implications have strong locality correspondence that they tend to be within the same paragraphs.

The results show that for most recognized stories, our method can find proper implication for them. This proves that discourse role identification is a promising way for anecdote implication recognition.

6.3 Evaluating Anecdote Recommendation

6.3.1 Automated Evaluation

Data We conducted experiments on the extracted anecdote database. We stored the title of the essay from which each anecdote is extracted. There are 8141 distinct titles in all. These titles are used as queries to simulate user interested topics. We randomly sampled 1000 queries respectively to construct the training set, development set and the test set. We collected relevant instances for each query as described in §5. Each query has 3.4 relevant anecdotes in average. For each training query, we randomly sampled the same number of irrelevant instances in order to maintain a balanced training data. For each query in development set and test set, we viewed all anecdotes from the anecdotes database as candidates.

Experimental settings The parameters of SVM were tuned on the development dataset. We trained a Word2Vec model using the skip-gram algorithm with hierarchical softmax (Mikolov et al., 2013) on a dataset from Baidu Baike. The vector size is 50. The vocabulary size is 1, 825, 833. We adopt the commonly used mean average precision (MAP) and nDCG (Järvelin and Kekäläinen, 2002) as metrics.

Model	MAP	nDCG@1	nDCG@5
QS-BM25	0.357	0.406	0.387
QI-BM25	0.738	0.624	0.766
QS-WE	0.362	0.386	0.384
QI-WE	0.716	0.59	0.747
LTR	**0.744**	**0.64**	**0.786**

Table 6: The evaluation results of anecdote recommendation on pseudo queries.

Results Table 6 presents the performance of various strategies. We can see that QS-BM25 and QS-WE perform worst among all strategies. This proves that vocabulary gap exists between queries and factual story descriptions of anecdotes. In contrast, great improvements are obtained when measuring relatedness between anecdotes and queries with anecdote implications. Both QI-BM25 and QI-WE achieve much better results compared with QS-BM25 and QS-WE. This indicates that the anecdote implications play important roles in bridging user intent and anecdotes. The word embedding based approaches don't have obvious superior performance compared with conventional BM25 approaches. But by combining all signals together, LTR — that represents our learning to rank model, gains further improvement compared with any single model. This means that learning the model automatically based on pseudo query strategy is feasible.

6.3.2 Human Evaluation

Pseudo queries based evaluation indicates that proposed approach can achieve high precision on top results. To gain deeper understanding of the usefulness and interpretability, we conducted evaluation on

Topic (translation, year)
尝试(Try to do, 1994), 战胜脆弱(Overcome the weakness, 1998), 答案是丰富多彩的(The answer is rich, 2000), 心灵的选择(The Choice of heart, 2002), 转折(The turning point, 2003), 包容(Be tolerant, 2004), 我有一双隐形的翅膀(I have a pair of invisible wings, 2009), 诚信(Be honest, 2011), 深入灵魂的热爱(Deep passion, 2015).

Table 7: Essay topics for user study.

score	Description of the meanings of scores
4	The anecdote is representative and clear. It can be used as evidence directly for the given topic.
3	The anecdote is representative but not complete. It provides clues for further exploring the details.
2	The anecdote is relevant, but not representative.
1	The anecdote is irrelevant to the given topic.

Table 8: Descriptions of the meaning of each score.

manually labeled data.

Topics We chose nine argumentative topics from the recent years' college entrance examinations in Bejing, China. The topics are shown in Table 7. We only chose the topics that the essay titles are fixed so that students needn't derive their own titles according to the prompt.

Annotation For each given topics, we used the QS-BM25, QI-BM25 and LTR systems to retrieve the top 20 anecdotes respectively. We merged their results together (removing the duplicate ones) and asked 5 raters to evaluate all the results respectively using a numerical score from 1 to 4. The descriptions of the meaning of each score is shown in Table 8.

score	1	2	3	4
QS-BM25	54%	16 %	9 %	21%
QI-BM25	28%	20%	11 %	41%
LTR	26%	13%	16%	45%

Table 9: Distributions of raters' scores on manually labeled data.

6.3.3 Results

Table 9 shows the average percentage of anecdotes belonging to each score retrieved by each system. More than 70% of anecdotes extracted by LTR and QI-BM25 are relevant to the given topics. In contrast, QS-BM25 provides many more irrelevant anecdotes. This indicates that anecdote implications are better to represent the topics of the anecdotes.

Based on LTR, about 45% anecdotes are viewed as representative enough and can be used as evidence directly. A large ratio of these anecdotes are about famous people. About 16% anecdotes are considered as representative, but users have to further explore, e.g., by search, to gain more information. Parts of the low quality anecdotes are due to incorrectly recognized person names and the failure of pronoun resolution. In addition, difficult queries, like *I have a pair of invisible wings*, lead to poor performance. Such queries are kind of rhetorical device so that students have to derive the thesis themselves. Since our method is mainly based on keywords, the relevance of retrieved anecdotes is not good except that some students had used similar expressions to express their claims.

6.4 Discussions

The results show that the proposed anecdote recommender can provide relevant and representative anecdotes to user interested topics. Two main factors contribute for this. First, we use argumentative essays as data resource so that the anecdotes extracted actually have been chosen carefully by the essay authors. As a result, most of them are representative. Second, we give structures to anecdotes that usually are not considered as a structure. The anecdote implication contributes great for finding relevant anecdotes. The idea of structured retrieval can be extended to other problems as well.

On the other hand, several limitations exist. First, anecdotes extracted from student essays may be limited in narrow scopes. With the development of argumentation mining, we can extend our work to

other domains. Second, we mainly consider the relevance of anecdotes in evaluation but don't care about whether the anecdotes support or attack the given topic. Third, information beyond topical relevance such as the popularity of an anecdote or a person can be exploited. Such information is not incorporated in the current *pseudo query* based training procedure. Further relevance feedback can be conducted. Finally, organizing and diversifying the recommended anecdotes are also interesting but ignored in this study. We leave these as future work.

7 Conclusion

This paper proposes anecdote recognition and recommendation task to support argumentative writing. We not only extract concise and informative anecdote stories, but also uncover the implications of facts. The enriched structured representation makes the extracted anecdotes interpretable and searchable. Our approach is based on discourse role identification in essays. The experimental results demonstrate the effectiveness of our approach. More than 60% of our extracted anecdotes have both well described stories and interpretable implications. The extracted anecdotes can be applied for anecdote recommendation. With the help of anecdote implications, the recommender is able to suggest relevant anecdotes in response to simulated user intent. This proves that anecdote implications are useful for closing the semantic gap between factual evidence and user interested topics.

Training Data Enrichment for Infrequent Discourse Relations

Abstract

Discourse parsing is a popular technique widely used in text understanding, sentiment analysis and other NLP tasks. However, for most discourse parsers, the performance varies significantly across different discourse relations. In this paper, we first validate the underfitting hypothesis, i.e., the less frequent a relation is in the training data, the poorer the performance on that relation. We then explore how to increase the number of positive training instances, without resorting to manually creating additional labeled data. We propose a training data enrichment framework that relies on co-training of two different discourse parsers on unlabeled documents. Importantly, we show that co-training alone is not sufficient. The framework requires a filtering step to ensure that only "good quality" unlabeled documents can be used for enrichment and re-training. We propose and evaluate two ways to perform the filtering. The first is to use an agreement score between the two parsers. The second is to use only the confidence score of the faster parser. Our empirical results show that agreement score can help to boost the performance on infrequent relations, and that the confidence score is a viable approximation of the agreement score for infrequent relations.

1 Introduction

Discourse parsing is widely used in text understanding (Allen et al., 2014), sentiment analysis (Bhatia et al., 2015) and other NLP tasks (Guzmán et al., 2014) (Gerani et al., 2016). A multi-sentential discourse parser takes a document as input, and returns its discourse structure that shows how clauses and sentences are related in the document, via the use of various discourse relations. For instance, the benchmark RST-DT dataset (Carlson et al., 2001) uses 18 discourse relations. Studies in the past decade on discourse parsing, such as (Ji and Eisenstein, 2014), (Feng and Hirst, 2014), and (Joty et al., 2015), greatly improved the performance of discourse parsing in general. However, it has been observed that the performance across the discourse relations varies significantly (Joty et al., 2015), and that poor performance may be linked to underfitting, i.e., a lack of training data (Feng and Hirst, 2014).

In this paper, we investigate the underfitting hypothesis and study how to improve the situation. Different discourse relations are usually unevenly distributed in a dataset, and some of them occur much less frequently than other relations. We call the former the *infrequent* relations. For example, in the very popular corpus — Rhetorical Structure Theory Discourse Treebank (RST-DT) (Carlson et al., 2001) which contains 385 documents, the frequency of "Elaboration" is 31.04%, while the frequency of "Summary" is only 0.88%. In another benchmark corpus the Penn Discourse Treebank (PDTB) 2.0 (Prasad et al., 2008), which contains about 2400 documents with discourse relations labeled for each pair of adjacent sentences, the relation "Conjunction" occurs 8759 times through the entire corpus, while the relations "Exception" and "Pragmatic concession" only appear 17 and 12 times respectively (Hernault et al., 2010). Given that the performance of most discourse parsers depends on the availability of training data, the key question here is whether underfitting affects the infrequent relations more than the frequent

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2603–2614, Osaka, Japan, December 11-17 2016.

ones. In Section 4, we will explicitly show that parsing performance of relations is correlated with the frequency of the relations.

Clearly, every discourse relation, infrequent or not, would benefit from the availability of more high-quality training data. However, creating such high-quality labeled data takes much time and effort to manually annotate documents with their discourse structures and relations. The question here is whether the infrequent relations are worthy of the extra effort required. It turns out that many infrequent relations actually play important roles in various NLP tasks. For example, the "Comparison" relation from RST-DT is known to indicate disagreement in a conversation (Horn, 1989) (Allen et al., 2014). Moreover, the "Instantiation" relation from PDTB is regarded as an important feature for sentence specificity prediction (Li and Nenkova, 2015).

The main objective of this paper is to explore how to mitigate the underfitting problem for infrequent relations — without manually creating labeled data for those relations. In particular, we aim to exploit the availability of a much larger amount of unlabeled data. The first step of our approach is to apply existing discourse parsers to the unlabeled data to generate more instances of infrequent relations, which are then used to re-train the existing parsers. Such co-training approaches have proved to be effective in solving similar problems in natural language processing (Li and Nenkova, 2015) and information retrieval (Blum and Mitchell, 1998).

There is, however, a fatal flaw relying on co-training alone. If existing discourse parsers are poor in determining infrequent relations, the extra (re-)training instances of infrequent relations created from unlabeled data may not be of high quality. Indeed, adding poor quality re-training instances would exacerbate the underfitting problem of infrequent relations. The second step of our approach is to apply a *filtering* step to the instances created from unlabeled data. The intention behind the filtering step is to *enrich* the re-training - that is, to select only the "high quality" instances to be used for re-training.

The workflow of our enrichment approach is shown in Figure 1, when it is applied to two discourse parsers, P1 and P2. P1 and P2 are initially trained on labeled data and then are applied to unlabeled data to generate new high-quality training examples for further re-training.

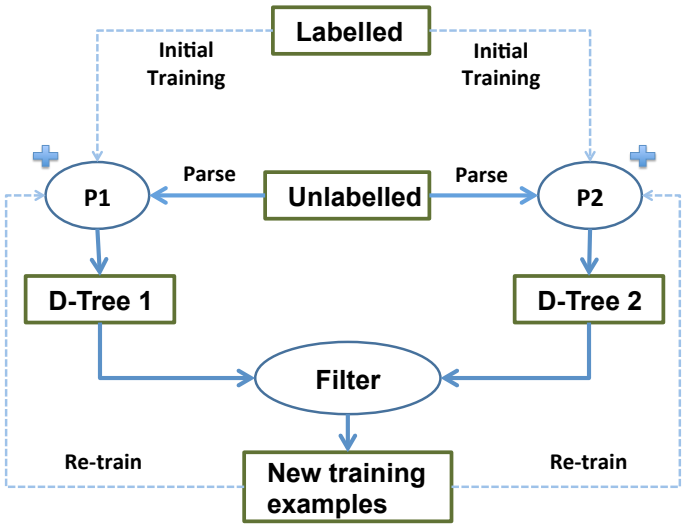

Figure 1: Workflow of our enrichment approach

The specific contributions of our paper are as follow:

- We explore one form of enrichment based on the notion of *agreement score* between two discourse parsers. Inspired by the theory on the success of ensembling for general classification (Dietterich, 2000), we choose two very different discourse parsers, namely the CKY-like CODRA parser by (Joty et al., 2015) and the Shift-Reduce (SR) parser by (Ji and Eisenstein, 2014). While Section 3 will give more details on why these two parsers are chosen, the key is that the parsers are based on

very different algorithms and feature sets for discourse parsing. Our agreement score is based on the F-score measure for comparing discourse trees as proposed in (Marcu, 2000). Only the discourse relation instances in discourse trees with high-enough agreement scores pass through the filter for re-training purposes. Section 4 will show that such enrichment with agreement score improves the performance of infrequent relations.

- We explore another form of enrichment based on just the confidence score of the SR-parser. The rationale is that while the CODRA parser is generally more accurate than the SR-parser, the SR-parser is two orders of magnitude faster. If a high-enough threshold on the confidence score of the SR-parser is used for enrichment, Section 4 will investigate whether the confidence score is a good approximation of the agreement score. If this approach is successful, an even larger number of unlabeled documents can be parsed rapidly to be used for re-training.

2 Related work

Recent discourse parsers have improved the overall performance of discourse parsing in different ways. (Joty et al., 2013) (Joty et al., 2015) proposed a two-stage document-level discourse parser CODRA, which builds a discourse tree by applying an optimal parsing algorithm to probabilities inferred from two Conditional Random Fields: one for intrasentential parsing and the other for multisentential parsing. This approach achieves good performance in discourse relation labeling. Based on their idea, (Feng and Hirst, 2014) developed a similar but much faster model that adopts a greedy bottom-up approach, with two linear-chain CRFs applied in cascade as local classifiers. On the other hand, (Ji and Eisenstein, 2014) proposed a Shift-Reduce (SR) parser that combines the machinery of large-margin transition-based structured prediction with representation learning. This method also reports a good overall performance with linear running time. However, all these state-of-the-art discourse parsers still perform badly on infrequent relations due to insufficient training examples.

The problem of lacking training examples also impacts other aspects of discourse parsing, for example parsing implicit relations. A key distinction in discourse parsing is between explicit and implicit relations. The former are signaled by a cue phrase like "because", while the latter are not and consequentially are more difficult to identify. Several studies have been conducted to tackle the problem of classifying implicit relations which do not have many explicit features and examples. (Zhou et al., 2010) presents a method to predict the missing connective based on a language model trained on an unlabeled corpus. The predicted connective is then used as a feature to classify the implicit relation. (McKeown and Biran, 2013) tackles the feature sparsity problem by aggregating implicit relations into larger groups. And recently (Lan et al., 2013) combines different data through multi-task learning. The method performs implicit and explicit relation classification in the PDTB framework as two tasks and relies on multi-task learning to obtain higher performance.

(Liu et al., 2016) proposes a multi-task neural networks that combines RST-DT, PDTB and unlabeled data together through multi-task learning process, and gets performance improvements on relatively infrequent relations, though they only apply their scheme on the four coarse top-level relations. Their scheme is based on retrieving more training instances from unlabeled data through cue phrases. This approach of using explicit examples to predict implicit examples has been shown to produce mixed results (Sporleder and Lascarides, 2008). Moreover, (Joty et al., 2015) has shown that there are many more features beyond cue phrases that are useful for discourse parsing. (Hernault et al., 2010) proposes a feature vector extension approach to improve classification of infrequent discourse relations. The approach is based on word co-occurrence. Partly because a simple discourse parser was used, their approach is shown to produce only minimal improvements in performance.

Unlike (Liu et al., 2016) and (Hernault et al., 2010), we aim to exploit more advanced parsers with higher performance, and also keep the finer-granularity of the relations, especially focusing on the infrequent relations. We employ the idea of *co-training*, which is first introduced by (Blum and Mitchell, 1998) with its application in helping the search engine better classify "academic course home page". Similar co-training efforts have been found effective in many NLP problems when only a small amount of labeled data is available. For example, (Wan, 2009) proposes a co-training approach for cross-lingual

sentiment classification, while (Li and Nenkova, 2015) applies co-training on predicting sentence specificity.

3 Our Enrichment Approach

The workflow of our enrichment approach is shown in Figure 1. First we use the labeled data to provide initial training of the two parsers. Then each parser is used to produce a discourse tree for each unlabeled document. After that, we apply a filtering step to select those "high quality" discourse trees, which are added to the original labeled data to form the "enriched training data" to re-train the two parsers.

In our approach, the first parser we pick is the CODRA parser (Joty et al., 2015), which applies a CKY parsing algorithm to probabilities inferred from two Conditional Random Fields for both intra-sentential and multi-sentential parsing. We pick the CODRA parser because of its optimal CKY parsing algorithm and its accuracy. The second parser we pick is the SR-parser (Ji and Eisenstein, 2014), which transforms the surface features into a latent space that facilitates RST discourse parsing. The main advantage of the SR-parser is that it can train and parse documents in almost linear time (regarding the document length), while the CODRA parser needs cubic time. Our choice of the two parsers is partly based on the fact that they rely on very different algorithms and feature sets, which is desired by the co-training algorithm. Although another discourse parser (Feng and Hirst, 2014) also delivers state-of-the-art performance, its approach and features are very similar to CODRA's, so we only wanted to select one of them. And due to the fact that Feng's parser is not publicly available and our existing experience on CODRA, we picked CODRA in our approach. Another reason of our choice on the SR-parser is that discourse parsing of documents in general can be slow in both training and parsing. Thus, the SR-parser is attractive in allowing us to explore the tradeoffs between accuracy and efficiency.

Co-training alone, however, is not sufficient. Since both the CODRA parser and the SR-parser performs poorly on infrequent relations, the extra (re-)training instances of infrequent relations created from unlabeled data may not be of high quality. The key idea is to enrich the re-training by selecting only the "high quality" instances. In this paper we investigate two forms of enrichment, based on the agreement score between the two parsers, and the confidence score given by the SR-parser.

To produce the agreement score between the two parsers, we use both parsers to parse every unlabeled document. Then we treat the parse tree produced by the CODRA parser as the ground truth, because in general the CODRA parser is more accurate than the SR-parser. After that, we treat the parse tree produced by the SR-parser as testing, and use the F-score for comparing discourse trees proposed in (Marcu, 2000) as the agreement score. Finally, if the agreement score passes a preset threshold, the unlabeled document is regarded as reliable and the discourse tree is added to enrich re-training.

The second form of enrichment examined in this paper is based on using the confidence score of the SR-parser as an approximation of the agreement score between the two parsers. The SR-parser generates a discourse tree by performing a set of actions. More specifically, each action creates a node in the tree by combining two text spans and by selecting a discourse relation for the pair. Since each action is chosen with a certain confidence score (which technically is the distance between the chosen action and the hyperplane, provided by the underlying Linear SVC algorithm), we use the average confidence of the actions performed to create the tree as the confidence score of the entire tree. If this approach is successful, an even larger number of unlabeled documents can be parsed rapidly for re-training.

Furthermore, we can also control the filtering threshold score at a finer granularity. That is, if the parser allows a user to feed a partial discourse tree or even just some nodes for training, we can set the filtering threshold on each node instead of each document. In this case, if a discourse tree has a high agreement/confidence score, but some nodes on the tree only have a low score, instead of adding the entire discourse tree to the new training set, we can remove those nodes with low score and add only those nodes with high scores to the new training set. This way, we can filter at a finer granularity. Moreover, based on this node-level filtering framework, we can actually set different threshold for different types of nodes, for example, we can set a lower threshold for infrequent relations, and a higher one for frequent relations.

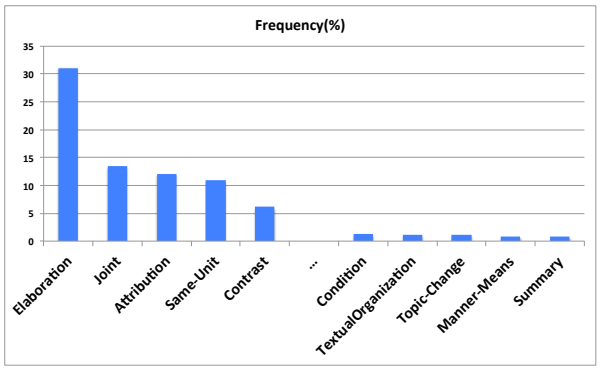

Figure 2: Distribution of the most frequent and the least frequent 5 relations in RST-DT

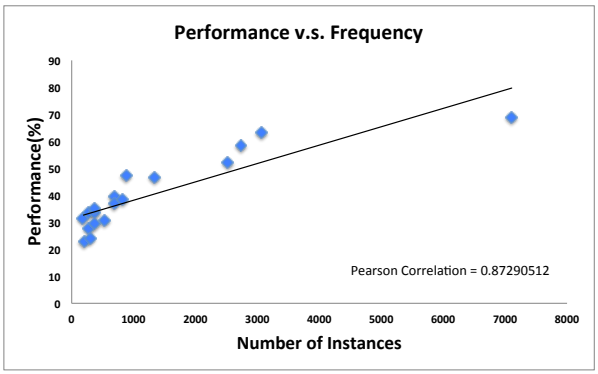

Figure 3: Performance versus Frequency for each relation

4 Empirical Evaluation

4.1 Datasets

In this paper, we use the RST-DT dataset as the gold standard labeled data. It consists of 385 documents selected from Penn Treebank (Marcus et al., 1993), which are all originally articles from the Wall Street Journal. Those 385 documents were divided by the author into two groups: the training set consisting of 347 documents, and the test set 38 documents. For results reported in this paper, we used those 347 documents as the initial training set. The remaining 38 documents made up the test set used to evaluate the performance of the parser re-trained using the enriched dataset.

For the unlabeled documents, we used 2000 Wall Street Journal articles from the Penn Treebank dataset (Marcus et al., 1993). In other words, the gold standard dataset and unlabeled dataset are from the same source; but there is no document belonging to both.

In discourse parsing, there are various performance measurements, such as on the structure (i.e., hierarchical spans) and the labels (i.e., nuclearity and relation classification). The results reported here focuses on relation classification. To evaluate the parsing performance based on the gold standard, we use the standard F-score measure, which is the harmonic mean of precision and recall (Abney et al., 1991). More specifically, we use the F-score measure for comparing discourse trees, as proposed in (Marcu, 2000).

4.2 The Underfitting Hypothesis: Performance vs Frequency

As for the discourse relations, we examine all the 18 coarse-grained relations defined in (Carlson et al., 2001). Figure 2 shows the most frequent and the least frequent five relations in all the 385 documents in the RST-DT dataset. We can see that the most frequent relations can be two order of magnitude higher in frequencies than those of the infrequent ones. For example, the "Elaboration" relation makes up over 31% of all the nodes in the entire dataset, while the "Topic Change" relation accounts for less than 0.5%.

Given the large disparity in relation frequencies, we next examine whether infrequent relations suffer from worse performance than the frequent relations, i.e., the underfitting hypothesis of a lack in training data of the infrequent relations. Here we used the 347 documents to train the SR-parser, and then tested the parser on the 38 documents. Figure 3 shows the performance of each relation (i.e., F-score) versus its frequency. We can see that for each relation, its performance has high correlation with its frequency. Indeed, the Pearson correlation coefficient is 0.87, validating the underfitting hypothesis. This suggests that it would be a reasonable approach to boost the performance of infrequent relations by enriching their training instances.

4.3 Effect of Enrichment on Infrequent Relations

The first form of enrichment examined below is based on the agreement score between the two parsers, as discussed in the previous section. Table 1 shows the improvements on the F-scores from the SR-parser

of the top-8 infrequent relations, based on a threshold of 0.5 in the filtering step. The different columns of the table show an increasing number of unlabeled documents used in enrichment, from 500 documents to 2000 documents. Figure 4 shows the relative F-score improvements across all the 18 relations, ranked from left to right in ascending order of frequency. As a specific example, the F-score of "Topic Change" improves 5.88% with 500 documents, and 13.15% with 2,000 documents.

Relation	500	1000	1500	2000
Summary	2.13	2.80	3.91	5.16
Manner-Means	16.62	21.13	21.61	22.08
Topic-Change	5.88	7.21	12.88	13.15
TextualOrganization	1.42	3.31	7.49	8.14
Condition	3.91	8.69	12.44	18.55
Comparison	3.19	6.06	6.95	10.42
Evaluation	2.83	4.76	8.09	10.98
Topic-Comment	2.69	4.55	6.73	9.48

Table 1: Relative F-scores improvements (%) on the top-8 infrequent relations

As shown in the table and the figure, there is a positive effect on performance by enrichment based on the agreement score. The larger the number of unlabeled documents used, the higher is the gain in performance for the top-8 infrequent relations. The exact magnitude of the gain varies.

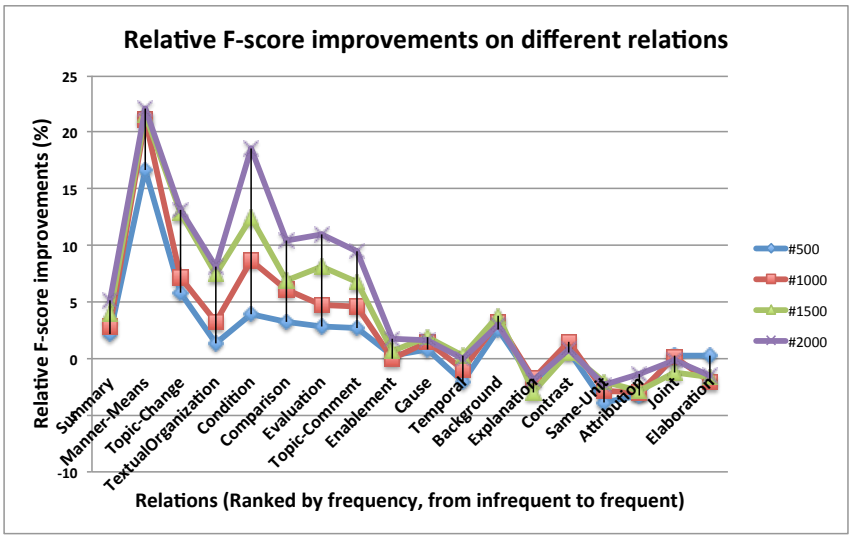

Figure 4: Relative F-score improvements on different relations

So far we have described data enrichment in terms of the number of unlabeled documents. The more detailed analysis is to examine the actual number of training instances created from the unlabeled documents for each relation. Figure 5 shows the actual number of training instances added for each relation, represented as a percentage relative to the frequency of the instances in the original training dataset. For example, for the "Condition" relation, there is a 35% increase in the actual number of instances with 500 documents, and this figure jumps to over 150% with 2,000 documents. With these additional training instances, the gain in F-score for the "Condition" relation is 18.55% from Table 1. For the "Topic Change" relation, it is a pleasant surprise that there is a relative F-score improvement of 13.15% based on about 50% more training instances.

The reader may wonder with 2000 more unlabeled documents, why there is only a modest increase in training instances for some of the infrequent relations. This increase of course depends on the filtering threshold. One temptation based on Table 1 is to lower the threshold to admit more training instances. This leads us to one of the most striking features of Figure 4 on how the relations are separated into

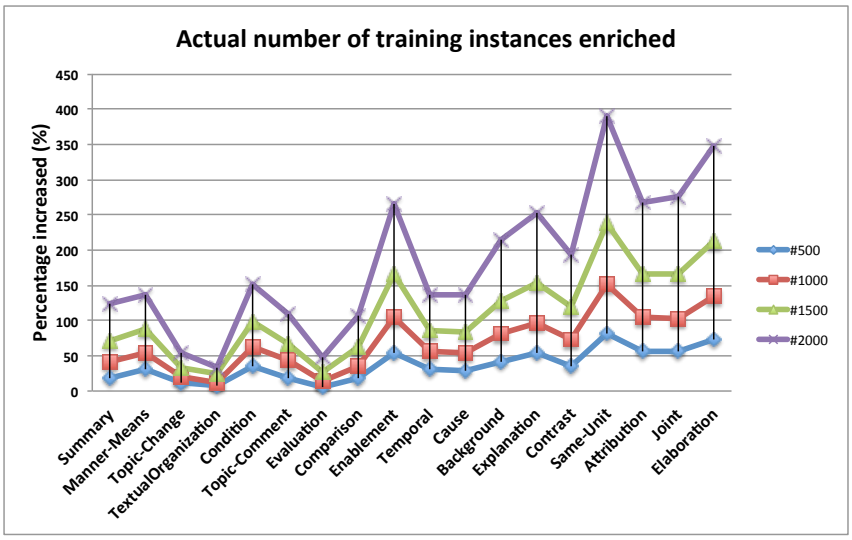

Figure 5: Actual number of training instances enriched (%)

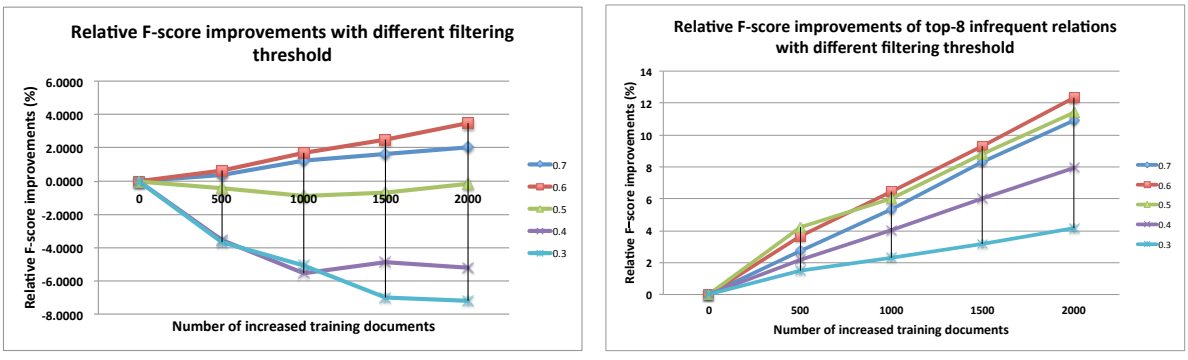
two clusters. While there are improvements for the infrequent relations, there is no gain, or even small negative impact, on the frequent relations. This phenomenon clearly shows that co-training *without filtering* can be harmful to performance. The filtering step is essential to guard against adding "false positive" instances for re-training. If the filtering threshold is set too low, then the frequent relations may suffer. On the other hand, if the filtering threshold is set too high, then only few training instances will be added to benefit the infrequent relations.

4.4 The Impact of the Filtering Threshold

The results presented so far are based on a filtering threshold of 0.5. To examine the impact of the filtering threshold on performance, we vary the threshold. Figure 6(a) shows how the relative F-score improvement changes with a filtering threshold from 0.3 to 0.7 aggregated across all the 18 relations. The results shown in the figure are based on all the instances in the entire dataset. In other words, the performance of the frequent relations, due to their much higher frequencies, completely dominates the performance of the infrequent ones. Thus, Figure 6(b) shows a corresponding graph aggregated across only the top-8 infrequent relations.



(a) Across all the 18 relations

(b) Across the top-8 infrequent relations

Figure 6: Changes in relative F-score with varying filtering agreement score threshold

Compared with the filtering threshold of 0.5 shown previously, there is further improvement when the threshold is raised to 0.6 and 0.7. Particularly from Figure 6(b), there is considerable improvement across the top-8 infrequent relations. Interestingly, the peak performance gain occurs with the threshold of 0.6 — not 0.7. This shows that when the threshold is raised from 0.6 to 0.7, the reduction in the number of

documents passing through the filter hurts the gain in performance.

The reader may wonder whether this kind of performance improvements will continue to grow under the effective threshold with more unlabeled resources added in. To explore the answer to this question, we employ the New York Times text corpus (Sandhaus, 2008) by adding a small subset of its documents to our existing unlabeled documents. Then we conduct the same experiment with the expanded unlabeled resources, and the result in Figure 7 shows that the performance will continue to improve at a lower rate and finally tend to stabilize.

Next let us examine the situation when the filtering threshold is reduced from 0.5 to 0.4 and 0.3. Aggregated across all the 18 relations, Figure 6(a) clearly shows that there is performance loss. Consistent with the performance loss shown in Figure 4 for the frequent relations, this is the situation when the extra training instances passing through the filter introduce too much noise and hurt overall performance. Interestingly, Figure 6(b) shows that there is always a positive performance gain for the top-8 infrequent relations, regardless of whether the filtering threshold is 0.3 or 0.7. This suggests that infrequent relations and frequent relations may need different threshold. We will follow up on this heuristic in Section 4.7.

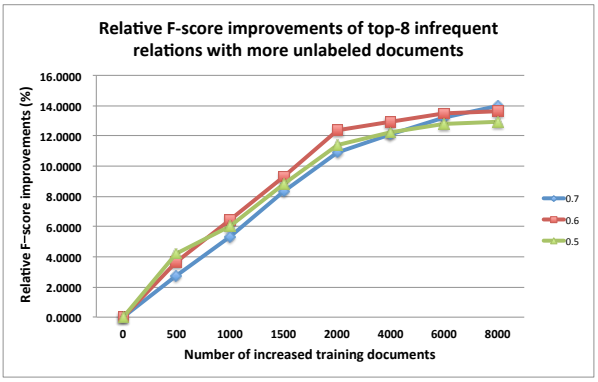


Figure 7: The impact of more unlabeled resources

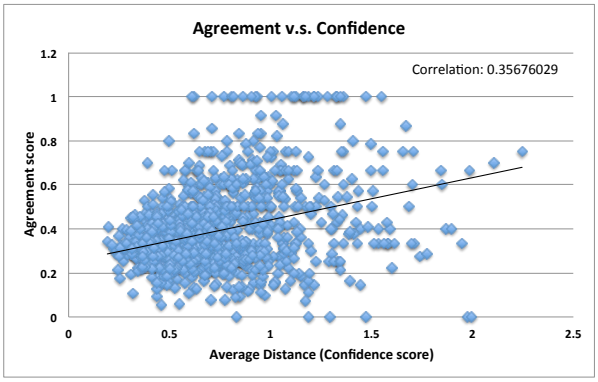

Figure 8: Agreement score v.s. confidence score

4.5 Using the Confidence Score to Approximate the Agreement Score

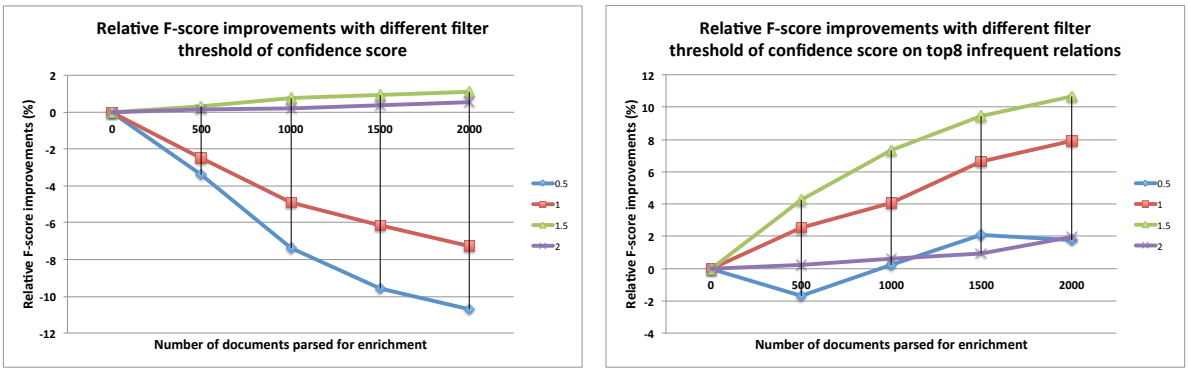
As discussed in Section 3, we explore a second form of enrichment. The agreement score reported so far requires the use of both the CODRA parser and the SR-parser. The former takes cubic time and the latter takes linear time. The idea here is to assess whether the confidence score generated from the faster SR-parser can be used to approximate the agreement score. If this approach is successful, an even larger number of unlabeled documents can be parsed rapidly to be used for re-training.

The first step of the assessment is to calculate the correlation between the agreement score and the confidence score of the SR-parser. As shown in Figure 8, which plots the correlation for all the 2,000 unlabeled documents, there is a weak correlation between the two scores. While the overall correlation is 0.36, it is promising to see that when the confidence score becomes higher (e.g., greater than 1.5), the correlation with the agreement score becomes stronger. It is also important to note that there is a significant drop in the number of documents passing the confidence score threshold of 2.

Corresponding to the two graphs in Figure 6, the two graphs in Figure 9 show the performance change using the confidence score of the SR-parser with varying filtering threshold. Figure 9(a) shows how the relative F-score changes with a filtering threshold from 0.5 to 2 aggregated across all the 18 relations. Like in Figure 6(a) before, the performance of the frequent relations, due to their superior frequencies, completely dominates the performance of the infrequent ones. Thus, Figure 9(b) shows a corresponding graph aggregated across only the top-8 infrequent relations.

In Figure 9(b), the peak performance gain occurs when the confidence score threshold is 1.5. Even when the confidence score is lowered to 1.0, the performance gain is still reasonable with 2,000 documents. But somewhat surprisingly, the performance gain drops significantly when the confidence score threshold is raised to 2. This can be explained by looking more closely back at Figure 8. The confidence

score threshold of 2 is too restrictive and very few unlabeled documents satisfy it; hence, the actual number of additional documents admitted for re-training is significantly reduced.



(a) On all 18 relations

(b) On top-8 infrequent relations

Figure 9: Overall F-score improvements with different enriched data quality via confidence score

A first glance of Figure 9(a) seems to suggest that using the confidence score of the SR-parser is ineffective. The best performance gain across all the 18 relations is barely above 1%, which is smaller than the corresponding gain in Figure 6(a). This ineffectiveness is completely due to the behavior of the frequent relations. However, Figure 9(b) paints a rather different picture. For the top-8 infrequent relations, there is a peak performance gain of about 10% with 2,000 documents. This gain is almost as good as the peak performance gain shown in Figure 6(b) with 2,000 documents. Given that the SR-parser is significantly faster than the CODRA parser, it is promising to use the confidence score of the SR-parser to approximate the agreement score, so that a larger number of unlabeled documents can be used for enrichment.

4.6 Adding enriched training instances in an iterative manner

The results shown so far are based on one round of re-training. As shown in Figure 1, data enrichment can be done iteratively. The table below shows the relative F-score improvement on the top-8 infrequent relations when enrichment is done in increments of 500 documents. Here we process 500 unlabeled documents, re-train the SR-parser with the documents passing through the filter, then process the next batch of 500 documents, and so on.

# of documents	Basic	Iterative (batches of 500 documents)
1000	4.05	4.61
1500	6.65	7.47
2000	7.90	8.95

Table 2: Relative F-scores improvements (%) on the top-8 infrequent relations

The results shown in the table used the confidence score of 1 as the filtering threshold. The first column is precisely the curve in Figure 9(b) for the confidence score of 1. The first row in the table, for example, shows that doing re-training twice (500 documents each time) boosts the performance when compared with re-training done once at the end. Similarly, the other rows show that there is some value in iterative re-training.

4.7 Filtering at a finer granularity

All the filtering experiments above are performed at the document level. That is, we calculate an agreement/confidence score for an entire discourse tree of a document, and if the score passes the threshold, this entire discourse tree along with every node on it will be added to the new training instances, even though some nodes on this tree may have low scores. So in this section, we will explore the idea of filtering at a finer granularity, e.g. at the node level. Due to the different mechanism of the two parsers used in

our framework, we picked the CODRA to conduct this experiment, because it is easier to filter discourse structures at node level and train its new model with partial discourse structures using CODRA. While we could not find a direct way to do it with the SR-parser.

In this experiment, we have performed both doc-level filtering and node-level filtering using the same experiment setting: we use the confidence score of CODRA itself to filter new candidate training examples, and the threshold is set to 0.5 here. The number of unlabeled documents used here is 500. The doc-level filtering works as described above, and for node-level filtering, every node with a confidence score higher than the threshold will be added to the new training set to retrain CODRA, no matter whether the document's discourse tree has a high confidence score that passes the threshold. Results of the two experiments are shown in Table 3. We can see that filtering at node-level has an advantage over filtering at doc-level for most discourse relations. And it is noteworthy that frequent relations are generally unharmed at node-level filtering, unlike at doc-level filtering.

Relation	**Doc-level**	**Node-level**	**Relation**	**Doc-level**	**Node-level**
Summary	4.265	6.811	Cause	1.827	1.965
Manner-Means	8.677	12.581	Temporal	-0.296	-0.246
Topic-Change	1.201	1.801	Background	-0.209	0.105
TextualOrganization	5.669	7.122	Explanation	-0.317	-0.106
Condition	6.656	7.488	Contrast	-0.066	0.131
Comparison	4.527	4.527	Same-Unit	-0.109	0.145
Evaluation	1.696	1.993	Attribution	-0.120	0.052
Topic-Comment	1.360	2.039	Joint	-0.211	-0.015
Enablement	2.999	3.314	Elaboration	-0.058	0.014

Table 3: Relative F-scores improvements (%) at different filtering granularities

Based on the control of filtering at a finer granularity, we can actually do more with the filtering threshold. Since in this case we can compare the score of each node to a threshold to determine whether it should be added to the new training set, we can actually set different thresholds for different types of relations. Though how to set different thresholds for different relations is still to be explored, we have run a small experiment with two different thresholds for infrequent and frequent relations separately and it shows a small increase on the performance. So we believe with more reasonable threshold set for different relations, in the future, greater improvements can be expected from using a varying threshold.

5 Conclusion

As the number of applications of discourse parsing in NLP is constantly growing, any improvement in discourse parsing performance can have considerable impact. In this paper, we first validate the underfitting hypothesis, i.e., the less frequent a relation is in the training data, the poorer the performance on that relation. This is a phenomenon that applies to most discourse parser. One solution is, of course, to create more labeled data, ideally for all the relations. However, given the resources required for manually creating labeled data for discourse parsing, we explore in this paper a training data enrichment framework that relies on co-training of the CODRA parser and the SR-parser on unlabeled documents. We also investigate using both the agreement score and the confidence score of the SR-parser to filter away "low quality" documents, whose presence in the re-training can hurt the performance. Our empirical results show that agreement score filtering can boost the performance of infrequent relations considerably. Our results also show that for infrequent relations, the confidence score of the SR-parser can also be used as a fast approximation of the agreement score.

So far our results show that our data enrichment framework is not effective for frequent relations. In ongoing work, we are studying how to augment our enrichment framework to boost the performance of even the frequent relations, and the varying threshold might be a promising solution. In the future, we plan to apply our framework to enrich training data for discourse structure and nuclearity analysis, and also to apply it to other discourse dataset(s) labeled in different ways (e.g. PDTB).

Inferring Discourse Relations from PDTB-style Discourse Labels for Argumentative Revision Classification

Abstract

Penn Discourse Treebank (PDTB)-style annotation focuses on labeling local discourse relations between text spans and typically ignores larger discourse contexts. In this paper we propose two approaches to infer discourse relations in a paragraph-level context from annotated PDTB labels. We investigate the utility of inferring such discourse information using the task of revision classification. Experimental results demonstrate that the inferred information can significantly improve classification performance compared to baselines, not only when PDTB annotation comes from humans but also from automatic parsers.

1 Introduction

Widely used in discourse research, Penn Discourse Treebank (PDTB)-style annotation (Prasad et al., 2008) adopts a lexically grounded approach by anchoring discourse relations according to discourse connectives. In a typical PDTB annotation process, an annotator first locates discourse connectives (explicit or implicit) then annotates text spans as their arguments. While the process of manual PDTB annotation has been demonstrated to yield reliable results (Alsaif and Markert, 2011; Danlos et al., 2012; Zhou and Xue, 2015; Zeyrek et al., 2013), it yields more shallow annotation when compared to another widely-used discourse scheme, namely Rhetorical Structure Theory (RST) (Mann and Thompson, 1988; Carlson et al., 2002). This is because when using RST a text is represented as a hierarchical discourse tree, while when using PDTB the relations exist only locally (typically between sentences or clauses).

The lack of discourse information across larger contexts potentially limits the utility of PDTB-style labels. Feng et al. (2014) found that when applied to the tasks of sentence ordering and essay scoring, an RST-style discourse parser outperformed a PDTB-style parser. Performance on both tasks was also likely impacted by parsing errors. To address both the local nature of PDTB-style annotations as well as the errors introduced by state-of-the-art discourse parsers, we propose to first build paragraph-level discourse structures from annotated PDTB labels, then to infer discourse relations based on these structures. We hypothesize that features extracted from inferred relations will improve performance in downstream applications, compared to features extracted from only original annotations.

To verify our hypotheses, we choose the task of argumentative revision classification (Zhang and Litman, 2015; Zhang and Litman, 2016), which aims to identify the purpose of an author's revisions during argumentative writing. This task first detects the differences between two drafts of a paper at the sentence level, then labels each revision using one of five categories: *Claim/Ideas*, *Warrant/Reasoning/Backing*, *Evidence*, *General Content* and *Surface*. While Zhang and Litman (2016) demonstrated decent classification performance without using discourse structure, an error analysis of their results suggests that discourse relations might improve performance (e.g., their current system has trouble differentiating between changing reasoning (*Warrant/Reasoning/Backing*) versus smoothing transitions (*General Content*)). One of the corpora used in their work has recently been annotated with PDTB-style relations, which allows us to explore the utilization of both manually and automatically-produced discourse relations for revision classification. Revision classification also allows us to utilize not only the discourse structure of each version of a paper, but also the differences in discourse structure across versions.

Draft2 Essay	(1) The lustful are those who long and crave for one another. (2) The person guilty of lust is put in this layer of hell because of his over indulgence of sexual-pleasure. (3) The man who is stuck in this layer is Hue Heffner. (4) He has devoted his entire life for other people 's lustful pleasure and his own. (5) He has spent millions on working on his mansion which is for the purpose of other lustful desires. (6) People who were stuck in this layer are constantly whipped around and " banging " into one another. (7) What you do in your Earthly presence follows with you into Hell. (8) For him and like many others he is now tortured in a whirlwind of torment with others lustful accommodators with himself.
Annotated PDTB	(1->2, EntRel), (2->3, Expansion), (3->4, Contingency), (4->5, Expansion), (5->6, EntRel), (6->7, Contingency), (7->8, Contingency)

Table 1: A paragraph from an essay about putting contemporaries into different levels of hell (top), and annotated PDTB relations between sentences (bottom). The paragraph can be divided into two segments (Section 3.2). In the first segment (sentences (1) to (3)) the author introduces the person to be put in the lustful layer. In the second segment (sentences (4) to (8)), the author states why this person belongs there and how he will be treated. PDTB relations are processed from PDTB annotations ignoring the discourse connectives, e.g. (1->2, EntRel) represents the discourse information: (Arg1: Sentence1, Arg2: Sentence2, Relation Type: EntRel).

2 Related Work

Previous applications of PDTB-style annotations have typically been based on the extraction of PDTB relation occurrence patterns. Lin et al. (2011) encoded PDTB information into the entity-grid (Barzilay and Lapata, 2008) model for textual coherence evaluation. Mithun and Kosseim (2013) utilized PDTB relations for blog summarization. A limitation of the pattern approach is that since it targets a whole paragraph/essay, it is not straightforward to use for prediction tasks on individual sentences. In our work we propose to infer contextual PDTB discourse relations for each sentence, thus enabling the utilization of less-local PDTB information during single sentence prediction.

The construction of our discourse structure looks similar to the building of an RST tree (Duverle and Prendinger, 2009), and there are also prior efforts in combining the benefits of RST and PDTB (e.g., when building a Chinese discourse corpus (Li et al., 2014)). However, the focus of our work is different. The construction of an RST tree aims at creating a discourse representation of the whole sentence/paragraph/essay. We focus on grouping semantically similar text and assigning higher priority to specific local discourse relations. We expect our structure to be able to select the relations that should be propagated to improve performance in downstream applications.

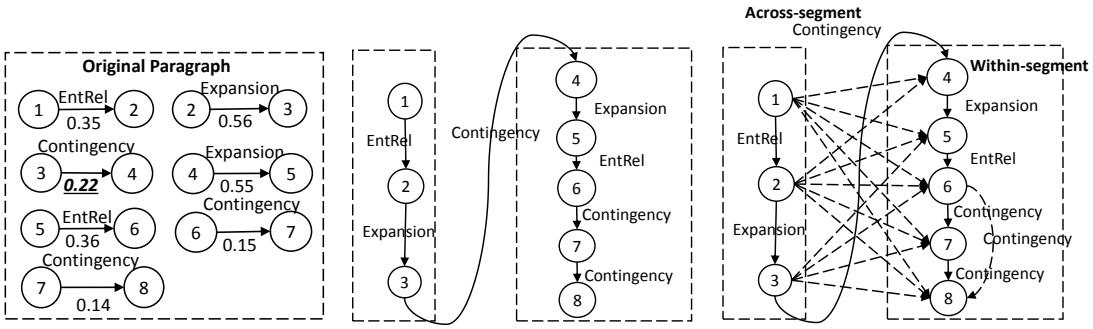
3 Inferring Discourse Information from PDTB-style Labels

3.1 Intuitions for PDTB relation inference

Different from other discourse annotations, the PDTB annotation schema anchors at the labeling of discourse connectives and labels text spans around the connective. The annotator either locates the "Explicit" connectives or manually fills in the "Implicit" connectives between two text spans. The text span where the connective structurally attaches to is called **Arg2**, while the other text span is called **Arg1**. The spans are usually used at the level of sentence/phrase. In (Prasad et al., 2014), five relation types are annotated: *Explicit*, *Implicit*, *AltLex*, *EntRel* and *NoRel*. Within the *Explicit*/*Implicit* relations, the senses of relations are further categorized at multiple levels. In Level-1, the relations are categorized to 4 senses: *Comparison*, *Contingency*, *Expansion* and *Temporal*. In this paper we focus on the type/sense of Level-1 relations only and ignore the discourse connectives[1]. *Arg1*, *Arg2* and the discourse relation type/sense are used as demonstrated in Table 1. For the *Explicit*/*Implicit* relations, we use the sense of the relation directly to represent the relation. Below we explain our intuitions for inferring new discourse relations within the paragraph. Sections 3.2 and 3.3 then detail our corresponding computational approaches.

Intuition 1. Latent discourse relations can be inferred from annotated discourse relations. In this paper we explore two possible cases: **1) Same type transition**: If sentence A has relation type T with sentence

[1]We plan to explore connectives in future work.



(a) Original PDTB annotation (b) After linear segmentation (c) After relation propagation

Figure 1: The construction of PDTBSegment structure of the example in Table 1. As sentence similarity between 3 and 4 is 0.22, smaller than the value 0.56 (before) and 0.55 (after), the paragraph is segmented to segment(1-3) and segment (4-8). Afterwards relations are inferred both within the segment and across the segments. The dashed lines represent the propagated relations.

B and sentence B has the same relation type with sentence C, we can infer that A has relation type T with C. In the example in Table 1, a *Contingency* relation between sentences 6 and 8 will be inferred from the *Contingency* relationships between sentences (6,7) and sentences (7,8). **2) Across segment propagation**: If a paragraph can be segmented to text segments semantically dissimilar to each other (i.e. the two text segments are serving different semantic purposes), the discourse relation of sentences on the boundary of two segments can be propagated to infer weaker relations between all sentences in the segments. In the example in Table 1, due to the discourse relation between sentences 3 and 4 and the segment boundary between them, the segment from 4 to 8 will also be viewed as a reasoning (*Contingency*) of the segment from 1 to 3 (why and how Hue Heffner belongs to the lustful level), and weak relations are inferred between sentences (1,2,3) and (4,5,6,7,8).

Intuition 2. The importance of discourse relations to argumentation varies even if the relation types are the same. The relations connecting the semantically dissimilar segments are likely to be more important than the relations within a segment. In Table 1, the *Contingency* relation between sentences 3 and 4 transits the thesis introduction to the arguments supporting the thesis. The *Contingency* relation between sentences 6 and 7 is just a transition to smooth the description of how Hue Heffner is going to be treated.

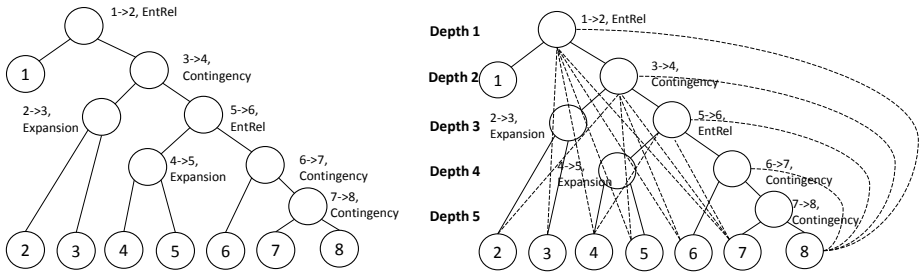
3.2 PDTBSegment

Based on intuition 1, the *PDTBSegment* approach emphasizes the inference of discourse relations.

Step1. Linear segmentation. Inspired by the TextTiling algorithm (Hearst, 1997) for linear segmentation, we utilize the "valley" of semantic similarity scores between sentences as the segmentation boundary. The summed word-embedding vector is calculated for each sentence[2] and cosine value between vectors is used as the similarity score. Similarity scores indicates a possible segmentation boundary. In the example of Figure 1(a), the similarity between (2,3) and the similarity between (4,5) are larger than the similarity between (3,4), in other words, sentence 3 and 4 has a low similarity score preceded by and followed by high similarity scores, thus the paragraph is first segmented into segment (1,2,3) and segment (4,5,6,7,8) as in Figure 1(b).

Step2. Relation inference. **1) Within segment.** We conduct "same type transition" for sentences within the same segment. As in Figure 1(c), there exists relation *Contingency* between 6 and 8 as the same relationship exists between 6, 7 and 7, 8. **2) Across segment.** "Across-segment propagation" is conducted for sentences in different segments. If there exists relation (type T) between two segments Seg1 and Seg2, a relation with type T is inferred for each sentence in Seg1 and each sentence in Seg2. In Figure 1(c), we propagate the *Contingency* relations between sentence (1,2,3) and sentences (4,5,6,7,8).

[2]Pre-trained word2vec vectors from (Mikolov et al., 2013).



(a) After tree structure construction (b) After relation propagation

Figure 2: PDTBTree structure of Table 1 example. The dashed lines represent the propagated relations.

Segment	1(Arg2)	2	3	4	5	6	7	8
1(Arg1)	N/A[a]	Ent	N/A[b]	Cont(2,0)[c]	Cont(2,1)	Cont(2,2)	Cont(2,3)	Cont(2,4)
2	N/A	N/A	Expan	Cont(1,0)	Cont(1,1)	Cont(1,2)	Cont(1,3)	Cont(1,4)
3	N/A	N/A	N/A	Cont	Cont(0,1)	Cont(0,2)	Cont(0,3)	Cont(0,4)
4	N/A	N/A	N/A	N/A	Expan	N/A	N/A	N/A
5	N/A	N/A	N/A	N/A	N/A	EntRel	N/A	N/A
6	N/A	N/A	N/A	N/A	N/A	N/A	Cont	Cont(1)
7	N/A	N/A	N/A	N/A	N/A	N/A	N/A	Cont
8	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A
Tree	1(Arg2)	2	3	4	5	6	7	8
1(Arg1)	N/A	Ent-1	Ent-1(0,1)[d]	Ent-1(0,1)	Ent-1(0,2)	Ent-1(0,2)	Ent-1 (0,3)	Ent-1(0,3)
2	N/A	N/A	Expan-3	Cont-2(1,0)	Cont-2(1,1)	Cont-2(1,1)	Cont-2(1,2)	Cont-2(1,3)
3	N/A	N/A	N/A	Cont-2	Cont-2(0,1)	Cont-2(0,1)	Cont-2(0,2)	Cont-2(0,3)

5	N/A	N/A	N/A	N/A	N/A	Ent-3	Ent-3(0,1)	Ent-3(0,2)
6	N/A	N/A	N/A	N/A	N/A	N/A	Cont-4	Cont-4(0,1)
7	N/A	N/A	N/A	N/A	N/A	N/A	N/A	Cont-5(0,1)
8	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A

Table 2: Relation matrix constructed for the PDTBSegment approach (Upper) and the PDTBTree approach (Below). Ent is short for EntRel, Expan short for Expansion and Cont short for Contingency.

[a]Relationship between clauses within the sentence is not used in relation inference.

[b]No relations can be inferred between 1 and 3.

[c]Cont(2,0) means distance to real Arg1 is 2 and distance to real Arg2 is 0. Here the inferred relation is coming from the labeled relation (3->4, Contingency). 3 is the real Arg1 and 4 is the real Arg2. Distance to real Arg1 is 2 as the the distance between 1 and 3 is 2.

[d]Ent-1(0,1) stands for Depth 1 distance, distance=0 for Arg1 and distance = 1 for Arg2.

3.3 PDTBTree

PDTBTree focuses on intuition 2 using sentence aggregation. To better separate important discourse relations, a hierarchical tree structure is constructed for each paragraph and relations then inferred.

Step 1. Tree construction. As in Figure 2(a), the tree is constructed iteratively starting with each sentence constructed as a leaf node. Semantic similarities between adjacent sentences are calculated in the same manner as the *PDTBSegment* approach. In each round, the two most similar nodes are selected and merged into one node and similarities between the merged node and its adjacent nodes are calculated[3]. The selection and merge of nodes repeats until there is only one root node left.

Discourse relations are assigned to the non-leaf nodes after tree construction. For each tree node, sentences in its left and right child are listed as $Nodes_{left}$ and $Nodes_{right}$. Relations with Arg1 in $Nodes_{left}$ and Arg2 in $Nodes_{right}$ are assigned to the merged node. For example, the discourse relation (1->2, EntRel) is assigned to the root node as sentence 1 is in its left child and sentence 2 is in its right child. After this step we bind each non-leaf node with one or several discourse relations.

Step 2. Relation inference. Relations are first assigned different levels of importance as depths. As in Figure 2(b), the assignment starts at the root node and traverses the whole tree until all the non-leaf nodes

[3]The similarity between merged nodes is calculated as the average of the similarity between their child leaf nodes.

are labeled. Depth starts from 1 and smaller number indicates larger importance. As in the example, we notice that the transition from the thesis to its reasoning (3->4) is recognized as a depth-2 relation while the transitions between sentences 6,7,8 are recognized as depth-4 and depth-5 relations.

Afterwards discourse relations are inferred by traversing up from the leaf nodes back to their parent nodes. The parent node is used as the discourse connector and its child leaf nodes are used as Arg1 and Arg2. For example, in Figure 2(b), sentence 3 is the left child of the node (3->4, Contingency) and sentence 5 is the right child. Thus we infer the discourse relation between 3 and 5 as (3->5, Contingency).

3.4 Constructing the relation matrix

For both approaches, relation matrices are constructed to represent the discourse information as in Table 2. Extraction of features using the matrix is described in the next section. Relations already labeled by the annotator/parser are directly recorded in the matrix. Observing that the reliability of an inferred relation decreases as the number of annotated relations connecting the arguments increases, we record not only the relation types but also the **"distance"** information for the inferred relations.

For the **PDTBSegment** approach, distances are recorded separately for within-segment relations and across-segment relations. For within-segment relations, the distance is recorded according to the number of sentences between Arg1 to Arg2. For example, distance for sentence 6 and 8 is recorded as 2 as there is one sentence between the two sentences. For across-segment relations, distances are recorded for both Arg1 and Arg2 according to their distances to the real Arg1/Arg2 of the across-segment relation as (Dist1, Dist2). For example, distance between sentence 1 and 5 is recorded as (2,1) as there is the distance of 2 between sentence 1 and 3 and there is the distance of 1 between sentence 4 and 5.

For the **PDTBTree** approach, we traverse up from Arg1 and Arg2 to their closest common parent node and count the distances for both arguments as (Dist1, Dist2). In Table 2, distance between sentence 2 and 5 is recorded as (1,1) as we back trace both nodes to their parent node (3->4). As sentence 2 is the real text span in relation node (2->3) and sentence 5 is in the node (5->6), we get distance 1 for sentence 2 as the distances between (2->3) and (3->4) in the tree is 1; similarly, we get distance 1 for sentence 5.

4 Task and Data Description

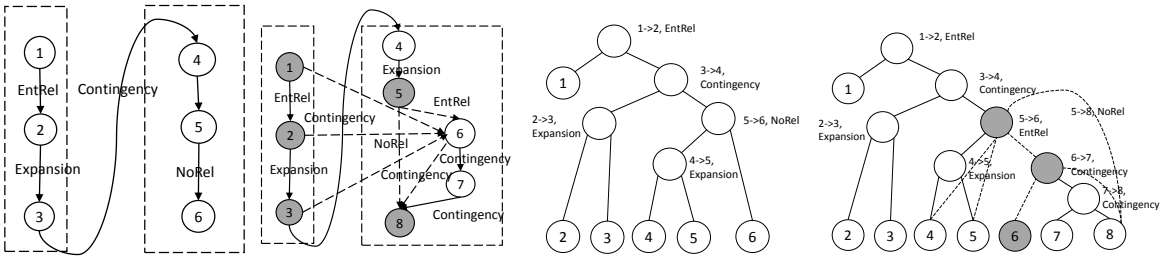
Argumentative revision classification. The task of revision classification aims to detect then categorize an author's changes to their writing. Revision research has been conducted on Wikipedia articles (Bronner and Monz, 2012; Daxenberger and Gurevych, 2013) and argument-oriented study essays (Zhang and Litman, 2015). The example in Table 1 contains a paragraph from a revised student essay. Comparing to its previous draft, the changes are the addition of sentence 6 and sentence 7. The addition of sentence 6 is labeled as (Null->6, "Add", "General Content"). The full classification process involves the alignment of sentences/clauses to locate changes (recognizing the alignment Null->6 and the revision operation "Add") and the classification of change types (identifying the revision type "General Content"). In this work we assume perfect alignment and focus on improving classification performance (the recognition of "General Content") by using inferred PDTB information.

Annotated revision dataset. To evaluate revision classification performance, we use the two corpora used in (Zhang and Litman, 2016)[4]. Each student wrote two essays: *Draft 1* where the students initially write the essay, and *Draft 2* where the students revise Draft 1 after receiving comments from other students. Corpus A contains 47 students (94 essays) and 1267 revised sentence pairs, talking about placing contemporaries into Dante's Inferno. Corpus B contains 63 students (126 essays) and 1044 revised sentence pairs, where students explain the rhetorical strategies used by the speaker/author of a previously read lecture/essay. Distribution of revisions is shown in the first columns of Tables 4 and 5.

PDTB annotation. Recently PDTB discourse information was annotated on corpus A by one of the early developers of the D-LTAG environment (which engendered the PDTB framework)[5] (Forbes et al., 2003; Webber, 2004; Forbes-Riley et al., 2016). Five relation types were annotated: *Explicit*, *Implicit*, *EntRel*, *AltLex* and *NoRel*. Within the *Explicit* and *Implicit* types, four level-1 senses were labeled:

[4]Both corpora are from high school AP English classes.

[5]Thus considered as an expert annotator.



(a) Segment for Draft 1 (b) Segment for Draft 2 (c) Tree for Draft 1 (d) Tree for Draft 2

Figure 3: The change of discourse structure from Draft 1 (D1) to Draft 2 (D2). The gray nodes are the affected nodes and the dashed lines are the affected relations. Sentences are aligned as (1->1), (2->2), (3->3), (4->4), (5->5), (6->8), (Null->6), (Null->7).

Features	Example
Loc	D1-Arg1[a]: N/A, D1-Arg2: N/A, D2-Arg1: Contingency, D2-Arg2: EntRel
Seg	**Individual**: WithinSegment: D1-Arg1: N/A, D1-Arg2: N/A, D2-Arg1: Contingency, D2-Arg2: EntRel, AcrossSegment: D2-Arg2: (Contingency, $\frac{1}{3}$)[b] **Structure**: WithinSegment[c]: (-1, 1, 0, 0, 0.5, 0, 0), AcrossSegment: (0, 0, 0, 0, $\frac{1}{3}$, 0, 0)
Tree	**Individual**: D1-Arg1: N/A, D1-Arg2: N/A, D2-Arg1: Contingency-4, D2-Arg2: (EntRel-1,$\frac{1}{8}$), (Contingency-2, $\frac{1}{4}$), EntRel-3 **Structure**: Depth1Vector: (0,0,0,0,0,0), Depth2Vector:(0,0,0,0,0,0), Depth3Vector: (-1,1,0,0,0,0), Depth4Vector: (0,0, 0,0,1,0,0)

Table 3: Examples of the features extracted for the added sentence 6 in Table 1.

[a]D1-Arg1 means features of sentence acting as Arg1 in the first Draft.
[b](Contingency, $\frac{1}{3}$) represents relation type Contingency with weight $\frac{1}{3}$.
[c]The columns of the change vector are (NoRel, EntRel, AltLex, Comparison, Contingency, Expansion, Temporal).

Comparison, *Contingency*, *Expansion* and *Temporal*. Similarly to (Prasad et al., 2011), the annotator relaxed the structural adjacency constraint, allowing the annotation of relations between non-adjacent sentences. Annotated and inferred PDTB information will be used to construct features for revision classification as described next.

5 Using Inferred PDTB for Classification

In this section we investigate whether using the annotated PDTB information itself can improve the classification performance, and whether such performance can be improved with the inferred PDTB information. For both of our inference approaches, we extract features individually to utilize the inferred relation type and further extract structure change features to utilize the PDTB structures built.

5.1 Features

The *PDTBSegment* and *PDTBTree* structures are constructed for both drafts as in Figure 3. Table 3 shows the PDTB features extracted for the added sentence 6 in Table 1, with features explained below.

Baseline features (Base). Features in (Zhang and Litman, 2015) are used as a baseline. Besides *Unigram* features, *Location* features encode the location of the revised sentence. *Textual* features encode revision operation, sentence length, edit distance between revised sentences and punctuation. *Language* features encode part of speech (POS) unigrams and difference in POS tag counts.

Features using the labeled local PDTB information (Local). Features are extracted as the types of relations a sentence is involved with (i.e. the relation where the sentence acts as Arg1 or Arg2.) Features are extracted for sentences in both drafts. If a sentence is added or deleted, the features for the empty sentence are marked as N/A.

Features using PDTBSegment (Segment).

Individual features Within each draft, the features of sentences are extracted based on the relation ma-

trix. Similar to **Local**, we extract the discourse relation type of each sentence acting as Arg1 and Arg2[6]. Features for across-segment relations are extracted separately since the discourse relations across segments are likely to be more important than relations within segments. Weights are assigned to relations according to their distance information. A within-segment relation with distance (d1) is assigned weight $\frac{1}{d1+1}$; an across-segment relation with distance (d1, d2) is assigned weight $\frac{1}{(d1+1)*(d2+1)}$. If a sentence is involved with multiple same-type relations, the relation with the largest weight is chosen.

Structure change features For these across draft features, the segment structures created for draft 1 and draft2 are compared. Nodes of segment structures are aligned according to the sentence alignment information. After comparison, the aligned nodes that are affected by the revision are selected, where the change of their related relations with the revised sentence are counted. For example in Figure 3(b), sentences 1, 2, 3, 5, 8 are affected by the addition of sentence 6. For sentence 1, 2, 3, sentence 6 brings addition of three across-segment relations. For sentence 5, the original "NoRel" label between sentence 5 and sentence 8 is removed. For sentence 8, relation between sentence 6 and sentence 8 is added. A vector of relation changes is thus created according to the relation matrix.

Features using PDTBTree (Tree).

Individual features Features are collected in a similar manner as the **PDTBSegment** approach. To enlarge the difference of different-depth relations, weight $\frac{1}{2^{d1+d2}}$ is assigned to a relation with distance (d1, d2) .

Structure change features Due to the complexity of the tree structure, only the non-leaf nodes that are directly related to the revised sentence (i.e. the sentence as Arg1 or Arg2 of the relation) are considered in the extraction of structure changes. As in Figure 3(d), the added sentence 6 acts as Arg2 in node (5->6) and Arg1 in node (6->7). Change of relations (4->6), (5->6) are considered as the changed relations of node (5->6). Change of relations (5->8) and (6->8) are the changed relations of node (6->7). Change vectors are calculated in similar manners as the **PDTBSegment** approach at each depth. To avoid data sparsity, the depth number is limited to 4 to reduce the number of features[7].

It is important to notice that as in the standard PDTB annotations, the spans of arguments may cover only a part of a sentence or multiple sentences. If the span covers only a part of the sentence and the two spans of the relation come from two different sentences, we use the relationship as the relation between the two sentences. If the two spans come from one sentence, we consider it as a self-relation. Such information is used in the extraction of local PDTB features but not used in relation inference. If a span of a relation covers multiple sentences, we infer relations as in the PDTBSegment approach (consider the multiple sentences span as a text segment). Also, it is possible to have more than one relation annotation between two sentences. In that case all the relations are kept and used in relation inference.

5.2 Experiments and Results

We repeated the experiment in (Zhang and Litman, 2016) using our new proposed feature group[8]. 5-class revision category classification[9] was conducted with the SVM[10] classifier. Two hypotheses are proposed: 1) For manually labeled PDTB relations, using features extracted from inferred relations has better performance than using baseline features or baseline with only local PDTB features. 2) For automatically labeled PDTB relations, using features extracted from the inferred relations reduces the noise introduced by the PDTB parser and has better performance than using only local PDTB features.

Based on the hypotheses, two experiments were conducted. In both experiments we compared the results using inferred information to the baseline results, and to the results with baseline features plus each individual feature group[11]. In Experiment 1, we experimented with the PDTB features extracted from manual labels on Corpus A (where we have manual annotations). In Experiment 2, we experimented

[6]The row of the sentence in the relation matrix corresponds to Arg1 and the column corresponds to Arg2.

[7]If the depth of tree is larger than 4, the depth of the relation is still considered as 4.

[8]In this paper we focus on the comparison of features and thus do not directly compare our approach with the sequence labeling approach used in their work

Average(1044)	0.503	0.495	**0.520**‡	0.503	0.466	0.483	0.495⋆	0.493⋆

Table 5: Experiment 2. With automatically labeled PDTB. B short for Base, B- is a weaker baseline using unigram and *Textual* features from the baseline approach. ⋆ indicates significantly better than B-. ‡ indicates significantly better than (B+local), **bold** indicates best.

with the PDTB features extracted from labels generated with Lin's automatic PDTB parser (Lin et al., 2014) on Corpora A[12] and B. All experiments were conducted using 10-fold (student) cross-validation with 300 features selected[13] using learning gain ratio. Tables 4 and 5 demonstrate the results.

Experiment 1 results provide support for our first hypothesis. Comparing to the baseline, Base+Local (using only features from the labeled PDTB relations) yields a significant improvement only when classifying *Evidence* revisions and a non-significant overall average improvement. In contrast, both Base+Segment and Base+Tree (our inference-based approaches) yield several significant improvements over the baseline[14]. Comparing to the baseline, the **PDTBSegment** approach yields significant improvement in the classification of *Warrant*, *Evidence* and *General Content* revisions and the **PDTBTree** approach yields significant improvement in the classification of all revisions except *Surface*. For the minority category *Evidence*, the **PDTBTree** approach improved F1 from 0.288 to 0.415. Comparing to the results using only labeled PDTB, the **PDTBSegment** approach yields significant improvement in the classification of *Warrant*, *Evidence* and *General*, while the **PDTBTree** approach yields significant improvement in the classification of *Claim*,*Warrant* and *Evidence* and a significant overall F1 improvement.

Experiment 2 results support our second hypothesis. On corpus A, we observe a significant performance drop ($p<0.05$) in average F1 score for all the (B+) feature groups comparing to the Experiment 1 results in Table 4, which indicates that the noisy output generated by the parser impacts the performance[15]. While we do not gain significant improvement over the baseline using the inferred relations, we still observe significantly better performance using the **PDTBSegment** approach comparing to using

[12]The same fold is used as Experiment 1.

[13]Features selected only on the training folds each round.

[14]We also tested using just individual features (without the structure change features) and both approaches still significantly outperform the baseline.

[15]We compared the output of the PDTB parser and the manual annotation on Corpus A, indicating that the F-measure for the relation prediction is 0.45.

only the automatically labeled relations. Meanwhile, we observe that the inferred PDTB features can still significantly improve the performance of a weaker baseline with *Unigram* and *Textual* features while the Local features can't, suggesting that the our approach is still effective even with the noisy parser output.

6 Conclusion and Future Works

This paper presented two approaches to construct a paragraph-level discourse structure from local PDTB discourse labels, and infer discourse relations within the structure. We applied our approaches on the task of argumentative revision classification with manually/automatically labeled PDTB information. Results demonstrated that using features extracted from inferred PDTB relations yields better revision classification performance than using features from original PDTB annotations. Results also showed that our method reduced the impact of the automatic PDTB parsing errors.

We believe our work can be expanded from two perspectives. 1) From the PDTB perspective, we can investigate our approach on other traditional PDTB applications such as coherence evaluation to see if we can still observe an improvement on these tasks. 2) From the argumentative revision classification perspective, we plan to explore what aspects of our proposed approach yields most robustness to errors from automatic PDTB parsers. We also want to try other discourse parsers in recent shallow discourse parsing shared tasks (CoNLL, 2016). We also plan to investigate whether the RST-style discourse information can also improve the classification performance and compare the results with our approach. We also plan to investigate whether our approaches can be applied to other type of writings besides argumentative writings.

Abstract

We examine the potential of recurrent neural networks for handling pragmatic inferences involving complex contextual cues for the task of article usage prediction. We train and compare several variants of Long Short-Term Memory (LSTM) networks with an attention mechanism. Our model outperforms a previous state-of-the-art system, achieving up to 96.63% accuracy on the WSJ/PTB corpus. In addition, we perform a series of analyses to understand the impact of various model choices. We find that the gain in performance can be attributed to the ability of LSTMs to pick up on contextual cues, both local and further away in distance, and that the model is able to solve cases involving reasoning about coreference and synonymy. We also show how the attention mechanism contributes to the interpretability of the model's effectiveness.

1 Introduction

Correctly performing pragmatic reasoning is at the core of many NLP tasks such as information extraction, automatic summarization, and machine translation. We focus in this paper on definiteness prediction, the task of determining whether a noun phrase should be definite or indefinite. In English, one instantiation of this task is to predict whether to use a definite article (*the*), indefinite article (*a(n)*), or no article at all. It has applications in machine translation (Heine, 1998; Netzer and Elhadad, 1998), and in L2 grammatical error detection and correction (Han et al., 2006).

Definiteness prediction is an interesting testbed for pragmatic reasoning, because both contextual and local cues are crucial to determining the acceptability of a particular choice of article. Consider the following example:

(1) *A/#the man entered the room. The/#a man turned on the TV.*

Factors such as discourse context, familiarity, and information status play a role in determining the choice of articles. Here, *man* is introduced into the discourse context by an indefinite article, then subsequently referred to by a definite article. On the other hand, non-context-dependent factors such as local syntactic and semantic restrictions may block the presence of an article. For example, demonstratives (e.g., *this*, *that*), certain quantifiers (e.g., *no*), and mass nouns (e.g., *money*) do not permit articles.

In this work, we investigate Long Short-Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997), a subclass of recurrent neural networks (RNNs) which have been popular recently in a variety of NLP tasks (Sutskever et al., 2014; Mikolov et al., 2010; Dyer et al., 2015). A number of reasons are often cited for the impressive performance gains of RNNs (Goldberg, 2015). First, they are able to take advantage of the patterns inherent in the data to learn features and representations suitable for complex interpretation tasks. Second, they can learn connections between processing units in the same layer, allowing the network to capture relations and patterns over an unbounded number of timesteps. Third, they provide an easy and natural way to inject external semantic knowledge by initializing the parameters of the model in an informed way. For example, the word embeddings can be initialized using pre-trained vectors such as `word2vec` (Mikolov et al., 2013).

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2625–2634, Osaka, Japan, December 11-17 2016.

We compare several versions of LSTMs to explore how each of these factors affects article usage prediction. We also explore a version of LSTMs that employs an attention mechanism. The primary motivation for the use of an attention mechanism is to investigate whether such LSTM models focus on certain parts of the sentence when making predictions, and if so, to gain more insight into what parts of the sentence affect the model's prediction.

Our model achieves state-of-the-art performance on definiteness prediction, outperforming a previous, classification-based model by De Felice (2008). Our best model achieves 96.63% accuracy on the WSJ/PTB corpus, representing a relative error reduction of 51% compared to the previous state of the art. Each of the factors we examined (initializing with pre-trained vectors, giving more context, giving POS tags, attention) contributes to the performance of the model, though in different degrees. We perform a number of analyses to understand the behavior of the models, and show in particular how the attention mechanism can be useful for interpreting the model predictions.

The most interesting contribution of this paper is highlighting the suitability of LSTMs for tackling complex cases of article usage where there is no obvious local cue for prediction. We find evidence that LSTMs given an extended context window can resolve cases of article usage that seem to require reasoning about coreferent entities involving synonymy. Our results suggest that recurrent neural network models such as LSTMs are a promising approach to capturing pragmatic knowledge.

2 Related Work

Characterizing definite descriptions has been one of the first problems considered in semantics and pragmatics, and indeed in the philosophy of language. Russell (1905) analyzed definite descriptions as having quantificational force by asserting the existence and uniqueness of the definite NP, whereas Strawson (1950) emphasized their anaphoric nature, and their ability to trigger a presupposition about the existence of the noun phrase in the discourse context.

In terms of corpus-based studies, Poesio and Vieira (1998) analyzed a subset of definite descriptions found in the WSJ, and asked annotators to classify them according to their function. They found that 50% of definite descriptions were classified as discourse-new, 30% as anaphoric, and 18% as associative or bridging. Lee et al. (2009) investigated the role of contextual information in predicting article usage in a user study.

There has been a variety of previous models on article prediction (Knight and Chander, 1994; Minnen et al., 2000; Han et al., 2006; Gamon et al., 2008). De Felice (2008) framed it as a MaxEnt classification task, extracting a number of linguistically motivated features from the context of each head noun. Turner and Charniak (2007) took an approach more similar to our own, viewing article selection as a language modelling problem by training a parser-based language model on the WSJ and North American News Corpus.

More generally, the use of distributed representations in discourse processing is becoming more widespread, with applications in discourse parsing (Kalchbrenner and Blunsom, 2013; Ji and Eisenstein, 2014; Li et al., 2014) and implicit discourse relation detection (Ji and Eisenstein, 2015). There have also been recent efforts to build distributed representations of linguistic units larger than a sentence (Le and Mikolov, 2014; Li et al., 2015). Hill et al. (2016) investigated several variants of LSTMs to predict function and content words, but they did not consider determiners in their study.

3 Model

We introduce several variants of LSTM models for definiteness prediction. LSTMs extend standard RNNs by providing additional memory control that can capture long-term dependencies between data samples that would be difficult to capture with standard RNNs. The memory control allows the model to carefully regulate how much the current input affects the new memory state, how much the previous memory state affects the new memory state and what elements of the memory should play a role in generating the output. We first present the LSTM variants that we experimented with, then describe the input representations which we used for the models.

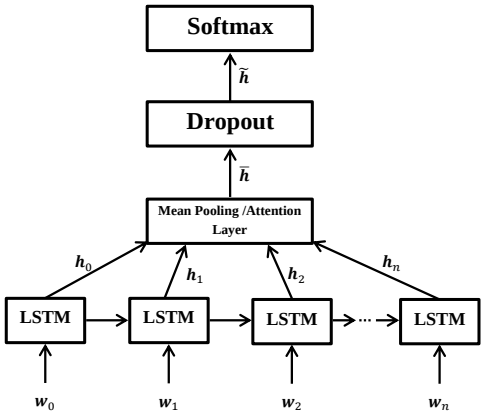

Figure 1: LSTM-based neural network model.

3.1 Vanilla Model

In a standard, "vanilla" LSTM (Figure 1), the model is given an input sequence, $w_0, w_1, \ldots, w_n$. Each w_i is a vector representation of an input word at timestep i, which is fed to an LSTM cell consisting of an input gate, an output gate, a forget gate, a cell state, and a hidden state (see (Graves, 2013) for more details). The outputs of the LSTM cells are fed to a mean pooling layer:

$$\overline{h} = \frac{1}{n} \sum_i h_i \tag{2}$$

Then, the dropout layer randomly suppresses output neurons of $\overline{h}$ during the forward pass of training with a pre-defined probability by setting them to zero. This in effect acts as a regularization mechanism (Srivastava et al., 2014). In the last stage, we perform classification using a three-input softmax unit.

3.2 Attention-based model

Attention mechanisms have recently attracted considerable interest in the deep learning community. Attention mechanisms are loosely inspired by theories of human visual attention in which specific regions of interest have high focus compared to other regions.

Compared to "vanilla" model, the attentive LSTM model replaces the mean pooling layer with a learned attention layer that leads to a weighted average of the timesteps. For each timestep i, the model learns:

$$c_i = \tanh(Mh_i + b) \tag{3}$$

$$a_i = \exp(c_i) / \sum_j \exp(c_j), \tag{4}$$

where M is a learned weight matrix, b is a bias term, c_i reflects the importance of the input at that timestep, and a_i is a normalized version of the importance over all timesteps in the sample. Then, the output is calculated as:

$$\overline{h} = \sum_i a_i h_i. \tag{5}$$

3.3 Input representation

We map each input token w_i to some learned embedding, which is then fed to the input layer of the LSTM. We investigate several different linguistically motivated factors for building this representation

Table 1: Number and distribution of noun phrases in the PTB corpus by the article type.

	none	the	a(n)
Training set	150606	49117	23907
Development set	11987	3898	1867
Test set	14676	4848	2155

beyond the standard "vanilla" LSTM model. First, we experiment with incorporating or not POS tags as a form of syntactic knowledge (+/−**POS**). To incorporate such knowledge, we concatenate the POS to the aforementioned learned embedding before feeding it to the input layer. The other factor that we consider is how to initialize the embedding associated with each word-type. We experiment with initializing it randomly, or with pre-trained vectors, which could inject knowledge derived from a large, external corpus. The intuition behind incorporating pre-trained vectors is that they might help the model recognize bridging references of those involving synonyms (e.g., *a* ***house*** *... the* ***home***). Thus, we compare the following options:

- **Random**: The embedding is initialized randomly.
- **word2vec**: The embedding is initialized by the SkipGram vectors of Mikolov et al. (2013) trained on the Google News corpus (about 100 billion words).
- **GloVe**: The embedding is initialized by the global vectors Pennington et al. (2014) that are trained on the Common Crawl corpus (840 billion tokens).

Both word2vec and GloVe word embeddings consist of 300 dimensions. To test whether compressing those embeddings would lead to a better prediction performance, we investigated the use of PCA to reduce the dimensionality of the word embeddings, but found that this did not influence performance on the development set.

4 Dataset

We use the Penn Treebank (PTB) corpus (Marcus et al., 1993) with the standard section splits for training (01–23), development (00, 24) and testing (22, 23). We extract all of the noun phrases present in the parsed corpus whose head noun's POS tag is one of `NN`, `NNS`, `NNP`, or `NNPS`. Also, we do not lemmatize, and ignore case and punctuation. Finally, we remove any occurrence of the relevant determiners (*the*, *a*, *an*) from all the data sets (training, development, test). The number of samples in the dataset is shown in Table 1.

In our experiments, we adopt one of two different sample configurations: the first focusing on a local context and the second extending the context to encompass one or more sentences. Specifically, for the former, we define a sample to be the set of tokens from the previous head noun of a noun phrase up to and including the head noun of the current noun phrase. For example, take the following passage (head nouns indicated in bold):

(6) For six **years**, T. Marshall Hahn **Jr.** has made corporate **acquisitions** in the George Bush **mode**: kind and gentle.

The following samples –relying on local context– are shown, with their labels: *For six years* – 'none', *T. Marshall Hahn Jr* – 'none', *has made corporate acquisitions* – 'none', *in George Bush mode* – 'the'.

For the sample configuration relying on the extended context, the sample is constructed in the same way (as described above) and, in addition, tokens from the previous sample(s) are added sequentially (in reverse) until a pre-specified total number of tokens per sample is reached. That way, the sample not only reflects local information from the current noun phrase, but also information that is contained in a previous sentence (or more).

Having these two distinct sample configurations allows us to compare, in general, the learning performance of the LSTM network between the two cases and to investigate, in particular, whether those networks are able to resolve cases that exhibit long range dependencies and complex cases that require contextual clues that go beyond the local context of a given article.

5 Experiments

We compare our LSTM models against the following systems. The first is the most frequent baseline (**Baseline**), which labels all noun phrases with the most frequent class of none. The second is a reimplementation of the classification-based method of De Felice (2008) (**LogReg**), which extracts features from a fixed context window for a multinomial logistic regression classifier. Our implementation differs from the one described in that work in two respects. First, we could not gain access to the list of mass and count nouns that she did. We approximated this by crawling the British National Corpus (Burnard, 2007) for instances of nouns that appear after *a/many/few* to identify count nouns, and *much/little/bit of* for mass nouns. During feature extraction on the PTB, nouns that have not been previously encountered are given the label unknown.

5.1 LSTM training

Many variations of the LSTM cell have been proposed in the literature; however, since we implement our model using Lasagne[1], we use the LSTM cell implemented by Lasagne and presented in (Graves, 2013). We use the AdaDelta algorithm (Zeiler, 2012) for learning the optimal network parameters and word embeddings. The model has a number of hyperparameters that were tuned on a development set. We list below the range that we explored (min, max) and the final value that was used [val]:

- Word embedding and hidden-layer dimensionality: (50, 200), [100]
- Dropout probability: (0.2, 0.7), [0.6]
- Minibatch size: (20, 200), [100]

6 Results

We present the results of our experiments in Table 2. Our LSTM models outperform LogReg and the baseline in terms of accuracy despite not having access to an extensive set of hand-crafted linguistic features. Incorporating pre-trained word vectors into the initialization results in a small but consistent improvement in performance, for both the version without and with POS tags. We notice, however, that the particular choice of the embedding, does not seem to make much of a difference, with GloVe very slightly outperforming word2vec. In all cases, using an attention mechanism in the learning model led to an improvement in the accuracy. We also contrast the learning performance of the network when fed samples relying on local context versus samples relying on the extended context. Most interestingly, POS tags do not seem as necessary for high performance in the extended case, as the discrepancy between using or not POS tags is almost negligible. This could be explained by the fact that an extended context allows the network to learn relevant syntactic cues from context which were only available with explicit POS tags in the case of local context. Overall, the best setting is using extended contexts and GloVe embeddings with POS tags and attention in the LSTM model, at 96.63% accuracy.

Our results improve upon different previously reported accuracies on this task. De Felice (2008) reported the best previous result of 92.15% accuracy, though this was on the BNC corpus. Our reimplementation of this work (LogReg) achieved 93.07 % on the WSJ-PTB corpus. Turner and Charniak (2007) reported an accuracy of 86.63% on ten-fold cross-validation over WSJ with additional training on an external corpus. We are able to achieve a higher accuracy on comparable data using a smaller amount of training data, though the models initialized with pre-trained word embeddings could arguably be said to be trained on large amounts of text.

Method			**Accuracy** (%)	
Baseline			67.70	
LogReg			93.07	
	Init.	**POS**	**Local contexts**	**Extended contexts**
LSTM	Random	−POS	83.94 - 83.96	95.82 - 96.08
LSTM	word2vec	−POS	84.91 - 84.93	96.40 - 96.53
LSTM	GloVe	−POS	85.35 - 85.75	96.37 - 96.43
LSTM	Random	+POS	94.11 - 94.12	95.95 - 96.08
LSTM	word2vec	+POS	94.50 - 94.52	96.20 - 96.25
LSTM	GloVe	+POS	94.64 - 94.67	96.38 - **96.63**

Table 2: Accuracy results for article prediction on the WSJ/PTB corpus. The LSTM models are distinguished by their initialization method (**Init.**), whether or not they used POS tags (**POS**), and whether they were give local or extended context. For each result for the LSTM models, we show the result for the model without attention (left) and with attention (right).

Method	**Class**	**P**	**R**	**F1**
Baseline	none	67.70	100.0	80.74
LogReg	a	75.05	70.49	72.70
	none	98.63	98.41	98.52
	the	84.10	86.94	85.50
Local LSTM+a	a	76.30	73.04	74.63
+ GloVe	none	99.55	99.42	99.49
+ POS	the	87.60	89.60	88.59
Extended LSTM+a	a	86.88	91.28	89.02
+ GloVe	none	98.02	96.99	97.50
+ POS	the	95.34	96.25	95.79

Table 3: Precision, Recall, and F1 results by class. We only show the 'none' class results of the baseline, as the baseline is to label everything as 'none'. LSTM+a represents the attention-based model.

These numbers conceal the large differences in performance between the different classes. Table 3 shows the breakdown of the results for each model by class label in terms of precision, recall, and F1. Because of space limitations, we only include results for selected models. Overall, the "none" class is the easiest to predict. This is expected, as various syntactic and semantic cues are highly indicative of the "none" class (e.g., presence of a demonstrative in the context or the head noun being a named entity).

Also, we consider the performance of the models on named entities versus non-named entities, as identified by the POS tag on the head noun. Table 4 shows the accuracy results divided into the two classes. As expected, named entities are easier for the model to predict, due to conventions about article usage related to named entities in English. The LogReg model already achieves high performance on named entities, and it is conceivable that with a larger amount of training data, it can approach the performance of the LSTM models, because it will see more conventions about named entities or classes of named entities. Both LSTM models improve on performance on both classes, and actually obtain a greater absolute improvement on the non-named entities. This could be seen as evidence that they actually are making better predictions for those cases that require long-range dependencies.

Finally, we conducted two-tailed paired sign tests (with a level of significance $\alpha = 0.05$) to examine whether the best performing LSTM model (GloVe + POS with attention and extended context) significantly outperformed the LogReg baseline, as well as other versions of the LSTM model, namely the best LSTM with local context, the best LSTM with random initialization and the best LSTM without

Method	NE	non-NE
Baseline	86.98	61.76
LogReg	97.27	91.77
Local LSTM+a + GloVe + POS	**98.88**	93.44
Extended LSTM+a + GloVe + POS	97.62	**96.48**

Table 4: Test set accuracy results for named entities (N = 5100) and non-named entities (N = 16579).

	Simple Cases		Complex Cases	
	fixed	dup.	syn.	semantics
	86	6	8	100
Total	92		108	

Table 5: Classification of 200 samples incorrectly predicted by the best performing LSTM model on the local context but correctly predicted by the best performing model on the extended context. With categories of simple cases including fixed expressions(*fixed*) and duplication of the head noun(*dup.*), complex cases of synonyms(*syn.*), and cases require semantic understanding(*semantics*)

POS tags. We found that, for the single case of the best LSTM model without POS tags, the difference between that LSTM model and the best performing LSTM model was not statistically significant (p= 0.41). For all the remaining models, we found a highly significant difference ($p < 10^{-6}$) between the best performing LSTM model and each of those models.

7 Analysis

We perform some additional analysis to understand the behavior of the models.

7.1 Local context versus extended context

In order to gain an insight into the possible reasons behind the large performance gains obtained when using the extended context, we compare the best performing LSTM model that uses local context to the best model relying on the extended context and investigate 200 samples out of the 957 samples that were incorrectly predicted by the former (local context) but correctly predicted by the latter (extended context).

We grouped the samples into two main categories: (1) simple cases where the decision can be made based on the noun phrase itself (e.g. fixed expressions such as "the other day", and named entities), or the same head noun was introduced in the earlier discourse context; (2) complex cases where contextual knowledge involving pragmatic reasoning is required (e.g., entity coreference involving synonymy, bridging reference).

Table 5 shows the break-down into those categories. Complex cases accounted for over half of the cases with 108 cases involving synonymy or other complex cases such as bridging references. The model using local context failed to predict those cases correctly, which can be explained by the fact that, with local context only, no obvious cues for predictions were available. This suggests that LSTM networks constitute learning models that can learn to predict complex cases given an appropriate contextual window.

7.2 Qualitative analysis using the attention weights

In order to gain a better understanding of how the model makes its predictions and whether the model is able to resolve complex cases, we consider the attention weights of several samples (i.e., the set of a_i weights). All of the following cases were incorrectly predicted using local context but correctly predicted when the LSTM network was fed samples with extended context. Note although the original sentences (shown below) include the determiners (for the classes 'a', and 'the'), the determiners are removed from

the samples that are fed to the neural network model as mentioned in Section 4. The samples have a fixed length of 50 tokens. To emphasize the article that is the focus of the prediction task in that particular sample, we present such article in bold in each of the examples. Finally, note that since a sample consists of 50 tokens, the average weight for a token is 0.02.

Consider the example:

(7) *... net income for the third quarter of 16.8 million or 41 cents a share reflecting [a] broad-based improvement in the company's core businesses. Retail profit surged but the company it was only a modest contributor to third-quarter results. A year ago, net, at* ***the*** *New York investment banking firm ...*

In this example, in addition to the tokens in the noun phrase "New York investment banking firm" receiving some of the highest weights, both "contributor" and "company" were among the 10 tokens with the highest weight (with all of them receiving a weight of more than 0.04). While the LSTM with local context incorrectly predicted such a sample, high weights on tokens such as "contributor" and "company" suggest that the LSTM had potentially made use of the extended context paying higher "attention" to those relevant tokens while mostly ignoring the contents of the rest of the sentence.

In the following example:

(8) *...companies. In a possible prelude to the resumption of talks between Boeing Co. and striking Machinists union members, a federal mediator said representatives of the two sides will meet with him tomorrow. It could be a long meeting or it could be a short one, said Doug Hammond,* ***the*** *mediator...*

in addition to "mediator" receiving the highest weight (approx. 0.05), both "Doug" and "Hammond" received weights of approx. 0.049 and 0.05. While resolving the case of "the mediator", the network correctly paid attention to the relevant tokens "Doug" and "Hammond".

Consider this example:

(9) *BMA's investment banker Alex Brown & Sons Inc. has been authorized to contact possible buyers for the unit. Laidlaw Transportation Ltd. said it raised its stake in ADT Ltd. of Bermuda to 29.4% from 28%. A spokesman for Laidlaw declined to disclose the price* ***the*** *Toronto transportation...*

In this example, for correctly predicting that "Toronto transportation" should have a label "the", the network focused on the tokens "Toronto" and "transportation" while also attributing high weights to the tokens in "Laidlaw Transportation Ltd." (with all of them receiving a weight of more than 0.04 and figuring in the 10 highest weights).

These samples demonstrate that the attention mechanism can give us useful feedback on why the model is making the predictions that it is, adding interpretability to deep models. Secondly, they provide evidence that RNNs are able to learn complex features in order to place importance to syntactically and semantically relevant cues for this pragmatic reasoning task. By potentially allocating high weights to relevant tokens in an extended context, the LSTM network could also learn to predict complex cases of article usage, explaining its performance gains.

8 Conclusion

We have shown that English article usage, a task requiring reasoning about both local and non-local cues, can be successfully predicted using an LSTM recurrent neural network. Despite using generic features, our model outperforms previous methods for article prediction that rely on limited context. Our model is very successful in predicting the 'none' class and in making predictions for named entities. We perform a series of analyses to investigate whether the performance gains are due to factors that are traditionally cited for RNN models. By examining the attention weights, we find evidence that the models are actually learning complex features such as various syntactic and semantic restrictions, which would have been encoded by manually constructed features in previous models. As for initializing with pre-trained word embeddings, this improves performance consistently across multiple models but only marginally. The

LSTM can also take advantage of long-ranged dependencies in making its prediction, because it can place high attention on any part of the input sequence from an arbitrary distance before the head noun. We also have shown that LSTM networks show strong performance in resolving complex semantic cases when given an extended contextual window spanning two or more sentences.

Our model does not rely on task-specific features, only task-specific training. Thus, the exact same model should be applicable to other tasks involving semantic and pragmatic knowledge. We are currently planning to conduct further experiments on predicting other linguistic constructions involving contextual awareness and presupposition.

Aspect Based Sentiment Analysis using Sentiment Flow with Local and Non-local Neighbor Information

Shubham Pateria
Samsung R&D Institute
Bangalore, India
s.pateria@samsung.com

Abstract

Aspect-level analysis of sentiments contained in a review text is important to reveal a detailed picture of consumer opinions. While a plethora of methods have been traditionally employed for this task, majority focus has been on analyzing only aspect-centered local information. However, incorporating information from non-local neighbor aspects may capture richer context and enhance sentiment prediction. This may especially be helpful to resolve poor prediction due to ambiguities in review text. The context around an aspect can be incorporated using semantic relations within text and inter-label dependencies in the output. On the output side, this becomes a structured prediction task. However, non-local label correlations are computationally heavy and intractable to infer for structured prediction models like Conditional Random Fields (CRF). Moreover, some prior intuition is required to incorporate non-local context. Thus, inspired by previous research on multi-stage prediction[1], we propose a two-level model for aspect-based analysis. The proposed model uses predicted probability estimates from first level to incorporate neighbor information in the second level. The model is evaluated on data taken from SemEval Workshops and Bing Liu's review collection. It shows comparatively better performance against few existing methods. Overall, we get prediction accuracy in a range of 83-88% and almost 3-4 point increment against baseline (first level only) scores.

1 Introduction

The voice of consumer is growing stronger. With numerous platforms now available for providing reviews, consumers find it easy to share their opinions and sentiments about a product, service or other subjects. Thus, it becomes essential to analyze such reviews in order to identify consumers preferences and grievances. Sentiment analysis for consumer reviews (or general text) is a prominent research area. Such analysis can be done on various levels - global (collection of text), sentence-level (where sentiment is assigned to one full sentence) or aspect-based. In Aspect Based Sentiment Analysis (ABSA), the problem of interest is to estimate sentiment associated with a specific aspect within a review. An example is given below,

Example 1. The **movie** had a $brilliant_+$ story. The **location** was $awesome_+$ and I must highly $praise_+$ the **camera-work**. However, I have to differ regarding the **acting**. It is hard to comprehend XYZ's **style** in such a role. Her on-screen **presence** is not the usual; I have to say, her **act** left me in a very bad_- mood. The rest of the **cast** was $ok_o ... average_o$ at best.

Here, the text in bold marks aspect and italic text marks sentiment-indicators. Also, (+,-,o) underscore notations indicate positive, negative and neutral sentiments, respectively. Usually, there can be one or several aspects within a single sentence. The sentiment associated with any aspect can mostly be inferred by checking the terms associated with it (e.g., *awesome* - **location**). However, this may not be very

[1] (Krishnan and Manning, 2006; Hoefel and Elkan, 2008)

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2635–2646, Osaka, Japan, December 11-17 2016.

beneficial if the statement is ambiguous. For e.g., *'I have to differ regarding the acting'* does not clearly indicate any sentiment on its own. Such ambiguities may be found frequently in reviews. Due to varied styles of different review writers, use of uncommon (even obscure) terms or phrases, terms or phrases conveying conflicting sentiments, or even due to limited data, a prediction system may be expected to mis-classify sentiments. One way to identify such ambiguities is by using prediction confidence scores (discussed in Section 4.2).

While addressing ambiguities, it may be assumed that there generally is some inherent *flow* in the sentiments. A review may have elements of discourse, such that, discourse-markers[2] like 'and', 'also', 'but' etc. can be used to identify sentiment flow or transition. Such terms may or may not be explicitly used, but presence of flow can be assumed. This idea of flow is not new. Recently, *Sentiment Flows* have been studied by Wachsmuth et al. (2015). They incorporated flow information while predicting global sentiments and also identified some frequent types of flows (Wachsmuth et al., 2014). Analysis using sentiment flow requires neighbor information. Here, a neighbor can be local or non-local. In Example 1, initial sentiment flow is positive. Then, the flow is broken by *However* and the sentences that follow are ambiguous. Towards the end, *very bad mood* sets a negative polarity towards **act**. For multi-class classification, it is difficult to predict sentiment associated with **acting** just from information of its local neighbors (**style** and **camera-work**). It is important to incorporate distant aspect **act**'s sentiment to approximately predict the negative shift in mood. This task can become more complex with more involved semantics (such as in reviews by expert critics).

The neighbor-dependencies can be holistically modeled by also considering correlations among polarity labels, thus making ABSA a structured prediction task. Previously, modified version of Condition Random Field (CRF) classifier has been proposed to predict local sentiments (Mao and Lebanon, 2006). However, while CRFs perform well for local dependencies, they may not be very suitable in standard form for ABSA after we consider non-local neighbors as well because inference over long-range would be expensive (Kazama and Torisawa, 2007; Krishnan and Manning, 2006). Moreover, we believe it would also be beneficial to incorporate textual terms surrounding local and non-local neighbors as input features. This would be difficult without some pre-intuition about non-local neighbor sentiments, lest the the input representation itself becomes complex.

To address these issues, we propose a two-level model for ABSA. The proposed model first performs classification using a baseline set of features. Based on this, the probability estimates are obtained which give indication about ambiguities, as well as, preliminary information about neighbor sentiments. Another classifier on top of this uses the local and non-local neighbor information (first-stage probabilities as well as textual terms) for prediction. In this paper, we discuss a preliminary work on this model. The rest of the paper is organized as follows. The structure used for internal representation of reviews is discussed in Section 3. The classification model using SVM classifier in both stages is discussed in Section 4. Further, in order to test a linear-chain CRF at second stage of our model, an independent experiment is performed using available CRF software. The CRF experiment uses different setup from SVM+SVM model and thus it is not meant for comparison with SVMs, but for independent evaluation. This is briefly discussed in sub-section 4.5 . An evaluation of the models is discussed in Section 5.

2 Related Works in ABSA

Three major steps in ABSA are aspect-term extraction, category detection and polarity estimation. There have been significant amount of work in these areas. Major work related to ABSA has appeared in SemEval Workshops[3]. Some notable contributions in these workshops discuss good practical methods for aspect and category extraction (Brun et al., 2016; Khalil et al., 2016; Toh et al., 2016; Saias, 2015). A lot of work has been done on aspect extraction, however, we would like to focus our discussion on sentiment prediction. The basic form of sentiment analysis at sentence-level or aspect-level uses local context of an aspect for input feature representation. Some notable works include that by Nakagawa et al. (2010) who use dependency-tree structures to model local word interactions; Choi and Cardie (2008)

[2]https://en.wikipedia.org/wiki/Discourse_marker

[3]http://alt.qcri.org/semeval2016/task5/, http://alt.qcri.org/semeval2015/task12/

apply inference rules for polarity reversals. Moreover, deep learning methods have also been explored for aspect-level (Wang et al., 2015) and sentence-level (Socher et al., 2013) analysis by exploiting vector representations of aspect-related terms. Discourse information has been very much favored to expand the context around sentiment targets. Discourse-based analysis has been profoundly covered in some previous works (Somasundaran et al., 2009a; Somasundaran et al., 2008; Somasundaran et al., 2009b; Mukherjee et al., 2012). These works cover different types of discourse relations, in detail, for sentiment analysis. Polanyi and Zaenen (2006) discuss valence-shift over sentences due to discourse markers. It is also natural to consider discourse for sentiment flow, as will be discussed later in this paper. Discourse has been used to model neighbor relations as well. Pang and Lee (2004) have explored the consistency of sentiment between neighbors. Also, Zhou et al. (2011) use the sentiment consistency or contrast as constraint on polarity assigned to neighbors. Lazaridou et al. (2013) encoded discourse relations into their supervised classifier's input features. Similar techniques are used in our model, however, for both local and non-local context. Apart from relational structures within text, it is also beneficial to model correlation among polarity labels. An important work in this direction is by Mao and Lebnon (2006) who introduced a modified CRF model to predict ordinal polarity labels. Wachsmuth et al. (2015) follow this work and discuss sentiment flow adaptability across domains. They also discuss ideas to constraint the label sequence lengths. The grouping method discussed later in this paper is inspired by their work. However, these works are still constrained to correlations between adjacent labels only. Some of the notable and relevant work exploring long distance (non-local) information are: work by Somasundaram et al. (2008) on opinion target relations and its application as constraint on predicted sentiments; work by Zhang et al. (2013) on using discourse relations as constraints for Markov Logic Network; and of special interest is the work by Yang and Cardie (2014) who incorporate discourse and coreference constraints into Posterior Regularization (PR) of a CRF. The works discussed above use some form of discourse or coreference relations for feature embedding or inference constraints. However, while we use discourse markers to separate aspect context, we do not restrict neighbor feature embedding based on discourse only. Instead, we propose a two-level model with a base level prediction from which a probability distribution over sentiment labels can be obtained. This serves as an intermediate intuition about sentiments. Using this, at second level, we sample important non-local neighbor units to embed non-local context into input features. Thus, such sampling is not necessarily restricted to presence of coreference or discourse. However, following the work of Yang and Cardie (2014), it would be interesting to explore the use of CRF at second level with PR constraints involving base level probabilities.

3 Review Representation

In this section, we discuss the structure of a review in the form of a graph of aspect-centered nodes.

3.1 Review Structure

A review can be modeled as a non-directed graph of connected aspects and sentiment nodes. The graph is depicted in Figure 1. For simplicity, the sentiment values are not shown as separate nodes but included within the aspect nodes. We define following attributes of the review graph:

- Aspect-Units (or Units): A Unit *U* is a node in review graph, and the basic entity which bundles the parameters associated with an aspect. Formation of units is discussed in Section 3.2
  U : (*aspect-terms*; *related-terms*; *sentiment information*)

- Groups: A group *G* is a cluster of continuous units with similar sentiment. In Example 1, under the assumption of sentiment flow, "The movie had a $brilliant_+$ story", "The location was $awesome_+$" and "I must highly $praise_+$ the camera-work" can be grouped under positive sentiment category. Similar grouping applies to other sentences or phrases as well. Consider the polarity sequence in Example 1, PP**P**-XXX-**NO**O, where P is positive label, N is negative, O is neutral and X ambiguous. After the grouping mentioned above, we consider that labels marked in bold can represent the polarity of a group of same sentiments. Henceforth, these will be referred to as *terminal labels*. A group *G* contains information about the cluster of units as,

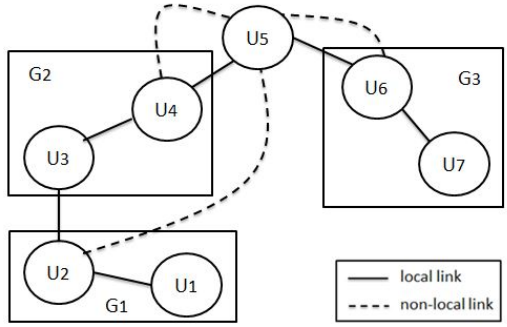

Figure 1: Review Structure around unit U_5.

Type	Markers
Additive	and, or, also, therefore, furthermore, consequently, thus, as a result, hence, subsequently, eventually, in addition, additionally, moreover, as well as
Contrast	though, although, however, but, despite, yet, still, nonetheless, nevertheless, in spite

Figure 2: Common discourse markers with shallow categorization.

G (*polarity*; *count*; *distance*)
Thus, polarity sequence in Example 1 can be reduced to this form as G(P;3;1)-G(X;3;0)-G(N;1;1)-G(O;2;2). Here, distance is taken from ambiguous group.

- Links: A Link *L* is a connection between two units or groups or a unit and a group. A link may or may not contain information about the sentiment flow. Three types of links are used:
  L{+} : Additive links. Terms like 'and', 'Moreover', 'Also' etc. make L{+} links.
  L{c} : Contrast links. Terms like 'but', 'however' etc. make L{c} links.
  L{x} : Undefined links, where a clear connection between two units may not exist. However, sentiment flow (or transition) can still exist. For instance, in Example 1, there no clear link between "**act** left me in a very bad_{-} mood" and "The rest of the **cast** was ok_{o}" This would be considered as L{x}.

3.2 Aspect Unit Formation

In order to form a unit, the terms in a review related to an aspect are extracted using parse relations. We use Stanford Parser (Marneffe et al., 2006) for this purpose. Consider following sentence : *The rice*

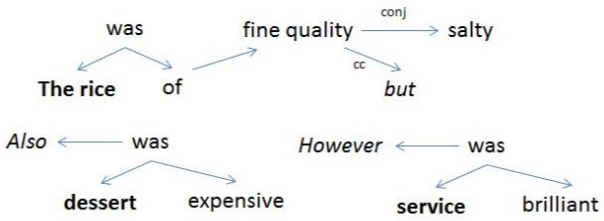

Figure 3: Approx. parsing.

was of fine quality but very salty. Also, dessert was a bit expensive. However, service was brilliant. A selective approximate parsing is shown in Figure 3. Here. *but* is an internal connector. *Also* and *However* are terminal connectors. Using the dependency relations, the units can be formed as follows: U_1 : {The rice was of fine quality but very salty}, U_2 : {dessert was a bit expensive}, U_3 : {service was brilliant}, with connections as: U_1–**(Also)**–U_2–**(However)**–U_3. *Also* and *However* become part of the Links.

4 Classification Model

The overall sentiment prediction process is divided into 2 stages: Base Prediction and Level-2 Prediction. Consider a feature set described for each aspect unit as $\phi(U_i)$ = (ϕ_1, ϕ_2...ϕ_m), where U_i is the i-th aspect unit in a sequence and any ϕ_j is a feature. Thus, input consists of a set ϕ = { $\phi(U_1)$, $\phi(U_2)$,...,$\phi(U_N)$

}. The aim of first stage or Level-1 prediction is to obtain an intermediate set of sentiment labels $\hat{P}$ = { $\hat{P}(U_1)$, $\hat{P}(U_2)$...$\hat{P}(U_N)$ } along with probability estimates for each. These predictions are used to form groups and sample neighbor information to be added to each input vector $\phi(U_i)$ for final prediction. We discuss our model with-respect-to 3 class classification (positive, negative and neutral) below.

4.1 Baseline Features

These are aspect-centered features formed using text surrounding a given aspect term(s).

Sentiment Scores : The scores of sentiment-indicator terms are aggregated into feature sets,
$\phi_{1k}(U_i) : (score_{positive}, score_{negative}, score_{neutral})$

Here, *k* indicates *kth* type of score-set. We use five score-set types (3 from lexicon corpus + 1 keyword-based + 1 neutral terms) as discussed below:

Sentiment Lexicons from external corpus: Bing Liu's lexicons (Bing Liu, 2012), MPQA subjectivity clues (Wiebe et al., 2005) and SentiWordnet (Stefano et al., 2010) lexicon corpus are used to obtain scores. Bing Liu's and MPQA corpus provide binary scores (positive: 1, negative: 0). These are used as binary features. SentiWordnet provides a range of scores for positive and negative categories.

Category Keywords: Apart from lexicons available in the external corpus, there may be terms which convey sentiments relative to categories. For e.g., *the acting was cheap* conveys negative sentiment while *the price was cheap* is positive despite the same term *cheap*. Such keywords are extracted by dividing the review data into category-specific documents and obtaining TF-IDF scores to identify frequent keywords and corresponding sentiment types. Frequency thresholds of min:0.3 & max:0.8 are set, based on best performance in our experiment.

Neutral terms: Several terms which occur in neutral sentences are not scored in external corpus. These are extracted by identifying frequent words or bi-grams in a collection of neutral sentences. The most frequent ones used in this paper are: 'average', 'normal', 'simple', 'okay', 'ok', 'not great', 'nothing great', 'mediocre', 'not good', 'decent', 'as expected', 'reasonable', 'moderate', 'typical', 'alright', 'fair'.

The score assigned to each sentiment-indicator is also subject to negation. In case of negation, binary scores are simply reversed. For SentiWordnet scores, negation is made in proportion to the scores as: pos = pos + $\frac{(neg-pos)}{2}$ and neg = neg + $\frac{(pos-neg)}{2}$. Here, pos and neg are positive and negative scores, respectively. A significant work on negation problem has been done by Zhu et al. (2014).Moreover, a unit may contain multiple sentiment terms. Thus, the scores are aggregated and normalized. However, as discussed in Section 3.2, the terms within an aspect-unit may be connected by discourse markers. The simplest strategy that can be used is to weigh the sentiment-indicators' scores according to their position in a unit and their relation with discourse markers (Mukherjee et al., 2012).

Bi-grams formed using terms in a unit. Bi-grams around negation terms are taken separately.
$\phi_{21}(U_i)$: *(bi-grams around negation)*, $\phi_{22}(U_i)$: *(other bi-grams)*,

A binary feature for **aspect-category** type can be used (if category has been extracted). This feature has minor effect (Table 3).
$\phi_3(U_i) : (category\ type)$

Local Context window: sentiment score features from previous and next aspect units.
$\phi_4(U_i)$: $\{\phi_{11}...\phi_{1n}\}(U_{i-1})$ and $\{\phi_{11}...\phi_{1n}\}(U_{i+1})$ (n=5 in this case)

4.2 Level-1 or Base Prediction Model

Base prediction is performed using feature set $\{\phi_{11}...\phi_{1n}, \phi_{21}, \phi_{22}, \phi_3, \phi_4\}$ (n=5 in this case). The distribution of features is non-linear as well as high-dimensional and Support Vector Machine (SVM) classifier with Radial Basis Function (RBF)[4] kernel is well-suited for this task due to its high-dimensional mapping and good margin. We use classifier from scikit-learn SVM (SVC) package[5]. A set of primary prediction labels $\hat{P}$ = { $\hat{P}(U_1)$, $\hat{P}(U_2)...\hat{P}(U_N)$ } (N = no. of aspects in a single review) is obtained from the base model using confidence scores over the *c* classes (c=3 in this case).

Confidence Scores or Probabilities

The scikit-learn SVM package provides two methods to obtain such scores[6]. First is the *predict_proba* function which provides probability distribution over different classes based on multi-class variant for Platt Scaling (Wu et al., 2004). Second is the *decision_function* which indicates the distance of input points from the hyperplane (or decision boundary). The prediction method (*predict*) of SVM uses *decision_function*. Platt Scaling based estimation may cause disagreement between outcome of *predict* function and the obtained $\arg\max$ (*predict_proba*). However, in the experiments, we found that $\arg\max$ (*predict_proba*) always corresponds to true class label when prediction is strong (high probability assigned to one class). When the classifier fails, the probability values across different classes have small separation (section 4.3). Thus, we stick to Platt Scaling (*predict_proba*) and obtain following:

proba(U_i) : $\{l_1, l_2, ..., l_c\}$, gives probability distribution (summing to 1) over c classes, such that,

$\hat{P}(U_i) = \arg\max$ (*proba*(U_i))

4.3 Ambiguity Criteria

As discussed in Section 4.2, *proba* values are used as confidence scores for base predictions. The ambiguous units are identified using *proba* by detecting low difference between any two probability values (low confidence). Following criteria is used for detection,

$\forall$ (l_q, l_r) $\in$ *proba*(U_i), where q $\neq$ r,
  if $|l_q - l_r| \leq$ *T1* **and** ($l_q >$ *T2* **or** $l_r >$ *T2*) **then**
    U_i is **ambiguous**

In our experiment with 3-class classification, we set *T1* = 0.20 and *T2* = 0.33 based on observations made on available data.[7]

4.4 Level-2 Prediction Model

Having obtained *proba* values, the final requirement is to predict polarity label set P = {$P(U_1)$, $P(U_2)...P(U_N)$}. The process of Level-2 model training and prediction are discussed below.

Training

Firstly, in order to incorporate local and non-local neighbor information, the neighbor units are grouped as described in Figure 4. Assignment of ambiguous unit's sentiment to a group is avoided here. This ensures that neighbor information consists of high confidence values during final prediction stage. After grouping, feature set $\mathbf{F}(U_i)$ is produced for a unit U_i as follows:

f_1 : list of *G*(polarity) values for max. 3 groups before unit, f_2 : list of *G*(polarity) values for max. 3 groups after unit. If unit U_i lies within *kth* group G_k, then the group is temporarily divided into

[4]http://research.cs.tamu.edu/prism/lectures/pr/pr_l19.pdf

[5]http://scikitlearn.org/stable/modules/generated/sklearn.svm.SVC.html

[6]http://scikit-learn.org/stable/modules/svm.html#scores-probabilities

[7]Since, three polarity classes are used, a homogeneous distribution will allot probability close to 0.33 to each. If either l_q or l_r has value greater than 0.33 (*T2*), assuming third value to be 0.33, then a l_q value of 0.53 will make l_r 0.13. In this case, l_q can be chosen as non-ambiguous and the difference between l_q and third value would be 0.20 (0.53-0.33), set as *T1*.

For m aspects in a review (training sample)
$k \leftarrow 1$
for i $\leftarrow$ 1 to *m* do
  if i = 1 **then**
    add U_i to G_k
    G_k{polarity} $\leftarrow$ {$\hat{P}(U_i)$, *proba*(U_i)}; G_k{count} $\leftarrow$ 1
  else if $\hat{P}(U_i) = \hat{P}(U_{i-1})$ **or** $\hat{P}(U_i)$ is *ambiguous* **then**
    add U_i to G_k
    G_k{count} $\leftarrow$ G_k{count} + 1 (0.5 if U_i **is** ambiguous)
  else
    $k \leftarrow k+1$
    add U_i to G_k
    G_k{polarity} $\leftarrow$ {$\hat{P}(U_i)$, *proba*(U_i)}
    G_k{count} $\leftarrow$ 1

Figure 4: Group formation using level-1 predictions.

$\{G_{k1}, U_i, G_{k2}\}$

f_3 : list of *G*(count) values for max. 3 groups before unit, f_4 : list of *G*(count) values for max. 3 groups after unit, f_5 : list of distances of max. 3 groups before unit, f_6 : list of distances of max. 3 groups after unit. The orders for these are maintained as per f_1 and f_2.

f_7 : link (type) between U_i and immediately previous group, f_8 : link (type) between U_i and immediately next group,

f_9 : Local feature set $\{\phi_{11}...\phi_{1n}, \phi_{21}, \phi_{22}, \phi_3, \phi_4\}(U_i)$, with ϕ_4 modified as

$\phi_4 = \{\phi_{11}...\phi_{1n}, \phi_{21}, \phi_{22}, \phi_3\}(U_{Terminal})$,

embedding the features of *terminal units* of max. 3 groups before and max. 3 after.

$f_{10} : \alpha(U_i)$, where

$$\alpha(U_i) = \begin{cases} 0 & , if\ U_i\ is\ ambiguous \\ argmax\ (proba(U_i))\ +\ 1 & , otherwise \end{cases}$$

These features are used to train a SVM classifier.

Prediction

The prediction on new data (or evaluation data) is made in a sequential manner (one-by-one). The $\hat{P}$ and *proba* are already available at this stage.

The final output is the required polarity set *P* = { $P(U_1)$, $P(U_2)$...$P(U_N)$}.

4.5 Experiment with CRF

In this paper, we have focused on method to incorporate non-local context information into input representation of aspect units. However, such method makes i.i.d assumption for output labels. Under sentiment flow property, there must be correlations between polarity labels as well, both adjacent and long-distance. Devising an efficient structured prediction model using long-distance dependencies is beyond scope of current work and is kept for future. Instead, we experiment with simple linear-chain CRF to get a glimpse into its performance on review text. CRFSUITE (Okazaki, 2007) is used to build a CRF classifier in python. This software provides an internal implementation of linear-chain (first-order Markov) CRF (Sutton and McCallum, 2010). This classifier is used at Level-2 of our model instead of SVM. However, SVM is preferred as base classifier (Level-1) due to its maximum-margin advantage (Hoefel and Elkan, 2008). For CRF (Level-2), features f_1 to f_{10} are used. However, prediction is made over full sequence of output labels and features $\mathbf{F}(U_1)$ to $\mathbf{F}(U_N)$ are fed together. Thus, the grouping is

Make Groups as discussed previously. Let U_i:G indicate the group that U_i belongs to. U_i:G_{prev} indicates the group previous to U_i:G and U_i:G_{next} indicates next group
for i ← 1 to N:
    P(U_i) ← final prediction for U_i
    replace polarity information of U_i with P(U_i) and new *proba*
    if P(U_i) = U_i:G{polarity} **then** *pass*
    else
        if U_i **is** first unit in a group **then**
            if P(U_i) = U_i:G_{prev} {polarity} **then** add U_i to previous group
            else make new group for U_i
        else if U_i **is** last unit in a group **then**
            if P(U_i) = U_i:G_{next} {polarity} **then** add U_i to next group
            else make new group for U_i
        else
            make new group for U_i

Figure 5: Final Prediction.

done only once unlike that described in Figure 5. For CRFUITE settings, LBFGS algorithm is used, with 'max_iterations' equal to 1000.

5 Evaluation

5.1 Experiment Setup

The data for experiment is obtained from SemEval Workshop (2016, 2015) data-sets for ABSA (Pontiki et al., 2016). The data is provided for Restaurant domain in English language and contains labels for aspect-terms, category and polarity. Additionally, data is also obtained from Bing Liu's Consumer Review collection (5 + 9 product data)[8]. This data is for Consumer Electronics (CE) domain, in English language, and has ordinal labels (-3, -2, -1, +1, +2, +3). For 3-class classification, (-1, +1) values are mapped to *neutral*, (+2, +3) to *positive* and remaining to negative class. The data divisions are given in Table 1. Bing Liu's data[9] is divided into 70:30 ratio for training and evaluation. Also, data for number of transitions is given in Table 2. While all reviews are used for experiments, reviews with more than 3 transitions are of special interest to study non-local dependencies. The SemEval - 2016 training data is a mix of SemEval - 2015 training & evaluation data. So, 2015 data is used only for comparison. The data-sets are not balanced; for e.g., in 2016 data, the proportions of pos:neg:neutral instances are 1:1/2:1/15, approximately. Thus, before training, the class weights are balanced in the SVM predictor. Aspect-categories are not provided in Bing Liu's data. Thus, the category related baseline features are dropped for this data.

Two types of training and evaluation (or test) setup are used. In *setup1*, only base model is used. The base model is trained on entire training set after 10-fold cross-validation. Then, predictions made on the test set. In *setup2*, 10-fold cross validation is performed on the training set with base model. However, this time the *proba* values for each validation partition are saved. Finally, the *proba* values for all validation partitions of training data are available, so the Level-2 model is trained on the entire training set. The combined model is then used for predictions on test set. Similar process has been used for multi-stage prediction previously (Krishnan and Manning, 2006)

The system is built using scikit-learn and NLTK (Bird et al., 2009) packages in Python 2.7. Parameters of SVM are set using Grid Search. For our experiments, C=100 and gamma in the range of 0.001 to 0.005 work well (gamma = 0.001 is chosen). RBF kernel is used and decision_function type is one-vs-rest. Before feeding into the model, the data is cleared of stopwords (using NLTK stopword list) and special

characters. The data is also lemmatized and all terms converted to lowercase. Also, in order to reduce the size of feature set, only 2000 best bi-grams are selected using Chi-square function[10].

5.2 Results and Discussion

The measure used for performance evaluation is the prediction Accuracy[11]. The results of evaluation are provided in Table 3. The results for *setup1* are listed under 'Base Model' and that for *setup2* are under 'Base + Level-2'. For base model, it can be seen that bi-grams and aggregated sentiment scores are the most significant features. It is to be noted that discourse-based aggregation shows good improvement in accuracy. This is expected because discourse can inherently help in incorporating consistency, contrast or negation of sentiment over a sentence, which is difficult to achieve by simple aggregation rules. We believe that with more detailed use of discourse relations, the performance can be further improved. On top of the base model, the combined 'Base + Level-2' model shows higher accuracy scores. Thus, embedding non-local neighbor features does provide richer context information, thereby also resolving sentiments associated with ambiguous sentences or phrases.

The performance of CRF (Level-2) in our experiment is below SVM (Level-2). This may seem counter-intuitive since a CRF should be able to model inter-label dependencies well. However, we wish to emphasize that the experiment with CRF is not aimed at comparison against SVM, but to check the performance of available CRF tool on review data. Firstly, the crfsuite library used for this experiment uses a linear-chain CRF model. If our intuition about non-local dependency holds, then linear-chain CRF should not be sufficient for a performance much superior than SVM. Secondly, the setup of SVM (level-2) is different from the input and output setup for crfsuite. For crfsuite, the full sequence of aspect unit features is fed as input, and full sequence of output labels is predicted at once. On the other hand, in the SVM (level-2) model we form new groups (or modify existing group information) as new labels are predicted. Thus, the context information provided as input changes as prediction proceeds. This is to include as much context information as possible during prediction. The difference in setup does not necessarily mean that CRF should perform below SVM, but it makes a definite comparison unfeasible. Devising a structured prediction method suited for non-local dependencies among polarity labels is kept as a future work. Such work would be more suitable to perform comparison between structured prediction and discrete prediction (i.e., with inter-label independence assumption).

The comparison of our two-stage model against few previous proposals is given in Table 4. Our

model performs relatively better for SemEval-2015 data. For SemEval-2016 data, the top-scoring system 'XRCE' shows better result. XRCE uses a feedback mechanism which provides information about feature relevance and cross-validation errors to the Feature Design step. We do not explore or replicate XRCE's design in detail. However, we believe that their feedback mechanism leads to more robust features and results in better accuracy.

5.3 Conclusion and Future Work

Concepts like *Sentiment Flow* and *Discourse relations* are important to address semantics of text for sentiment analysis. Such approach basically concerns with: (1) Incorporating local as well as non-local neighbor information as features and (2) structured prediction of a sequence of polarity labels with some constraint on correlation between non-adjacent labels. This problem needs to be approached in holistic manner. However, under non-locality assumption, the existing methods for structured prediction may become too complex. Moreover, relations like discourse and coreference can also be used to embed non-local context as features. However, it is important to extend this concept towards more data-driven approach. Thus, in this paper, we propose a multi-level model where a probability distribution obtained from first level can be used to incorporate non-local neighbor features, in addition to discourse, for further level of prediction. We show that multi-level model with non-local information can achieve some improvement in aspect-based prediction. The model evaluated on different data-sets performs in the 83-88% accuracy range. Nonetheless, it is important to explore more robust methods in theory and practice. The methods proposed by Kazama and Torisawa (2007), and Collins (2002) provide good basis for this. Also, it would be interesting to explore CRF with Posterior Regularization constraints taken from first level predictions, building upon work by Yang and Cardie (2014). Moreover, prediction can be improved by aggregating sentiment at sentence or phrase-level using discourse markers. The technique used in this paper is rudimentary. In Rhetorical Structure Theory, much intricate discourse relations have been proposed and there have been interesting works in this area exploring richer discourse concepts. Thus, in further work, we would expand the discourse relations used in sentiment aggregation as well as for linking aspect-units.

Abstract

In the literature, various supervised learning approaches have been adopted to address the task of reader emotion classification. However, the classification performance greatly suffers when the size of the labeled data is limited. In this paper, we propose a two-view label propagation approach to semi-supervised reader emotion classification by exploiting two views, namely *source* text and *response* text in a label propagation algorithm. Specifically, our approach depends on two word-document bipartite graphs to model the relationship among the samples in the two views respectively. Besides, the two bipartite graphs are integrated by linking each *source* text sample with its corresponding *response* text sample via a length-sensitive transition probability. In this way, our two-view label propagation approach to semi-supervised reader emotion classification largely alleviates the reliance on the strong sufficiency and independence assumptions of the two views, as required in co-training. Empirical evaluation demonstrates the effectiveness of our two-view label propagation approach to semi-supervised reader emotion classification.

1 Introduction

***Source* Text (*News*)**: *An earthquake of 7.0 magnitude struck China in Lushan County of Ya'an, Sichuan Province, causing serious casualties and property losses, and millions of people in distress……* **Writer Emotion:** *Neutral* **Reader Emotion**:  (*Sadness*),  (*Worry*)
***Response* Text (*Comments*)**: (1) *Be sure to cherish the golden rescue time.* (2) *Why there is always an earthquake, so sad, wish all the best.* (3) *I experienced this quake, all too suddenly, and I will never forget.*

Figure 1: An example of a news article, together with its writer and reader emotions

Emotion classification aims to predict the involving emotion towards a piece of text. For a particular text, there always exist two kinds of emotions, namely writer emotion and reader emotion, where the former concerns the emotion produced by the writer who writes the text and the latter concerns the

emotion produced by the reader who reads the text. For instance, in Figure 1, given the news text about earthquake, the writer emotion is more likely to be *neutral* due to the professionalism of the news reporter, while the reader emotion might be *sadness*, or *worry*. Recent years have seen growing interest in reader emotion classification due to its importance in more and more real-life applications, such as content recommendation and online advertisement.

Conventional approaches to reader emotion classification conceptualize the task as a supervised learning problem and rely on a large-scale human-annotated data for model learning. Although such supervised approaches deliver reasonably good performance, the reliance on labeled data, which is normally difficult and highly expensive to obtain, presents a major obstacle to the widespread application of reader emotion classification.

To alleviate the problem above, Liu et al. (2013) originally propose a semi-supervised learning approach to reader emotion classification to improve the performance by enlarging the labeled data with automatically inferred annotations of unlabeled instances. Their basic idea mainly lies on unique characteristics in reader emotion analysis, different from the case in writer emotion analysis. That is, apart from the *source* text (e.g., *news* text), another type of text, the *response* text (e.g., *comment* text) written by the reader as a response to the *source* text, is available to help determine the reader emotion of the *source* text. For example, in Figure 1, the *comment* "*Why there is always an earthquake, so sad, wish all the best*" explicitly express reader emotion *sadness*. Therefore, the *source* text and the *response* text are casted respectively as two views in a co-training algorithm to perform semi-supervised learning.

However, the success of co-training largely depends on two strong underlying assumptions, i.e., sufficiency and independence, of the two views (Blum and Mitchell, 1998), which are actually violated in reader emotion classification when the *source* text and *response* text are utilized as two views.

On one hand, the *response* text often lacks sufficient information to correctly predict the label of an instance, since the response text tends to be short. For example, in Figure 1, if there is only one existing comment, e.g., (1) "*Be sure to cherish the golden rescue time*", the reader emotion is difficult to predict because no emotion is clearly expressed in this sentence. Even worse, as an extreme example, the *source* text (e.g., some newly posted *news*) sometimes has no *response* at all.

On the other hand, the *response* text normally depends on the *source* text, since both the *response text* and the *source* text talk about the same topics. It is really hard for them to meet the view independence assumption in co-training.

In this paper, we propose a novel semi-supervised learning approach, namely two-view label propagation (LP), to reader emotion classification. As an extension of traditional label propagation with a single view (Zhu and Ghahramani, 2002), our two-view LP approach depends on two graphs, i.e., one depicting the connections among the *source* text samples and the other depicting the connections among the *response* text samples. Besides, the two graphs are integrated by linking each *source* text sample with its corresponding *response* text sample to capture the dependence between the *source* text and the *response* text. Such a two-view LP approach thus avoids the independence assumption, as required in traditional co-training. Finally, we assign a variable weight between each *source* text sample and its *response* text sample to address the information insufficiency in the *response* text. Specifically, we design a length-sensitive linear function to calculate the transition probability between the source and response text samples.

The remainder of this paper is organized as follows. Section 2 overviews related work on emotion classification. Section 3 introduces the baseline approach to semi-supervised reader emotion classification with single-view label propagation. Section 4 presents our two-view label propagation approach to semi-supervised reader emotion classification. Section 5 empirically evaluates our approach. Finally, Section 6 gives the conclusion and future work.

2 Related Work

Among the large number of studies in sentiment analysis over the last decade (Pang et al., 2002; Turney, 2002; Alm et al., 2005; Wilson et al., 2009), only a small portion focus on emotion classification.

Besides those on emotion resource construction, such as emotion lexicon building (Xu et al., 2010; Volkova et al., 2012; Staiano and Guerini, 2014) and sentence-level or document-level corpus construction (Quan and Ren, 2009; Das and Bandyopadhyay, 2009), most of previous studies on emotion classification are devoted to designing novel classification approaches to emotion classification (Alm et al.,

Symbol	Definition
L_s	Labeled *source*-text data
L_r	Labeled *response*-text data
U_s	Unlabeled *source*-text data
U_r	Unlabeled *response*-text data
G_s	Graph of the *source*-text data
G_r	Graph of the *response*-text data
$G_{s,r}$	Joint graph of both the *resource* and *response* text data
M_s	The transition probability matrix among the *source* text data
M_r	The transition probability matrix among the *response* text data
$M_{s,r}$	The transition probability matrix among the *source* and *response*-text data

Table 1: Symbol definition

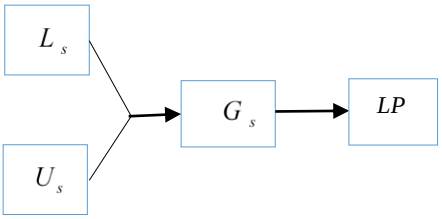

Figure 2: The framework of single-view label propagation approach to semi-supervised learning on reader emotion classification

2005; Chen et al., 2010; Purver and Battersby, 2012; Hasegawa et al., 2013; Qadir and Riloff, 2014), mainly from the supervised learning paradigm.

Compared with above studies on writer emotion classification, studies on reader emotion classification are much limited. Lin et al. (2007) first describe the task of reader emotion classification on news articles with some standard machine learning approaches. Lin et al. (2008) further exploit more features to improve the performance.

More recently, Liu et al. (2013) propose a co-training approach to semi-supervised learning on reader emotion classification by considering the *message* text and the *comment* text as two views. However, their success is much limited due to the required two strong assumptions on co-training, i.e. sufficiency and independence assumptions on the two views in co-training.

3 Single-view LP to Semi-supervised Reader Emotion Classification

In reader emotion classification, each target (e.g., a *news* article) is represented by two kinds of text, namely *source* text and *response* text. Formally, we refer the training data containing the *source* text samples as L_s and the one containing the *response* text samples as L_r. In this study, we only consider two emotion categories, i.e., *positive* and *negative* emotions. The task of semi-supervised learning on reader emotion classification is to leverage the training data L_s and L_r, together with the unlabeled data U_s and U_r, to train a classifier. For clarity, Table 1 illustrates some important symbols.

Figure 2 illustrates the framework of the LP-based semi-supervised approach to when only the view of the *source* text is utilized. Traditional label propagation (LP) is a graph-based semi-supervised learning approach with a single view (Zhu and Ghahramani, 2002). In general, a LP-based approach to semi-supervised learning consists of two main steps: graph construction to represent the relationship among the document samples and label propagation to propagate the labels of the labeled data to the unlabeled

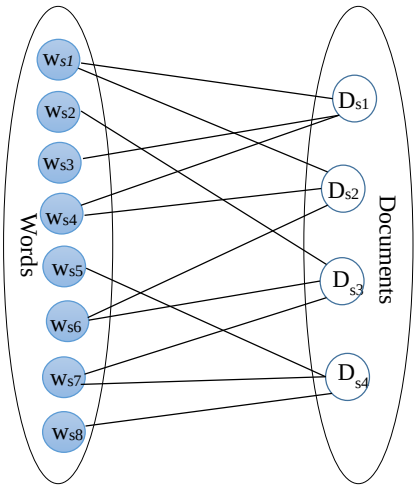

Figure 3: The word-document bipartite graph

Input:

P: The $n \times 2$ matrix, while p_{ir} represents the probability of document D_i (i=1...n) with label r (r=0,1);

M : The $n \times n$ transition probability matrix

Output:

The unlabeled data with prediction labels

Procedure:

1) Initialize P as P_0
   a) Assign each labeled sample with a fixed probability distribution (1, 0) or (0,1) according to its label r;
   b) Assign each unlabeled sample with an initial probability distribution (0.5, 0.5);
2) Loop until P converges;
   a) Propagate the labels of any vertex to nearby vertices by $P_t = M^T \cdot P_{t+1}$;
   b) Clamp the labeled data, that is, replace the probabilities of the labeled samples in P_{t+1} with their initial ones in P_0;
3) Assign each unlabeled instance with a label by computing $\arg\max_r p_{ir}$

Figure 4: The LP algorithm

data in the obtained graph.

In detail, in the first step, we adopt a word-document bipartite graph to model the relationship among the document samples due to its excellent performance in sentiment classification (Sindhwani and Melville, 2008). Figure 3 illustrates the structure of the word-document bipartite graph, in which the nodes consist of two parts: all documents and all words extracted from the documents. An undirected edge (D_i, w_k) exists if and only if document D_i contains word w_k. Let x_{ik} be the frequency of word w_k in document D_i. From the bipartite graph, the probability of walking from document D_i to word w_k can be calculated as $x_{ik} / \sum_k x_{ik}$ and the probability of walking from word w_k to document d_j can be calculated as $x_{jk} / \sum_j x_{jk}$. Thus the probability of walking from document D_i to document D_j though the word w_k can be calculated as $(x_{ik} / \sum_k x_{ik}) \cdot (x_{jk} / \sum_j x_{jk})$. When all words are considered, we get the transition probability from D_i to D_j as:

$$t_{ij} = \sum_k \frac{x_{ik}}{\sum_k x_{ik}} \cdot \frac{x_{jk}}{\sum_j x_{jk}} \quad (1)$$

and the transition probability matrix $M = \{t_{ij}\}$.

In the second step, we adopt the standard LP algorithm to perform semi-supervised learning. In detail, Figure 4 illustrates the LP algorithm (Zhu and Ghahramani, 2002), during which the probabilities of the labeled data are clamped in each loop using their initial ones and act as a force to propagate their labels to the unlabeled data.

4. Two-View LP to Semi-supervised Reader Emotion Classification

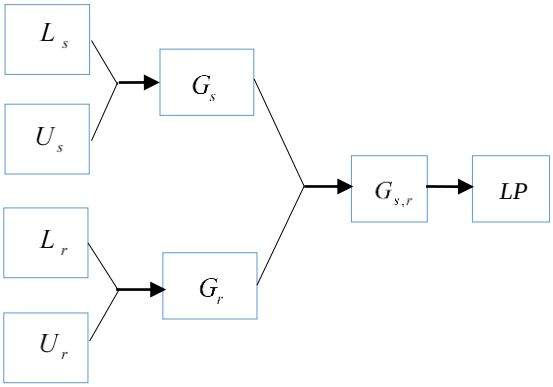

Figure 5: The framework of our two-view label propagation approach to semi-supervised learning on reader emotion classification

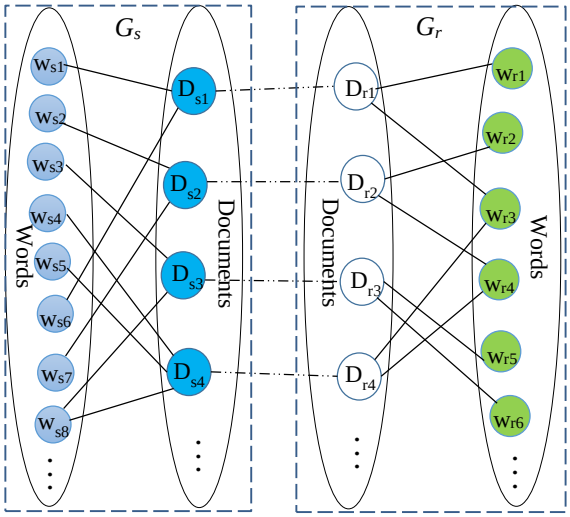

Figure 6: The joint two-view graph that contains both the *source* and *response* text sub-graphs

Figure 5 illustrates the framework of our LP-based semi-supervised approach to reader emotion classification when two views, i.e., the *source* text and the *response* text, are utilized. The graph in our approach consists of two sub-graphs, i.e., G_s and G_r, and each of them is modeled as a word-document bipartite graph. Each pair of the *source* text document and its corresponding *response* text document is connected to join the two sub-graphs together. Figure 6 illustrates the joint two-view graph of both the *source* text and *response* text data.

Basically, the transition probability between the *source* text document and its corresponding *response* text document can be set to 1, assuming that they exhibit the same category. Therefore, the transition probability matrix $M_{s,r}$ of the joint graph $G_{s,r}$ can be represented as follows:

$$M_{s,r} = \begin{bmatrix} M_s & I \\ I & M_r \end{bmatrix} \quad (2)$$

Where I is an identity matrix of dimension n, containing ones along the diagonal and zeros in all other positions; M_s and M_r are the transition probability matrixes, calculated using formula (1) in the sub-graphs, G_s and G_r, respectively.

However, when a *response* text contains too few information or even no words, it becomes a noisy sample. In this scenario, it is not appropriate to propagate the emotion label of its *source*-text sample to this noisy sample. Therefore, for the *source* text sample and its corresponding *response* text sample (e.g., D_{s1} and D_{r1} as shown in Figure 6, we design a function to measure the transition probability by taking the length of the *response* text into account, as follows:

$$t_{s_i,r_i}(z_{r_i}) = \begin{cases} 1 & z_{r_i} \geq l_{max} \\ z_{r_i} / l_{max} & z_{r_i} < l_{max} \end{cases} \quad (3)$$

Where z_{r_i} is the length of the response text document D_{r_i}, defined as the number of the words in the *response* text document; l_{max} denotes the threshold of the document length. If the length is larger than this threshold, it is given a transition probability of 1. If the length is smaller than this threshold, the longer the *response* text sample it is, the higher transition probability it has.

Accordingly, the transition probability matrix $M_{s,r}$ of the joint graph $G_{s,r}$ can be refined as follows:

$$M_{s,r} = \begin{bmatrix} M_s & I' \\ I' & M_r \end{bmatrix} \quad (4)$$

Where I' is a matrix of dimension n, containing the transition probabilities, calculated using formula (3).

5. Experimentation

We systematically evaluate our semi-supervised learning approach to reader emotion classification.

5.1 Experimental Settings

Data collection: The data is collected from Yahoo! Kimo News (http://tw.news.yahoo.com). Each *news* article and its *comments* are considered as a *source*-text sample and a *response*-text sample, respectively. Besides, each *news* article is voted with emotion tags from eight categories: *happy*, *sad*, *angry*, *mean-ingless*, *boring*, *heartwarming*, *worried*, and *useful*. Following Liu et al. (2013), we consider *happy* and *heartwarming* as *positive* category while *sad*, *angry*, *boring*, and *worried* as *negative* category. The emotion label of a news article is automatically derived from the votes, i.e. the *news* article with over 10 votes of *positive* (*negative*) emotions is assigned with a *positive* (or *negative*) label. Unlike Liu et al. (2013), we do not filter those news articles with less than 5 comments.

Data setting: We randomly select 1300 positive and 1300 negative *source* and *response* instances for the empirical study. Among them, 300 positive and 300 negative *source* and *response* instances are used as test data while the remaining 1000 positive and 1000 negative *source* and *response* instances are used as training data. In the training data, we select 0.5%, 1%, and 2% data as initial labeled data and the remaining data as unlabeled data respectively.

Features: Each *source* (or *response*) text is treated as a bag-of-words and transformed into binary vectors encoding the presence or absence of word unigrams.

Classification algorithm: The maximum entropy (ME) classifier implemented with the Mallet Toolkits (http://mallet.cs.umass.edu/).

Evaluation Measurement: The performance is evaluated using the standard accuracy measurement.

Significance test: *T*-test is used to evaluate the significance of the performance difference between two approaches (Yang and Liu, 1999).

5.2 Experimental Results on Single-view LP

In this section, we compare different approaches to semi-supervised learning on reader emotion classification when only one view is utilized. For fair comparison, we implement following approaches:

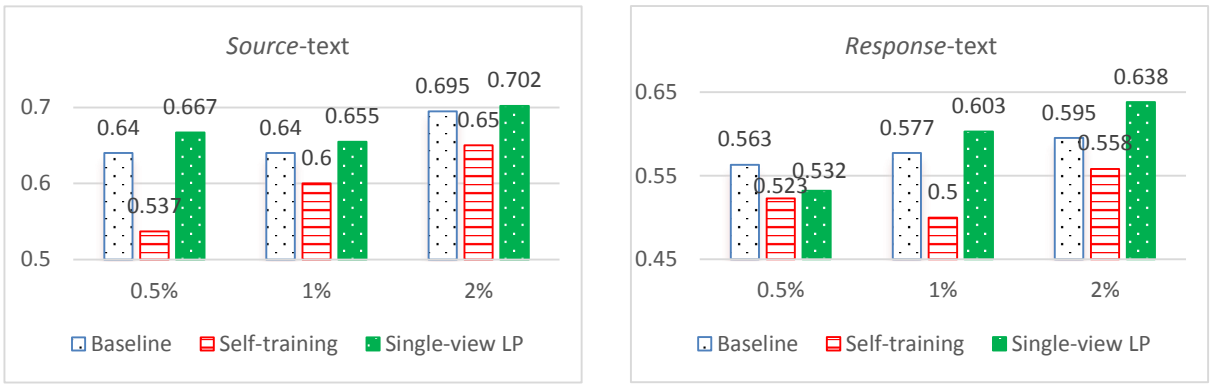

Figure 7: Performance comparison of different semi-supervised learning approaches to reader emotion classification when only one view is utilized

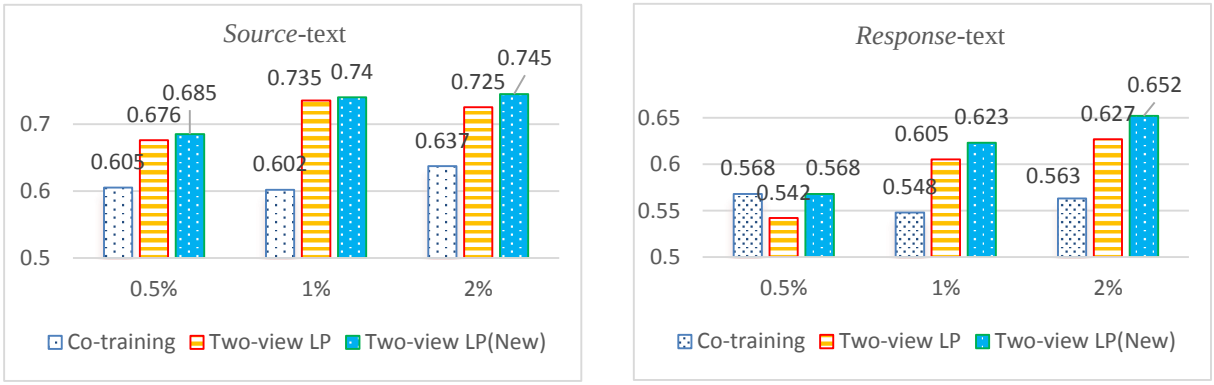

Figure 8: Performance comparison of different semi-supervised learning approaches to reader emotion classification when two views are utilized

- **Baseline**: using only labeled data to train the classifier for predicting the reader emotion of each view (No unlabeled data is used.)
- **Self-training**: using self-training, a simple bootstrapping approach, to iteratively add the high-confident unlabeled samples as automatically labeled samples in each view.
- **Single-view LP**: first using the word-document bipartite graph to model the relationship among the document samples in each view and then applying label propagation to perform semi-supervised learning as introduced in Section 3.1.

Figure 7 shows the performance of different approaches when either the *source*-text or the *response*-text view is utilized. From the figure, we can see that self-training performs dramatically worse than the single-view LP approach, even worse than the baseline approach. In general, the single-view LP approach is effective on using unlabeled data to improve the performance, although the average improvement is limited with around 2%. Besides, the single-view LP approach fails in the case when only 0.5% of the training data are used as initial labeled data. This is possibly because too few initial labeled samples make it extremely difficult to correctly bootstrap enough unlabeled samples.

5.3 Experimental Results on Two-view LP

In this section, we compare different approaches to semi-supervised learning on reader emotion classification when two views are utilized. For comparison, we implement following approaches:

- **Co-training**: using the *source*–text and *response*-text as two views in co-training, as described in Liu et al. (2013).
- **Two-view LP**: our two-view LP approach with the unique transition probability of 1 between the *source*-text sample and its *response*-text sample.
- **Two-view LP (New)**: the two-view LP approach with a variable transition probability between the *source* text sample and its corresponding *response* text sample, as calculated with formula (3). Here,

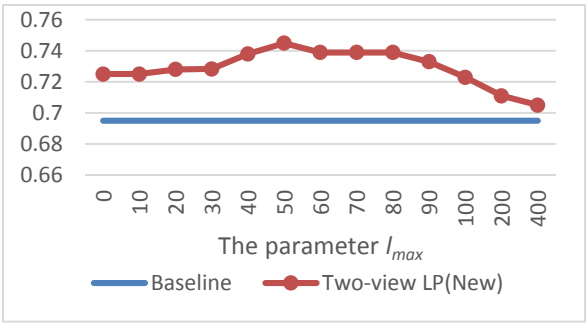

Figure 9: Sensitiveness of the performance on parameter l_{max}

parameter l_{max} is fine-tuned to be 50.

Figure 8 shows the performance of different approaches when both the *source*-text and the *response*-text views are utilized. From this figure, we can see that the two-view LP approach performs much better than co-training. Significance test shows that the improvement of two-view LP (New) over two-view LP is significant (p-value<0.05). This indicates the appropriateness of a variable transition probability between the *source* text sample and its corresponding *response* text sample.

From both Figure 7 and Figure 8, we can see that co-training fails to exploit unlabeled data to improve the performance, quite different from that in Liu et al. (2013). This is mainly due to the fact that the *response* text samples in our data contain much less comments. This makes the sufficiency assumption violated in co-training. Furthermore, we find that two-view LP significantly outperforms single-view LP (p-value<0.05) with a large margin. This verifies the effectiveness of using two views to perform semi-supervised learning on reader emotion classification.

Finally, Figure 9 shows the performance of two-view LP (New) with varying values of parameter l_{max} when testing on the *source*-text samples. Due to the space limitation, we only show the performance when using 2% training data as the initial labeled data. From this figure, we can see that our approach performs consistently well when the parameter is set from 40 to 90, which is a very broad range.

6. Conclusion

In this paper, we propose a novel approach, namely, two-view label propagation, to semi-supervised learning on reader emotion classification. Our approach consists of two main steps: (1) constructing a joint graph containing two word-document bipartite sub-graphs; (2) performing label propagation to incorporate the unlabeled data. Furthermore, we design a length-sensitive function to measure the transition probability from a *source* text sample to its responding *response* text sample. Experimental studies demonstrate that our two-view label propagation approach is capable of employing the two views and unlabeled data to improve the performance.

This work mainly focuses on reader emotion classification with only two categories, i.e., *positive* and *negative* emotions. In the future work, we will explore semi-supervised learning on reader emotion classification when more fine-grained categories, such as *happiness*, *sadness*, and *anger*, are considered. Moreover, given the wide potential of the two-view LP approach, we will explore it in other NLP tasks where two views are involved.

A Joint Sentiment-Target-Stance Model for Stance Classification in Tweets

Javid Ebrahimi, Dejing Dou, Daniel Lowd

Abstract

Classifying the stance expressed in online microblogging social media is an emerging problem in opinion mining. We propose a probabilistic approach to stance classification in tweets, which models stance, target of stance, and sentiment of tweet, jointly. Instead of simply conjoining the sentiment or target variables as extra variables to the feature space, we use a novel formulation to incorporate three-way interactions among sentiment-stance-input variables and three-way interactions among target-stance-input variables. The proposed specification intuitively aims to discriminate sentiment features from target features for stance classification. In addition, regularizing a single stance classifier, which handles all targets, acts as a soft weight-sharing among them. We demonstrate that discriminative training of this model achieves the state-of-the-art results in supervised stance classification, and its generative training obtains competitive results in the weakly supervised setting.

1 Introduction

Stance Classification (SC) is the task of inferring from text whether the author is in favor of a given target, against it, or has a neutral position toward it. This task, which can be complex even for humans (Walker et al., 2012a), is related to argument mining, subjectivity analysis, and sentiment classification. Generic sentiment classification is formulated as determining whether a piece of text is positive, negative, or neutral. However, in SC, systems must detect favorability toward a given (pre-chosen) target of interest. In this sense, SC is more similar to target-dependent sentiment classification (Jiang et al., 2011), with a major difference that the target of the stance might not be explicitly mentioned in text or might not be the target of the opinion (Mohammad et al., 2016). For example, the tweet below implies a stance against Donald Trump, through expressing support for Hillary Clinton.

> Target: Donald Trump
> My vote is definitely for Hillary. Can't trust #gop candidates.

This is an interesting task to study on social networks because of the abundance of personalized and opinionated language. Given the growing significance of the role social media is playing in our world, studying stance classification can be beneficial among others, in identifying electoral issues and understanding how public stance is shaped (Mohammad et al., 2015).

SemEval 2016 Task 6 organizers (Mohammad et al., 2016) released a joint stance and sentiment annotated dataset. Studying the correlation between sentiment and stance and how the former can help detect the latter is an important research question that we address in this paper. Our approach relies on one observation for stance detection in tweets. Ignoring general words and stopwords, a lot of the time, we can expect a rough dichotomy on the remaining n-grams of the tweets. Concretely, a stance-related n-gram either refers to a topic related to the target or bears a sentiment. In Table 1 *Christian*, *religion*, *Feminism*, and *campaign* are of the first type, while *murder* and *enjoyed* are of the second type. We design the model such that the probability of a stance y given the text x, and its associated target t and

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2656–2665, Osaka, Japan, December 11-17 2016.

(1) **Target**: legalization of abortion, **Stance**:Against, **Sentiment**:Negative Hillary, Here's one Christian whose religious views will never adapt to include abortion. Abortion is murder. (2) **Target**: Hillary Clinton, **Stance**:Favor, **Sentiment**:Positive Enjoyed @jamiaw article on feminism + @hillaryclinton. We are building campaign that engages ppl through an intersectional lens.

Table 1: Two examples from SemEval 2016 Task 6.A on two of the targets specified in the corpus.

sentiment s, is proportional to the product of two components. The first component measures the consistency of x with sentiment s and stance y, while the second component measures the consistency of x with target t and stance y. The model learns how to discriminate among the target-specific features and sentiment-specific features, the latter of which might be generalized across different targets. This is further improved by performing regularization on one single classifier, as opposed to a different classifier for each target, which so far has been the standard way to do stance classification.

Our discriminative model works effectively for supervised stance classification tasks. However, manual annotation requires painstaking work by researchers, which can be even more difficult for tasks such as sentiment annotation (Mohammad, 2016). To this end, we propose a generative model, which works properly for stance prediction especially in weakly supervised settings, in which labeled instances are few and labels might be noisy.

Our contributions are as follows:

1. We address the modeling of interactions among target of stance, stance itself, and sentiment in text, by an undirected graphical model.

2. We use one single classifier for stance classification across multiple targets, as opposed to previous works, which use a separate classifier for each target. We demonstrate how our particular model specification and shared regularization can improve stance classification across multiple targets.

3. We develop both discriminative and generative training algorithms, which achieve the state-of-the-art results on supervised and competitive results for weakly supervised stance classification tasks, respectively.

2 Related Work

Previous work has focused on congressional debates (Thomas et al., 2006; Yessenalina et al., 2010), company-internal discussions (Agrawal et al., 2003), and debates in online forums (Anand et al., 2011; Somasundaran and Wiebe, 2010). There is a growing interest in performing stance classification on other media. For example, Faulkner (2014) detected document-level stance in student essays. Sobhani et al. (2015) extracted arguments used in online news comments to detect stance. The data from the Emergent Project[1] was used to classify the stance of article headlines (Ferreira and Vlachos, 2016). SemEval-2016 Task 6 (Mohammad et al., 2016) involved two stance detection subtasks in tweets in supervised and weakly supervised settings.

Somasundaran and Wiebe (2010) developed a baseline for stance classification using features based on modal verbs and sentiments. Anand et al. (2011) augmented the *n*-gram features with lexicon-based and dependency-based features. FrameNet semantic frames have also been incorporated in (Hasan and Ng, 2013; Hasan and Ng, 2014). SC has newly been posed as collective classification. For example, citation structure (Burfoot et al., 2011) or rebuttal links (Walker et al., 2012b), are used as extra information to model agreements or disagreements in debate posts and to infer their labels. In (Murakami and Raymond, 2010) a *maximum cut* method is used to aggregate stances in multiple posts to infer a user's stance on the target. Sridhar et al. (2015) use Probabilistic Soft Logic (PSL) to collectively classify the stance of users and stance in posts. PSL has also been used to augment a weakly-labeled tweet collection by incorporating Twitter's network-based features (Ebrahimi et al., 2016). Similarly, Rajadesingan et al.

[1] http://towcenter.org/research/lies-damn-lies-and-viral-content/

(2014), use a retweet-based label propagation method, which starts from a set of opinionated users and labeled tweets by the people who are in the retweet network. Since arguments and counter-arguments occur in sequences, Hasan and Ng (2014) were able to pose stance classification in debate forums as a sequence labeling task.

Tweets pose some challenges that preclude the use of standard off-the-shelf NLP feature extractors (Dey and Haque, 2009). Tweets have restricted length, which sometime makes the author use unstructured or incoherent statements. This is aggravated by the highly informal language that is common on Twitter, which includes grammatical errors. Not surprisingly, the results of SemEval 2016 Task 6 (Mohammad et al., 2016) showed the effectiveness of simple word *n*-grams and character *n*-grams, in addition to deep neural network approaches that automatically extract features. We use *n*-gram features in this work. But we will briefly discuss how our (discriminative) formulation can be incorporated into neural nets too.

In the next sections, we present effective baselines for joint modeling of targets, sentiments, and stances by a simple log-linear approach. We develop both generative and discriminative models and perform experiments on SemEval 2016 Tasks 6.A and 6.B (Mohammad et al., 2016).

3 STS: Joint Sentiment-Target-Stance Modeling

3.1 Log-Linear STS Model

In this paper, $\mathbf{x} \in \mathbb{R}^V$ is a vector of input features and $y \in Y$ is a discrete stance label, which we handle by a one-hot vector $\boldsymbol{e}_y \in \mathbb{R}^M$. Similar vectors, $\boldsymbol{e}_s \in \mathbb{R}^P$ and $\boldsymbol{e}_t \in \mathbb{R}^Q$, are defined for sentiment and target variables respectively. The model is defined over tensors $\Lambda^1 \in \mathbb{R}^{P \times V \times M}$ and $\Lambda^2 \in \mathbb{R}^{Q \times V \times M}$. Λ^1 and Λ^2 govern the sentiment-stance-feature and target-stance-feature interactions respectively. We define the following energy function,

$$E(y|\mathbf{x}, s, t; \Lambda^1, \Lambda^2) = -\sum_k \mathbf{x}_k(\lambda^1_{s,k,y} + \lambda^2_{t,k,y})$$

The negative of the energy associated with the stance label y, given the text $\mathbf{x}$, and its associated target t and sentiment s, is equal to the summation of two components. The first one measures the consistency of $\mathbf{x}$ with sentiment s and stance y, while the second one measures the consistency of $\mathbf{x}$ with target t and stance y. This specification is a log-linear model with feature functions $\phi^1(t, k, y) = \mathbb{1}(T = t, \mathbf{x}_k = 1, Y = y)$ and $\phi^2(s, k, y) = \mathbb{1}(S = s, \mathbf{x}_k = 1, Y = y)$, where $\mathbb{1}$ is the indicator function.

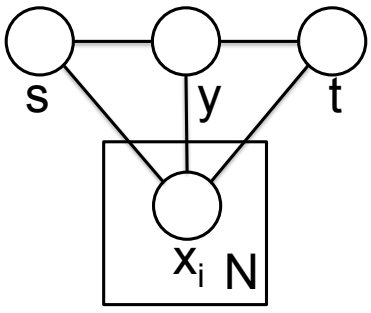

Figure 1: Plate model for STS

We build $p_\theta(y, s, t, \mathbf{x})$, a generatively trained model, and $p_\theta(y|s, t, \mathbf{x})$, a discriminatively trained model. For both models, the inference problem, the probability of output y conditioned on inputs, is given by,

$$p(y|\mathbf{x}, s, t) = \frac{\exp\big(\mathbf{x}^T(\boldsymbol{e}_s^T \Lambda^1 \boldsymbol{e}_y + \boldsymbol{e}_t^T \Lambda^2 \boldsymbol{e}_y)\big)}{\sum_{y'} \exp\big(\mathbf{x}^T(\boldsymbol{e}_s^T \Lambda^1 \boldsymbol{e}_{y'} + \boldsymbol{e}_t^T \Lambda^2 \boldsymbol{e}_{y'})\big)} \quad (1)$$

where $\boldsymbol{a}^T \Lambda \boldsymbol{b}$ is a bilinear tensor product which results in a vector, $h \in \mathbb{R}^V$. We use this tensor-based notation mainly to facilitate the description of the generative training algorithm.

3.2 Generative Training

Consider the training dataset $\mathcal{D}_{train}$, containing instances of the binary feature vector $\mathbf{x}$. To train a generative model, we use minimization of the negative joint log-likelihood.

$$\mathcal{L}(\mathcal{D}_{train}) = -\sum_{i=1}^{|\mathcal{D}_{train}|} \log p(\mathbf{y}_{(i)}, \mathbf{s}_{(i)}, \mathbf{t}_{(i)}, \mathbf{x}_{(i)})$$

In order to minimize the negative log-likelihood, we would compute its gradient with respect to the model parameters. The exact gradient, for any parameter $\theta \in \{\Lambda^1, \Lambda^2\}$, can be written as,

$$\frac{\partial \log p(\mathbf{y}_{(i)}, \mathbf{s}_{(i)}, \mathbf{t}_{(i)}, \mathbf{x}_{(i)})}{\partial \theta} = -\mathbf{E}_{\text{data}}\left[\frac{\partial E(\mathbf{y}_{(i)}, \mathbf{s}_{(i)}, \mathbf{t}_{(i)}, \mathbf{x}_{(i)})}{\partial \theta}\right] + \mathbf{E}_{\text{model}}\left[\frac{\partial E(\mathbf{y}, \mathbf{s}, \mathbf{t}, \mathbf{x})}{\partial \theta}\right] \quad (2)$$

While the first expectation can be computed in closed form, the second expectation is intractable due to the partition function. However, we can approximate it by generating a sample from the underlying distribution estimated by an MCMC algorithm such as Gibbs sampling. But instead of running the Gibbs chain for the whole burn-in period, we can run the chain for only k steps. This approximation method is called k-contrastive divergence (CD) (Hinton, 2002), which can be interpreted as optimizing a difference of Kullback-Leibler divergences. The novelty of this approach is in setting the sampler's initial state for variables at a training sample $(\mathbf{y}_{(i)}, \mathbf{s}_{(i)}, \mathbf{t}_{(i)}, \mathbf{x}_{(i)})$; this way the energy surface is modified only around the data points. We used CD-1 in our work.

Given the conditional independence assertions and the binary features, it is straightforward to show[2],

$$p(\mathbf{x}|y, s, t) = \prod_k p(x_k = 1|y, s, t) = \prod_k \text{sigm}\big(\boldsymbol{e}_{\mathbf{x}_k}^T(\boldsymbol{e}_s^T \Lambda^1 \boldsymbol{e}_y + \boldsymbol{e}_t^T \Lambda^2 \boldsymbol{e}_y)\big)$$

where $\boldsymbol{e}_{\mathbf{x}_k}$ is the one-hot representation of feature $\mathbf{x}_k$. We note that if sentiment and target variables were treated as additional input variables and conditional independence was applied to them as well, this generative specification would become identical to *naive Bayes*, and no approximation would be necessary. It can also be shown that $p(y|\mathbf{x}, s, t)$ and other conditional distributions needed to perform Gibbs sampling, $p(s|\mathbf{x}, y)$ and $p(t|\mathbf{x}, y)$, all follow a softmax distribution (Salakhutdinov and Hinton, 2009). See Equation 1.

The gradient with respect to the l_{th} slice of the tensors Λ^1 and Λ^2 can be approximated by:

$$\frac{\partial E(\theta)}{\partial \Lambda^1_{[l]}} = -\sum_i (\mathbf{y}^l_{(i)} \boldsymbol{e}_{s_{(i)}} \mathbf{x}^T_{(i)} - \hat{\mathbf{y}}^l_{(i)} \hat{\mathbf{s}}_{(\mathbf{i})} \hat{\mathbf{x}}^T_{(i)}) \quad (3)$$

$$\frac{\partial E(\theta)}{\partial \Lambda^2_{[l]}} = -\sum_i (\mathbf{y}^l_{(i)} \boldsymbol{e}_{t_{(i)}} \mathbf{x}^T_{(i)} - \hat{\mathbf{y}}^l_{(i)} \hat{\mathbf{t}}_{(\mathbf{i})} \hat{\mathbf{x}}^T_{(i)}) \quad (4)$$

where $\hat{\mathbf{y}}_i$, $\hat{\mathbf{x}}_i$, $\hat{\mathbf{t}}_i$, and $\hat{\mathbf{s}}_i$ are samples from $p(y|\mathbf{x}, s, t)$, $p(\mathbf{x}|y, s, t)$, $p(t|\mathbf{x}, y)$, and $p(s|\mathbf{x}, y)$ after CD-1, respectively. However, we use a version of CD (Mnih and Hinton, 2007) in which, instead of sampling and obtaining a binary vector, we set $\hat{\mathbf{y}}_i$, $\hat{\mathbf{x}}_i$, $\hat{\mathbf{t}}_i$, and $\hat{\mathbf{s}}_i$ to the vector of probabilities given by the respective probability distributions.

3.3 Discriminative Training

To train a discriminative model, we minimize the *cross-entropy* error,

$$J(\theta) = -\sum_i^{|\mathcal{D}_{train}|} \sum_l \mathbb{1}(\mathbf{y}_{(i)} = l) \log p(l|\mathbf{s}_{(i)}, \mathbf{t}_{(i)}, \mathbf{x}_{(i)})$$

[2]For the sake of simplicity of presentation, we omit the bias units which are needed for generative training.

	Overall				Atheism	Climate	Feminism	Hillary	Abortion
Method	F_{favor}	$F_{against}$	$MicF_{avg}$	$MacF_{avg}$	F_{avg}	F_{avg}	F_{avg}	F_{avg}	F_{avg}
CNN	61.98	72.67	67.33	58.57	63.34	**52.69**	51.33	64.41	61.09
RNN	59.32	76.33	67.82	56.02	61.47	41.63	**62.09**	57.67	57.28
SVM	62.98	74.98	68.98	58.01	65.19	42.35	57.46	58.63	66.42
MaxEnt	60.78	73.41	67.10	56.37	60.82	41.43	55.73	59.87	63.99
NB	58.05	71.11	64.58	55.51	63.69	40.46	49.58	64.77	58.64
Disc-TS	62.96	76.12	69.55	58.85	61.90	41.73	56.76	63.91	**69.94**
Disc-STS	**64.43**	**77.62**	**71.03**	**61.40**	65.52	41.18	57.90	**74.48**	67.94
Gen-STS	61.43	77.02	69.23	60.41	**67.09**	50.04	53.77	71.25	59.92

Table 2: Results for Task A, reporting the official competition metric, overall $MicF_{avg}$, along with F_{avg} for each individual target, and the average of all individual F_{avg}, $MacF_{avg}$.

The gradients with respect to the l_{th} slice of the tensor Λ^1 and Λ^2 can be computed exactly,

$$\frac{\partial J(\theta)}{\partial \Lambda^1_{[l]}} = -\sum_i \boldsymbol{e}_{s_{(i)}} \mathbf{x}^T_{(i)} \big(\mathbb{1}(\mathbf{y}_{(i)} = l) - p(l|\mathbf{s}_{(i)}, \mathbf{t}_{(i)}, \mathbf{x}_{(i)})\big) \tag{5}$$

$$\frac{\partial J(\theta)}{\partial \Lambda^2_{[l]}} = -\sum_i \boldsymbol{e}_{t_{(i)}} \mathbf{x}^T_{(i)} \big(\mathbb{1}(\mathbf{y}_{(i)} = l) - p(l|\mathbf{s}_{(i)}, \mathbf{t}_{(i)}, \mathbf{x}_{(i)})\big) \tag{6}$$

In both discriminative and generative cases, the gradients can be regarded as update rules for the weights of the model, which are untied based on the sentiment (updates on Λ^1) or the target (updates on Λ^2) in the tweet.

4 Experiments

SemEval 2016 Task 6 (Mohammad et al., 2016) defined two stance classification tasks/datasets. The first one (Task 6.A) was a traditional supervised task, while the second one (Task 6.B) was a weakly supervised task wherein no tweet was stance-annotated. For both tasks, we used binary n-gram features: word n-grams (1–3 gram) and character n-grams (2–5 gram). We used $\ell 2$ regularization for our discriminative (Disc-STS) and generative (Gen-STS) models. For Task A, model hyper-parameters were estimated by cross-validation on the training set. For Task B, we used the dataset of the supervised task as the development set. Gen-STS was trained by stochastic gradient descent, and the learning rate was set to 0.0005. Disc-STS was trained in batch mode, and we used L-BFGS for optimization. Task B contains noisy stance labels; because of this, we performed early stopping in training to avoid overfitting to the wrong model. To this end, during parameter tuning on the development set, we used a larger range for the progress threshold in our grid search.

4.1 Supervised Task

SemEval-2016 Task 6.A provided stance-annotated tweets toward five targets: "Atheism", "Climate Change is a Real Concern", "Feminist Movement", "Hillary Clinton", and "Legalization of Abortion". The dataset contained 2,914 and 1,249 tweets for training and testing respectively.

4.1.1 Results

Table 2 shows the results for Task A. CNN (Wei et al., 2016) and RNN (Zarrella and Marsh, 2016) are convolutional neural network and recurrent neural network models that were the second best and the best system in the competition respectively. Both systems use pre-trained word embeddings before training for the task, which improves generalization and allows them to achieve good results on the task. The SVM classifier was the linear-kernel SVM used by task organizers, which was trained on the same features as ours (i.e., word n-grams (1–3 gram) and character n-grams (2–5 gram)). Two other reasonable baselines, which resemble our discriminative and generative models respectively, are *maximum entropy* (MaxEnt), and *naive Bayes* (NB) classifiers.

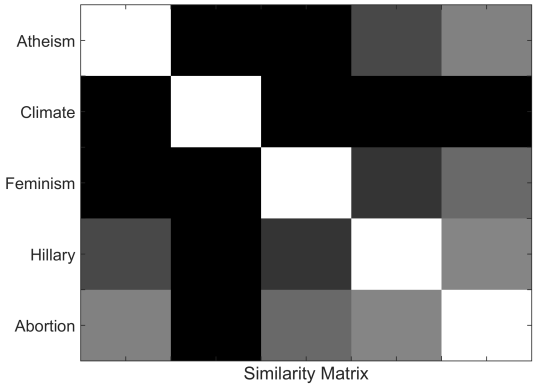

Figure 2: Similarity matrix of the weight vectors for task A targets. Lighter color denotes higher similarity.

The $MicF_{avg}$ metric is the mean of F_{favor} and $F_{against}$, which are the harmonic mean of Recall and Precision for each class. The metric $MicF_{avg}$ can be regarded as a micro-average of F-scores across targets. Alternatively, one could also determine the mean of the F_{avg} scores for each of the targets, the mean of which determines the ($MacF_{avg}$) metric.

Both Disc-STS and Gen-STS gain substantial gains over their natural baselines, MaxEnt and NB. Disc-STS improves the previous state-of-the-art results by 2.05% and 3.4% in Micro F1 and Macro F1 scores respectively. CNN and Gen-STS perform better on the "Climate" target, which is highly imbalanced (i.e., only 3.8% against). Unlike all the other baselines, which trained separate classifiers for each target, our approach can benefit from generalized features across multiple targets. Figure 2 displays the cosine similarity between the weight vectors for each of the targets. The weights used for this measure, were taken from the slice for that target, namely $\Lambda^2_{[target,:,:]}$.

Comparing MaxEnt and Disc-TS, the biggest improvement is found on the "Abortion" target. The performance on the targets, which are more similar to other targets in the corpus, is generally boosted significantly, compared with those that are not. The only difference between the two models is shared regularization across all the targets, which is causing the improvement.

Another way to investigate the inner workings of the model is to check if the model is able to discriminate sentiment features from target features. To do this, we represent the words based on the weights associated with them in the model. We concatenate the word-specific slices in the tensor parameter, namely $\Lambda^1_{[:,word,:]}$ and $\Lambda^2_{[:,word,:]}$, and compute the cosine similarity between pairs of word vectors. Table 3 shows the most similar words to 4 query words: two target-based and two sentiment-bearing words. It can be seen that among the top words similar to the sentiment-bearing words are some other sentiment-bearing words (positive or negative). The words similar to "climate" are clearly related to the target of "climate change". The words similar to "anti-choice" are about the target of "abortion", in addition to another related target, "feminism".

Given the significance of regularization and the dichotomy on the features, group lasso regularization (Yogatama and Smith, 2014), based on sentiment and target groups, can potentially improve our results.

We also report results on two subsets of the test set; (1) a subset where opinion is expressed toward the target; (2) a subset where opinion is expressed toward some other entity. Table 4 shows these results along with the overall $MicF_{avg}$, for the ease of reference.

4.2 Weakly Supervised Task

SemEval-2016 Task 6.B provided around 78,000 tweets associated with "Donald Trump". The tweets were gathered by polling Twitter for hashtags associated with Donald Trump. The protocol of the task only allowed minimal manual labeling, i.e. "tweets or sentences that are manually labeled for stance" were not allowed, but "manually labeling a handful of hashtags" and the use of other resources, e.g. lexicons, sentiment analyzers, etc., was permitted. This test set contained 707 tweets.

anti-choice	climate	excellent	crap
anti-abortion	global	together	asks
#feminism	co2	note	hack
effort	last	despite	hates
mentality	june	interesting	slut
benefits	warming	hate	shatter
unsafe	agriculture	retarded	#vaw
#reprorights	environmental	hatred	misogynistic
cunt	summer	warrior	adultery
types	mines	1st	either
banned	reducing	scum	societal

Table 3: Top similar words to 4 query words.

	Opinion toward		All
Method	Target	Other	
CNN	71.07	**46.66**	67.33
RNN	72.49	44.48	67.82
SVM	74.54	43.20	68.98
Disc-TS	74.60	44.95	69.55
Disc-STS	76.36	46.44	**71.03**
Gen-STS	**76.53**	43.39	69.23

Table 4: Results for Task A (the official competition metric F_{avg}) on different subsets of the test data.

4.2.1 Preprocessing

We only considered the tweets which contain no URL, are not retweets, are not shorter than 40 characters, and have at most three hashtags and three mentions. Following the protocol of the task, we start from labeling some hashtags. Among the most frequent hashtags in the training data, we manually labeled a handful of hashtags that are favorable to Trump, e.g., *#MakeAmericaGreatAgain*, and a handful of hashtags that are against him, e.g., *#TrumpYoureFired*. See Table 5 for a complete list of these hashtags. This weakly supervised approach gives us a dataset with *noisy* labels; for example, the tweet "*his #MakeAmericaGreatAgain #Tag is a bummer.*" is against Trump, incorrectly labeled favorable. Tweets that have at least one positive, or one negative hashtag/regex, and do not have both a positive and a negative hashtag/regex, are considered as our initial *favorable* and *against* instances. The final weakly labeled dataset consisted of a modest number of 1367 instances (544 against and 823 favorable).

We use a sentiment analyzer for tweets, VADER (Hutto and Gilbert, 2014), to classify the sentiments of the tweets. Here, we are dealing with only one target, but we still classify the tweets based on their topics. To do this, we use the standard topic modeling technique, LDA (Blei et al., 2003). This gives us an approximate fine-grained view of the topics of discussion in the data (e.g., immigration, Mexico, Obama, etc.). The number of topics (potential targets) was determined by the Elbow method (Thorndike, 1953), which was found to be 4. Finally, the topic distributions for the tweets were binarized (i.e., one for the dimension with the maximum value and zero for others).

4.2.2 Results

In Table 6 we compare our results with the best system in Task 6.B, which is the same CNN (Wei et al., 2016) system in Task 6.A, and state-of-the-art model, BiCond (Augenstein et al., 2016), which uses a bidirectional conditional LSTM encoding model. To handle the "neither" class we do the following: if the absolute value of the difference between the probability values of the two classes is less than a random number ($\epsilon|\epsilon \in (0, 0.1]$), then we classify it as "neither".

Figure 3 shows the impact of the amount of the training data on the performance of our models. Due to the limited nature of our data collection scheme, which tends to exploit only parts of the space of the

Disc-STS	39.59	55.43	47.51

Table 6: Evaluation on SemEval-2016 Task 6.B.

data, it is reasonable to expect that after a certain amount of data is seen, the performance of the system improves marginally as more training data is added. The discriminative model converges more quickly and performs poorly. Its performance improves marginally after seeing only 10% of the training data (i.e., 137 instances) and deteriorates soon. On the other hand, the generative model converges later with a much better F1 score. We also added 5% misclassification noise to the stance labels in the task A dataset but did not observe a similar pattern; instead, the discriminative classifier performed consistently better than the generative one and was less sensitive to the noise.

What we see in Figure 3 can be ascribed to the fragmentary view of the data created because of the hashtag-based process of bootstrapping a training set. In other words, the small number of tweets, which we harvest, covers only part of the test-data distribution. This is worsened by the lack of neutral tweets in the bootstrapped training set. Previous works have shown that variants of generative models alone, or their combination with discriminative models (Larochelle and Bengio, 2008; Nigam et al., 2000), are useful for classification especially when the amount of training data is limited (NG and Jordan, 2002). A detailed analysis of this phenomenon will be undertaken in the future.

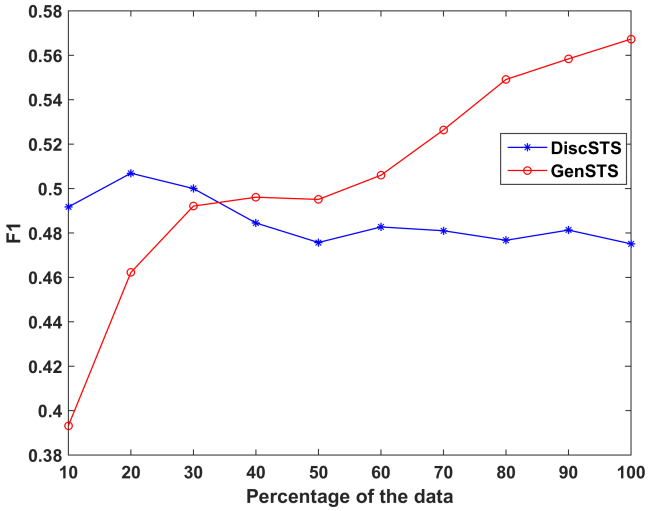

Figure 3: Comparison of GenSTS and DiscSTS on Task b. F1 is plotted against the amount of training data, i.e., percentage of the noisy-labeled data actually used for training. DiscSTS performs better initially and converges more quickly. GenSTS performs significantly better as more data is added.

5 Conclusion and Future Work

In this paper, we presented a log-linear approach for stance classification on tweets. The model employed sentiment and target variables in a novel way, wherein three-way interactions among input-sentiment-

stance variables and three-way interactions among input-target-stance variables were measured. Our findings show that the best way to use sentiments to improve stance classification is through these multi-way interactions. In addition, we demonstrated that by simply sharing regularization parameters among multiple targets, we are able to generalize features across multiple targets. While discriminative models are known to work better in classification tasks, generative models can also be useful when the data sample is small. Our results on a weakly labeled stance dataset proved that our generative model can in fact be much more effective than its discriminative counterpart.

For future work, our model can be easily incorporated in deep discriminative neural nets by replacing the standard softmax layer, effectively creating a multi-dimensional softmax layer. This has applications in tasks, wherein metadata exists; for example, a sentiment classification task for product reviews, in which metadata about the user and the products are also available. Moreover, the generative learning can be improved by replacing contrastive divergence with a more recent sampling method, SampleRank (Rohanimanesh et al., 2011), and using F1 score as the cost function.

Abstract

An important difference between traditional AI systems and human intelligence is the human ability to harness commonsense knowledge gleaned from a lifetime of learning and experience to make informed decisions. This allows humans to adapt easily to novel situations where AI fails catastrophically due to a lack of situation-specific rules and generalization capabilities. Commonsense knowledge also provides background information that enables humans to successfully operate in social situations where such knowledge is typically assumed. Since commonsense consists of information that humans take for granted, gathering it is an extremely difficult task. Previous versions of SenticNet were focused on collecting this kind of knowledge for sentiment analysis but they were heavily limited by their inability to generalize. SenticNet 4 overcomes such limitations by leveraging on conceptual primitives automatically generated by means of hierarchical clustering and dimensionality reduction.

1 Introduction

The opportunity to capture the opinion of the general public has raised growing interest within both the scientific community as well as the business world, due to the remarkable benefits to be had from marketing and financial prediction, which has led to many exciting open challenges (Pang and Lee, 2008; Liu, 2012). Mining opinions and sentiments from natural language, however, is an extremely difficult task as it requires a deep understanding of most of the explicit and implicit, regular and irregular, syntactic and semantic rules of a language. Existing approaches to sentiment analysis mainly rely on parts of text in which opinions are explicitly expressed such as polarity terms, affect words, and their co-occurrence frequencies. However, opinions and sentiments are often conveyed implicitly through latent semantics, which make purely syntactic approaches ineffective.

SenticNet (Cambria et al., 2014) captures such latent information in terms of *semantics* and *sentics*, i.e., the denotative and connotative information commonly associated with real-world objects, actions, events, and people. SenticNet steps away from blindly using keywords and word co-occurrence counts, and instead relies on the implicit meaning associated with commonsense concepts. Superior to purely syntactic techniques, SenticNet can detect subtly expressed sentiments by enabling the analysis of multiword expressions that do not explicitly convey emotion, but are instead related to concepts that do so. The main limitation of SenticNet is that it is unable to generalize instances of concepts, e.g., `eat_pasta` or `slurp_noodles`: unless there is an exact match, SenticNet 3 raises a not-found error.

In SenticNet 4, however, both verb and noun concepts are linked to primitives so that, for example, concepts such as `eat_pasta` or `slurp_noodles` are generalized as `INGEST_FOOD`. In this way, most concept inflections can be captured by the knowledge base: verb concepts like `eat`, `slurp`, `munch` are all represented by their conceptual primitive `INGEST` while noun concepts like `pasta`, `noodles`, `steak` are replaced with their ontological parent `FOOD`.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2666–2677, Osaka, Japan, December 11-17 2016.

The idea behind this generalization is that there is a finite set of mental primitives for affect-bearing concepts and a finite set of principles of mental combination governing their interaction. Conceptual primitives are automatically discovered in SenticNet through the ensemble application of hierarchical clustering and dimensionality reduction.

The rest of the paper is organized as follows: Section 2 presents related work in the field of sentiment analysis; Section 3 proposes an excursus on conceptual primitives; Sections 4 and 5 describe in detail how noun concepts and verb concepts are generalized, respectively; Section 6 proposes experimental results on two different state-of-the-art datasets; finally, Section 7 provides concluding remarks.

2 Related Work

Sentiment analysis systems can be broadly categorized into knowledge-based or statistics-based systems (Cambria, 2016). While the use of knowledge bases was initially more popular for the identification of sentiment polarity in text, recently sentiment analysis researchers have been increasingly using statistics-based approaches, with a special focus on supervised statistical methods. Pang et al. (Pang et al., 2002) pioneered this trend by comparing the performance of different machine learning algorithms on a movie review dataset and obtained a 82% accuracy for polarity detection. A recent approach by Socher et al. (Socher et al., 2013) obtained a 85% accuracy on the same dataset using a recursive neural tensor network. Yu and Hatzivassiloglou (Yu and Hatzivassiloglou, 2003) used semantic orientation of words to identify polarity at sentence level. Melville et al. (Melville et al., 2009) developed a framework that exploits word-class association information for domain-dependent sentiment analysis.

More recent studies exploit microblogging text or Twitter-specific features such as emoticons, hashtags, URLs, @symbols, capitalizations, and elongations to enhance sentiment analysis of tweets. Tang et al. (Tang et al., 2014a) used a convolutional neural network (CNN) to obtain word embeddings for words frequently used in tweets. Dos Santos et al. (dos Santos and Gatti, 2014) also focused on deep CNN for sentiment detection in short texts. Recent approaches also focus on developing word embeddings based on sentiment corpora (Tang et al., 2014b). Such word vectors include more affective clues than regular word vectors and produce better results for tasks such as emotion recognition (Poria et al., 2016b) and aspect extraction (Poria et al., 2016a).

Statistical methods, however, are generally semantically weak (Cambria and White, 2014). This means that, with the exception of obvious affect keywords, other lexical or co-occurrence elements in a statistical model have little predictive value individually. As a result, statistical text classifiers only work with acceptable accuracy when given a sufficiently large text input. Hence, while these methods may be able to affectively classify user's text on the page or paragraph level, they do not work well on smaller text units such as sentences. Concept-level sentiment analysis, instead, focuses on a semantic analysis of text through the use of web ontologies or semantic networks, which allows for the aggregation of the conceptual and affective information associated with natural language opinions (Cambria and Hussain, 2015; Gezici et al., 2013; Araújo et al., 2014; Bravo-Marquez et al., 2014; Recupero et al., 2014).

By relying on large semantic knowledge bases, such approaches step away from the blind use of keywords and word co-occurrence counts, relying instead on the implicit features associated with natural language concepts. Unlike purely syntactic techniques, concept-based approaches are also able to detect sentiments expressed in a subtle manner; e.g., through the analysis of concepts that do not explicitly convey any emotion, but which are implicitly linked to other concepts that do so. The bag-of-concepts model can represent semantics associated with natural language much better than bag-of-words. In the latter, in fact, concepts like `pretty_ugly` or `sad_smile` would be split into two separate words, disrupting both semantics and sentics of the input sentence.

3 Conceptual Primitives

It is inherent to human nature to try to categorize things, events and people, finding patterns and forms they have in common. One of the most intuitive ways to relate two entities is through their similarity. According to Gestalt theory (Smith, 1988), similarity is one of six principles that guide human perception of the world.

Similarity is a quality that makes one thing or person like another and 'similar' means having characteristics in common. There are many ways in which objects can be perceived as similar, based on things like color, shape, size and texture. If we move away from mere visual stimuli, we can apply the same principles to define similarity between concepts based on shared semantic features. Previous versions of SenticNet exploited this principle to cluster natural language concepts sharing similar affective properties. Finding groups of similar concepts, however, does not ensure full coverage of all possible semantic inflections of multiword expressions.

In this work, we leverage on such similarities to deduce conceptual primitives that can better generalize SenticNet's commonsense knowledge. This generalization is inspired by different theories on conceptual primitives, including Roger Schank's conceptual dependency theory (Schank, 1972), Ray Jackendoff's work on explanatory semantic representation (Jackendoff, 1976), and Anna Wierzbicka's book on primes and universals (Wierzbicka, 1996), but also theoretical studies on knowledge representation (Minsky, 1975; Rumelhart and Ortony, 1977). All such theories claim that a decompositional method is necessary to explore conceptualization. In the same manner a physical scientist understands matter by breaking it down into progressively smaller parts, a scientific study of conceptualization proceeds by decomposing meaning into smaller parts. Clearly, this decomposition cannot go on forever: at some point we must find semantic atoms that cannot be further decomposed. This is the level of conceptual structure; mental representation that encodes basic understanding and commonsense by means of primitive conceptual elements out of which meanings are built.

In SenticNet, this 'decomposition' translates into the generalization of multiword expressions that convey a specific set of emotions and, hence, carry a particular polarity. The motivation behind this process of generalization is that there are countless ways to express the same concept in natural language and having a comprehensive list of all the possible concept inflections is almost impossible. While lexical inflections such as conjugation and declension can be solved with lemmatization, semantic inflections such as the use of synonyms or semantically-related concepts need to be tackled by analogical reasoning.

If multiword expressions like `attain_knowledge` and `acquire_know-how` are encountered in text, SenticNet 3 is unable to process them because there is no entry for such concepts in the knowledge base. SenticNet 3, however, does contain a multiword expression that is highly semantically related to those two concepts, that is, `acquire_knowledge`. By working at the primitive level, SenticNet 4 is able to bridge this semantic gap, as `attain_knowledge`, `acquire_know-how`, and `acquire_knowledge` are all represented by the same conceptual primitive: `GET_INFORMATION`.

By automatically inferring conceptual primitives for SenticNet concepts, we aim to broadly extend the coverage of the commonsense knowledge base and better perform sentiment analysis tasks such as polarity detection and emotion recognition from text. As shown in the next two sections, this is done via generalizing noun concepts by means of hierarchical clustering as well as discovering conceptual primitives for verb concepts by means of dimensionality reduction.

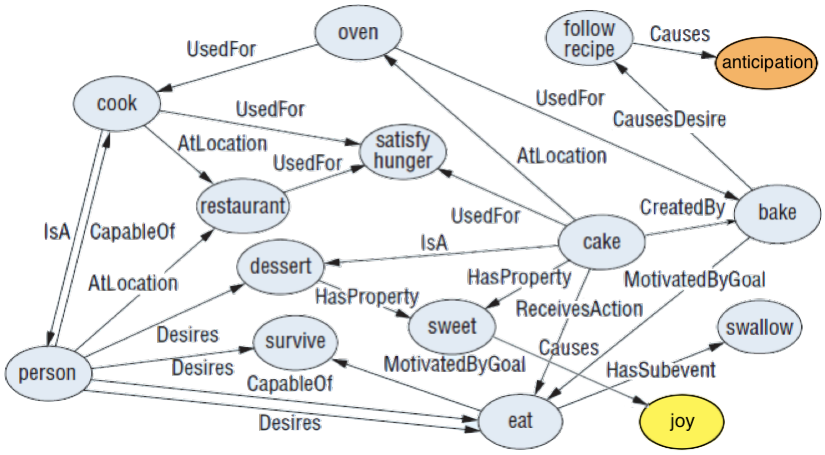

Figure 1: A sketch of the AffectNet graph showing part of the semantic network for the concept `cake`.

4 Noun Concept Generalization

The first step towards generalizing multiword expressions in SenticNet is to build a hierarchical classification of its noun concepts (or object concepts) so that nouns such as `cat`, `dog` or `pet` can be identified as `ANIMAL`. Such classification is implemented by applying hierarchical clustering on a semantic network of commonsense knowledge. It is important to note that each generalization inherits the emotional information and the polarity of its instance concepts. In the case of `cat` and `dog`, for example, the primitive is actually `ANIMAL+` since `cat` and `dog` are associated with positive emotions. Conversely, for animals that are associated with negative emotions such as fear (e.g., `white_shark`) or disgust (e.g., `cockroach`), the corresponding primitive is `ANIMAL−`.

4.1 AffectNet

AffectNet (Cambria and Hussain, 2015) is an affective commonsense knowledge base built upon ConceptNet (Speer and Havasi, 2012), the graph representation of the Open Mind corpus, and WordNet-Affect (Strapparava and Valitutti, 2004), a linguistic resource for the lexical representation of affect (Fig. 1). The resource is represented as a semantic network where nodes are multiword expressions of commonsense knowledge and the links between these are relations that interconnect them. The knowledge encoded by AffectNet is constantly expanding as new versions of ConceptNet are continuously released and new affective commonsense knowledge is crowdsourced through games. AffectNet is first converted into a matrix by dividing each assertion into two parts: a concept and a feature, where a feature is simply the assertion with the first or the second concept left unspecified such as 'a wheel is part of' or 'is a kind of liquid'.

The entries in the resulting matrix are positive or negative numbers, assigned according to the reliability of the assertions, with their magnitude increasing logarithmically with the confidence score. Because the AffectNet graph is made of triples based on the format <concept-relationship-concept>, the entire knowledge repository can be visualized as a large matrix, with every known concept of some statement being a row and every known semantic feature (relationship+concept) being a column. Such a representation has several advantages including the possibility to perform cumulative analogy (Tversky, 1977), executed by first selecting a set of nearest neighbors (in terms of similarity) of the input concept and then by projecting known properties of this set onto unknown properties of the concept (Table 1).

4.2 Group Average Agglomerative Clustering

Direct objects in verb+noun concepts, such as `buy_cake` or `eat_burger`, exhibit semantic coherence in that they tend to generate lexical items and phrases with related semantics. Most words related to the same verb tend to share some semantic characteristics. Our commonsense-based approach is similar to the process undertaken by humans when finding similar items – we look at what the *meanings* of the items have in common. In AffectNet, concepts inter-define one another, with directed edges indicating semantic dependencies between concepts.

Concepts	Semantic Features (*relationship+concept*)							
	..	*Causes* joy	*IsA* event	*UsedFor* housekeeping	*LocatedAt* party_venue	*PartOf* celebration	*MotivatedByGoal* clean_room	..
⋮		⋮	⋮	⋮	⋮	⋮	⋮	
`wedding`	..	0.94	0.86	0	0.79	0.88	0	..
`broom`	..	0	0	0.83	0	0	0.87	..
`buy_cake`	..	**?**	**0.78**	**0**	**0.80**	**0.91**	**0**	..
`birthday`	..	0.97	0.85	0	0.99	0.98	0	..
`sweep_floor`	..	0	0	0.79	0	0	0.91	..
⋮		⋮	⋮	⋮	⋮	⋮	⋮	

Table 1: Cumulative analogy allows for the inference of new pieces of knowledge by comparing similar concepts, e.g., `buy_cake` causes joy because `wedding` and `birthday` (which are similar) do so.

The traditional way to define features for any particular concept c in a semantic network is to consider the set of concepts reachable via outbound edges from c. The proposed algorithm exploits hierarchical clustering to generate from such features conceptual primitives, which represent the core semantics of each concept. Based on experiments with various clustering algorithms, e.g., k-means and expectation-maximization clustering, we determined that group average agglomerative clustering (GAAC) provides the highest accuracy. GAAC partitions data into trees (Berkhin, 2006) containing *child* and *sibling* clusters. It generates dendrograms specifying nested groupings of data at various levels (Jain and Dubes, 1988). During clustering, concepts are represented as vectors of commonsense features extracted from AffectNet. The proximity matrix is constructed with concepts as rows and features as columns. If a feature is an outbound link of a concept, the corresponding entry in the matrix is 1 and it is 0 in other situations. Cosine distance is used as the distance metric. Agglomerative algorithms are bottom-up in nature. GAAC, in particular, consists of the following steps:

1. Compute proximity matrix. Each data item is an initial cluster.
2. From the proximity matrix, form pair of clusters by merging. Update proximity matrix to reflect merges.
3. Repeat until all clusters are merged.

The resulting dendrogram is pruned at a height depending on the number of desired clusters. The *group average* between the clusters is given by the average similarity distance between the groups. Distances between two clusters and similarity measures are given by the equations below:

$$X_{sum} = \sum_{c_m \in \omega_i \cup \omega_i} \sum_{c_n \in \omega_i \cup \omega_j, c_n \neq c_m} \overrightarrow{c_n}.\overrightarrow{c_m} \tag{1}$$

$$sim\,(\omega_i, \omega_j) = \frac{1}{(N_i + N_j)\,(N_i + N_j - 1)} X_{sum} \tag{2}$$

where $\overrightarrow{c}$ is the vector of the concept of length c, vector entries are boolean (1 if the feature is present, 0 otherwise), and N_i, N_j is the number of features in ω_i and ω_j, respectively (which denote clusters). The main drawback of the hierarchical clustering algorithm is its running complexity (Berkhin, 2006), which averages $\theta(N^2 log\ N)$. We chose to utilize average link clustering as our clustering is connectivity-based. The concept proximity matrix consists of features from AffectNet and 'good' connections are deemed to occur when two concepts share multiple features. After clustering, the number of clusters is determined and the dendrogram is pruned accordingly.

Each cluster is later split into a positive and a negative sub-cluster. Cluster instances are assigned to either the positive or the negative sub-cluster depending on their polarity in SenticNet 3. For example, `cobra` and `cat` end up being in the same cluster (`ANIMAL`) after applying GAAC but, since they have opposite polarity in SenticNet 3, they are later assigned to different sub-clusters (`ANIMAL-` and `ANIMAL+`, respectively). Noun concepts for which no specific categorization is discovered are grouped under one of three most general noun primitives, namely: `SOMETHING`, `SOMEONE`, and `SOMEWHERE` (also divided into positive and negative sub-clusters). Table 2 provides an example of the results of polarity-driven feature-based clustering for 24 noun concepts.

SOMETHING- ANIMAL-	SOMETHING+ ANIMAL+	SOMEONE- PROFESSIONAL-	SOMEONE+ PROFESSIONAL+	SOMEWHERE- NATURE-	SOMEWHERE+ NATURE+
cockroach	horse	gravedigger	doctor	dry_steppe	oasis
rat	cat	coroner	scientist	desert	sandy_beach
cobra	puppy	executioner	teacher	wild_forest	natural_park
termite	pet	mortician	sea_captain	polar_desert	seaside

Table 2: Example of feature-based clustering for polarity-driven conceptual primitive inference.

5 Verb Concept Generalization

The second step in generalizing SenticNet concepts is to define conceptual primitives for verb concepts (or action concepts) so that, for example, verbs like `acquire`, `attain` or `collect` can be identified as `GET`. Such classification is implemented by applying dimensionality reduction techniques on the vector space representation of AffectNet. As with noun concepts, verb concepts are also associated with a polarity but, in this case, polarity is more relevant to the opposite meanings (or outcomes) these action concepts represent, as in `INCREASE` versus `DECREASE`. This allows for reasoning about verb+noun combinations to be as per algebraic multiplication, where negative multiplied by positive (or vice versa) results in a negative, e.g., `DECREASE_GAIN` (or `INCREASE_LOSS`), multiplying two positives produces a positive, e.g., `INCREASE_PLEASURE`, and negative multiplied by negative results in a positive, e.g., `DECREASE_PAIN`.

5.1 AffectiveSpace

The human mind constructs intelligible meanings by continuously compressing over vital relations (Fauconnier and Turner, 2003). The compression principles aim to transform diffuse and distended conceptual structures into more focused versions so they can become more congenial for human understanding. In order to emulate such a process, we use simple but powerful meta-algorithms which underlie neuronal learning (Lee et al., 2011). These meta-algorithms should be fast, scalable, effective, with few-to-no specific assumptions and biologically plausible. Optimizing all the $\approx 10^{15}$connections formed through the last few million years of evolution is very unlikely. Objectively speaking, however, nature probably only optimizes the global connectivity (mainly the white matter) but leaves the other details to randomness (Balduzzi, 2013).

In this work, we use random projections (Bingham and Mannila, 2001) on the matrix representation of AffectNet in order to compress the semantic features associated with commonsense concepts and, hence, better perform analogical reasoning on these. Random projections are a data-oblivious method to map an original high-dimensional dataset into a much lower-dimensional subspace by using a Gaussian $\mathrm{N}(0,1)$ matrix, while at the same time, preserving pair-wise distances with high probability. This theoretically-solid and empirically-verified statement follows Johnson and Lindenstrauss's Lemma (Balduzzi, 2013), which states that, with high probability, for all pairs of points $\mathrm{x}, \mathrm{y} \in \mathrm{X}$ simultaneously:

$$\sqrt{\frac{m}{d}} \parallel x - y \parallel_2 (1-\varepsilon) \leq \parallel \Phi x - \Phi y \parallel_2 \leq \sqrt{\frac{m}{d}} \parallel x - y \parallel_2 (1+\varepsilon) \tag{3}$$

where X is a set of vectors in Euclidean space, d is the original dimension of this Euclidean space, m is the dimension of the space we wish to reduce the data points to, ε is a tolerance parameter measuring the maximum allowed distortion extent rate of the metric space, and Φ is a random matrix. Structured random projections for making matrix multiplication much faster was introduced in (Sarlos, 2006). When the number of features is much larger than the number of training samples ($d \gg n$), subsampled randomized Hadamard transform (SRHT) is preferred, as it behaves very much like Gaussian random matrices but accelerates the process from $\mathcal{O}(n\,d)$ to $\mathcal{O}(n\,log\,d)$ time (Lu et al., 2013). Following (Tropp, 2011; Lu et al., 2013), for $d = 2^p$ (where p is any positive integer), a SRHT can be defined as:

$$\Phi = \sqrt{\frac{d}{m}} \mathrm{RHD} \tag{4}$$

where • m is the number we want to subsample from d features randomly;

• R is a random $m \times d$ matrix. The rows of R are m uniform samples (without replacement) from the standard basis of $\mathbb{R}^d$;

• H$\in \mathbb{R}^{d \times d}$ is a normalized Walsh-Hadamard matrix, which is defined recursively:

$H_d = \begin{bmatrix} H_{d/2} & H_{d/2} \\ H_{d/2} & -H_{d/2} \end{bmatrix}$ with $H_2 = \begin{bmatrix} +1 & +1 \\ +1 & -1 \end{bmatrix}$;

• D is a $d \times d$ diagonal matrix and the diagonal elements are i.i.d. Rademacher random variables.

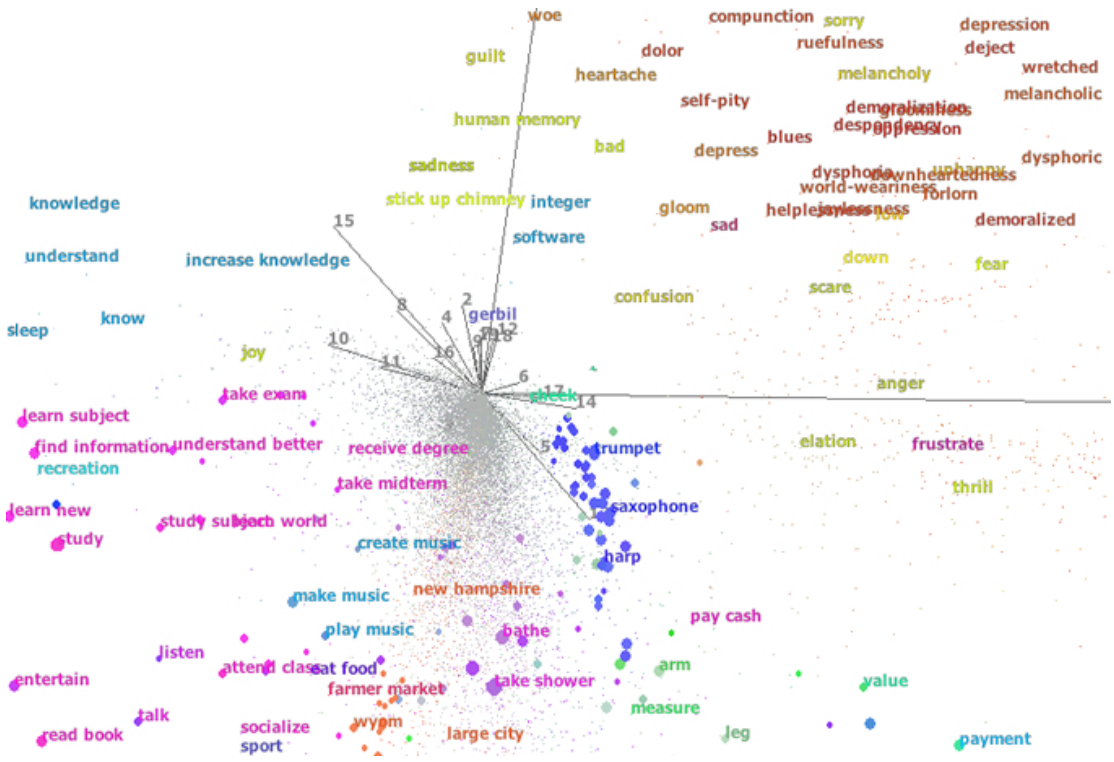

Figure 2: In AffectiveSpace, commonsense concepts gravitate around positive and negative emotions.

Our subsequent analysis only relies on the distances and angles between pairs of vectors (i.e., the Euclidean geometry information) and it is sufficient to set the projected space to be logarithmic in the size of the data (Ailon and Chazelle, 2010) and, hence, apply SRHT. The result is AffectiveSpace (Cambria et al., 2015), a vector space model where commonsense concepts and emotions are represented by vectors of m coordinates (Fig. 2).

By exploiting the information sharing property of random projections, concepts with the same semantic and affective valence are likely to have similar features – that is, concepts conveying the same meaning and emotion tend to fall near each other in AffectiveSpace. Similarity does not depend on concepts' absolute position in the vector space, but rather on the angle these make with the origin. For example, concepts such as `birthday_party`, `celebrate`, and `buy_cake` are found very closely positioned in the vector space, while concepts like `lose_faith`, `depressed`, and `shed_tear` are found in a completely different direction (nearly opposite with respect to the centre of the space).

5.2 Semi-Supervised Verb Propagation

AffectiveSpace allows for analogical reasoning about multiword expressions so that concepts such as `buy_groceries` and `go_shopping` will be detected as being semantically similar. In order to generalize verb concepts, however, we need to discriminate such reasoning according to actions, so that a concept like `buy_groceries` would be associated with concepts related to the verb `buy`, e.g., `buy_milk` or `purchase_vegetable`.

To this end, we leverage on VerbNet (Schuler, 2005), the largest English verb lexicon currently available, and Sentic LDA (Poria et al., 2016c), a classification framework that integrates commonsense in the calculation of word distributions in the linear discriminant analysis (LDA) algorithm. In particular, we use a semi-supervised version of Sentic LDA in order to incorporate both supervised (VerbNet-labeled) and unsupervised information in such a way that a proper semantic space which reflects the desired information (verb concepts) is obtained. Given a set of verbs and a large amount of unlabeled instances in AffectiveSpace, the between-class scatter is to be maximized and the within-class scatter of VerbNet instances is to be minimized, keeping the semantic relatedness of all the other instances simultaneously.

Each instance is denoted as $v_i \in \mathcal{A}^m$, which is the m-dimensional vector after being processed by random projections. For each verb instance, there is a label $y_i \in \{1, \ldots, q\}$, where q is the number of verb classes. Then, the between-class scatter and the within-class scatter matrices are defined as follows:

$$S_w = \sum_{j=1}^{q} \sum_{i=1}^{l_j} (v_i - \mu_j)(v_i - \mu_j)^T \tag{5}$$

$$S_b = \sum_{j=1}^{q} l_j (\mu_j - \mu)(\mu_j - \mu)^T \tag{6}$$

where $\mu_j = \frac{1}{l_j} \sum_{i=1}^{l_j} v_i$ $(j = 1, 2, ..., q)$ is the mean of the samples in class j, l_j is the number of verb instances in class j and $\mu = \frac{1}{l} \sum_{i=1}^{l} v_i$ is the mean of all the labeled samples. A total scatter matrix on all the instances in AffectiveSpace is also defined:

$$S_t = \sum_{i=1}^{k} (v_i - \mu_k)(v_i - \mu_k)^T \tag{7}$$

where k is the total number of instances in AffectiveSpace and μ_k is the mean of all the instances. Our objective is then to find a projection matrix W to project the semantic space to a lower-dimensional space, which is more discriminative towards verb concepts:

$$W^* = \arg \max_{W \in \mathcal{A}^{m \times m'}} \frac{|W^T S_b W|}{|W^T (S_w + \lambda_1 S_t + \lambda_2 I) W|} \tag{8}$$

where I is identity matrix, and λ_1 and λ_2 are control parameters, obtained through a grid search, for balancing the trade-off between verb discriminant and semantic regularizations. The optimal solution is given by:

$$(S_w + \lambda_1 S_t + \lambda_2 I) w_j^* = \eta_j S_b w_j^* \quad j = 1, ..., m' \tag{9}$$

where w_j^* $(j = 1, ..., m')$ are the eigenvectors corresponding to the m' largest eigenvalues of $(S_w + \lambda_1 S_t + \lambda_2 I)^{-1} S_b$. Here, $m' = q - 1$ is selected, where q is the total verb primitive number. After the projection, the new space preserves both semantic relatedness and action concept grouping based on the information coming from AffectNet and VerbNet, respectively.

6 Evaluation

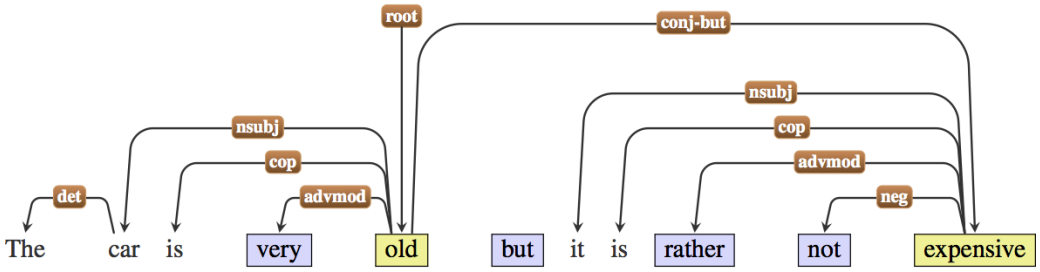
In order to perform a qualitative evaluation of SenticNet 4 (available both as a standalone XML repository[1] and as an API[2]), we asked five annotators to judge the plausibility of inferred conceptual primitives. We obtained an overall accuracy of 91% with Cohen's kappa score of 0.84. As for the quantitative evaluation, we tested SenticNet 4 against two well-known sentiment resources, namely: the Blitzer Dataset (Blitzer et al., 2007) and the Movie Review Dataset (Pang and Lee, 2005).

6.1 Performing Polarity Detection with SenticNet

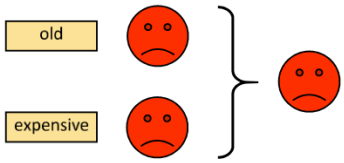
While SenticNet can be used as any other sentiment lexicon, e.g., concept matching or bag-of-concepts model, the right way to use the knowledge base for the task of polarity detection is in conjunction with sentic patterns (Poria et al., 2015). Sentic patterns are sentiment-specific linguistic patterns that infer polarity by allowing affective information to flow from concept to concept based on the dependency relation between clauses. The main idea behind such patterns can be best illustrated by analogy with an electronic circuit, in which few 'elements' are 'sources' of the charge or signal, while many elements operate on the signal by transforming it or combining different signals. This implements a rudimentary type of semantic processing, where the 'meaning' of a sentence is reduced to only one value: its polarity.

[1] `http://sentic.net/senticnet-4.0.zip`

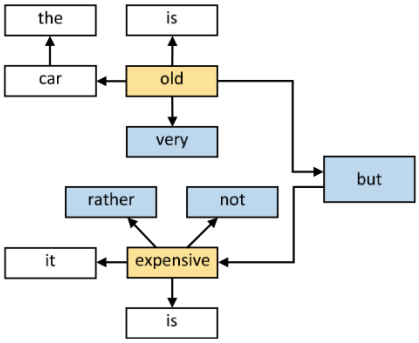
[2] `http://sentic.net/api`



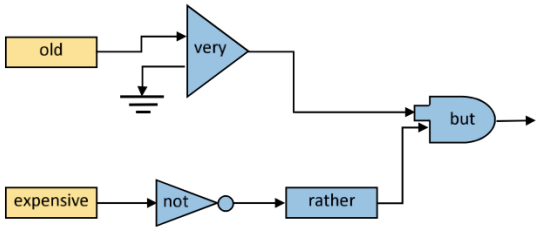
(a) Dependency tree of a sentence.



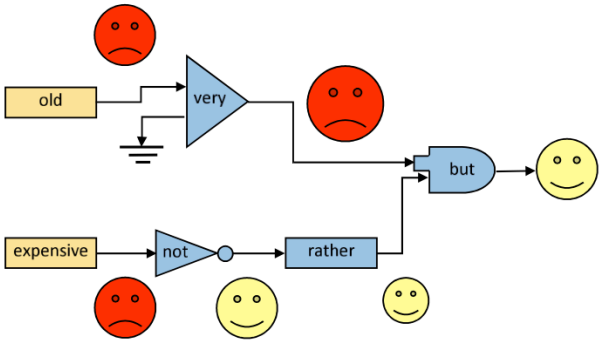
(b) The old way: averaging over a bag of sentiment words. The overall polarity of a sentence is given by the algebraic sum of the polarity values associated with each affect word divided by the total number of words.



(c) The dependency tree of a sentence resembles an electronic circuit: words shown in blue can be thought as a sort of "boolean operations" acting on other words.



(d) The electronic circuit metaphor: sentiment words are "sources" while other words are "elements", e.g., *very* is an amplifier, *not* is a logical complement, *rather* is a resistor, *but* is an OR-like element that gives preference to one of its inputs.



(e) The final sentiment data flow of the "signal" in the "circuit".

Figure 3: In sentic patterns, the structure of a sentence is like an electronic circuit where logical operators channel sentiment data-flows to output an overall polarity.

Sentic patterns are applied to the dependency syntactic tree of a sentence, as shown in Figure 3(a). The only two words that have intrinsic polarity are shown in yellow color; the words that modify the meaning of other words in the manner similar to contextual valence shifters (Polanyi and Zaenen, 2006) are shown in blue. A baseline that completely ignores sentence structure, as well as words that have no intrinsic polarity, is shown in Figure 3(b): the only two words left are negative and, hence, the total polarity is negative. However, the syntactic tree can be re-interpreted in the form of a 'circuit' where the 'signal' flows from one element (or subtree) to another, as shown in Figure 3(c). After removing the words not used for polarity calculation (in white), a circuit with elements resembling electronic amplifiers, logical complements, and resistors is obtained, as shown in Figure 3(d),

Figure 3(e) illustrates the idea at work: the sentiment flows from polarity words through shifters and combining words. The two polarity-bearing words in this example are negative. The negative effect of the word 'old' is amplified by the intensifier 'very'. However, the negative effect of the word 'expensive' is inverted by the negation, and the resulting positive value is decreased by the 'resistor'. Finally, the values of the two phrases are combined by the conjunction 'but', so that the overall polarity has the same sign as that of the second component (positive).

6.2 SenticNet 4 vs. SenticNet 3

The Blitzer Dataset consists of product reviews in seven different domains. For each domain there are 1,000 positive and 1,000 negative reviews. In evaluating SenticNet 4, we only used reviews under the *electronics* category. From these, we randomly extracted 7,210 non-neutral sentences: 3,800 of which were marked as positive and 3,410 as negative. We then compared the performance of SenticNet 4 with its predecessor SenticNet 3 for the task of sentence-level polarity detection, using sentic patterns. The results are shown in Table 3.

Table 3: Comparison on the Blitzer Dataset

Framework	Accuracy
Sentic Patterns and SenticNet 3	87.0%
Sentic Patterns and SenticNet 4	91.3%

6.3 SenticNet 4 vs. Statistical Methods

The Movie Review Dataset includes 1,000 positive and 1,000 negative movie reviews collected from Rotten Tomatoes[3]. Originally, Pang and Lee manually labeled each review as positive or negative. Later, Socher et al. (Socher et al., 2012; Socher et al., 2013) annotated this dataset at sentence level. They extracted 11,855 sentences from the reviews and manually labeled them using a fine-grained inventory of five sentiment labels: *strong positive*, *positive*, *neutral*, *negative*, and *strong negative*. Since in this work we consider only binary classification, we removed neutral sentences from the dataset and merged germane labels. Thus, the final dataset contained 4,800 positive sentences and 4,813 negative ones. The results of the classification with SenticNet 3 and SenticNet 4 are shown in Table 4.

Table 4: Comparison on the Movie Review Dataset

Framework	Accuracy
Socher et al., 2012	80.0%
Socher et al., 2013	85.4%
Sentic Patterns and SenticNet 3	86.2%
Sentic Patterns and SenticNet 4	90.1%

7 Conclusion

The distillation of knowledge from the huge amount of unstructured information on the Web is a key factor for tasks such as social media marketing, brand positioning, and financial prediction. Commonsense reasoning is a good solution for sentiment analysis but the scalability of commonsense knowledge bases is a major factor that jeopardizises the efficiency of concept extraction and polarity detection. A first possible step in solving this problem is to generalize pieces of commonsense knowledge in terms of conceptual primitives that could catch most semantic inflections of natural language concepts.

In this work, we used an ensemble of hierarchical clustering and dimensionality reduction for automatically discovering the primitives for both noun and verb concepts in SenticNet. This generalization process allowed us to largely extend the coverage of the commonsense knowledge base and, hence, to boost the accuracy of SenticNet for sentence-level polarity detection in comparison with both the previous version of the resource and with state-of-the-art statistical sentiment analysis research.

In the future, we plan to discover new conceptual primitives in a more automatic and scalable way by means of dependency-based word embeddings. In particular, we will exploit the internally-learned context embeddings of the skip-gram model in conjunction with the standard target word embeddings, to weigh context compatibility together with word similarity.

Joint Embedding of Hierarchical Categories and Entities for Concept Categorization and Dataless Classification

Abstract

Existing work learning distributed representations of knowledge base entities has largely failed to incorporate rich categorical structure, and is unable to induce category representations. We propose a new framework that embeds entities and categories jointly into a semantic space, by integrating structured knowledge and taxonomy hierarchy from large knowledge bases. Our framework enables to compute meaningful semantic relatedness between entities and categories in a principled way, and can handle both single-word and multiple-word concepts. Our method shows significant improvement on the tasks of concept categorization and dataless hierarchical classification.

1 Introduction

Hierarchies, most commonly represented as tree or directed acyclic graph (DAG) structures, provide a natural way to categorize and locate knowledge in large knowledge bases (KBs) . For example, WordNet (Fellbaum, 1998), Freebase (Bollacker et al., 2008), and Wikipedia [1] use hierarchical taxonomy to organize entities into category hierarchies. These hierarchical categories could benefit applications such as object and concept categorization (Verma et al., 2012; Rothenhäusler and Schütze, 2009), document classification (Gopal and Yang, 2013; Hu et al., 2016), and link prediction on knowledge graphs (Lin et al., 2015; Zhang et al., 2016). In all of these applications, it is essential to have a good representation of categories and entities as well as a good semantic relatedness measure.

In this paper, we propose two models to learn distributed representations of both entities and categories from large-scale knowledge bases (KBs). The **Category Embedding (CE) model** extends the entity embedding method of (Hu et al., 2015) and induces category embeddings in addition to entity vectors. The **Hierarchical Category Embedding (HCE) model** further enhances the CE model by integrating category hierarchical structure. The resulting entity and category vectors effectively capture meaningful semantic relatedness between entities and categories.

We train the category and entity vectors on Wikipedia, and evaluate our methods from two applications: **concept categorization** (Baroni and Lenci, 2010) and **dataless hierarchical classification** (Song and Roth, 2014). Our method achieves state-of-the-art performance on both tasks.

Figure 1 shows an overview of the research elements in this paper. In summary, we make the following contributions:

- We incorporate category information into entity embeddings with the proposed CE model to get entity and category embeddings simultaneously.
- We leverage category hierarchies and develop the HCE model to enhance the embedding quality.
- We propose a new concept categorization method based on nearest neighbor classification. Our method avoids the granularity disparity issue of categories which has plagued traditional clustering-based methods.

- We construct a new concept categorization dataset from Wikipedia.
- We show strong potential of utilizing entity embeddings on dataless classification.

2 Related Work

Entity embedding method is based on the analysis of distributional semantics, e.g., the recently proposed skip-gram model (Mikolov et al., 2013) that learns to predict context words given target words. This model tries to maximize the average log likelihood of the context words so that the embeddings encode meaningful semantics. For instance, entity hierarchy embedding (Hu et al., 2015) extends it to predict context entities given target entity in KBs. (Yamada et al., 2016) proposed a method to jointly embed words and entities by optimizing word-word, entity-word, and entity-entity predicting models. Our models extend this line of research by incorporating hierarchical category information to embed categories and entities in a joint semantic space.

Relational embedding, also known as knowledge graph embedding, is a family of methods to represent entities as vectors and relations as operations applied to entities such that certain properties are preserved (Paccanaro and Hinton, 2001; Bordes et al., 2011; Nickel et al., 2012; Bordes et al., 2013; Neelakantan and Chang, 2015). For instance, the linear relational embedding (Paccanaro and Hinton, 2001) applies a relation to an entity based on matrix-vector multiplication, while TransE (Bordes et al., 2013) simplifies the operation to vector addition. To derive the embedding representation, they minimize a global loss function considering all (entity, relation, entity) triplets so that the embeddings encode meaningful semantics. Our approach differs from this line as we learn from raw text in addition to knowledge graphs, and methodologically use probabilistic models instead of transition-based models.

Category embedding has been widely explored within different context. (Weinberger and Chapelle, 2009) initially proposed a taxonomy embedding to achieve document categorization and derive the embeddings of taxonomies of topics in form of topic prototypes. Furthermore, (Hwang and Sigal, 2014) proposed a discriminative learning framework that can give category embeddings by approximating each category embeddings as a sum of its direct super-category plus a sparse combination of attributes. These methods have primarily targeted on documents/object classification rather than entity representations.

Several recent methods are proposed to extend word representation to phrases (Yin and Schütze, 2014; Yu and Dredze, 2015; Passos et al., 2014). However, they do not use structured knowledge to derive phrase representations.

3 Joint Embedding of Categories and Entities

In order to find representations for categories and entities that can capture their semantic relatedness, we use existing hierarchical categories and entities labeled with these categories, and explore two methods: 1) **Category Embedding model** (CE Model): it replaces the entities in the context with their directly labeled categories to build categories' context; 2) **Hierarchical Category Embedding** (HCE Model): it further incorporates all ancestor categories of the context entities to utilize the hierarchical information.

3.1 Category Embedding (CE) Model

Our category embedding (CE) model is based on the Skip-gram word embedding model(Mikolov et al., 2013). The skip-gram model aims at generating word representations that are good at predicting *context* words surrounding a *target* word in a sliding window. Previous work (Hu et al., 2015) extends the entity's context to the whole article that describes the entity and acquires a set of entity pairs $\mathbf{D} = \{(e_t, e_c)\}$, where e_t denotes the *target* entity and e_c denotes the *context* entity.

Our CE model extends those approaches by incorporating category information. In KBs such as Wikipedia, category hierarchies are usually given as DAG or tree structures, and entities are categorized into one or more categories as leaves. Thus, in KBs, each entity e_t is labeled with one or more categories $(c_1, c_2, ..., c_k), k \geq 1$ and described by an article containing other *context* entities (see Data in Figure 1).

To learn embeddings of entities and categories simultaneously, we adopt a method that incorporates the labeled categories into the entities when predicting the context entities, similar to TWE-1 model (Liu et al., 2015) which incorporates topic information with words to predict context words. For example, if e_t is the *target* entity in the document, its labeled categories $(c_1, c_2, ..., c_k)$ would be combined with the entity e_t to predict the context entities like e_{c1} and e_{c2} (see CE Model in Figure 1). For each target-context entity pair (e_t, e_c), the probability of e_c being context of e_t is defined as the following softmax:

$$P(e_c|e_t) = \frac{\exp(e_t \cdot e_c)}{\sum_{e \in \mathbf{E}} \exp(e_t \cdot e)}, \tag{1}$$

where $\mathbf{E}$ denotes the set of all entity vectors, and $\exp$ is the exponential function. For convenience, here we abuse the notation of e_t and e_c to denote a target entity vector and a context entity vector respectively.

Similar to TWE-1 model, We learn the target and context vectors by maximizing the average log probability:

$$L = \frac{1}{|\mathbf{D}|} \sum_{(e_c, e_t) \in \mathbf{D}} \Big[\log P(e_c|e_t) + \sum_{c_i \in \mathbf{C}(e_t)} \log P(e_c|c_i) \Big], \tag{2}$$

where $\mathbf{D}$ is the set of all entity pairs and we abuse the notation of c_i to denote a category vector, and $\mathbf{C}(e_t)$ denotes the categories of entity e_t.

3.2 Hierarchical Category Embedding(HCE) Model

From the design above, we can get the embeddings of all categories and entities in KBs without capturing the semantics of hierarchical structure of categories. In a category hierarchy, the categories at lower layers will cover fewer but more specific concepts than categories at upper layers. To capture this feature, we extend the CE model to further incorporate the ancestor categories of the target entity when predicting the context entities (see HCE Model in Figure 1). If a category is near an entity, its ancestor categories would also be close to that entity. On the other hand, an increasing distance of the category from the target entity would decrease the power of that category in predicting context entities. Therefore, given the target entity e_t and the context entity e_c, the objective is to maximize the following weighted average log probability:

$$L = \frac{1}{|\mathbf{D}|} \sum_{(e_c, e_t) \in \mathbf{D}} \Big[\log P(e_c|e_t) + \sum_{c_i \in \mathbf{A}(e_t)} w_i \log P(e_c|c_i) \Big], \tag{3}$$

where $\mathbf{A}(e_t)$ represents the set of ancestor categories of entity e_t, and w_i is the weight of each category in predicting the context entity. To implement the intuition that a category is more relevant to its closer ancestor, for example, "NBC Mystery Movies" is more relevant to "Mystery Movies" than "Entertainment", we set $w_i \propto \frac{1}{l(c_c, c_i)}$ where $l(c_c, c_i)$ denotes the average number of steps going down from category c_i to category c_c, and it is constrained with $\sum_i w_i = 1$.

Figure 2 presents the results of our HCE model for DOTA-all data set (see Section 5.1.1). The visualization shows that our embedding method is able to clearly separate entities into distinct categories.

Figure 2: Category and entity embedding visualization of the DOTA-all data set (see Section 5.1.1). We use t-SNE (Van der Maaten and Hinton, 2008) algorithms to map vectors into a 2-dimensional space. Labels with the same color are entities belonging to the same category. Labels surrounded by a box are categories vectors.

3.3 Learning

Learning CE and HCE models follows the optimization scheme of skip-gram model (Mikolov et al., 2013). We use negative sampling to reformulate the objective function, which is then optimized through stochastic gradient descent (SGD).

Specifically, the likelihood of each context entity of a target entity is defined with the softmax function in Eq. 1, which iterates over all entities. Thus, it is computationally intractable. We apply the standard negative sampling technique to transform the objective function in equation (3) to equation (4) below and then optimize it through SGD:

$$L = \sum_{(e_c,e_t)\in\mathbf{D}} \Big[\log\sigma(e_c\cdot e_t) + \sum_{c_i\in\mathbf{A}(e_t)} w_i \log\sigma(e_c\cdot c_i)\Big] + \sum_{(e'_c,e_t)\in\mathbf{D}'} \Big[\log\sigma(-e'_c\cdot e_t) + \sum_{c_i\in\mathbf{A}(e_t)} w_i \log\sigma(-e'_c\cdot c_i)\Big], \quad (4)$$

where $\mathbf{D}'$ is the set of negative sample pairs and $\sigma(x) = 1/(1+\exp(-x))$ is the sigmoid function.

4 Applications

We apply our category and entity embedding to two applications: concept categorization and dataless hierarchical classification.

4.1 Concept Categorization

Concept[2] categorization, also known as *concept learning* or *noun categorization*, is a process of assigning a concept to one candidate category, given a set of concepts and candidate categories. Traditionally, concept categorization is achieved by **concept clustering** due to the lack of category representations. Since our model can generate representations of categories, we propose a new method of using **nearest neighbor (NN) classification** to directly categorize each concept to a certain category.

The **concept clustering** is defined as: given a set of concepts like *dog, cat, apple* and the corresponding gold standard categorizations like *animal, fruit*, apply a word space model to project all the concepts to

[2]In this paper, concept and entity denote the same thing.

a semantic space and perform clustering. The clustering results can be evaluated by comparing with the gold standard categorizations. Since we have representation of categories, we propose **nearest neighbor (NN) classification** to categorize concepts by directly comparing concept vectors with candidate category vectors. Precisely, given a set of concepts $\mathbf{E}$ and a set of candidate categories $\mathbf{C}$, we convert all concepts to concept vectors and all candidate categories to category vectors. Then we use the equation $c = \text{argmin}_{c_i \in \mathbf{C}} ||c_i - e||$ to assign the concept vector e with category c.

Since purity works as a standard evaluation metric for clustering (Rothenhäusler and Schütze, 2009), to compare our model with the concept clustering, we also use purity to measure our model's performance. Specifically, **purity** is defined as:

$$\text{purity}(\mathbf{\Omega}, \mathbf{G}) = \frac{1}{n} \sum_k \max_j |\omega_k \cap g_j|, \tag{5}$$

where $\mathbf{\Omega}$ denotes a clustering solution, $\mathbf{G}$ is a set of gold standard classes, n is the number of instances, k is the cluster index and j is the class index, ω_k represents the set of labels in a cluster and g_j is the set of labels in a class. A higher purity indicates better model performance.

4.2 Dataless Classification

Dataless classification uses the similarity between documents and labels in an enriched semantic space to determine in which category the given document is. It has been proved that explicit semantic analysis (ESA) (Gabrilovich and Markovitch, 2007) has shown superior performance on dataless classification (Song and Roth, 2014). ESA uses a bag-of-entities retrieved from Wikipedia to represent the text. For example, the document *"Jordan plays basketball"* can be represented as a ESA sparse vector of {*Michael Jordan:48.3, Basketball:29.8, Air Jordan: 28.8, Outline of basketball: 28.5, Chicago Bulls: 23.6*} in an ESA implementation. After converting documents and short label descriptions to ESA vectors, a nearest neighbor classifier is applied to assign labels for each document.

Due to sparsity problem of ESA vectors, sparse vector densification is introduced to augment the similarity calculation between two ESA vectors (Song and Roth, 2015). This is achieved by considering pairwise similarity between entities in ESA vectors. However, they simply use word2vec (Mikolov et al., 2013) to derive entity representation. We extend it by directly applying entity embeddings and show the potential of entity embeddings to improve dataless classification.

We use averaged F_1 scores to measure the performance of all methods (Yang, 1999). Let TP_i, FP_i, FN_i denote the true-positive, false-positive and false-negative values for the ith label in label set T, the micro- and macro-averaged F_1 scores are defined as: $MicroF_1 = 2\overline{P} * \overline{R}/(\overline{P} + \overline{R})$ and $MacroF_1 = \frac{1}{|T|} \sum_i^{|T|} \frac{2P_i * R_i}{P_i + R_i}$, where $P_i = TP_i/(TP_i + FP_i)$ and $R_i = TP_i/(TP_i + FN_i)$ are precision and recall for ith label, $\overline{P} = \sum_i^{|T|} TP_i / \sum_i^{|T|} (TP_i + FP_i)$ and $\overline{R} = \sum_i^{|T|} TP_i / \sum_i^{|T|} (TP_i + FN_i)$ are averaged precision and recall for all labels.

5 Experiments

In the experiments, we use the dataset collected from Wikipedia on Dec. 1, 2015[3] as the training data. We preprocess the category hierarchy by pruning administrative categories and deleting bottom-up edges to construct a DAG. The final version of data contains 5,373,165 entities and 793,856 categories organized as a DAG with a maximum depth of 18. The root category is "main topic classifications". We train category and entity vectors in dimensions of 50, 100, 200, 250, 300, 400, 500, with batch size $B = 500$ and negative sample size $k = 10$.

With the training dataset defined above, we conduct experiments on two applications: concept categorization and dataless hierarchical classification.

[3] https://dumps.wikimedia.org/wikidatawiki/20151201/

5.1 Concept Categorization

5.1.1 Datasets

There are two datasets used in this experiment. The first one is the **Battig** test set introduced by (Baroni and Lenci, 2010), which includes 83 concepts from 10 categories. The **Battig** test set only contains single-word concepts without any multiple-word concepts (e.g., "table tennis"). Hence, using this dataset restricts the power of concept categorization to single-word level. We use this dataset because it has been used as a benchmark for most previous approaches for concept categorization.

Due to the limitations of the **Battig** test set, we construct a new entity categorization dataset **DOTA** (Dataset Of enTity cAtegorization) with 450 entities categorized into 15 categories (refer to Appendix A). All the categories and entities are extracted from Wikipedia, so the resulting dataset does not necessarily contains only single-word entities. Thus, the dataset can be split into two parts, **DOTA-single** that contains 300 single-word entities categorized into 15 categories and **DOTA-mult** that contains 150 multiple-word entities categorized into the same 15 categories. We design the **DOTA** dataset based on the following principles:

Coverage vs Granularity: Firstly, the dataset should cover at least one category of Wikipedia's main topics including "Culture", "Geography", "Health", "Mathematics", "Nature", "People", "Philosophy", "Religion", "Society" and "Technology". Secondly, categories should be in different granularity, from large categories (e.g.,"philosophy") to small categories (e.g., "dogs"). Large categories are ones that are located within 5 layers away from the root, medium categories are 6-10 layers away from the root, while small categories have distance of 11-18 to the root. Our dataset consists of 1/3 large categories, 1/3 medium categories, and 1/3 small categories.

Single-Words vs Multiple-Words: Previous concept categorization datasets only contain single-words. However, some concepts are multiple-words and cannot be simply represented by single-words. For example, the concept "hot dog" is very different from the concept "dog". Therefore, we make each category of the dataset contain 10 multiple-word entities and 20 single-word entities.

5.1.2 Baselines

We compare our entity and category embeddings with the following state of the art word and entity embeddings.

WE$_{Mikolov}$(Mikolov et al., 2013): We trained word embeddings with Mikolov's word2vec toolkit[4] on the same Wikipedia corpus as ours (1.7 billion tokens) and then applied the Skip-gram model with negative sample size of 10 and window size of 5 in dimensionality of 50, 100, 200, 250, 300, 400, 500.

WE$_{Senna}$ (Collobert et al., 2011): We downloaded this 50-dimension word embedding[5] trained on Wikipedia over 2 months. We use this embedding as a baseline because it is also trained on Wikipedia.

Given the above semantic representation of words, we derive each entity/category embedding by averaging all word vectors among each entity/category label. If the label is a phrase that has been embedded (e.g., Mikolov's embedding contains some common phrases), we direct use the phrase embedding.

HEE (Hu et al., 2015): This Hierarchical Entity Embedding method uses the whole Wikipedia hierarchy to train entity embeddings and distance metrics. We used the tools provided by the authors to train entity embeddings on the same Wikipedia corpus as ours. We set the batch size B = 500, the initial learning rate η = 0.1 and decrease it by a factor of 5 whenever the objective value does not increase, and the negative sample size k = 5 as suggested by the authors. This method doesn't provide a way of learning category embeddings. Therefore, it cannot be used in the **nearest neighbor classification** method.

TransE (Bordes et al., 2013): It is a state of the art relational embedding method introduced in Section. 2, which embeds entities and relations at the same time. It can be extended to derive category embeddings, since categories can be seen as a special entity type. To make comparisons fair enough, we adopt three different versions of TransE to derive entity and category embedding to compare with our methods. **TransE**$_1$: Use entities and categories as two entity types and the direct-labeled-category relation. So the triplets we have is in the form of (entity, direct-labeled-category, category). **TransE**$_2$: Add

[4]https://code.google.com/archive/p/word2vec/

[5]http://ronan.collobert.com/senna/

to TransE$_1$ with the hierarchy structure of wikipedia categories. Namely, add the super-category relation between categories. Therefore we have new triplets in the form of (category, super-category, category).
TransE$_3$: To make it use full information as ours, we extend TransE$_2$ to utilize context entity relationship described in Section. 3.1. Therefore we add new triplets in the form of (entity, context-entity, entity).

HC: To further evaluate the advantage of utilizing category hierarchy in training entity and category embedding, we also compare our Hierarchical Category Embedding (HCE) model with our Category Embedding (CE) model that has no hierarchical information.

5.1.3 Results

In the experiments, we used scikit-learn (Pedregosa et al., 2011) to perform clustering. We tested k-means and hierarchical clustering with different distance metrics (euclidean, cosine) and linkage criterion (ward, complete, average). All these choices along with the vector dimensionality are treated as our models' hyper-parameters. For selecting hyper-parameters, we randomly split the Battig and Dota datasets to 50% of validation data and 50% of test data, evenly across all categories. We trained all the embeddings (except SENNA) on the same Wikipedia dump and tuned hyper-parameters on the validation set. For experiments on Dota dataset, since the ground truth is contained in our Wikipedia corpus, we deleted all category-entity links contained in Dota dataset from our category hierarchy to train HEE, TransE and HCE embeddings to make comprison fair enough.

Table. 1a shows the experimental results of the **concept clustering** method. It is clear that **hierarchical category embedding** (HCE) model outperforms other methods in all datasets. Our model achieves a purity of 89% on Battig and 89% on DOTA-all.

	Battig	DOTA-single	DOTA-mult	DOTA-all
WE$_{Senna}$ (50,50)	0.74	0.61	0.43	0.45
WE$_{Mikolov}$ (400,400)	0.86	0.83	0.73	0.78
HEE (400,400)	0.82	0.83	0.80	0.81
TransE$_1$ (300,250)	0.67	0.71	0.68	0.69
TransE$_2$ (400,300)	0.73	0.78	0.75	0.76
TransE$_3$ (200,400)	0.43	0.53	0.50	0.51
CE (300,200)	0.84	0.86	0.83	0.85
HCE (400,400)	**0.89**	**0.92**	**0.88**	**0.89**

(a) Purity of **concept clustering** method

	Battig	DOTA-single	DOTA-mult	DOTA-all
WE$_{Senna}$ (50,50)	0.44	0.52	0.32	0.45
WE$_{Mikolov}$ (400,400)	0.74	0.74	0.67	0.72
HEE	-	-	-	-
TransE$_1$ (300,250)	0.66	0.72	0.69	0.71
TransE$_2$ (400,300)	0.75	0.80	0.77	0.79
TransE$_3$ (300,400)	0.46	0.55	0.52	0.54
CE (200,200)	0.79	0.89	0.85	0.88
HCE (400,400)	**0.87**	**0.93**	**0.91**	**0.92**

(b) Purity of **NN classification** method

Table 1: Purity of **nearest neighbor (NN) classification** and **concept clustering** methods with different embeddings on Battig and DOTA datasets. The two numbers given in each parentheses are the vector dimensionality among {50,100,200,250,300,400,500} that produce the best results on Battig and Dota validation set respectively. All the purity scores are calculated under such choices of hyper-parameters on the test set.

For word embeddings like Mikolov and Senna, the performance drops a lot from single-word entity categorization to multiple-word entity categorization, because these embeddings mainly contain single words. To get the embeddings of multiple-word, we use the mean word vectors to denote multiple-word embeddings. However, the meaning of a multiple-word is not simply the aggregation of the meaning of the words it contains. The good performance of HEE shows the high quality of its entity embeddings. By incorporating category hierarchy information, TransE$_2$ gets an advantage over TransE$_1$. This advantage can also be observed when we incorporate category hierarchy information into CE. However, further incorporating of context entities deteriorates the performance of TransE. This may due to the nature of transition-based models that assume relationships as transitions among entities. They get much noise when introduced with many context entity triplets along with only one entity-to-context-entity relation type.

Table.1b shows the experimental results of the **nearest neighbor (NN) classification** method. The results indicate the feasibility of using category vectors to directly predict the concept categories without clustering entities. Our model achieves a purity of 87% on Battig and 92% on DOTA-all.

5.2 Dataless Classification

5.2.1 Datasets

20Newsgroups Data(20NG): The 20 newsgroups dataset (Lang, 1995) contains about 20,000 newsgroups documents evenly categorized to 20 newsgroups, and further categorized to six super-classes. We use the same label description provided by (Song and Roth, 2014).

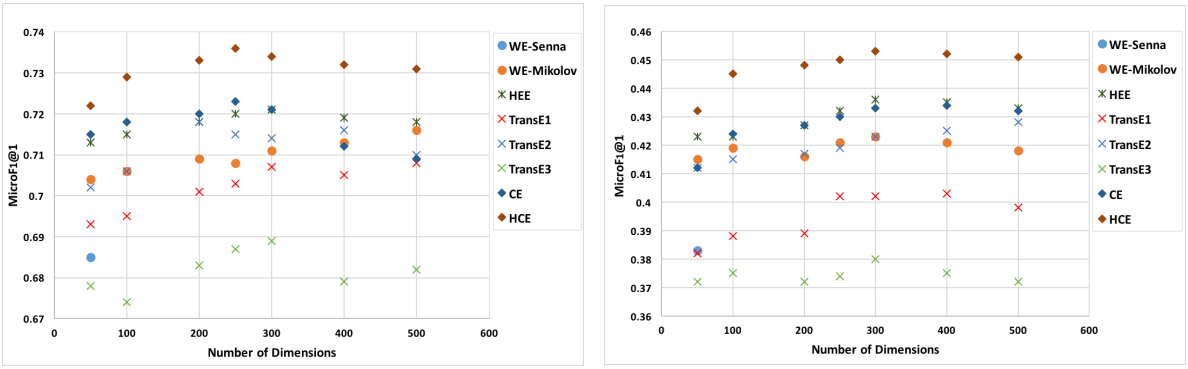
RCV1 Dataset: The RCV1 dataset (Lewis et al., 2004) contains 804,414 manually labeled newswire documents, and categorized with respect to three controlled vocabularies: industries, topics and regions. We use topics as our hierarchical classification problem. There are 103 categories including all nodes except for the root in the hierarchy, and the maximum depth is 4. To ease the computational cost of comparison, we follow the chronological split proposed in (Lewis et al., 2004) to use the first 23,149 documents marked as training samples in the dataset. The dataset also provides the name and the description of each category label.

5.2.2 Implementation Details

The baseline of similarity measure between each label and each document is cosine similarity between corresponding ESA vectors. We use ESA with 500 entities, and augment similarity measure by plugging in different embeddings introduced in Section. 5.1.2 with Hungarian sparse vector densification method described in (Song and Roth, 2015). The Hungarian method is a combinatorial optimization algorithm aiming to find an optimal assignment matching the two sides of a bipartite graph on a one-to-one basis. We average over all cosine similarities of entity pairs produced by the Hungarian method to produce similarity between ESA vectors. In addition, we cut off all entity similarities below 0.85 and map them to zero empirically.

For classification, We use the bottom-up pure dataless hierarchical classification algorithm which proved to be superior in (Song and Roth, 2014) and set the threshold δ to be 0.95 empirically.

5.2.3 Results



(a) 20newsgroups: bottom-up (ESA:0.682)

(b) RCV1: bottom-up (ESA:0.371)

Figure 3: MicroF$_1$@1 results of ESA augmented with different embeddings for dataless hierarchical classification. It is clear the ESA densified with HCE performs best on dataless hierarchical classification.

We perform dataless hierarchical classification using the same ESA settings, densified with different embedding methods for similarity calculation. Figure. 3 presents the classification performance with different embedding methods in dimensionality of {50,100,200,250,300,400,500}. It is clear that ESA densified with HCE stably outperform other competitive methods on these two datasets, which indicates the high quality of entity embeddings derived by HCE.

Besides, we observe that entity embedding methods such as TransE$_2$, HEE and HCE perform better than word embedding methods. This is because ESA represents text as bag-of-entities, and entity embeddings successfully encode entity similarities. Compared with bag-of-words baselines in (Song and Roth, 2014), it is clear that bag-of-entities models can better capture semantic relatedness between documents and short category descriptions.

6 Conclusion

In this paper, we proposed a framework to learn entity and category embeddings to capture semantic relatedness between entities and categories. This framework can incorporate taxonomy hierarchy from large scale knowledge bases. Experiments on both concept categorization and dataless hierarchical classification indicate the potential usage of category and entity embeddings on more other NLP applications.

Abstract

Topic modeling and word embedding are two important techniques for deriving latent semantics from data. General-purpose topic models typically work in coarse granularity by capturing word co-occurrence at the document/sentence level. In contrast, word embedding models usually work in fine granularity by modeling word co-occurrence within small sliding windows. With the aim of deriving latent semantics by capturing word co-occurrence information at different levels of granularity, we propose a novel model named *Latent Topic Embedding* (LTE), which seamlessly integrates topic generation and embedding learning in one unified framework. We further propose an efficient Monte Carlo EM algorithm to estimate the parameters of interest. By retaining the individual advantages of topic modeling and word embedding, LTE results in better latent topics and word embedding. Experimental results verify the superiority of LTE over the state-of-the-arts in real-life applications.

1 Introduction

Topic modeling and word embedding are gaining significant momentum in the field of text mining. General-purpose topic models such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003) and Sentence LDA (Jo and Oh, 2011) usually utilize word co-occurrences at the document/sentence level to compose the "topics", which capture the latent semantics between words. These models are plagued by the simplistic bag-of-words assumption, which ignores the valuable sub-sequence information between words. Some recent endeavors introduced n-gram information into topic models (Wallach, 2006), however, the size of vocabulary is significantly enlarged and these techniques are hardly feasible for real-life applications. Therefore, the technique of topic modeling needs a remedy for solving the word sequence problem with fairly low cost. Word embedding models such as Word2Vec (Mikolov et al., 2013a) map words into distributed representations. Word embedding models primarily focus on the word co-occurrences within small sliding windows, which enable word embedding to capture (at least partially) the information of word sequences. One key problem of the existing word embedding models is that they are typically short-sighted and are not aware of the themes of the document.

With their differences, the core of topic modeling and word embedding is based upon the assumption that the words co-occurring frequently should have semantic commonality. In light of their individual advantages and drawbacks, we see that the two techniques are essentially complimentary and can be integrated to enhance each other. In this paper, we propose the *Latent Topic Embedding* (LTE) to seamlessly integrate topic modeling and word embedding in one framework. In the generative process of LTE, we assume that the observed words in document can be generated through two channels: one is through the Multinomial distribution and the other is based upon topic embeddings as well as word embeddings. In this way, the embedding information influences the result of topic modeling while the topic information affects the training of word embeddings in return. LTE enables topic modeling to utilize word sequence information and it equips word embeddings with the document-level vision. We propose a Monte Carlo

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2689–2698, Osaka, Japan, December 11-17 2016.

EM algorithm to efficiently infer the parameters of interest in LTE. Extensive experiments on real-life applications verify the superiority of LTE over several strong baselines.

The rest of this paper is organized as follows. In Section 2, we review the related work. In Section 3, we discuss the technical details of LTE. In Section 4, we illustrate how to conduct parameter inference for LTE. In Section 5, we present the experimental results. Finally, we conclude this paper in Section 6.

2 Related Work

The present work is related to previous research on topic modeling and word embedding. Latent Dirichlet allocation (LDA) is a generative probabilistic model for collections of discrete data such as text corpora (Blei et al., 2003)(Griffiths and Steyvers, 2004). LDA and its variants has been widely employed in many texting mining scenarios (Wang and McCallum, 2006)(Krestel et al., 2009)(Xu et al., 2009)(Jiang et al., 2013) and demonstrated promising performance. It is worth mentioning that some work such as the bigram topic model (Wallach, 2006) aims to alleviate the negative effect of bag-of-words assumption in LDA. However, considerable computational cost is involved since the bigram model creates a multinomial distribution for each pair of the topics and the words, the amount of which is usually voluminous. While topic modeling received intensive research in the field of Bayesian network research, word embedding received much attention in the field of neural network. Word embedding (Bengio et al., 2003) is proposed to fight the curse of dimensionality by learning a distributed representation for words which allows each training sentence to inform the model about an exponential number of semantically neighboring sentences. Mikolov presented several extensions of Skip-gram that improve both the quality of the vectors and the training speed (Mikolov et al., 2013b) (Mikolov et al., 2013a). Paragraph vector that is an unsupervised algorithm that learns fixed-length feature representations from variable-length pieces of texts was proposed in (Le and Mikolov, 2014). Word embedding is adapted for incorporating contextual information in learning vector-space representations of situated language (Bamman et al., 2014). A more relevant work is (Liu et al., 2015), which inputs the result of topic modeling into word embedding models to learn the topical word embedding. The major difference between this work and ours is that they did not aim to integrate topic modeling and word embedding and yet only utilizes the result of topic modeling as the input of word embedding models. Recently, (Nguyen et al., 2015) extended two Dirichlet multinomial topic models by incorporating word embeddings to improve the word-topic mapping. (Li et al., 2016) proposed a generative model that replaces the Multinomial word generation assumption of LDA with embedding based assumption.

Although topic modeling and word embedding receive intensive attention in recent years, to the best of our knowledge, there is no previous endeavor on integrating them together as a joint learning task to enhance each other. LTE paves the way for collectively modeling of word co-occurrence information at different granularity levels while retaining the topic modeling result as well as the word embedding result.

3 Generative Process of Latent Topic Embedding

Latent Topic Embedding (LTE) views each document as a bag of sentences and each sentence is composed of words. The generative process of LTE is formally depicted in Algorithm 1. For each topic k, the corresponding multinomial topic-word distribution ϕ_k is drawn from $Dirichlet(\beta)$. When generating a document, a multinomial document-topic distribution θ_d is drawn from $Dirichlet(\alpha)$. For each sentence s in the document, we draw a latent topic z_{ds} based on the document-topic distribution. For each token in the document, we drawn an indicator i from Bernoulli(τ). If i is 0, the word w is generated according to topic-word distribution $\phi_{z_{ds}}$. If i is 1, the word w is generated according to topic-word distribution $P(w|z_{ds}, C_w, M)$, which is defined as follows:

$$P(w|z_{ds}, C_w, M) = P(v_w|\mathbf{x}_w) = \frac{e^{\mathbf{x}_w \cdot v_w}}{\sum_{w'} e^{\mathbf{x}_w \cdot v_{w'}}}. \quad (1)$$

In Eq. (1), C_w stands for the sliding window for w. Specifically, C_w contains several words that precedes w. where $M = \{\mathbf{v_w}, \mathbf{v_z}\}$ stands for the word embedding and the topic embedding, $\mathbf{x}_w$ is the result

of element-wise addition of the word embeddings of C_w and the topic embedding indexed by z_{ds} (i.e., $\mathbf{x}_w = \mathbf{v}_{c_w} \oplus v_{z_{ds}}$) and v_w is the embedding of w. The parameters of interest are ϕ, θ and M.

4 Training LTE

In Section 4.1, we describe how to sample the latent topics for sentences. In Section 4.2, we discuss how to optimize the vectors via stochastic gradient descent. The parameter inference algorithm is formally presented in Section 4.3.

4.1 Sampling Latent Variables

By translating the generative process of LTE into joint distribution, we aim to maximize the likelihood of the observed words $\mathbf{w}$: $P(\mathbf{w}|\alpha, \beta, \tau, M)$. Ideally, we would compute optimal M by maximizing $P(\mathbf{w}|\alpha, \beta, \tau, M)$ directly. However, evaluating this likelihood is intractable and what can be computed is the complete likelihood $p(\mathbf{w}, \mathbf{i}, \mathbf{z}|\alpha, \beta, \tau, M)$:

$$P(\mathbf{w}, \mathbf{i}, \mathbf{z}|\alpha, \beta, \tau, M) = P(\mathbf{z}|\alpha)P(\mathbf{i}|\tau)P(\mathbf{w}|\mathbf{z}, \mathbf{i}, \beta, M)$$
$$= \Big(\frac{\Gamma(\sum_{z=1}^{T}\alpha_z)}{\prod_{z=1}^{T}\Gamma(\alpha_z)}\Big)^D \prod_{d=1}^{D} \frac{\prod_{z=1}^{T}\Gamma(m_{dz}+\alpha_z)}{\Gamma(\sum_{z=1}^{T}(m_{dz}+\alpha_z))} \Big(\frac{\Gamma(\sum_{v=1}^{V}\beta_v)}{\prod_{v=1}^{V}\Gamma(\beta_v)}\Big)^T \prod_{z=1}^{T} \frac{\prod_{v=1}^{V}\Gamma(n_{zv}+\beta_v)}{\Gamma(\sum_{v=1}^{V}(n_{zv}+\beta_v))} \quad (2)$$
$$\prod_{d=1}^{D}\prod_{s\in d}\prod_{w\in s} P(v_w|\mathbf{x}_w)^{\mathcal{I}(i_w=1)} \times (1-\tau)^A \tau^B,$$

where m_{dz} is the number of sentences that are assigned to topic z in document d. n_{zv} is the number of times that v is assigned to topic z through Multinominal distribution and $\Gamma(\cdot)$ indicates Gamma function, A is the number of 0 that are generated by the Bernoulli distribution and B is the number of 1 that are generated by the Bernoulli distribution. By applying Bayes rule, the full conditional of assigning topic k to z_{ds} is obtained as follows:

$$P(z_{ds} = k, \mathbf{i}_{ds}|\mathbf{w}, \mathbf{z}_{-ds}, \mathbf{i}_{-ds}, \alpha, \beta, \tau, M) = (1-\tau)^{A_s}\tau^{B_s}$$
$$\frac{m_{dk}+\alpha_k}{\sum_{k'=1}^{K}(m_{dk'}+\alpha_{k'})} \frac{\Gamma(\sum_{w=1}^{W}(n_{kw}+\beta_w))}{\Gamma(\sum_{w=1}^{W}(n_{kw}+\beta_w+N_{iw}))} \prod_{w\in\mathbf{W}\&i_w=0} \frac{\Gamma(n_{kw}+\beta_w+N_{iw})}{\Gamma(n_{kw}+\beta_w)} \prod_{w\in s\&i_w=1} P(v_w|\mathbf{x}_w) \quad (3)$$

The possible combinations of $\mathbf{i}_{ds}$ is exponential in the length of the sentence s. Similar to (Nguyen et al., 2015), we conduct approximation of the above equation and integrate out $\mathbf{i}_{ds}$,

$$P(z_{ds}=k|\mathbf{w},\mathbf{z}_{-ds},\mathbf{i}_{-ds},\alpha,\beta,\tau,M)\approx\frac{m_{dk}+\alpha_k}{\sum_{k'=1}^{K}(m_{dk'}+\alpha_{k'})}\prod_{w\in s}\big((1-\tau)\frac{n_{kw}+\beta_w}{\sum_{w=1}^{W}(n_{kw}+\beta_w)}+\tau P(v_w|\mathbf{x}_w)\big) \tag{4}$$

Exactly calculating $P(v_w|\mathbf{x}_w)$ is computational infeasible, since the normalization term involves all the words in the vocabulary. Thus, we utilize noise contrastive estimation (NCE) to approximate it. The advantage of NCE is that it allows us to fit models that are not explicitly normalized making the training time effectively independent of the vocabulary size. Thus, we will be able to drop the normalization factor from the above equation, and simply use $e^{\mathbf{x}_w\cdot v_w}$ in place of $P(\mathbf{x}_w|v_w)$. Similar to the method described in (Mnih and Teh, 2012)(Dyer, 2014), we fixing the normalized constants in $P(\mathbf{x}_w|v_w)$ to 1, then we obtain the following approximation:

$$P(z_{ds}=k|\mathbf{w},\mathbf{z}_{-ds},\mathbf{i}_{-ds},\alpha,\beta,\tau,M)\propto(m_{dk}+\alpha_k)\prod_{w\in s}\big((1-\tau)\frac{n_{kw}+\beta_w}{\sum_{w=1}^{W}(n_{kw}+\beta_w)}+\tau e^{\mathbf{x}_w\cdot v_w}\big) \tag{5}$$

For each word w in sentence s, its latent indicator i_w is sampled as follows:

$$P(i_w=0|z_{ds}=k)\propto(1-\tau)\frac{n_{kw}+\beta_w}{\sum_{w=1}^{W}(n_{kw}+\beta_w)} \tag{6}$$

$$P(i_w=1|z_{ds}=k)\propto\tau e^{\mathbf{x}_w\cdot v_w} \tag{7}$$

The above sampling process repeats for a predefined number of iterations. It is worth mentioning that there are works about scaling up Gibbs sampling or make it more efficient. Since the topic of designing better Gibbs sampling algorithms is beyond the scope of this paper, interested readers may refer to (Newman et al., 2009) and (Wang et al., 2009) for more detailed information.

4.2 Embedding Optimization

Now we convert the joint likelihood in Eq. (2) to its logarithm form, which is defined as follows:

$$\begin{aligned}\mathcal{L}(\mathbf{w},\mathbf{i},\mathbf{z};\alpha,\beta,\tau,M)=D\log\Big(\frac{\Gamma(\sum_{z=1}^{T}\alpha_z)}{\prod_{z=1}^{T}\Gamma(\alpha_z)}\Big)+\sum_d\sum_z\log(\Gamma(m_{dz}+\alpha_z))-\\ \sum_d\log(\Gamma(\sum_z(m_{dz}+\alpha_z)))T\log\Big(\frac{\Gamma(\sum_{v=1}^{V}\beta_v)}{\prod_{v=1}^{V}\Gamma(\beta_v)}\Big)+\sum_z\sum_v\log(\Gamma(n_{zv}+\beta_v))-\\ \sum_z\log(\Gamma(\sum_v(n_{zv}+\beta_v)))+\sum_d\sum_{s\in d}\sum_{w\in s\&i_w=1}\log P(v_w|\mathbf{x}_w)+A\log(1-\tau)+B\log\tau.\end{aligned} \tag{8}$$

Eq. (8) is a separable function. Each hyperparameter can be independently maximized. The hyperparameters α, β and τ can be straightforwardly optimized by Newton-Raphson algorithm like (Blei et al., 2003). As we usually utilize fixed α and β, the focus now is to illustrate how to optimize the vectors in M through maximizing $\sum_d\sum_{s\in d}\sum_{w\in s\&i_w=1}\log P(v_w|\mathbf{x}_w)$whose corresponding NCE log-likelihood is as follows:

$$\begin{aligned}\sum_d\sum_{s\in d}\sum_{u\in w\cup NEG(w)}\Big\{&l_u^{c_w}\cdot\log[\sigma(\mathbf{x}_w\cdot v_u-\log(\frac{|NEG|}{|V|}))]+\\ &[1-l_u^{c_w}]\cdot\log[1-\sigma(\mathbf{x}_w\cdot v_u-\log(\frac{|NEG|}{|V|}))]\Big\},\end{aligned} \tag{9}$$

where $\sigma(\cdot)$ to denote the sigmoid function, |NEG| is the number of negative samples for each word and $|V|$ is the size of vocabulary. We use stochastic gradient descent to optimize the embedding, the update formula for v_u in C_w is as follows:

$$v_u:=v_u+\eta\sum_{u'\in w\cup NEG(w)}\Big[l_{u'}^{c_w}-\sigma(\mathbf{x}_w\cdot v_{u'}-\log(\frac{|NEG|}{|V|}))\Big]\cdot v_{u'}, \tag{10}$$

where $NEG(w)$ stands for the negative samples of w. The update formula for the topic embedding v_z is as follows:

$$v_z := v_z + \eta \sum_{u' \in w \cup NEG(w)} \left[l_{u'}^{c_w} - \sigma(\mathbf{x}_w \cdot v_{u'} - \log(\frac{|NEG|}{|V|})) \right] \cdot v_{u'}. \tag{11}$$

4.3 Monte Carlo EM

Based on the above discussion, we now formally present the parameter inference of LTE in Algorithm 2. After applying this algorithm, we obtain the quantities of interest such as Θ, Φ the topic embeddings and the word embeddings. Note that LTE covers both the outputs of topic model and the output of word embedding. Theoretically, it can be applied in any scenario where topic modeling or word embedding is previously utilized. In the experiments, we will show that retaining both the outputs of topic model and word embedding is critical for comprehensively capturing different kinds of latent semantics in text.

Algorithm 2: Monte Carlo EM

repeat
  run Gibbs sampling according to Eq. (5)(6)(7) ;
  optimize the corresponding parameters according to Eq. (10) and (11);
until *a predefined number of iterations*;

5 Experiments

In this section, we evaluate the performance of LTE. Unless otherwise stated, the experimental results are obtained when the size of the embedding is set to 20 and the size of the sliding window is 5. Similar insights are obtained when varying the two parameters and we skip them due to space limitation. In Section 5.1, we present some topic examples. In Section 5.2, we show the result of perplexity evaluation. In Section 5.3, we evaluate the the performance LTE through a task of topical word extraction.

Table 1: LTE Topic Examples (The number in brackets is the frequency of the word)

	Multinomial Perspective	Embedding Perspective
Topic1	Taiwan(2332), China(30904), issue(19080), unity(2165), relationship(6052), principle(2256), Taiwan independence(20), people(4172), mainland(1125), peace(699)	party(2), legislator(21), two states theory(1), tamper(42), attentively(1), Frank Hsieh(2), beautify(141), Taiwan independence(20), Tsai Ing-wen(12)
Topic2	space(4507), satellite(244), technology(9673), system(7348), country(10619), international(5937), research(6571), data(3845), utilize(4035), earth(1170)	battery(484), spacecraft(10), sun(1686), antenna(156), circuit(259), airship(121), optics(97), transducer(221), physics(120), satellite(244)
Topic3	children(2950), woman(1053), violence(490), committee(936), behavior(4218), family(3918), society(10239), government(6141), measure (1734), right(1565)	drugster(12), antenatal(35), cancer(676), diarrhea(310), teenager(617), girl(2160), sexual abuse(4), patriarch(2431), nonage(63), Zhu Lin(5)
Topic4	central government(1838), conference(2004), work(18347) people(4172), the Communist Party of China(436), National People's Congress(408), member(3986), today(8322), State Department(970), committee member(493)	Hebei province(993), vice-governor(40), Shenyang city(657), Public security bureau(384), deputy mayor(118), deputy secretary(106), deputy director general(191), Hupei(585), accept bribes(125)

5.1 LTE Topics

An informal but important measure of the success of the proposed model is the plausibility of the discovered search topics (Doyle and Elkan, 2009). Hence, we can qualitatively evaluate LTE through viewing its latent topics. An import feature of LTE is that it discovers latent topics from two perspectives. The first perspective is based on the Θ parameter, which corresponds to the Multinomial distributions over the vocabulary. The second perspective is based on the topic embedding and word embedding, i.e., the

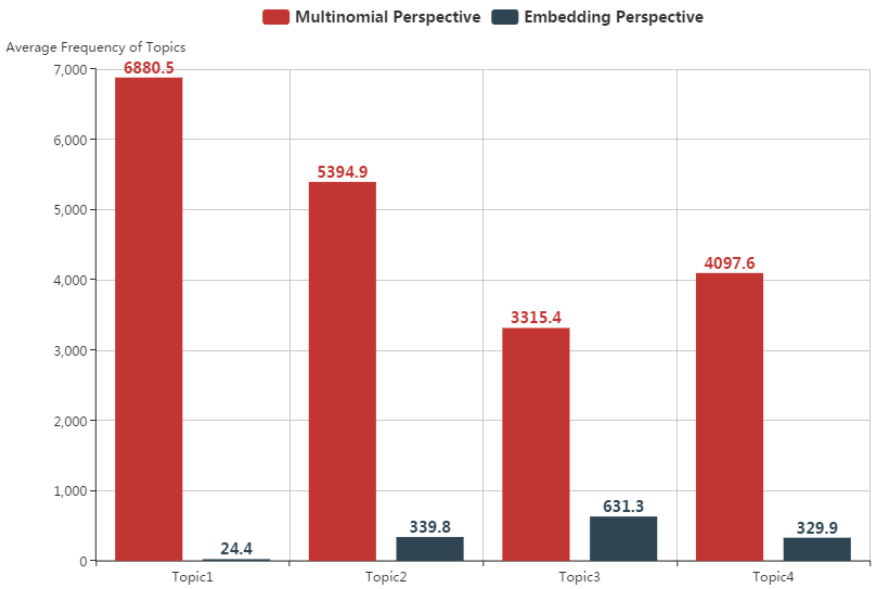

Figure 1: Average Word Frequency of the Two Perspectives

words whose embeddings have the highest cosine similarity with the topic embedding can be considered as the content of this topic. We utilize Web page dataset for the experiment. Some topic examples are presented in Table 1[1]. We observe that the words are semantically coherent in both of the two perspectives. For example, Topic 1 is about political issues between mainland China and Taiwan, Topic 2 is related to space technology, Topic 3 discusses the well-being of women and children and Topic 4 contains words about the political system of China. For each topic, the words from the two perspectives are semantically relevant and complimentary to each other.

An important insight is obtained from analyzing the frequencies of words in topics. The average word frequencies of the two perspectives are presented in Figure 1. We can see that word frequency of the second perspective is significantly smaller than that of the first perspective. For example, in Topic 1, the average word frequency of the first perspective is 6880.5 while that of the second perspective is only 24.4. This phenomenon shed light on an big advantage of LTE in text mining: bridging the semantic relevance between words with different frequencies. LTE overcomes the inherent problem of topic models that the topics are usually dominated by words of high frequency. By using the topic and word embeddings, we can effectively discover the semantics of words of relatively low frequency.

5.2 Perplexity Evaluation

We proceed to quantitatively compare LTE with LDA and the state-of-the-arts (i.e., Topical Word Embedding (TWE-1) (Liu et al., 2015) and Latent Feature-Dirichlet Multinomial Mixture (LFDMM) (Nguyen et al., 2015)) in terms of perplexity, which is a standard measure of evaluating the generalization performance of a probabilistic model (Rosen-Zvi et al., 2004). A lower perplexity indicates better generalization performance. A holdout dataset containing about ten thousand Web pages are utilized for perplexity evaluation. The result of perplexity comparison is presented in Figure 2. Since TWE-1 reuses the result of LDA, they have exactly the same performance in terms of perplexity. When varying the number of topics from 10 to 100, LTE always achieves the lowest perplexity, showing that generative process of LTE is a reasonable assumption for the data. An important observation is that LTE significantly outperforms LFDMM, showing that adding the sentence assumption and jointly utilizing word embedding and topic embedding to generate words result in better fit for the latent data structure of natural language documents. Perplexity is an indicator of the quality of the Multinomial topics. We observe that jointly

[1]The original Chinese words are translated into English to enhance readability.

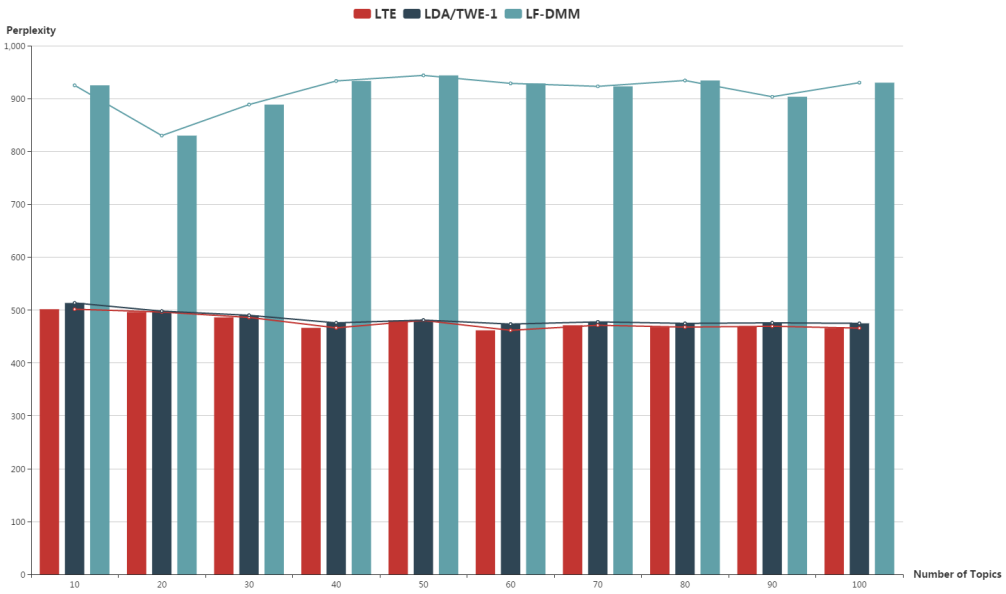

Figure 2: Perplexity on Holdout Data

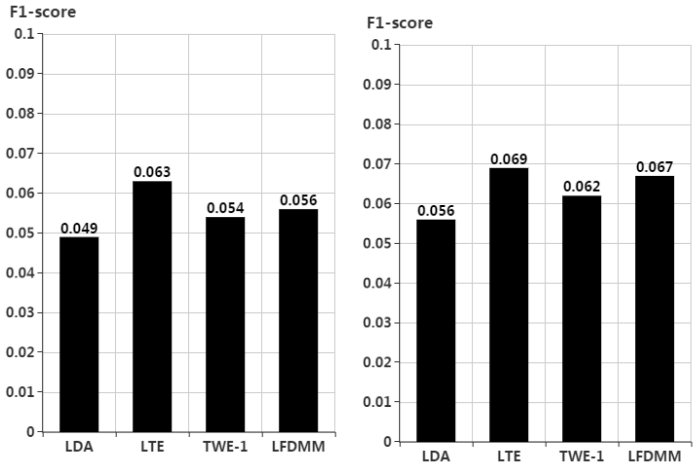
training of multinomial topics and embeddings does not harm the quality of the Multinomial topics. Rather, the joint training paradigm of LTE slightly improves the quality of the Multinomial topics. This observation verifies our assumption that the collectively utilizing co-occurrence information of different granularity has the potential of improving the performance of topic models.

5.3 Topical Word Extraction

We now evaluate the performance of LTE in the scenario of topical word extraction, which is critical for natural language understanding in modern search engines. Given a document, the goal of topical word extraction is to find some words that are highly relevant to the document theme. Conventionally, LDA plays an important role in topical word extraction (Zhao et al., 2011)(Pasquier, 2010). The existing methods based LDA are usually plagued by the weakness of capturing the semantics of words with low frequency. In this section, we study whether the embeddings generated by LTE are able to alleviate this problem. Ten thousands Web pages are utilized for this evaluation and the ground truth (i.e., the words that are highly relevant to the document theme) is manually prepared by human experts.

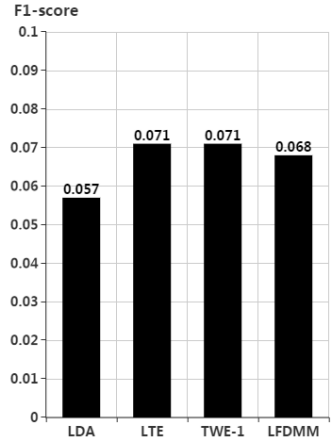
To derive the topical words for a document d, we first calculate the score of each word w in d and the score reflect the relevance between w and the themes of d. Then we sort all the words according to their scores and select the top-k words as the topical words of d. For TWE-1, LFDMM and LTE, the score of a word w is calculated based on embeddings by $score(w) = \sum_z P(z|d) \cos(v_w, v_z)$, where cos is the cosine similarity between two embeddings. As for LDA, we rely on the multinomial topics and calculate the score by $score(w) = \sum_z P(z|d)P(w|z)$. We compare the performance of these models in terms of $F1$ score, which is the harmonic mean of precision and recall.

The experimental result is shown in Figure 3. The models under-study tend to have higher $F1$ scores when the number of topical words increases. We observe that LDA always demonstrates the worst performance. The reason is that LDA is prone to select the frequent words and risks missing some words highly relevant to the document theme. In contrast, embedding information is less sensitive to the effect of word frequency. Therefore, TWE-1, LFDMM and LTE demonstrate better performance than LDA when the number of topical words varies from 3 to 10. LTE always demonstrates the highest $F1$ score. Comparing to TWE-1 and LFDMM which either reuse the output of LDA or Word2Vec, LTE jointly trains the Multinomial parameters and the embeddings, which are complimentary to each other and is effective to result in better topic modeling results and embeddings.

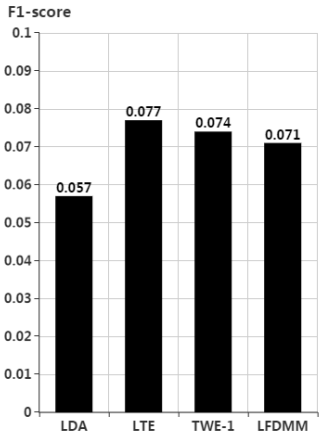


(a) Topical Word Amount = 3

(b) Topical Word Amount = 5



(c) Topical Word Amount = 7



(d) Topical Word Amount = 10

Figure 3: Topical Word Extraction

6 Conclusion

In this paper, we propose LTE to seamlessly integrate topic model and word embedding into one joint learning framework. We discuss a Monte Carlo EM algorithm for learning the parameter of LTE. LTE does not only output topic-related distributions but also generates distributed representation for words and latent topics. By applying LTE, we obtain coherent latent topics and the embedding generated by LTE are effective for identifying topical words of documents. Extensive experiments verify our assumption that topic modeling and word embedding are potentially complimentary for each other. While LTE is a specific model for off-the-shelf usage, the technique discussed in this paper can be easily transfer to many other scenarios where integrating other topic modeling and word embedding techniques are needed.

Abstract

Word embeddings have been demonstrated to benefit NLP tasks impressively. Yet, there is room for improvement in the vector representations, because current word embeddings typically contain unnecessary information, i.e., *noise*. We propose two novel models to improve word embeddings by unsupervised learning, in order to yield word denoising embeddings. The word denoising embeddings are obtained by strengthening salient information and weakening noise in the original word embeddings, based on a deep feed-forward neural network filter. Results from benchmark tasks show that the filtered word denoising embeddings outperform the original word embeddings.

1 Introduction

Word embeddings aim to represent words as low-dimensional dense vectors. In comparison to distributional count vectors, word embeddings address the problematic sparsity of word vectors and achieved impressive results in many NLP tasks such as sentiment analysis (e.g., Kim (2014)), word similarity (e.g., Pennington et al. (2014)), and parsing (e.g., Lazaridou et al. (2013)). Moreover, word embeddings are attractive because they can be learned in an unsupervised fashion from unlabeled raw corpora. There are two main approaches to create word embeddings. The first approach makes use of neural-based techniques to learn word embeddings, such as the Skip-gram model (Mikolov et al., 2013). The second approach is based on matrix factorization (Pennington et al., 2014), building word embeddings by factorizing word-context co-occurrence matrices.

In recent years, a number of approaches have focused on improving word embeddings, often by integrating lexical resources. For example, Adel and Schütze (2014) applied coreference chains to Skip-gram models in order to create word embeddings for antonym identification. Pham et al. (2015) proposed an extension of a Skip-gram model by integrating synonyms and antonyms from WordNet. Their extended Skip-gram model outperformed a standard Skip-gram model on both general semantic tasks and distinguishing antonyms from synonyms. In a similar spirit, Nguyen et al. (2016) integrated distributional lexical contrast into every single context of a target word in a Skip-gram model for training word embeddings. The resulting word embeddings were used in similarity tasks, and to distinguish between antonyms and synonyms. Faruqui et al. (2015) improved word embeddings without relying on lexical resources, by applying ideas from sparse coding to transform dense word embeddings into sparse word embeddings. The dense vectors in their models can be transformed into sparse overcomplete vectors or sparse binary overcomplete vectors. They showed that the resulting vector representations were more similar to interpretable features in NLP and outperformed the original vector representations on several benchmark tasks.

In this paper, we aim to improve word embeddings by reducing their noise. The hypothesis behind our approaches is that word embeddings contain unnecessary information, i.e. *noise*. We start out with the idea of learning word embeddings as suggested by Mikolov et al. (2013), relying on the distributional hypothesis (Harris, 1954) that words with similar distributions have related meanings. We address those

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2699–2707, Osaka, Japan, December 11-17 2016.

distributions in embedded vectors of words that decrease the value of such vector representations. For instance, consider the sentence *the quick brown fox gazing at the cloud jumped over the lazy dog*. The context *jumped* can be used to predict the words *fox*, *cloud* and *dog* in a window size of 5 words; however, a *cloud* cannot *jump*. The context `jumped` is therefore considered as noise in the embedded vector of `cloud`. We propose two novel models to smooth word embeddings by filtering noise: We strengthen salient contexts and weaken unnecessary contexts.

The first proposed model is referred to as *complete word denoising embeddings model (CompEmb)*. Given a set of original word embeddings, we use a filter to learn a denoising matrix, and then project the set of original word embeddings into this denoising matrix to produce a set of complete word denoising embeddings. The second proposed model is referred to as *overcomplete word denoising embeddings model (OverCompEmb)*. We make use of a sparse coding method to transform an input set of original word embeddings into a set of overcomplete word embeddings, which is considered as the "overcomplete process". We then apply a filter to train a denoising matrix, and thereafter project the set of original word embeddings into the denoising matrix to generate a set of overcomplete word denoising embeddings. The key idea in our models is to use a filter for learning the denoising matrix. The architecture of the filter is a feed-forward, non-linear and parameterized neural network with a fixed depth that can be used to learn the denoising matrices and reduce noise in word embeddings. Using state-of-the-art word embeddings as input vectors, we show that the resulting word denoising embeddings outperform the original word embeddings on several benchmark tasks such as word similarity and word relatedness tasks, synonymy detection and noun phrase classification. Furthermore, the implementation of our models is made publicly available[1].

The remainder of this paper is organized as follows: Section 2 presents the two proposed models, the loss function, and the sparse coding technique for overcomplete vectors. In Section 3, we demonstrate the experiments on evaluating the effects of our word denoising embeddings, tuning hyperparameters, and we analyze the effects of filter depth. Finally, Section 4 concludes the paper.

2 Learning Word Denoising Embeddings

In this section, we present the two contributions of this paper. Figure 1 illustrates our two models to learn denoising for word embeddings. The first model on the top, the complete word denoising embeddings model "CompEmb" (Section 2.1), filters noise from word embeddings $\mathbf{X}$ to produce complete word denoising embeddings $\mathbf{X}^*$, in which the vector length of $\mathbf{X}^*$ in comparison to $\mathbf{X}$ is unchanged after denoising (called *complete*). The second model at the bottom of the figure, the overcomplete word denoising embeddings model "OverCompEmb" (Section 2.2), filters noise from word embeddings $\mathbf{X}$ to yield overcomplete word denoising embeddings $\mathbf{Z}^*$, in which the vector length of $\mathbf{Z}^*$ tends to be greater than the vector length of $\mathbf{X}$ (called *overcomplete*).

For the notations, let $\mathbf{X} \in \mathbb{R}^{V \times L}$ is an input set of word embeddings in which V is the vocabulary size, and L is the vector length of $\mathbf{X}$. Furthermore, $\mathbf{Z} \in \mathbb{R}^{V \times K}$ is the overcomplete word embeddings in which K is the vector length of $\mathbf{Z}$ ($K > L$); finally, $\mathbf{D} \in \mathbb{R}^{L \times L}$ is the pre-trained dictionary (Section 2.4).

2.1 Complete Word Denoising Embeddings

In this subsection, we aim to reduce noise in the given input word embeddings $\mathbf{X}$ by learning a denoising matrix $\mathbf{Q_c}$. The complete word denoising embeddings $\mathbf{X}^*$ are then generated by projecting $\mathbf{X}$ into $\mathbf{Q_c}$. More specifically, given an input $\mathbf{X} \in \mathbb{R}^{V \times L}$, we seek to optimize the following objective function:

$$\underset{\mathbf{X},\mathbf{Q_c},\mathbf{S}}{\operatorname{argmin}} \sum_{i=1}^{V} \|\mathbf{x_i} - f(\mathbf{x_i}, \mathbf{Q_c}, \mathbf{S})\| + \alpha \|\mathbf{S}\|_1 \tag{1}$$

where f is a filter; $\mathbf{S}$ is a lateral inhibition matrix; and α is a regularization hyperparameter. Inspired by studies on sparse modeling, the matrix $\mathbf{S}$ is chosen to be symmetric and has zero on the diagonal.

[1] `https://github.com/nguyenkh/NeuralDenoising`

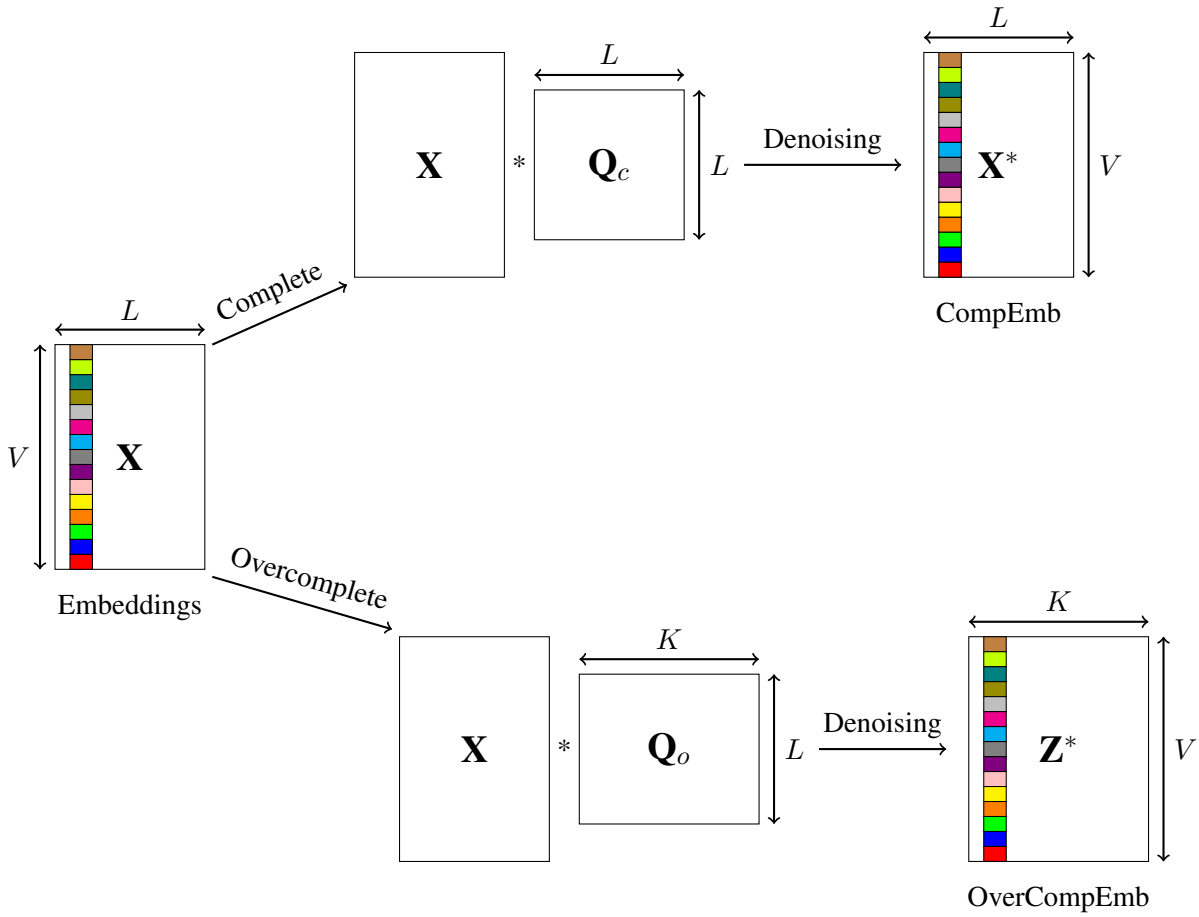

Figure 1: Illustration of word denoising embeddings methods, with complete word denoising embeddings at the top, and overcomplete word denoising embeddings at the bottom.

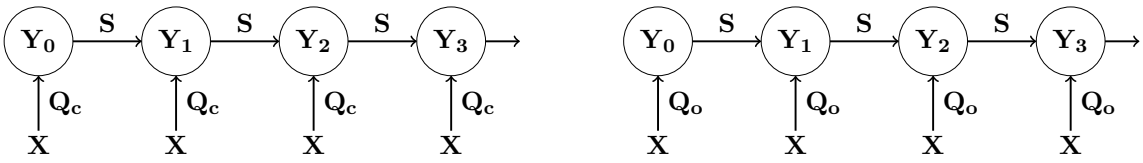
The goal of this matrix is to implement excitatory interaction between neurons, and to increase the convergence speed of the neural network (Szlam et al., 2011). More concretely, the matrices $\mathbf{Q_c}$ and $\mathbf{S}$ are initialized with $\mathbf{I}$ and E, which are identity matrices, and the Lipschitz constant:

$$\begin{aligned}&\mathbf{Q_c} = \tfrac{1}{E}\mathbf{D}; \mathbf{S} = \mathbf{I} - \tfrac{1}{E}\mathbf{D^T D}\\ &E > \text{ the largest eigenvalue of } \mathbf{D^T D}\\ &\mathbf{D} \in \mathbb{R}^{L\times L} \text{ be pre-trained dictionary}\end{aligned}$$

The underlying idea for reducing noise is to make use of a filter f to learn a denoising matrix $\mathbf{Q_c}$; hence, we design the filter f as a non-linear, parameterized, feed-forward architecture with a fixed depth that can be trained to approximate $f(\mathbf{X}, \mathbf{Q_c}, \mathbf{S})$ to $\mathbf{X}$ as in Figure 2a. As a result, noise from word embeddings will be filtered by layers of the filter f. The filter f is encoded as a recursive function by iterating over the number of fixed depth T, as the following recursive Equation 2 shows:

$$\begin{aligned}&\mathbf{Y} = f(\mathbf{X}, \mathbf{Q_c}, \mathbf{S})\\ &\mathbf{Y}(0) = \mathcal{G}(\mathbf{X}\mathbf{Q_c})\\ &\mathbf{Y}(k+1) = \mathcal{G}(\mathbf{X}\mathbf{Q_c} + \mathbf{Y}(k)\mathbf{S})\\ &0 \le k < T\end{aligned} \tag{2}$$

$\mathcal{G}$ is a non-linear activation function. The matrices $\mathbf{Q_c}$ and $\mathbf{S}$ are learned to produce the lowest possible error in a given number of iterations. Matrix $\mathbf{S}$, in the architecture of filter f, acts as a controllable matrix to filter unnecessary information on embedded vectors, and to impose restrictions on further reducing the



(a) CompEmb (b) OverCompEmb

Figure 2: Architecture of the filters with the fixed depth $T = 3$.

computational burden (e.g., solving low-rank approximation problem or keeping the number of terms at zero (Gregor and LeCun, 2010)). Moreover, the initialization of the matrices $\mathbf{Q_c}$, $\mathbf{S}$ and E enhances a highly efficient minimization of the objective function in Equation 1, due to the pre-trained dictionary $\mathbf{D}$ that carries the information of reconstructing $\mathbf{X}$.

The architecture of the filter f is a recursive feed-forward neural network with the fixed depth T, so the number of T plays a significant role in controlling the approximation of $\mathbf{X}^*$. The effects of T will be discussed later in Section 3.4. When $\mathbf{Q_c}$ is trained, the complete word denoising embeddings $\mathbf{X}^*$ are yielded by projecting $\mathbf{X}$ into $\mathbf{Q_c}$, as shown by the following Equation 3:

$$\mathbf{X}^* = \mathcal{G}(\mathbf{X}\mathbf{Q_c}) \tag{3}$$

2.2 Overcomplete Word Denoising Embeddings

Now we introduce our method to reduce noise and overcomplete vectors in the given input word embeddings. To obtain overcomplete word embeddings, we first use a sparse coding method to transform the given input word embeddings $\mathbf{X}$ into overcomplete word embeddings $\mathbf{Z}$. Secondly, we use overcomplete word embeddings $\mathbf{Z}$ as the intermediate word embeddings to optimize the objective function: A set of input word embeddings $\mathbf{X} \in \mathbb{R}^{V \times L}$ is transformed to overcomplete word embeddings $\mathbf{Z} \in \mathbb{R}^{V \times K}$ by applying sparse coding method in Section 2.4. We then make use of the pre-trained dictionary $\mathbf{D} \in \mathbb{R}^{L \times K}$ and $\mathbf{Z} \in \mathbb{R}^{V \times K}$ to learn the denoising matrix $\mathbf{Q_o}$ by minimizing the following Equation 4:

$$\underset{\mathbf{X},\mathbf{Q_o},\mathbf{S}}{\operatorname{argmin}} \sum_{i=1}^{V} \|\mathbf{z_i} - f(\mathbf{x_i}, \mathbf{Q_o}, \mathbf{S})\| + \alpha\|\mathbf{S}\|_1 \tag{4}$$

The initialization of the parameters $\mathbf{Q_o}$, $\mathbf{S}$, E and α follows the same procedure as described in Section 2.1, and with the same interpretation of the filter architecture in Figure 2b. The overcomplete word denoising embeddings $\mathbf{Z}^*$ are then generated by projecting $\mathbf{X}$ into the denoising matrix $\mathbf{Q_o}$ and using the non-linear activation function $\mathcal{G}$ in the following Equation 5:

$$\mathbf{Z}^* = \mathcal{G}(\mathbf{X}\mathbf{Q_o}) \tag{5}$$

2.3 Loss Function

For each pair of term vectors $\mathbf{x_i} \in \mathbf{X}$ and $\mathbf{y_i} \in \mathbf{Y} = f(\mathbf{X}, \mathbf{Q_c}, \mathbf{S})$, we make use of the cosine similarity to measure the similarity between $\mathbf{x_i}$ and $\mathbf{y_i}$ as follows:

$$sim(\mathbf{x_i}, \mathbf{y_i}) = \frac{\mathbf{x_i} \cdot \mathbf{y_i}}{\|\mathbf{x_i}\|\|\mathbf{y_i}\|} \tag{6}$$

Let Δ be the difference between $sim(\mathbf{x_i}, \mathbf{x_i})$ and $sim(\mathbf{x_i}, \mathbf{y_i})$, equivalently $\Delta = 1 - sim(\mathbf{x_i}, \mathbf{y_i})$. We then optimize the objective function in Equation 1 by minimizing Δ; and the same loss function is also applied to optimize the objective function in Equation 4. Training is done through Stochastic Gradient Descent with the Adadelta update rule (Zeiler, 2012).

2.4 Sparse Coding

Sparse coding is a method to represent vector representations as a sparse linear combination of elementary atoms of a given dictionary. The underlying assumption of sparse coding is that the input vectors can be reconstructed accurately as a linear combination of some basis vectors and a few number of non-zero coefficients (Olshausen and Field, 1996).

The goal is to approximate a dense vector in $\mathbb{R}^L$ by a sparse linear combination of a few columns of a matrix $\mathbf{D} \in \mathbb{R}^{L \times K}$ in which K is a new vector length and the matrix $\mathbf{D}$ be called a *dictionary*. Concretely, given V input vectors of L dimensions $\mathbf{X} = [x_1, x_2, ..., x_V]$, the dictionary and sparse vectors can be formulated as the following minimization problem:

$$\min_{\mathbf{D} \in \mathcal{C}, \mathbf{Z} \in \mathbb{R}^{K \times V}} \sum_{i=1}^{V} \|\mathbf{x_i} - \mathbf{D}\mathbf{z}_i\|_2^2 + \lambda \|\mathbf{z}_i\|_1 \tag{7}$$

$\mathbf{Z} = [z_1, ..., z_V]$ carries the decomposition coefficients of $\mathbf{X} = [x_1, x_2, ..., x_V]$; and λ represents a scalar to control the sparsity level of $\mathbf{Z}$. The dictionary $\mathbf{D}$ is typically learned by minimizing Equation 7 over input vectors $\mathbf{X}$. In the case of overcomplete representations $\mathbf{Z}$, the vector length K is typically implied as $K = \gamma L$ ($\gamma > 0$).

In the method of overcomplete word denoising embeddings (Section 2.2), our approach makes use of overcomplete word embeddings $\mathbf{Z}$ as the intermediate word embeddings reconstructed by applying a sparse coding method to word embeddings $\mathbf{X}$. The overcomplete word embeddings $\mathbf{Z}$ are then utilized to optimize Equation 4. To obtain overcomplete word embeddings $\mathbf{Z}$ and dictionaries, we use the `SPAMS` package[2] to implement sparse coding for word embeddings $\mathbf{X}$ and to train the dictionaries $\mathbf{D}$.

3 Experiments

3.1 Experimental Settings

As input word embeddings, we rely on two state-of-the-art word embeddings methods: word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014). We use the `word2vec` tool[3] and the web corpus *ENCOW14A* (Schäfer and Bildhauer, 2012; Schäfer, 2015) which contains approximately 14.5 billion tokens, in order to train Skip-gram models with 100 and 300 dimensions. For the GloVe method, we use pre-trained vectors of 100 and 300 dimensions[4] that were trained on 6 billion words from Wikipedia and English Gigaword. The $\tanh$ function is used as the non-linear activation function in both approaches. The fixed depth of filter T is set to 3; further hyperparameters are chosen as discussed in Section 3.2. To train the networks, we use the `Theano` framework (Theano Development Team, 2016) to implement our models with a mini-batch size of 100. Regularization is applied by dropouts of 0.5 and 0.2 for input and output layers (without tuning), respectively.

3.2 Hyperparameter Tuning

In both methods of denoising word embeddings, the ℓ_1 regularization penalty α is set to 0.5 without tuning in Equation 1 and 4. The method of learning overcomplete word denoising embeddings relies on the mediate word embeddings $\mathbf{Z}$ to minimize the objective function in Equation 4. The sparsity of $\mathbf{Z}$ depends on the ℓ_1 regularization λ in Equation 7; and the length vector K of $\mathbf{Z}$ is implied as $K = \gamma L$. Therefore, we aim to tune λ and γ such that $\mathbf{Z}$ represents the nearest approximation of the original vector representation $\mathbf{X}$. We perform a grid search on $\lambda \in \{1.0, 0.5, 0.1, 10^{-3}, 10^{-6}\}$ and $\gamma \in \{2, 3, 5, 7, 10, 13, 15\}$, developing on the word similarity task WordSim353 (to be discussed on Section 3.3). The hyperparameter tunings are illustrated in Figures 3a and 3b for sparsity and overcomplete vector length tuning, respectively. In both approaches, we set λ to 10^{-6} and γ to 10 for the sparsity and length of overcomplete word embeddings.

3.3 Effects of Word Denoising Embeddings

In this section, we quantify the effects of word denoising embeddings on three kinds of tasks: similarity and relatedness tasks, detecting synonymy, and bracketed noun phrase classification task. In comparison to the performance of word denoising embeddings, we take into account state-of-the-art word embeddings (Skip-gram and GloVe word embeddings) as baselines. Besides, we also use the public source code[5] to re-implement the two methods suggested by Faruqui et al. (2015) which are vectors $\mathbf{A}$ (sparse overcomplete vectors) and $\mathbf{B}$ (sparse binary overcomplete vectors).

The effects of the word denoising embeddings on the tasks are shown in Table 1. The results show that the vectors $\mathbf{X}^*$ and $\mathbf{Z}^*$ outperform the original vectors $\mathbf{X}$, $\mathbf{A}$ and $\mathbf{B}$, except for the NP task, in which the vectors $\mathbf{B}$ based on the 300-dimensional GloVe vectors are best. The effect of the vectors $\mathbf{Z}^*$ is slightly less impressive, when compared to the overcomplete vectors $\mathbf{X}^*$. The overcomplete word embeddings $\mathbf{Z}$ strongly differ from the word embeddings $\mathbf{X}$; hence, the denoising is affected. However, the performance of the vectors $\mathbf{Z}^*$ still outperforms the original vectors $\mathbf{X}$, $\mathbf{A}$ and $\mathbf{B}$ after the denoising process.

3.3.1 Relatedness and Similarity Tasks

For the relatedness task, we use two kinds of datasets: MEN (Bruni et al., 2014) consists of 3000 word pairs comprising 656 nouns, 57 adjectives and 38 verbs. The WordSim-353 relatedness dataset (Finkelstein et al., 2001) contains 252 word pairs. Concerning the similarity tasks, we evaluate the denoising vectors again on two kinds of datasets: *SimLex-999* (Hill et al., 2015) contains 999 word pairs including 666 noun, 222 verb and 111 adjective pairs. The WordSim-353 similarity dataset consists of 203 word pairs. In addition, we evaluate our denoising vectors on the WordSim-353 dataset which contains 353 pairs for both similarity and relatedness relations. We calculate cosine similarity between the vectors of two words forming a test pair, and report the Spearman rank-order correlation coefficient ρ (Siegel and Castellan, 1988) against the respective gold standards of human ratings.

3.3.2 Synonymy

We evaluate on 80 TOEFL (Test of English as a Foreign Language) synonym questions (Landauer and Dumais, 1997) and 50 ESL (English as a Second Language) questions (Turney, 2001). The first dataset represents a subset of 80 multiple-choice synonym questions from the TOEFL test: a word is paired with four options, one of which is a valid synonym. The second dataset contains 50 multiple-choice synonym questions, and the goal is to choose a valid synonym from four options. For each question, we compute the cosine similarity between the target word and the four candidates. The suggested answer is the candidate with the highest cosine score. We use accuracy to evaluate the performance.

3.3.3 Phrase parsing as Classification

Lazaridou et al. (2013) introduced a dataset of noun phrases (NP) in which each NP consists of three elements: the first element is either an adjective or a noun, and the other elements are all nouns. For a given NP (such as *blood pressure medicine*), the task is to predict whether it is a left-bracketed NP, e.g., *(blood pressure) medicine*, or a right-bracketed NP, e.g., *blood (pressure medicine)*.

The dataset contains 2227 noun phrases split into 10 folds. For each NP, we use the average of word vectors as features to feed into the classifier by tuning the hyperparameters (w_1, w_2 and w_3) for each element (e_1, e_2 and e_3) within the NP: $\vec{e}_{NP} = \frac{1}{3}(w_1\vec{e}_1 + w_2\vec{e}_2 + w_3\vec{e}_3)$. We then employ the classification of the NPs by using a Support Vector Machine (SVM) with Radial Basis Function kernel. The classifier is tuned on the first fold, and cross-validation accuracy is reported on the nine remaining folds.

3.4 Effects of Filter Depth

As mentioned above, the architecture of the filter f is a feed-forward network with a fixed depth T. For each stage T, the filter f attempts to reduce the noise within input vectors by approximating these vectors based on vectors of a previous stage $T-1$. In order to investigate the effects of each stage T, we use pre-trained GloVe vectors with 100 dimensions to evaluate the denoising performance of the vectors on detecting synonymy in the TOEFL dataset across several stages of T.

The results are presented in Figure 4. The accuracy of synonymy detection increases sharply from 63.2% to 88.6% according to the number of stages T from 0 to 3. However, the denoising performance of vectors falls with the number of stages $T > 3$. This evaluation shows that the filter f with a consistently fixed depth T can be trained to efficiently filter noise for word embeddings. In other words, the number of stages T exceeds a consistent number T (with $T > 3$ in our case), leading to the loss of salient information in the vectors.

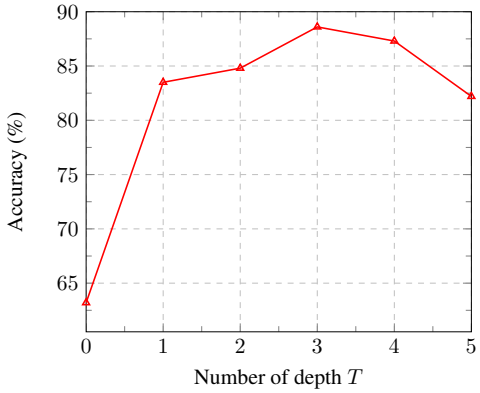

Figure 4: Effects of the filter with depth T on filtering noise.

4 Conclusion

To the best of our knowledge, we are the first to work on filtering noise in word embeddings. In this paper, we have presented two novel models to improve word embeddings by reducing noise in state-of-the-art word embeddings models. The underlying idea in our models was to make use of a deep feed-forward neural network filter to reduce noise. The first model generated complete word denoising embeddings; the second model yielded overcomplete word denoising embeddings. We demonstrated that the word denoising embeddings outperform the originally state-of-the-art word embeddings on several benchmark tasks.
