Figure 6: F_1 (left: entity_1 correct, right: entity_2 correct) for all languages and models.

This does not seem to be a general rule that can be applied. We would like to point out though that this is exactly the reason why we have created this dataset in the first place. We wanted to observe the performance of models on different languages on the relation extraction task and now, thanks to our dataset, this is possible. The fact that there is no simple explanation for the difference in model performance shows that deeper analysis for each language is necessary.

Another observation is that we obtain significantly higher F_1 for entity_1 than for entity_2, which suggests that entity_1 is simpler. This seems to be true, because entity_1 typically occurs at the beginning of the sentence, while entity_2 does not have any consistent location.

In the future, we plan to train our model on the EN-full dataset and to predict multiple plausible entity pairs for the same sentence. We would also like to extend the dataset to include entity types and sentences containing multiple relations.

Another promising direction is data augmentation by "cross-matching" entities and relations in the dataset with sentences in the dataset. This cross-match could search for two cases.

1. Sentences that contain multiple relations between the same 2 entities.
2. Sentences that contain more than 2 entities (e.g. 3), with different relations between them.

In both cases, the sentence could be added to the dataset multiple times.

Abstract

Imposing the style of one image onto another is called *style transfer*. For example, the style of a Van Gogh painting might be imposed on a photograph to yield an interesting hybrid. This paper applies the adaptive normalization used for image style transfer to language semantics, i.e., the *style* is the way the words are said (tone of voice and facial expressions) and these are style-transferred onto the text. The goal is to learn richer representations for multi-modal utterances using style-transferred multi-modal features. The proposed Style-Transfer Transformer (STT) grafts a stepped styled adaptive layer-normalization onto a transformer network, the output from which is used in sentiment analysis and emotion recognition problems. In addition to achieving performance on par with the state-of-the art (but using less than a third of the model parameters), we examine the relative contributions of each mode when used in the downstream applications.

1 Introduction

Multi-modal language analysis expands textual analysis by utilizing co-occurring acoustic and visual information, and has recently become a popular topic in machine learning (Morency et al., 2011; Baltrušaitis et al., 2018). In both sentiment analysis (Wang et al., 2016; Zadeh et al., 2016) and emotion recognition (Busso et al., 2008; Mittal et al., 2019), the three modalities are combined to better represent the sentiment or emotional meaning of a passage. The idea of combing textual, acoustic, and visual features is obvious: individual modalities are not always able to convey as accurate an impression as multi-modal features, which typically provide more complete information. For instance, Fig. 1 shows a caricature where the sentiment may be easily understood from the audio and video, but not from textual analysis alone.

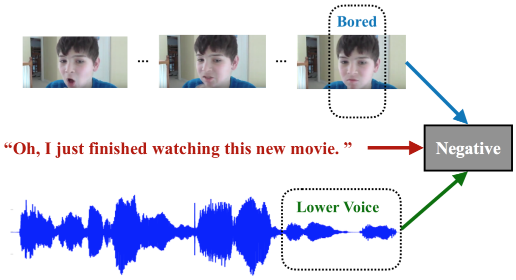

Figure 1: An example of multi-modal sentiment analysis. In this example, textual information is unrelated to the underlying sentiment while acoustic and visual features reflect the perceived sentiment.

Combining textual, acoustic, and visual features can be accomplished in a variety of ways ((Tsai et al., 2018; Zadeh et al., 2018a; Liang et al., 2018; Mai et al., 2019; Sun et al., 2019b; Mittal et al., 2019)). Among these, (Wang et al., 2018b; Sun et al., 2019a) consider text as the backbone and study methods to inject acoustic and visual information into the textual features that are typically extracted via pre-trained word/language models, e.g., Glove (Pennington et al., 2014), ELMO (Peters et al., 2018), and BERT (Devlin et al., 2018).

This paper also uses textual features as a backbone and studies a novel way of injecting non-text features into a primarily text-only model. A *style* vector is learned from the acoustic and visual features. This style vector is then transferred to a text input transformer encoder via **S**tepped **Ad**aptive **La**yer **N**ormalization (SAdLaN). While adaptive style transfer in image processing literature is well studied (Karras et al., 2018; Huang and Belongie,

April 19 - 23, 2021.

2017; Park et al., 2019), the novelty in our work is to consider the corresponding audio and video to be the *style* of the text and transfer the non-verbal features' information to text-based models via the effective SAdLaN. Concretely, our model replaces the original layer normalization in the text transformer encoder with the proposed SAdLaN, which learns style scale and style bias from non-text features. The proposed model is named as Style-Transfer Transformer (STT) and it is tested on three benchmark datasets.

This paper makes three contributions. First, our model's performance is on par with the state-of-the-art but using only less than one third of the model parameters. Since our model does not require training a multimodal transformer from scratch to achieve the same results, the style transfer method benefits from both reduced model size and training time. Second, we introduce the Stepped Adaptive Layer Normalization (SAdLaN), which performs adaptive normalization as a function of the layer of the DNN encoder. Third, we study the contributions of each modality towards use in our downstream applications. While we know that multimodal embeddings would contribute more than each individual modality, such an examination highlights the relative strength of each mode, particularly on sentiment classification tasks.

The rest of this paper is organized as follows. Section 2 reviews the related work. Section 3 describes our proposed method Style Transfer Transformer (STT). Section 4 and 5 presents experimental results, and Section 6 concludes this work.

2 Related Work

Multi-modal Language Analysis: Previous work on multi-modal language analysis typically learns a novel network structure to capture interactions between text, audio, and video features via supervised learning. Liu et al. (2018) develop an efficient low-rank tensor fusion mechanism to learn the outer-product representation of multi-modal features, while (Zadeh et al., 2018a) learn a multi-modal memory gate that is applied to an LSTM to capture the flow of information in the different modalities. In their work (Liang et al., 2018) learn a specialized multi-modal fusion model by applying a novel multistage fusion in the recurrent network. Recently, the multi-modal transformer introduced by (Tsai et al., 2019) achieves the state-of-the-art performance by using bi-directional cross modal relationships between the different modalities. Note that the transformer architecture in STT is the same as in (Tsai et al., 2019). However, we depart from their modeling procedure by encoding audio and video jointly using a single bimodal transformer block, thereby eliminating additional cross modal attention blocks.

Adaptive Normalization: Adaptive normalization is widely used in image processing and computer vision. Huang and Belongie (2017) proposes adaptive instance normalization, which learns the affine parameters from the style vector to perform a style transfer in the image encoder's feature space. Karras et al. (2018) applies the AdIN in the generative adversarial network (GAN) to generate fake multi-styled human faces. Park et al. (2019) proposes a spatially-adaptive normalization for image semantic synthesis. Wang et al. (2018a) applies a spatial feature transformation for image super-resolution. This paper introduces the SAdLaN framework in which a bimodal style vector is transferred as a function of the DNN's depth.

Adapter Method in Pre-trained Language Models: Due to the enormous size of pre-trained language models (e.g. BERT, XLNet), the procedure of fine-tuning the models on downstream data may be inefficient. To address this "adapter" based methods have been developed. In their work (Houlsby et al., 2019) apply the task-specific layer at each encoder layer of BERT. Each task-specific layer contains two feed-forward projectors: one down-projects (maps the input vector to a low-dimensional space) and the other up-projects (maps the prior layer's output back to its original dimension). During training, only the parameters in these task-specific layers are updated. Stickland and Murray (2019) proposes another method: the task-specific layer is applied between the two layer-normalization in the encoder. Wang et al. (2020) applies parallel adapters which each learn different information from the knowledge base in order to enable the model to deal with the multi-task learning task.

Our proposed SAdLaN is motivated by the the adapter designed in (Houlsby et al., 2019). In their work, the authors find that lower layers of the transformer have less impact on the fine tuning objective of a given task, while higher layers are more vital (this is an intuitive observation, because, lower layers are more likely to learn semantic meanings while the higher layers are more related to the specifics of the task). When using SAdLaN, lower layers of the STT are changed as little as possible to enable the model to learn basic semantic information from the input text, while the top layers allow a larger effect influenced by the style factors.

3 Style Transfer Transformer (STT)

We define the text, audio, and video features for a given utterance as $f_t \in \mathbb{R}^{l\times d_t}, f_a \in \mathbb{R}^{l\times d_a}, f_v \in \mathbb{R}^{l\times d_v}$, where l is the length of the modality sequence and d_t, d_a, d_v are embedding dimensions of each modality (each modalities' sequence length is forced to be the same by applying alignment). Figure 2 (*left*) shows an overview of our model STT. It consists of the following four steps:

- Step 1: learn a style vector from the audio and video features.
- Step 2: use the learned style vector during adaptive layer normalization for a text input transformer model.
- Step 3: take the style transferred text representation and pass it through a GRU to get the final multimodal embedding.
- Step 4: use this multimodal embedding for a downstream task.

Step 1 Learn a style vector: In keeping with the hypothesis that the text modality is the major contributor to the learned multimodal embedding, a style encoder is first applied to acoustic (f_a) and visual (f_v) features to learn the non-verbal style vector $f_s \in \mathbb{R}^{l_s}$. The STT first concatenates audio and video sequences at each time step, i.e., $f_{av} \in \mathbb{R}^{l\times(d_a+d_v)}$. The concatenated f_{av} is then input into the transformer model $\textsc{Transformer}_{av}$, which is a basic self-attention multi-head transformer encoder (with query = key = value; see (Vaswani et al., 2017)). The final state of $\textsc{Transformer}_{av}$ is the style vector f_s.

Step 2 Adaptive style transfer onto text: The original layer norm (Ba et al., 2016) is defined as:

$$f_y = \frac{f_x - \mathbb{E}[f_x]}{\sqrt{\text{Var}[f_x]+\epsilon}} \times \gamma + \beta \qquad (1)$$

where f_x is the input vector to the layer normalization, ϵ is a value added to the denominator for numerical stability, and γ, β are scalar and bias factors computed from the data for normalization. The style transfer techniques for image processing applications use factors s, b learned from a style vector to replace γ, β (Huang and Belongie, 2017; Karras et al., 2018).

Inspired by these, we propose our Stepped Adaptive Layer Normalization technique (SAdLaN). It also computes factors from our style vector f_s for the normalization, but with the key difference that it takes into account the depths of the layers. Since lower layers of the transformer have less impact on the fine tuning objective for a given task while higher layers are more vital to the task, the lower layers of the STT should be changed as little as possible to enable the model to learn basic semantic information from the input text, while the top layers should allow a larger effect influenced by the style factors.

Figure 2 (*right*) shows how the SAdLaN is applied to a text transformer encoder. Formally, we input the style vector f_s to a MLP layer to compute factors s^i, b^i for the normalization of the ith layer, and introduce a novel stepped ratio factor r_i where r_i gradually increases as a function of the depth of the layer. SAdLaN for the ith layer is then defined as:

$$\begin{aligned} f_y^i = (&\frac{f_x^i - \mathbb{E}[f_x^i]}{\sqrt{\text{Var}[f_x^i]+\epsilon}} \times \gamma + \beta) \\ &\times (1 + s^i \times r_i) + (b^i \times r_i). \end{aligned} \qquad (2)$$

Here γ and β are computed as in the original layer norm (without using the style vector). The s^i, b^i are factors learned from the style vector: at each layer i, the learned style vector f_s is input to a specific MLP to learn the factors s^i, b^i. The r_i are defined as

$$r_i = (i-1) \times \frac{\text{ratio}}{\#\text{layers}} \qquad (3)$$

where ratio is a constant value used to limit the maximum r_i value. Thus, small r_i indicate the style factors have little impact on the layer norm and vice versa. Note that SAdLaN reduces to the original layer norm (1) when $\text{ratio} = 0$.

Step 3 Style transferred multimodal embedding: The output of the last adapted layer from Step 2 is considered to be the style transferred text sequence. This styled text sequence is then passed through a GRU to learn the final multimodal embedding.

Step 4 Downstream applications: Multimodal embeddings learned in Step 3 can be passed to a softmax layer or a MLP for any downstream task of choice.

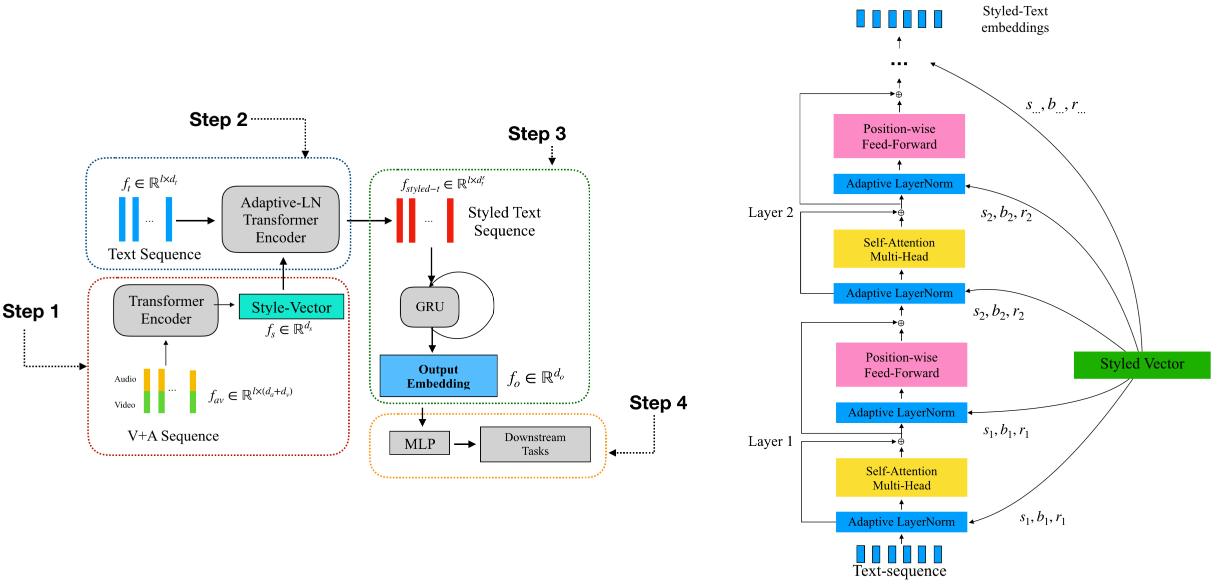

Figure 2: *left:* An overview of the STT model. First, a style vector is learned from audio and video features. Second, the style vector is used along with the text to learn a styled-text sequence by a transformer encoder with the adaptive layer normalization. Finally, use a GRU to get the final multimodal embedding and use a MLP for the downstream task. See the main text for the details. *right:* The STT Transformer encoder with the adaptive layer normalization. Scalar and bias factors are learned from the style vector. Smaller ratios are applied to the bottom layers so that accurate semantic features can be captured, while larger ratios are applied to top layers to encourage the learning of the styled features.

4 Experimental Setup

This section provides a brief overview of the experimental setup, datasets, and baseline methods used for comparison.

4.1 Data sets

In order to test the performance of the STT, three benchmark multi-modal datasets are selected: i) CMU-MOSI, ii) CMU-MOSEI (Zadeh et al., 2016, 2018b), and iii) IEMOCAP (Busso et al., 2008). The first two are standard datasets for sentiment analysis while IEMOCAP is a standard emotion recognition dataset.

- **CMU-MOSI:** This data set contains 2199 utterance-level video segments. Each video segment is labeled with sentiment scores that range from -3 (extremely negative sentiment) to $+3$ (extremely positive sentiment).

- **CMU-MOSEI:** This data set contains 22856 utterance-level video segments. Annotation of each segment is the same as in the CMU-MOSI dataset.

- **IEMOCAP:** The original dataset contains 10000 examples with 9 different emotion annotations. In this paper, we follow (Tsai et al., 2019) and choose four emotions (angry, sad, happy, and neutral) with balanced distributions for the evaluation.

4.2 Baselines

We compare the proposed STT with several baselines: i) Early and Late Fusion LSTM (Zadeh et al., 2016), ii) **RAVEN** (Wang et al., 2018b), iii) **MCTN** (Tsai et al., 2018), iv) **LMF** (Liu et al., 2018), and v) **RMFN** (Liang et al., 2018). The state of the art **Mult** (Tsai et al., 2019), which applies 6 cross-modal transformers to learn cross relationships between modalities, is also included in our evaluations.

To keep comparisons fair, our experiments use the same multimodal features as in (Liu et al., 2018; Zadeh et al., 2016, 2018a; Liang et al., 2018; Tsai et al., 2019). Here are some high level details with regards to each modalities' features:

- **Textual features:** Glove (Pennington et al., 2014) word embeddings of 300 dimensions are used as inputs to obtain textual features.

- **Acoustic features:** They are extracted by COVAREP (Degottex et al., 2014) and have 74 dimensions. These features contain information on frequency, volume, pitch, MFCC, etc.

	MOSI	MOSEI	IEMOCAP
batch size	48	128	48
learning rate	0.002	0.0001	0.003
transformer hidden dim	40	40	40
GRU hidden dim	60	40	60
# of encoder layers	8	8	4
# of heads	8	10	8
style ratio	0.3	0.2	0.25
dropout	0.2	0.5	0.3

Table 1: This table presents the best hyper-parameter settings of the STT model for all data sets reported in our experiments.

They are aligned at the word-level: for every word, its corresponding acoustic feature is the average of all audio frame's features between the start time and the end time of that specific word.

- **Visual features:** They are extracted by Facet (iMotions, 2017) and have 34 dimensions. Features include facial landmarks, action units, etc. They are also aligned at the word level.

In consistency with prior work on these three datasets, several performance metrics are used to evaluate the models. On CMU-MOSI and CMU-MOSEI, binary accuracy, weighted F1 score, mean absolute error, 7-class accuracy, and correlation with human labels are reported. For IEMOCAP, binary accuracy and weighted f1 score are used.

Hyperparameters: We perform grid search on the hyperparameter values. For STT, i) the learning rates of Adam are from 0.0001 to 0.001; ii) dropout ratios are from 0 to 0.5; iii) transformer encoder's hidden layers are of dimensions 40 and 60; iv) hidden states of GRU are of dimensions 40 and 60; v) the numbers of transformer encoder layers are from 4 to 8; vi) the numbers of heads in the multi-head attention layer are 8 and 10; vii) style ratios are from 0.1 to 0.5. The best hyper-parameter settings in our experiments are presented in table 1.

5 Experimental Results

Tables 2 and 3 report results from the baselines and STT on the three benchmark data sets. We can see that STT performs on par with the baselines and SOTA considered in our experiments. Since there exists a disparity between the results reported in (Tsai et al., 2019) and the results obtained from reproducing the source code released by the authors, we report numbers from reproduced Mult as Mult_{rep} and report numbers from the paper as $\text{Mult}_{\text{paper}}$. Note that STT beats the performance of Mult_{rep} while matching the performance of $\text{Mult}_{\text{paper}}$. To keep comparisons fair, we compare STT with the averages of scores attained by $\text{Mult}_{\text{paper}}$ and Mult_{rep} and note that on all three benchmark datasets on average we do better than Mult. While one may argue that reproducing the baseline is essential, we can offer as an explanation that the lack of clarity in reproducibility should not penalize our modeling efforts. To document our experimental evaluations and hypothesis in a credible manner, we report numbers from the paper as well as the reproduction. Furthermore, we note that STT is more efficient than Mult: it achieves better performance using less than a third number of parameters. See Table 4. This is because it uses 2 transformer blocks as opposed to 6 blocks in Mult.

To verify if the performance of STT increases with the number of parameters, we investigate increasing: 1) the dimension of the transformer encoder's hidden layer, 2) the number of encoder layers and number of heads, and 3) the number of layers in the GRU. However, we do not find improvements in performance by increasing the number of model parameters. We posit that this performance limitation is due to the relatively crude features extracted for audio and video analysis and suggest exploration in this direction for improved performance.

5.1 Ablation Studies

In this section we present results from ablation studies performed by i) varying ratio and studying the effect of different ratio values on the transformer's performance, ii) providing as input to the transformer unimodal features for downstream sentiment classification tasks, as well as iii) evaluating the effects of non verbal features.

5.1.1 Study 1: Varying Stepped Ratio

Table 5 presents results from the ablation study that shows the performance of different ratio values in equation (2). When $\text{ratio} = 0$, the model contains only a single transformer using text as the only input and standard layer normalization. This setup is meant to demonstrate the performance of STT when using text alone. "No stepped ratio" means the same style scalar and bias are used for all layers, i.e., $r_i = 1$ for all i in (2). Varying the ratio from 0.1 to 2 investigates the influence of its values.

Table 5 shows the effect of the stepped ratio on

Data View	CMU-MOSI					CMU-MOSEI

no stepped ratio	79.9	79.8	0.912	37.4	0.697

Table 5: Ablation study and effect of different ratios on CMU-MOSI. Ratio values vary in different levels as defined in (2). "ratio = 0" means the original layer normalization is applied. "no stepped ratio" means that the scale and bias terms are applied equally to all layers.

the performance. Using $\mathrm{ratio} = 0$, i.e., using only text features, worsens the performance. This is intuitive since additional modalities capture information not present in text. On the other hand, a large ratio like 1 or 2 degrades the performance of STT. This is also consistent with our intuition, since large ratios correspond to an almost complete dependency on the audio and video features (which are not as deeply studied as the representation of text). Thus an intermediate value for ratio should work best, and our experiments suggest a value of about 0.3. This supports our hypothesis that one should utilize the text embedding to capture the major semantics and utilize the audio and video embeddings to capture additional crucial stylistic information injected into text in a more gentle manner.

Finally, we see that using the stepped ratio is better than setting the same stepped ratio at each layer. This is consistent with our intuition that lower layers of the transformer model corresponds to basic semantics that should remain unaffected by external information.

5.1.2 Study 2: Unimodal Input Features

To study the effects of audio or video only input to the transformer model, we set up experiments in which the STT takes as input each of audio or video modes alone. For each modality, we vary the stepped ratio from 0.1 to -0.5 and report the best numbers. Table 6 presents results from STT using unimodal text or audio input when evaluated against the CMU-MOSI data set. From Table 6, while it is hard to determine if individually audio or video makes for a better input on the sentiment classification task, it is evident that the combined bimodal (audio+video) input does better than each unimodal input.

5.1.3 Study 3: Effect of Non-verbal Features

The results in Table 6 quantitatively show the effectiveness of non-verbal features, however, it's also vital to demonstrate that the non-verbal features can help to successfully classify specific examples' sentiments. Figures 3 and 4 present two case-studies that show how the STT model is able to capture non-verbal information effectively by comparing

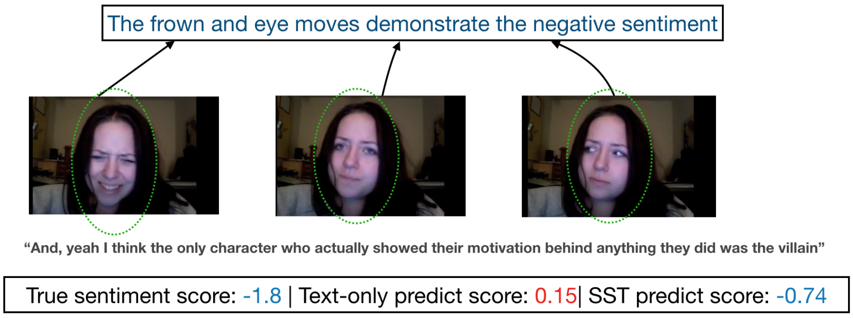

Figure 3: Case Study Example 1. The text in this utterance doesn't have a clear sentiment, however, the woman's frown and eye movements reveal her disappointment in the characters' motivations.

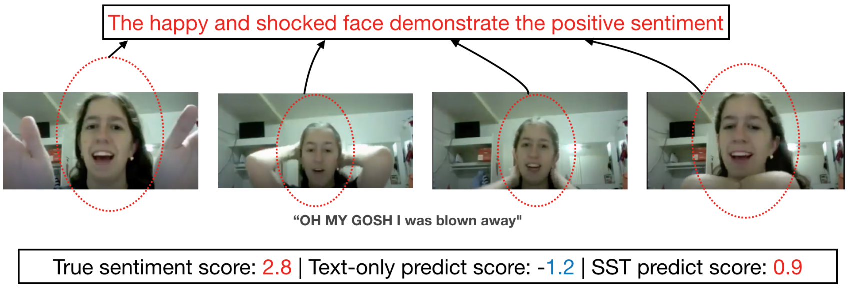

Figure 4: Case Study Example 2. The text "blown away" alone may be ambiguous. However, combined with the woman's happy facial expressions, the overall support is towards a strong positive sentiment.

	Acc-2	F-score	MAE	Acc-7	Corr
STT without audio/video	81.1	81.0	0.871	37.4	0.718
STT with audio	81.1	81.4	0.887	38.0	0.711
STT with video	81.7	81.5	0.888	37.9	0.720
STT with audio and video	**82.4**	**82.2**	**0.847**	**38.9**	**0.733**

Table 6: This table presents the effect of unimodal audio/video inputs to STT when evaluated on the CMU-MOSI data set.

the prediction of our STT model with that of a text-only model (stepped ratio $= 0$). We select two typical examples where our STT model is able to predict the correct sentiment score while the text only model is not. Figure 3 shows an example in which the text is neutral but the facial expression clearly demonstrates a negative sentiment. The STT model is able to predict the negative sentiment by using the facial features. Figure 4 shows another example with ambiguous text "blown away." Again, the text-only model does not predict correctly, but our STT is able to exploit the information in the visual features to predict the true sentiment.

5.2 Applications in Pre-trained Language Models

Our proposed method replaces the vanilla layer normalization in the transformer's layers with a stepped style adaptive layer normalization (SAdLaN). The same technique can also be applied to expand the capabilities of a pre-trained text-only transformer model. To validate this, we consider a pre-trained language model BERT and apply SAdLaN to every layer in BERT. This allows applying it on multimodal data sets, by fine-tuning the SAdLaN parameters or fine-tuning both the SAdLaN and BERT parameters. To clarify, differences in results reported in the previous sections and here lie in the transformer architecture. Since the BERT language model is pre-trained in prior work, the number of transformer layers differ in BERT and STT. The BERT language model in addition to using the transformer architecture also follows a *cloze* task in the language model. Unlike BERT, STT does not perform random masking on word tokens in the input.

It is also possible to combine styled layer normalization with the adapter method (Houlsby et al., 2019). The adapter method injects some trainable modules called adapters between the feed-forward layer and the layer-normalization in each transformer encoder layer of BERT. Each adapter contains two feed-forward projection layers, connected by a non-linear activation. The first feed-forward layer projects its input (of dimension d) to a smaller dimension, then the second layer maps the output

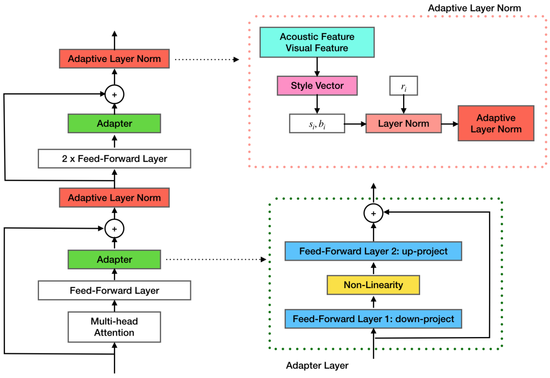

Figure 5: This figure illustrates injecting the adapter and the adaptive layer-normalization into BERT's transformer encoders. At each encoder layer of the BERT model, the adapter network is injected between the feed-forward layer and the adaptive layer normalization. During fine tuning, any part of the model can be frozen for ablation studies.

of the first layer back to dimension d. Houlsby et al. (2019) showed that injecting adapters and fine-tuning only the parameters of the adapters achieve competitive results against fine-tuning the whole BERT. We can combine SAdLaN with adapters to achieve similar results that again use fewer trainable parameters. Figure 5 illustrates the combination.

We now present experiments on these applications of SAdLaN (combined with BERT, or with BERT+adapters). The BERT model used in our experiments is the "bert-base-uncased" version in (Devlin et al., 2018). Evaluation uses the CMU-MOSI and CMU-MOSEI datasets. Raw text is used as the input textual feature instead of the pretrained Glove embeddings used in the other experiments, while acoustic and visual features remain the same.

Results: Tables 7 and 8 present the performance of different methods fine-tuning BERT on multi-modal data.

- The BERT model performs roughly the same with or without SAdLaN (see the first two rows in both tables). This is likely due to the large model parameters in BERT (110M) as opposed to the much fewer parameters in SAdLaN ($\leq$ 1M).

- Updating only the parameters of SAdLaN and the final logistic regression layer demonstrates an obvious improvement compared to using the final regression layer only (see the third to fifth rows). This confirms that our method is able to inject acoustic and visual information into the transformer model.

- Combining SAdLaN with the adapter method performs better than using the adapter method alone (see the last two rows). In this case, the performance is similar to fine-tuning the whole BERT (in the first row), while updating far fewer parameters (about only 1.5%). Thus our method improves the adapter method and enables efficient training on multimodal tasks.

6 Conclusion and Future Work

Inspired by the success of style transfer algorithms in image processing, this paper proposed the novel Style Transfer Transformer (STT) in which layer-normalization in the transformer model is replaced with a style Stepped Adaptive Layer Normalization (SAdLaN). The model is used to learn comprehensive multimodal representations for sentiment analysis and emotion recognition. Experiments on benchmark data sets established the effectiveness of the proposed method. Furthermore, ablation studies provided supports for our hypothesis of injecting audio and video to highly efficient text embeddings enhances the performance of the text embedding in multimodal tasks without the need for larger models or training data.

While our work is a first step towards learning multimodal embeddings via style transfer of non textual features onto text, as part of future work we will consider learning to inject non-verbal information into the text model in a recursive manner in order to achieve a higher model performance. The acoustic and visual features can be processed separately; besides of analyzing examples that benefit from the STT, it's also worthwhile to study examples that are negatively impacted by the method. While transformer models promise improved results, reproducibility in these models is a cause for concern since transformer models are particularly sensitive to initial conditions. As part of future work we will perform experiments to establish significance in observed results and report averaged hyper-parameters.

Abstract

The great majority of languages in the world are considered under-resourced for the successful application of deep learning methods. In this work, we propose a meta-learning approach to document classification in limited-resource setting and demonstrate its effectiveness in two different settings: few-shot, cross-lingual adaptation to previously unseen languages; and multilingual joint training when limited target-language data is available during training. We conduct a systematic comparison of several meta-learning methods, investigate multiple settings in terms of data availability and show that meta-learning thrives in settings with a heterogeneous task distribution. We propose a simple, yet effective adjustment to existing meta-learning methods which allows for better and more stable learning, and set a new state of the art on several languages while performing on-par on others, using only a small amount of labeled data.

1 Introduction

There are more than 7000 languages around the world and, of them, around 6% account for 94% of the population.[1] Even for the 6% most spoken languages, very few of them possess adequate resources for natural language research and, when they do, resources in different domains are highly imbalanced. Additionally, human language is dynamic in nature: new words and domains emerge continuously and hence no model learned in a particular time will remain valid forever.

With the aim of extending the global reach of Natural Language Processing (NLP) technology, much recent research has focused on the development of multilingual models and methods to efficiently transfer knowledge across languages. Among these advances are multilingual word vectors which aim to give word-translation pairs a similar encoding in some embedding space (Mikolov et al., 2013a; Lample et al., 2017). There has also been a lot of work on multilingual sentence and word encoders that either explicitly utilizes corpora of bi-texts (Artetxe and Schwenk, 2019; Lample and Conneau, 2019) or jointly trains language models for many languages in one encoder (Devlin et al., 2018; Conneau et al., 2019). Although great progress has been made in cross-lingual transfer learning, these methods either do not close the gap with performance in a single high-resource language (Artetxe and Schwenk, 2019; Conneau et al., 2019), e.g., because of cultural differences in languages which are not accounted for, or are impractically expensive (Lai et al., 2019).

Meta-learning, or *learning to learn* (Schmidhuber, 1987; Bengio et al., 1990; Thrun and Pratt, 1998), is a learning paradigm which focuses on the quick adaption of a learner to new tasks. The idea is that by training a learner to adapt quickly and from a few examples on a diverse set of training tasks, the learner can also generalize to unseen tasks at test time. Meta-learning has recently emerged as a promising technique for few-shot learning for a wide array of tasks (Finn et al., 2017; Koch et al., 2015; Ravi and Larochelle, 2017) including NLP (Dou et al., 2019; Gu et al., 2018). To our best knowledge, no previous work has been done in investigating meta-learning as a framework for multilingual and cross-lingual few-shot learning. We propose such a framework and demonstrate its effectiveness in document classification tasks. The only current study on meta-learning for cross-lingual few-shot learning is the one by (Nooralahzadeh et al., 2020), focusing on natural language inference and multilingual question answering. In their work, the authors focus on applying meta-learning to learn to adapt a monolingually trained classi-

fier to new languages. In contrast to this work, we instead show that, in many cases, it is more favourable to not initialize the meta-learning process from a monolingually trained classifier, but rather reserve its respective training data for meta-learning instead.

Our contributions are as follows: 1) We propose a meta-learning approach to few-shot cross-lingual and multilingual adaptation and demonstrate its effectiveness on document classification tasks over traditional supervised learning; 2) We provide an extensive comparison of meta-learning methods on multilingual and cross-lingual few-shot learning and release our code to facilitate further research in the field;[2] 3) We analyse the effectiveness of meta-learning under a number of different parameter initializations and multiple settings in terms of data availability, and show that meta-learning can effectively learn from few examples and diverse data distributions; 4) We introduce a simple yet effective modification to existing methods and empirically show that it stabilizes training and converges faster to better local optima; 5) We set a new state of the art on several languages and achieve on-par results on others using only a small amount of data.

2 Meta-learning methods

Meta-learning, or *learning to learn*, aims to create models that can learn new skills or adapt to new tasks rapidly from few training examples. Unlike traditional machine learning, datasets for either training or testing, which are referred to as *meta-train* and *meta-test* datasets, comprise of many tasks sampled from a distribution of tasks $p(\mathcal{D})$ rather than individual data points. Each task is associated with a dataset $\mathcal{D}$ which contains both feature vectors and ground truth labels and is split into a *support set* and a *query set*, $\mathcal{D} = \{S, Q\}$. The support set is used for fast adaptation and the query set is used to evaluate performance and compute a loss with respect to model parameter initialization. Generally, some model f_θ parameterized by θ, often referred to as the *base-learner*, is considered. A cycle of fast-adaptation on a support-set followed by updating the parameter initialization of the base-learner based on the loss on the query-set is called an *episode*. In the case of classification, the optimal parameters maximize the probability of the true labels across multiple batches $Q \subset \mathcal{D}$

$$\theta^* := \underset{\theta}{argmax} \mathbb{E}_{Q \subset \mathcal{D}}[\sum_{(x,y) \in Q} P_\theta(y|x)] \quad (1)$$

In few-shot classification/fast learning, the goal is to minimize the prediction error on data samples with unknown labels given a small support set for learning. *Meta-training* (Algorithm 1) consists of updating the parameters of the base-learner by performing many of the formerly described *episodes*, until some stop criterion is reached.

Following this procedure, the extended definition of optimal parameters is given in Eq. 2 to include fast adaptation based on the support set. The underlined parts mark the difference between traditional supervised-learning and meta-learning. The optimal parameters θ^* are obtained by solving

$$\underset{\theta}{argmax} \underline{\mathbb{E}_{l \subset L}[} \mathbb{E}_{\underline{S^l \subset \mathcal{D}}, Q^l \subset \mathcal{D}}[\textstyle\sum_{(x,y) \in Q^l} P_\theta(y|x, \underline{S^l})]\underline{]} \quad (2)$$

In this work, we focus on metric- and optimization-based meta-learning algorithms. In the following sections, their respective characteristics and the update methods in Algorithm 1 are introduced.

2.1 Prototypical Networks

Prototypical Networks (Snell et al., 2017) belong to the metric-based family of meta-learning algorithms. Typically they consist of an embedding network f_θ and a distance function $d(x_1, x_2)$ such as Euclidean distance. The embedding network is used to encode all samples in the support set S_c and compute *prototypes* μ_c per class $c \in C$ by computing the mean of the sample encodings of that respective class

$$\mu_c := \frac{1}{|S_c|} \sum_{(x_i, y_i) \in S_c} f_\theta(x_i) \quad (3)$$

---

[2] `https://github.com/mrvoh/meta_learning_multilingual_doc_classification`

Using the computed prototypes, Prototypical Networks classify a new sample as

$$p(y=c|x) = \frac{exp(-d(f_\theta(x),\mu_c)}{\sum_{c' \in C} exp(-d(f_\theta(x),\mu_{c'})} \quad (4)$$

Wang et al. (2019) show that despite their simplicity, Prototypical Networks can perform on par or better than other state-of-the-art meta-learning methods when all sample encodings are centered around the overall mean of all classes and consecutively L2-normalized. We also adopt this strategy.

2.2 MAML

Model-Agnostic Meta-Learning (MAML) (Finn et al., 2017) is an optimization-based method that uses the following objective function

$$\theta^* := \underset{\theta}{argmin} \sum_{D_l \sim p(D)} \mathcal{L}_l(f_{\theta_l^{(k)}}) \quad (5)$$

$\mathcal{L}_l(f_{\theta_l^{(k)}})$ is the loss on the query set after updating the base-learner for k steps on the support set. Hence, MAML directly optimizes the base-learner such that fast-adaptation of θ, often referred to as *inner-loop optimization*, results in task-specific parameters $\theta_l^{(k)}$ which generalize well on the task. Setting B as the batch size, MAML implements its MetaUpdate, which is also referred to as *outer-loop optimization*, as

$$\theta = \theta - \beta \frac{1}{B} \sum_{D_l \sim p(\mathcal{D})} (\nabla_\theta \mathcal{L}_l(f_{\theta_l^{(k)}})) \quad (6)$$

Such a MetaUpdate requires computing second order derivatives and, in turn, holding $\theta_l^{(j)} \forall j = 1, \ldots, k$ in memory. A first-order approximation of MAML (foMAML), which ignores second order derivatives, can be used to bypass this problem:

$$\theta = \theta - \beta \frac{1}{B} \sum_{D_l \sim p(\mathcal{D})} (\nabla_{\theta_l^{(k)}} \mathcal{L}_l(f_{\theta_l^{(k)}})) \quad (7)$$

Following previous work (Antoniou et al., 2018), we also adopt the following improvements in our framework for all MAML-based methods:

Per-step Layer Normalization weights Layer normalization weights and biases are not updated in the inner-loop. Sharing one set of weights and biases across inner-loop steps implicitly assumes that the feature distribution between layers stays the same at every step of the inner optimization.

Per-layer per-step learnable inner-loop learning rate Instead of using a shared learning rate for all parameters, the authors propose to initialize a learning rate per layer and per step and jointly learn their values in the MetaUpdate steps.

Cosine annealing of outer-loop learning rate It has shown to be crucial to model performance to anneal the learning rate using some annealing function (Loshchilov and Hutter, 2016).

2.3 Reptile

Reptile (Nichol et al., 2018) is a first-order optimization-based meta-learning algorithm which is designed to move the weights towards a manifold of the weighted averages of task-specific parameters $\theta_l^{(k)}$:

$$\theta = \theta - \beta \frac{1}{B} \sum_{D^l \sim p(\mathcal{D})} (\theta_l^{(k)} - \theta) \quad (8)$$

Despite its simplicity, it has shown competitive or superior performance against MAML, e.g., on Natural Language Understanding (Dou et al., 2019).

2.4 ProtoMAML

Triantafillou et al. (2020) introduce ProtoMAML as a meta-learning method which combines the complementary strengths of Prototypical Networks and MAML by leveraging the inductive bias of the use of prototypes instead of random initialization of the final linear layer of the network. Snell et al. (2017) show that Prototypical Networks are equivalent to a linear model when Euclidean distance is used. Using the definition of prototypes μ_c as per Eq. 3, the weights w_c and bias b_c corresponding to class c can be computed as follows

$$\mathbf{w}_c := 2\mu_c \qquad b_c := -\mu_c^T \mu_c \quad (9)$$

ProtoMAML is defined as the adaptation of MAML where the final linear layer is parameterized as per Eq. 9 at the start of each episode using the support set. Due to this initialization, it allows modeling a varying number of classes per episode.

ProtoMAMLn Inspired by Wang et al. (2019), we propose a simple, yet effective adaptation to ProtoMAML by applying L_2 normalization to the prototypes themselves, referred to as ProtoMAMLn, and, again, use a first-order approximation (foProtoMAMLn). We demonstrate that doing so leads to a more stable, faster and effective learning algorithm at only constant extra computational cost ($\mathcal{O}(1)$).

We hypothesize the normalization to be particularly beneficial in case of a relatively high-dimensional final feature space – in case of BERT-like models typically 768 dimensions. Let x be a sample and $\hat{x} = f_\theta(x)$ be the encoding of the sample in the final feature space. Since the final activation function is the *tanh* activation, all entries of both $\hat{x}$ and μ_c have values between -1 and 1. The pre-softmax activation for class c is computed as $\hat{x}^T\mu_c$. Due to the size of the vectors and the scale of their respective entries, this in-product can yield a wide range of values, which in turn results in relatively high loss values, making the inner-loop optimization unstable.

3 Related work

3.1 Multilingual NLP

Just as the deep learning era for monolingual NLP started with the invention of dense, low-dimensional vector representations for words (Mikolov et al., 2013b) so did cross-lingual NLP with works like those of Mikolov et al. (2013a); Faruqui et al. (2014). More recently, multilingual and/or cross-lingual NLP is approached by training one shared encoder for multiple languages at once, either by explicitly aligning representations with the use of parallel corpora (Artetxe and Schwenk, 2019; Lample and Conneau, 2019) or by jointly training on some monolingual language model objective, such as the Masked Language Model (MLM) (Devlin et al., 2018), in multiple languages (Devlin et al., 2018; Conneau et al., 2019).

The formerly described language models aim to create a shared embedding space for multiple languages with the hope that fine-tuning in one language does not degrade performance in others. Lai et al. (2019) argue that just aligning languages is not sufficient to generalize performance to new languages due to the phenomenon they describe as *domain drift*. Domain drift accounts for all differences for the same tasks in different languages which cannot be captured by a perfect translation system, such as differences in culture. They instead propose a multi-step approach which utilizes a multilingual teacher trained with Unsupervised Data Augmentation (UDA) (Xie et al., 2019) to create labels for a student model that is pretrained on large amounts of unlabeled data in the target language and domain using the MLM objective. With their method, the authors obtain state-of-the-art results on the MLDoc document classification task (Schwenk and Li, 2018) and the Amazon Sentiment Polarity Review task (Prettenhofer and Stein, 2010). A downside, however, is the high computational cost involved. For every language and domain combination: 1) a machine translation system has to be inferred on a large amount of unlabeled samples; 2) the UDA method needs to be applied to obtain a teacher model to generate pseudo-labels on the unlabeled in-domain data; 3) a language model must be finetuned, which involves forwards and backwards computation of a softmax function over a large output space (e.g., 50k tokens for mBERT and 250k tokens for XLM-RoBERTa). The final classifier is then obtained by 4) training the finetuned language model on the pseudo-labels generated by the teacher.

3.2 Meta-learning in NLP

Monolingual Bansal et al. (2019) apply meta-learning to a wide range of NLP tasks within a monolingual setting and show superior performance for parameter initialization over self-supervised pretraining and multi-task learning. Their method is an adaptation of MAML where a combination of a text-encoder, BERT (Devlin et al., 2018), is coupled with a parameter generator that learns to generate task-dependent initializations of the classification head such that meta-learning can be performed across tasks with disjoint label spaces. Obamuyide and Vlachos (2019b) apply meta-learning on the task of relation extraction; Obamuyide and Vlachos (2019a) apply lifelong meta-learning for relation extraction; Chen et al. (2019) apply meta-learning for few-shot learning on missing link prediction in knowledge graphs.

Multilingual Gu et al. (2018) apply meta-learning to Neural Machine Translation (NMT) and show its advantage over strong baselines such as cross-lingual transfer learning. By viewing each language pair as a task, the authors apply MAML to obtain competitive NMT systems with as little as 600 parallel sentences. To our best knowledge, the only application of meta-learning for cross-lingual few-shot learning is the one by Nooralahzadeh et al. (2020). The authors study the application of X-MAML, a MAML-based variant, to cross-lingual Natural Language Inference (XNLI) (Conneau et al., 2018) and Multilingual Question Answering (MLQA) (Lewis et al., 2019) in both a cross-domain and cross-language setting. X-MAML works by pretraining some model M on a high-resource task h to obtain initial model parameters θ_{mono}. Consecutively, a set L of one or more auxiliary languages is taken, and MAML is applied to achieve fast adaptation of θ_{mono} for $l \in L$. In their experiments, the authors use either one or two auxiliary languages and evaluate their method in both a zero- and few-shot setting. It should be noted that, in the few-shot setting, the full development set (2.5k instances) is used to finetune the model, which is not in line with other work on few-shot learning, such as (Bansal et al., 2019). Also, there is a discrepancy in the training set used for the baselines and their proposed method. All reported baselines are either zero-shot evaluations of θ_{mono} or of θ_{mono} finetuned on the development set of the target language, whereas their proposed method additionally uses the development set in either one or two auxiliary languages during meta-training.

4 Data

In this section, we give an overview of the datasets we use and the respective classification tasks.

MLDoc Schwenk and Li (2018) published an improved version of the Reuters Corpus Volume 2 (Lewis et al., 2004) with balanced class priors for all languages. MLDoc consists of news stories in 8 languages: English, Spanish, French, Italian, Russian, Japanese and Chinese. Each news story is manually classified into one of four groups: *Corporate/Industrial, Economics, Government/Social* and *Markets*. The train datasets contain 10k samples whereas the test sets contain 4k samples.

Amazon Sentiment Polarity Another widely used dataset for cross-lingual text classification is the Amazon Sentiment Analysis dataset (Prettenhofer and Stein, 2010). The dataset is a collection of product reviews in English, French, German and Japanese in three categories: *books dvds* and *music*. Each sample consists of the original review accompanied by meta-data such as the rating of the reviewed product expressed as an integer on a scale from one to five. In this work, we consider the sentiment polarity task where we distinguish between positive (rating > 3) and negative (rating < 3) reviews. When all product categories are concatenated, the dataset consists of 6K samples per language per dataset (train, test). We extend this with Chinese product reviews in the cosmetics domain from JD.com (Zhang et al., 2015), a large e-commerce website in China. The train and test sets contain 2k and 20k samples respectively.

5 Experiments

We use XLM-RoBERTa (Conneau et al., 2019), a strong multilingual model, as the base-learner in all models. We quantify the strengths and weaknesses of meta-learning as opposed to traditional supervised learning in both a cross- and a multilingual joint-training setting with limited resources.

Cross-lingual adaptation Here, the available data is split into multiple subsets: the auxiliary languages l_{aux} which are used in meta-training, the validation language l_{dev} which is used to monitor performance, and the target languages l_{tgt} which are kept *unseen* until meta-testing. Two scenarios in terms of amounts of available data are considered. A small sample of the available training data of l_{aux} is taken to create a limited-resource setting, whereas all available training data of l_{aux} is used in a high-resource setting. The chosen training data per language is split evenly and stratified over two disjoint sets from which the meta-training support and query samples are sampled, respectively. For meta-testing, one batch (16 samples) is taken from the training data of each target language as support set, while we test on the whole test set per target language (i.e., the query set).

Multilingual joint training We also investigate meta-learning as an approach to multilingual joint-training in the same limited-resource setting as previously described for the cross-lingual experiments. The difference is that instead of learning to generalize to $l_{tgt} \neq l_{aux}$ from few examples, here $l_{tgt} = l_{aux}$. If we can show that one can learn many similar tasks across languages from few examples per language, using a total number of examples in the same order of magnitude as in "traditional" supervised learning for training a monolingual classifier, this might be an incentive to change data collection processes in practice.

For both experimental settings above, we examine the influence of additionally using all training data from a high-resource language l_{src} during meta-training, English.

MetaUpdate Method	Num inner-loop steps	Inner-loop lr	Class-head lr multiplier	Inner-optimizer lr
Reptile	2,3,5	1e-5, 5e-5, 1e-4	1, 10	-
foMAML	2,3,5	1e-5, 1e-4, 1e-3	1, 10	3e-5, 6e-5, 1e-4
foProtoMAMLn	2,3,5	1e-5, 1e-4, 1e-3	1, 10	3e-5, 6e-5, 1e-4

Table 1: Search range per hyper-parameter. We consider the number of update steps in the inner-loop, *Num inner-loop steps*, the (initial) learning rate of the inner-loop, *Inner-loop lr*, the factor by which the learning rate of the classification head is multiplied, *Class-head lr multiplier*, and, if applicable, the learning rate with which the inner-loop optimizer is updated, *Inner-optimizer lr*. The chosen value is underlined.

Table 2: Average accuracy of 5 different seeds on the unseen target languages for MLDoc. Δ corresponds to the average accuracy across test languages.

5.1 Specifics per dataset

MLDoc As MLDoc has sufficient languages, we set l_{src} = English and l_{dev} = Spanish. The remaining languages are split in two groups: $l_{aux} = \{$German, Italian, Japanese$\}$; and $l_{tgt} = \{$French, Russian, Chinese$\}$. In the limited-resource setting, we randomly sample 64 samples per language in l_{aux} for training. Apart from comparing low- and high-resource settings, we also quantify the influence of augmenting the training set l_{aux} with a high-resource source language l_{src}, English.

Amazon Sentiment Polarity The fact that the Amazon dataset (augmented with Chinese) comprises of only five languages has some implications for our experimental design. In the cross-lingual experiments, where l_{aux}, l_{dev} and l_{tgt} should be disjoint, only three languages, including English, remain for meta-training. As we consider two languages too little data for meta-training, we do not experiment with leaving out the English data. Hence, for meta-training, the data consists of l_{src} = English, as well as two languages in l_{aux}. We always keep one language unseen until meta-testing, and alter l_{aux} such that we can meta-test on every language. We set l_{dev} = French in all cases except when French is used as the target language; then, l_{dev} = Chinese. In the limited-resource setting, a total of 128 samples per language in l_{aux} is used.

For the multilingual joint-training experiments there are enough languages available to quantify the influence of English during meta-training. When English is excluded, it is used for meta-validation. When included, we average results over two sets of experiments: one where l_{dev} = French and one where l_{dev} = Chinese.

5.2 Baselines

We introduce baselines trained in a standard supervised, non-episodic fashion. Again, we use XLM-RoBERTa-base as the base-learner in all models.

Zero-shot This baseline assumes sufficient training data for the task to be available in one language l_{src} (English). The base-learner is trained in a non-episodic manner using mini-batch gradient descent with cross-entropy loss. Performance is monitored during training on a held-out validation set in l_{src}, the model with the lowest loss is selected, and then evaluated on the same task in the target languages.

Non-episodic The second baseline aims to quantify the exact impact of learning a model through the meta-learning paradigm versus standard super-

Table 3: Average accuracy of 5 different seeds on the unseen target languages for Amazon. Δ corresponds to the average accuracy across test languages.

vised learning. The model learns from exactly the same data as the meta-learning algorithms, but in a non-episodic manner: i.e., merging support and query sets in l_{aux} (and l_{src} when included) and training using mini-batch gradient descent with cross-entropy loss. During testing, the trained model is independently finetuned for 5 steps on the support set (one mini-batch) of each target language l_{tgt}.

5.3 Training setup and hyper-parameters

We use the Ranger optimizer, an adapted version of Adam (Kingma and Ba, 2014) with improved stability at the beginning of training – by accounting for the variance in adaptive learning rates (Liu et al., 2019) – and improved robustness and convergence speed (Zhang et al., 2019; Yong et al., 2020). We use a batch size of 16 and a learning rate of 3e-5 to which we apply cosine annealing. For meta-training, we perform 100 epochs of 100 episodes and perform evaluation with 5 different seeds on the meta-validation set after each epoch. One epoch consists of 100 update steps where each update step consists of a batch of 4 episodes. Early-stopping with a patience of 3 epochs is performed to avoid overfitting. For the non-episodic baselines, we train for 10 epochs on the auxiliary languages while validating after each epoch. All models are created using the PyTorch library (Paszke et al., 2017) and trained on a single 24Gb NVIDIA Titan RTX GPU.

We perform grid search on MLDoc in order to determine optimal hyperparameters for the MetaUpdate methods. The hyper-parameters resulting in the lowest loss on l_{dev} = Spanish are used in all experiments. The number of update steps in the inner-loop is 5; the (initial) learning rate of the inner-loop is 1e-5 for MAML and ProtoMAML and 5e-5 for Reptile; the factor by which the learning rate of the classification head is multiplied is 10 for MAML and ProtoMAML and 1 for Reptile; when applicable, the learning rate with which the inner-loop optimizer is updated is 6e-5. See Table 1 for the considered grid.

6 Results

Cross-lingual adaptation Tables 2 and 3 show the accuracy scores on the target languages on MLDoc and Amazon respectively. We start by noting the strong multilingual capabilities of XLM-RoBERTa as our base-learner: Adding the full training datasets in three extra languages (i.e., comparing the zero-shot with the non-episodic baseline in the high-resource, 'Included' setting) results in a mere 1.2% points increase in accuracy on average for MLDoc and 0.6% points for Amazon. Although the zero-shot[3] and non-episodic baselines are strong, in the majority of cases, a meta-learning approach improves performance. This holds especially for our version of ProtoMAML (ProtoMAMLn), which achieves the highest average accuracy in all considered settings.

The substantial improvements for Russian on MLDoc and Chinese on Amazon indicate that meta-learning is most advantageous when the considered task distribution is somewhat heterogeneous or, in other words, when *domain drift* (Lai et al., 2019) is present. For the Chinese data used for the sentiment polarity task, the presence of domain drift is obvious as the data is collected from a different website and concerns different products than the other languages. For Russian in the MLDoc dataset, it holds that the non-episodic baseline has the smallest gain in performance when adding English data (l_{src}) in the limited-resource setting (0.2% absolute gain as

---

[3] The zero-shot baseline is only applicable in the 'Included' setting, as the English data is not available under 'Excluded'.

Table 4: Average accuracy of 5 different seeds on the target languages in the joint-training setting for MLDoc and Amazon. Δ corresponds to the average accuracy across test languages.

opposed to 5.7% on average for the remaining languages) and even a decrease of 2.4% points when adding English data in the high-resource setting. Especially for these languages with domain drift, our version of ProtoMAML (foProtoMAMLn) outperforms the non-episodic baselines with a relatively large margin. For instance, in Table 2 in the high-resource setting with English included during training, foProtoMAMLn improves over the non-episodic baseline with 9.1% points whereas the average gain over the remaining languages is 0.9% points. A similar trend can be seen in Table 3 where, in the limited-resource setting, foProtoMAMLn outperforms the non-episodic baseline with 1.9% points on Chinese, with comparatively smaller gains on average for the remaining languages.

Joint training In this setting, we achieve a new state of the art on MLDoc for German, Italian, Japanese and Russian using our method, foProtoMAMLn (Table 4).[4] The previous state of the art for German and Russian is held by Lai et al. (2019) (95.73% and 84.65% respectively). For Japanese and Italian, it is held by Eisenschlos et al. (2019) (80.55% and 80.12% respectively). The state of the art for French and Chinese is also held by Lai et al. (2019) (96.05% and 93.32% respectively). On the Amazon dataset, foProtoMAMLn also outperforms all other methods on average. The state of the art is held by (2019) with 93.3%, 94.2% and 90.6% for French, German and Chinese respectively and, although we do not outperform it, the differences are rather small – between 0.2% (Chinese) and 3.4% points (German) – even when grid search is based on MLDoc, while we use a much less computationally expensive approach.

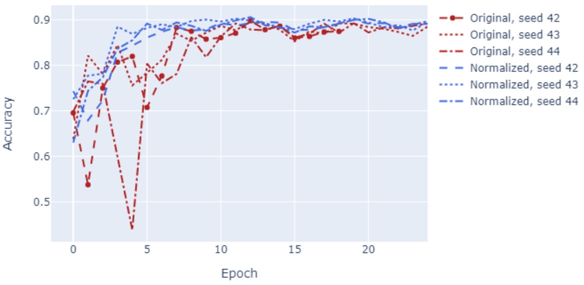

Figure 1: Validation accuracy for 3 seeds for original foProtoMAML and our new method, foProtoMAMLn.

Again, we use Russian in MLDoc to exemplify the difference between meta-learning and standard supervised learning. When comparing the difference in performance between excluding and including English meta-training episodes (l_{src}), opposite trends are noticeable: for standard supervised, non-episodic learning, performance drops slightly by 0.3%, whereas all meta-learning algorithms gain between 2.2% and 6.7% in absolute accuracy. This confirms our earlier finding that meta-learning benefits from, and usefully exploits heterogeneity in data distributions; in contrast, this harms performance in the standard supervised-learning case.

7 Ablations

foProtoMAMLn Figure 1 shows the development of the validation accuracy during training for 25 epochs for the original foProtoMAML and our model, foProtoMAMLn. By applying L_2 normalization to the prototypes, we obtain a more stable version of foProtoMAML which empirically converges faster. We furthermore re-run the high-

Table 6: Average accuracy of 5 different seeds on unseen target languages for Amazon when initializing from monolingual classifier in l_{src}. *Diff*: difference in average accuracy Δ across languages compared to initializing from the XLM-RoBERTa language model.

resource experiments with English for both MLDoc and Amazon using the original foProtoMAML (Table 5) and find it performs 4.3% and 1.7% accuracy points worse on average, respectively, further demonstrating the effectiveness of our approach.

Initializing from a monolingual classifier In our experiments, we often assume the presence of a source language (English). We now investigate (in the l_{src} = en 'Excluded' setting) whether it is beneficial to pre-train the base-learner in a standard supervised way on this source language and use the obtained checkpoint θ_{mono} as an initialization for meta-training (Table 6) rather than initializing from the transformer checkpoint.

We observe that only ProtoNet consistently improves performance, whereas foProtoMAMLn suffers the most with a decrease of 3.1% and 3.96% in accuracy in the low- and high-resource setting respectively. We surmise this difference is attributable to two factors. Intuitively, the monolingual classifier aims to learn a transformation from the input space to the final feature space, from which the prototypes for ProtoNet and ProtoMAML are created, in which the learned classes are encoded in their own disjoint sub-spaces such that a linear combination of these features can be used to correctly classify instances. ProtoNet aims to learn a similar transformation, but uses a Nearest Neighbours approach to classify instances instead. ProtoMAML on the other hand benefits the most from prototypes which can be used to classify instances *after* the inner-loop updates have been performed. This, in combination with the fact that the first-order approximation of ProtoMAML cannot differentiate through the creation of the prototypes, could explain the difference in performance gain with respect to ProtoNet.

8 Conclusion

We proposed a meta-learning framework for few-shot cross- and multilingual joint-learning for document classification tasks in different domains. We demonstrated that it leads to consistent gains over traditional supervised learning on a wide array of data availability and diversity settings, and showed that it thrives in settings with a heterogenous task distribution. We presented an effective adaptation to ProtoMAML and, among others, obtained a new state of the art on German, Italian, Japanese and Russian in the few-shot setting on MLDoc.

Abstract

Biomedical question-answering (QA) has gained increased attention for its capability to provide users with high-quality information from a vast scientific literature. Although an increasing number of biomedical QA datasets has been recently made available, those resources are still rather limited and expensive to produce. Transfer learning via pre-trained language models (LMs) has been shown as a promising approach to leverage existing general-purpose knowledge. However, fine-tuning these large models can be costly and time consuming, often yielding limited benefits when adapting to specific themes of specialised domains, such as the COVID-19 literature. To bootstrap further their domain adaptation, we propose a simple yet unexplored approach, which we call *biomedical entity-aware masking* (BEM). We encourage masked language models to learn entity-centric knowledge based on the pivotal entities characterizing the domain at hand, and employ those entities to drive the LM fine-tuning. The resulting strategy is a downstream process applicable to a wide variety of masked LMs, not requiring additional memory or components in the neural architectures. Experimental results show performance on par with state-of-the-art models on several biomedical QA datasets.

1 Introduction

Biomedical question-answering (QA) aims to provide users with succinct answers given their queries by analysing a large-scale scientific literature. It enables clinicians, public health officials and end-users to quickly access the rapid flow of specialised knowledge continuously produced. This has led the research community's effort towards developing specialised models and tools for biomedical QA and assessing their performance on benchmark datasets such as BioASQ (Tsatsaronis et al., 2015). Producing such data is time-consuming and requires involving domain experts, making it an expensive process. As a result, high-quality biomedical QA datasets are a scarce resource. The recently released CovidQA collection (Tang et al., 2020), the first manually curated dataset about COVID-19 related issues, provides only 127 question-answer pairs. Even one of the largest available biomedical QA datasets, BioASQ, only contains a few thousand questions.

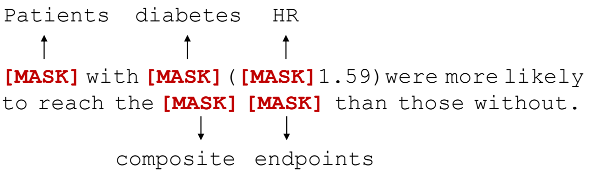

Figure 1: An excerpt of a sentence masked via the BEM strategy, where the masked words were chosen through a biomedical named entity recognizer. In contrast, BERT (Devlin et al., 2019) would randomly select the words to be masked, without attention to the relevant concepts characterizing a technical domain.

There have been attempts to fine-tune pre-trained large-scale language models for general-purpose QA tasks (Rajpurkar et al., 2016; Liu et al., 2019; Raffel et al., 2020) and then use them directly for biomedical QA. Furthermore, there has also been increasing interest in developing domain-specific language models, such as BioBERT (Lee et al., 2019) or RoBERTa-Biomed (Gururangan et al., 2020), leveraging the vast medical literature available. While achieving state-of-the-art results on the QA task, these models come with a high computational cost: BioBERT needs ten days on eight GPUs to train (Lee et al., 2019), making it prohibitive for researchers with no access to massive computing resources.

An alternative approach to incorporating external knowledge into pre-trained language models is to drive the LM to focus on pivotal entities characterising the domain at hand during the fine-

The mean incubation period was 5.6 days when excluding Wuhan residents—slightly larger than the estimate without right truncation [...].

Figure 2: A schematic representation of the main steps involved in fine-tuning masked language models for the QA task through the biomedical entity-aware masking (BEM) strategy.

tuning stage. Similar ideas were explored in works by Zhang et al. (2019), Sun et al. (2020), which proposed the ERNIE model. However, their adaptation strategy was designed to generally improve the LM representations rather than adapting it to a particular domain, requiring additional objective functions and memory. In this work we aim to enrich existing general-purpose LM models (e.g. BERT (Devlin et al., 2019)) with the knowledge related to key medical concepts. In addition, we want domain-specific LMs (e.g. BioBERT) to re-encode the already acquired information around the medical entities of interests for a particular topic or theme (e.g. literature relating to COVID-19).

Therefore, to facilitate further domain adaptation, we propose a simple yet unexplored approach based on a novel masking strategy to fine-tune a LM. Our approach introduces a *biomedical entity-aware masking* (BEM) strategy encouraging masked language models (MLMs) to learn entity-centric knowledge (§2). We first identify a set of entities characterising the domain at hand using a domain-specific entity recogniser (SciSpacy (Neumann et al., 2019)), and then employ a subset of those entities to drive the masking strategy while fine-tuning (Figure 1). The resulting BEM strategy is applicable to a vast variety of MLMs and does not require additional memory or components in the neural architectures. Experimental results show performance on a par with the state-of-the-art models for biomedical QA tasks (§4) on several biomedical QA datasets. A further qualitative assessment provides an insight into how QA pairs benefit from the proposed approach.

2 BEM: A Biomedical Entity-Aware Masking Strategy

The fundamental principle of a masked language model (MLM) is to generate word representations that can be used to predict the missing tokens of an input text. While this general principle is adopted in the vast majority of MLMs, the particular way in which the tokens to be masked are chosen can vary considerably. We thus proceed analysing the random masking strategy adopted in BERT (Devlin et al., 2019) which has inspired most of the existing approaches, and we then introduce the biomedical entity-aware masking strategy used to fine-tune MLMs in the biomedical domain.

BERT Masking strategy. The masking strategy adopted in BERT randomly replaces a predefined proportion of words with a special `[MASK]` token and the model is required to predict them. In BERT, 15% of tokens are chosen uniformly at random, 10% of them are swapped into random tokens (thus, resulting in an overall 1.5% of the tokens randomly swapped). This introduces a rather limited amount of noise with the aim of making the predictions more robust to trivial associations between the masked tokens and the context. While another 10% of the selected tokens are kept without modifications, the remaining 80% of them are replaced with the `[MASK]` token.

Biomedical Entity-Aware Masking Strategy We describe an entity-aware masking strategy which only masks biomedical entities detected by a domain-specific named entity recogniser (SciS-

Table 1: Performance of language models on the CovidQA and BioASQ 7b1 dataset. Values referenced with * come from the Tang et al. (2020) work and with † from Yoon et al. (2020).

pacy[1]). Compared to the random masking strategy described above, which is used to pre-train the masked language models, the introduced entity-aware masking strategy is adopted to boost the fine-tuning process for biomedical documents. In this phase, rather than randomly choosing the tokens to be masked, we inform the model of the relevant tokens to pay attention to, and encourage the model to refine its representations using the new surrounding context.

Replacing strategy We decompose the BEM strategy into two steps: (1) *recognition* and (2) *sub-sampling and substitution*. During the *recognition phase*, a set of biomedical entities $\mathcal{E}$ is identified in advance over a training corpus.

Then, at the *sub-sampling and substitution* stage, we first sample a proportion ρ of biomedical entities $\mathcal{E}_f \in \mathcal{E}$. The resulting entity subsets $\mathcal{E}_f$ is thus dynamically computed at batch time, in order to introduce a diverse and flexible spectrum of masked entities during training. For consistency, we use the same tokeniser for the documents d_i in the batch and the entities $e_j \in \mathcal{E}$. Then, we substitute all the k entity mentions $w^k_{e_j}$ in d_i with the special token `[MASK]`, making sure that no consecutive entities are replaced. The substitution takes place at batch time, so that the substitution is a downstream process suitable for a wide typology of MLMs. A diagram synthesizing the involved steps is reported in Figure 2.

3 Evaluation Design

Biomedical Reading Comprehension. We represent a document as $d_i := (s^i_0, \ldots, s^i_{j-1})$, a sequence of sentences, in turn defined as $s_j := (w^j_0, \ldots, w^j_{k-1})$, with w_k a word occurring in s_j. Given a question q, the task is to retrieve the span $w^j_s, \ldots, w^j_{s+t}$ from a document d_j that can answer the question. We assume the extractive QA setting where the answer span to be extracted lies entirely within one, or more than one document d_i.

In addition, for consistency with the CovidQA dataset and to compare with results in Tang et al. (2020), we consider a further and sightly modified setting in which the task consists of retrieving the sentence s^i_j that most likely contains the exact answer. This sentence level QA task mitigates the non-trivial ambiguities intrinsic to the definition of the exact span for an answer, an issue particularly relevant in the medical domain and well-know in the literature (Voorhees and Tice, 1999)[2].

Datasets. We assess the performance of the proposed masking strategies on two biomedical datasets: CovidQA and BioASQ.

---

[1] https://scispacy.apps.allenai.org/

[2] Consider, for instance, the following QA pair: *"What is the incubation period of the virus?"*, *"6.4 days (95% 175 CI 5.3 to 7.6)"*, where a model returning just *"6.4 days"* would be considered wrong.

BERT with STM	BERT with BEM

Table 2: Examples of questions and retrieved answers using BERT fine-tuned either with its original masking approach or with the biomedical entity-aware masking (BEM) strategy.

CovidQA (Tang et al., 2020) is a manually curated dataset based on the AI2's COVID-19 Open Research Dataset (Wang et al., 2020). It consists of 127 question-answer pairs with 27 questions and 85 unique related articles. This dataset is too small for supervised training, but is a valuable resource for zero-shot evaluation to assess the unsupervised and transfer capability of models.

BioASQ (Tsatsaronis et al., 2015) is one of the larger biomedical QA datasets available with over 2000 question-answer pairs. To use it within the extractive questions answering framework, we convert the questions into the SQuAD dataset format (Rajpurkar et al., 2016), consisting of question-answer pairs and the corresponding *passages*, medical articles containing the answers or clues with a length varying from a sentence to a paragraph. When multiple passages are available for a single question, we form additional question-context pairs combined subsequently in a postprocessing step to choose the answer with highest probability, similarly to Yoon et al. (2020). For consistency with the CovidQA dataset, we report our evaluation exclusively on the factoid questions of the BioASQ 7b Phase B1.

Baselines. We use the following unsupervised neural models as baselines: the out-of-the-box BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), as well as their variants BioBERT (Lee et al., 2019) and RoBERTa-Biomed (Gururangan et al., 2020) fine-tuned on medical and scientific corpora.

To highlight the impact of different fine-tuning strategies, we examine several configurations depending on the data and the masking strategy adopted. We experiment using the BioASQ QA training pairs during the fine-tuning stage and denote the models using them with `+BioASQ`. When we fine-tune the models on the corpus consisting of PubMed articles referred within the BioASQ and AI2's COVID-19 Open Research dataset, we compare two masking strategies denoted as `+STM` and `+BEM`, where `+STM` indicates the standard masking strategy of the model at hand and `+BEM` is our proposed strategy. We additionally report the T5 (Raffel et al., 2020) performance over CovidQA, which constitutes the current state-of-the-art (Tang et al., 2020)[3].

Metrics. To facilitate comparisons, we adopt the same evaluation scores used in Tang et al. (2020) to assess the models on the CovidQA dataset, i.e. mean reciprocal rank (MRR), precision at rank one (P@1), and recall at rank three (R@3); similarly, for the BioASQ dataset, we use the strict accuracy (SAcc), lenient accuracy (LAcc) and MRR, the BioASQ challenge's official metrics.

4 Experimental Results and Discussion

We report the results on the QA tasks in Table 1.

Among the unsupervised models, BERT achieves slightly better performance than RoBERTa on CovidQA, yet the situation is reversed on BioASQ (rows 1,5). The low precision of the two models (especially on the BioASQ dataset) confirms the difficulties in generalising to the biomedical domain. Specialised language

---

[3] We attach supplementary results in Appx. A on SQuAD (Tab. A1) and the *perplexity* of MLMs when fine-tuned on the medical collection with different masking strategies (Fig. A1)

models such as RoBERTa-Biomed and BioBERT show a significant improvement on the CovidQA dataset, but a rather limited one on BioASQ (rows 9,13), highlighting the importance of having larger medical corpora to assess the model's effectiveness. A general boost in performance is shared across models fine-tuned on the QA tasks, with a large benefit from the BioASQ QA. The performance gains obtained by the specialised models (BioBERT and RoBERTa-Biomed) suggest the importance of transferring not only the domain knowledge but also the ability to perform the QA task itself (rows 9,10; 13,14).

A further fine-tuning step before the training over the QA pairs has been proven beneficial for all of the models. The BEM masking strategy has significantly amplified the model's generalisability, with an increased adaptation to the biomedical themes shown by the notable improvement in R@3 and MRR; with the R@3 outperforming the state-of-the-art results of T5 fine-tuned on MS-MARCO (Bajaj et al., 2018) and proving the effectiveness of the BEM strategy.

Table 2 reports questions from the CovidQA related to three statistical indices (i.e. Odds Ratio, Hazard Ratio and Relative Risk) to assess the risk of an event occurring in a group (e.g. infections or death). We notice that even though the indices are mentioned as abbreviations, BERT fine-tuned with the STM is able to retrieve sentences with the exact answer for just one of three questions. By contrast, BERT fine-tuned with the BEM strategy succeeds in retrieving at least one correct sentence for each question. This example suggests the importance of placing the emphasis on the entities, which might be overlooked by LMs during the training process despite being available.

5 Related Work

Our work is closely related to two lines of research: the design of masking strategies for LMs and the development of specialized models for the biomedical domain.

Masking strategies. Building on top of the BERT's masking strategy (Devlin et al., 2019), a wide variety of approaches has been proposed (Liu et al., 2019; Yang et al., 2019; Jiang et al., 2020).

A family of masking approaches aimed at leveraging entity and phrase occurrences in text. SpanBERT, Joshi et al. (2020) proposed to mask and predict whole spans rather than standalone tokens and to make use of an auxiliary objective function. ERNIE (Zhang et al., 2019) is instead developed to mask well-known named entities and phrases to improve the external knowledge encoded. Similarly, KnowBERT (Peters et al., 2019) explicitly model entity spans and use an entity linker to an external knowledge base to form knowledge enhanced entity-span representations. However, despite the analogies with the BEM approach, the above masking strategies were designed to generally improve the LM representations rather than adapting them to particular domains, requiring additional objective functions and memory.

Biomedical LMs. Particular attention has been devoted to the adaptation of LMs to the medical domain, with different corpora and tasks requiring tailored methodologies. BioBERT (Lee et al., 2019) is a biomedical language model based on BERT-*Base* with additional pre-training on biomedical documents from the PubMed and PMC collections using the same training settings adopted in BERT. BioMed-RoBERTa (Gururangan et al., 2020) is instead based on RoBERTa-*Base* (Liu et al., 2019) using a corpus of 2.27M articles from the Semantic Scholar dataset (Ammar et al., 2018). SciBERT (Beltagy et al., 2019) follows the BERT's masking strategy to pre-train the model from scratch using a scientific corpus composed of papers from Semantic Scholar (Ammar et al., 2018). Out of the 1.14M papers used, more than 80% belong to the biomedical domain.

6 Conclusion

We presented BEM, a biomedical entity-aware masking strategy to boost LM adaptation to low-resource biomedical QA. It uses an entity-driven masking strategy to fine-tune LMs and effectively lead them in learning entity-centric knowledge based on the pivotal entities characterizing the domain at hand. Experimental results have shown the benefits of such an approach on several metrics for biomedical QA tasks.

A Appendix

We further examined whether the fine-tuning of the QA pairs affects not only the model adaptation to the QA task but it further helps realign the repression for the domain at hand. The report scores point out that the vanilla LMs are the ones gaining the most when using in-domain QA pairs, such as BioASQ, compared to the SQuAD (rows 2,3; 9,10). The advantage tends to be reduced on already specialised LMs (rows 16,17; 23;24).

Table A1: Performance of language models on the CovidQA and BioASQ 7b1 dataset. Values referenced with * comes from the Tang et al. (2020) work and with † from Yoon et al. (2020).

In Figure A1, we report the LM perplexity obtained when fine-tuning the model with the standard masking strategy versus the BEM strategy with different proportion of medical entities. Vanilla LMs experienced a huge gain with just a small fraction of entities, while already specialised LMs has a lower but still significant improvement. This could be expected as the specialised LMs has already encoded a large domain knowledge with representations that need to be realigned to the new ones.

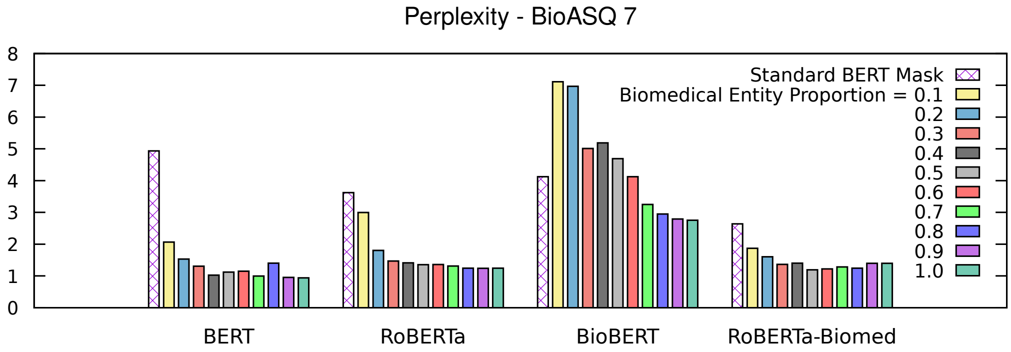

Figure A1: Perplexity of MLMs using different masking strategies on the collection of medical articles.

Attention-based Relational Graph Convolutional Network for Target-Oriented Opinion Words Extraction

Abstract

Target-oriented opinion words extraction (TOWE) is a subtask of aspect-based sentiment analysis (ABSA). It aims to extract the corresponding opinion words for a given opinion target in a review sentence. Intuitively, the relation between an opinion target and an opinion word mostly relies on syntactics. In this study, we design a directed syntactic dependency graph based on a dependency tree to establish a path from the target to candidate opinions. Subsequently, we propose a novel attention-based relational graph convolutional neural network (ARGCN) to exploit syntactic information over dependency graphs. Moreover, to explicitly extract the corresponding opinion words toward the given opinion target, we effectively encode target information in our model with the target-aware representation. Empirical results demonstrate that our model significantly outperforms all of the existing models on four benchmark datasets. Extensive analysis also demonstrates the effectiveness of each component of our models. Our code is available at `https://github.com/wcwowwwww/towe-eacl`.

1 Introduction

Target-oriented opinion words extraction (TOWE) (Fan et al., 2019) is a subtask of aspect-based sentiment analysis (ABSA) (Hu and Liu, 2004; Pontiki et al., 2016). Given a review and an opinion target in the sentence, the objective of TOWE is to extract the corresponding opinion words describing or evaluating the opinion targets from the review. Opinion targets are the words or phrases representing features or entities toward which users express their attitudes, whereas opinion words referring to those terms are used to express attitudes or opinions explicitly.

The food is tasty and portion sizes are appropriate.
Target: food Opinion: tasty

The food is tasty and portion sizes are appropriate.
Target: portion size Opinion: appropriate

Figure 1: Examples of TOWE task. The words highlighted in orange represent the given opinion targets, whereas the words in blue represent the corresponding opinion words.

Figure 1 shows two examples of TOWE. In the review "*The food is tasty and portion sizes are appropriate* .", the terms "*food*" and "*portion sizes*" are two given opinion targets. TOWE needs to extract the word "*tasty*" as the opinion word for the opinion target "*food*" and the opinion word "*appropriate*" for the opinion target "*portion sizes*".

Therefore, the first challenge is to effectively introduce the opinion target information into our model. Fan et al. (2019) designed the IO-BiLSTM to encode the context before and after the given opinion targets separately to represent the position of the existing opinion targets. Wu et al. (2020) introduced position embeddings based on the relative distance toward opinion targets. However, both studies only introduce parts of target information (the position information of targets). In this paper, we introduce the target-aware representation to fully exploit opinion target information in a concise way, which is especially important when our models are used for real-world reviews.

Becase TOWE can be viewed as a syntactic task, a natural solution is analysing the relationship between opinion targets and opinion words by dependency parsing. Recently, owing to the great success of graph convolutional networks (GCNs) in various fields (Kipf and Welling, 2016; Chen et al., 2018; Marcheggiani et al., 2018), a few researchers have attempted to encode the syntactic

---

April 19 - 23, 2021. ©2021 Association for Computational Linguistics

dependency information with GCNs to build a robust dependency encoder. For example, GCNs over the dependency tree have been exploited to perform semantic role labelling (Marcheggiani and Titov, 2017) and named entity recognition (Cetoli et al., 2017).In addition, several studies explore GCNs over a dependency graph to complete the ABSA task (Sun et al. (2019), Zhang et al. (2019), Liang et al. (2020), Wang et al. (2020)).

However, it is worth mentioning that TOWE is defined as a sequence labelling task, and the manner in which GCNs are applied to TOWE effectively is yet to be explored. In this study, we first construct a directed graph based on a dependency tree to be more suitable for TOWE. Subsequently, we propose ARGCN, which can enhance our model by encoding syntactic information. ARGCN can be seen as extending the Relational Graph Convolutional Networks (R-GCNs) (Schlichtkrull et al., 2018) with the distance-aware attention mechanism. ARGCN can consider the semantic relevance and syntactic relevance between words simultaneously when it propagates information. In addition, sequential information is extremely important for sequence-labelling tasks. Therefore, after using multi-layer graph convolutions to encode syntactic information, we feed the syntactic representation to a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) to capture the sequential information.

Experiments on four benchmark datasets demonstrate that our base model, Target-BiLSTM which is a BiLSTM with target-aware inputs has a similar or better performance than the state-of-the-art model, although we do not introduce extra external knowledge. In addiction, our full model ARGCN further improves the performance and significantly outperforms all of the existing models on four benchmark datasets. Furthermore, extensive experiments

demonstrate the effectiveness and necessity of all components in our full model. To the best of our knowledge, it is the first work on applying GCNs to the TOWE task.

The contributions of this paper can be summarized as follows.

- We propose target-aware representation to effectively introduce opinion target information. An empirical study shows it is significant and extensible for the TOWE task.
- We exploit syntactic dependency graphs of sentences and establish the relations between opinion targets and the corresponding opinion words.
- We propose a novel attention-based relational graph convolutional network, ARGCN, an extension of R-GCNs suited to encode syntactic dependency information.
- We propose an ARGCN-based TOWE model. Experimental results show that it significantly outperforms the state-of-the-art model on all datasets of the TOWE task.

2 Related Work

As subtasks of ABSA, a series of early studies focused on opinion targets extraction, including unsupervised/semi-supervised methods (Qiu et al., 2011; Liu et al., 2012, 2013) and supervised methods (Jakob and Gurevych, 2010; Li et al., 2010). Some recent studies extracted opinion targets and opinion words jointly in a uniform framework and achieved promising results (Wang et al., 2016; Li and Lam, 2017). However, they did not extract the corresponding relation between opinion targets and opinion words. Moreover, studies on extracting paired opinion relations are rare (Hu and Liu, 2004; Zhuang et al., 2006). Because it is important for downstream sentiment analysis and real-world applications, Fan et al. (2019) proposed a new subtask of ABSA, target-oriented word extraction, aiming to extract the corresponding opinion words for the given opinion targets in a review. They released four benchmark datasets for evaluation, designed a target-fused model, and achieved excellent performance. Wu et al. (2020) adopted transfer learning to transfer latent opinion information from the sentiment analysis model to the TOWE model. In this study, we also focus on the TOWE task.

Since Kipf and Welling (2016) proposed their GCN with some simplifications on ChebNet (Defferrard et al., 2016), a variety of graph convolutional networks appeared (Veličković et al., 2018; Schlichtkrull et al., 2018; Busbridge et al., 2019) and achieved great success in many fields, including computer vision (Chen et al., 2018; Garcia and Estrach, 2018; Wang et al., 2019), natural language processing (Marcheggiani and Titov, 2017; Marcheggiani et al., 2018; Yao et al., 2019; Wang et al., 2020) and even in chemistry (De Cao and Kipf, 2018). One of the reasons why GCNs work well in several fields is that they can naturally process the graph-structured data to greatly exploit

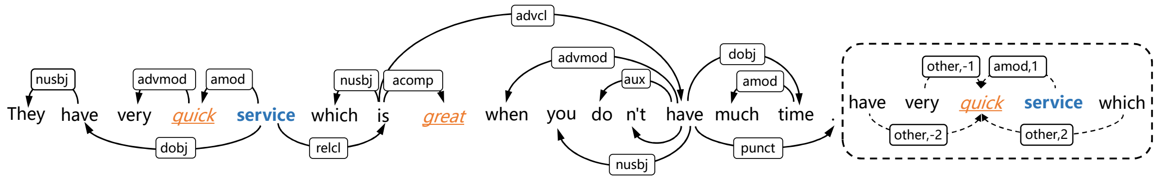

Figure 2: An example of the syntactic dependency graph based on dependency tree generated by spaCy[*]dependency parser. “service” is the given opinion target. “quick” and “great” are two corresponding opinion words. In the left figure, we show the reshaped dependency graph before adding extra edges for those who do not have dependency relation but have close distance (closer than a threshold D). In the right figure, we can see that each edge has two features: dependency relation and distance. And we show all edges coming towards the word ”quick” in the final graph as an example.

the latent information behind the graph structure. Therefore, they are proven to be efficient especially with only a small amount of data (Kipf and Welling, 2016; Garcia and Estrach, 2018).

Recently, a few studies have tried applying GCNs over the dependency graph to complete some ABSA tasks. Sun et al. (2019) proposed the CDT to perform GCN over a dependency tree together with contextual representations extracted by BiLSTM. Liang et al. (2020) introduced dependency relational embedding to GCN (Kipf and Welling, 2016) to complete ABSA with their DREGCN. Specially, the R-GAT-ABSA (Wang et al., 2020) is a newly proposed architecture for the ABSA task. It focuses on the GAT (Veličković et al., 2018) and extends it by introducing relational embedding for calculating relational attention.

3 Our Methods

3.1 Task Formalization

TOWE aims to extract corresponding opinion words based on the given opinion targets. Formally, we have a review sentence $s = \{w_1, w_2, ..., w_n\}$ containing n words. Then, we adopt the BIO tagging scheme (Ramshaw and Marcus, 1999) as Fan et al. (2019) do in their paper. For each words in the sentence, we tag them as $y_i \in \{B, I, O\}$ (B: Beginning, I: Inside, O: Others). For example, the sentence in figure 1 is tagged as “*The/O food/O is/O [tasty/B] and/O portion/O sizes/O are/O appropriate/O ./O*”, indicating the opinion word “*tasty*” for target “*food*”.

3.2 Target-Aware Representation

As described above, we should extract the corresponding opinion words based on the given opinion targets. Therefore, our model should be aware of which words are the opinion targets and identify the corresponding opinion words. All previous studies only encode the position information for targets. In contrast, we directly introduce category embeddings with respect to the target tag of words to fully introduce target information in the TOWE model. Figure 3 shows an overview of our model.

We denote the category embedding table as $\mathbf{T}^t \in \mathbb{R}^{3\times d^t}$, where d^t is the dimension of the category embedding. Next, we can obtain the target embedding of each word and form a target embedding matrix of a sentence as $\mathbf{E}^t = [\mathbf{e}_1^t; \mathbf{e}_2^t; \cdots ; \mathbf{e}_n^t]$.

To retain the target information clearly when feeding to the next module, we concatenate it together with the word representation.

$$\mathbf{e}_i = [\mathbf{e}_i^w, \mathbf{e}_i^t] \tag{1}$$

where e_i^w is word representation of word i, [,] represents the concatenation operation.

Thus, our model can understand which words are opinion targets. The target embedding table is jointly optimized during training so that our model can learn the proper target embeddings specifically for the TOWE task.

For simplicity, we denote our target-aware representation as $\mathbf{E} = [\mathbf{e}_1; \mathbf{e}_2; \cdots ; \mathbf{e}_n]$ and then feed it to the following modules.

3.3 Syntactic Dependency Graph

In this section, we provide a detailed description of our method of building a suitable syntactic dependency graph for the TOWE task. For a given sentence $s = \{w_1, w_2, \cdots , w_n\}$, after dependency parsing, we obtain a dependency tree. Figure 2 is the original dependency tree of the sentence “The food is tasty and portion sizes are appropriate .”. Next, we add some edges whose relative distance in the sentence is smaller than a given threshold D.

We formally define the directed graph as $G = \{V, E, \mathcal{R}, \mathcal{P}\}$, where $V = \{v_i\}_{i=1}^n$ is the set of nodes, which are words in a sentence, $E =$

---

[*] `https://spacy.io/`

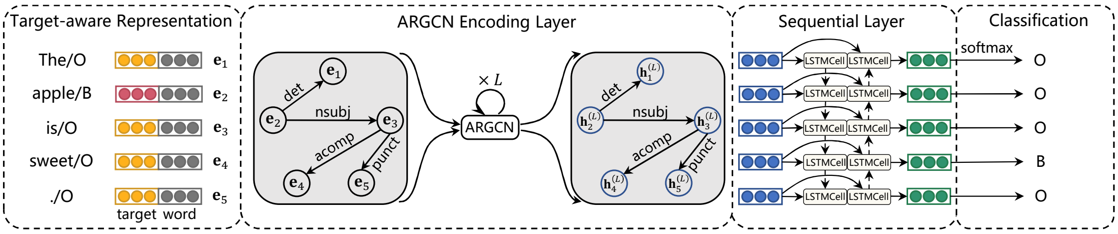

Figure 3: Overview of ARGCN. We generate the target-aware representation as the input node representation. Then, L-layers of ARGCN are applied over our syntactic dependency graph. After encoding, we capture sequential information with BiLSTM. Finally, we perform prediction with softmax classifier. Because of space limits, we omit other edges except for those who have dependency relations.

$\{e_{ij}\}_{i,j=1}^{n}$ is the set of edges, and $\mathcal{R} = \{r_{ij}\}_{i,j=1}^{n}$ is the set of edge relational types, where r_{ij} is the corresponding dependency relation from v_i to v_j. If there is not any dependency relation between v_i and v_j whose relative distance is smaller than D, we add an edge between them and set a special edge type for it, such as *other*. $\mathcal{P} = \{p_{ij}\}_{i,j=1}^{n}$ represents the set of relative positions, and p_{ij} is the relative position from v_i to v_j in the sentence. Note that e_{ij} indicates v_i is the neighbour of v_j.

To ensure the target information can correctly propagate to the latent opinion words, we redirect some specific dependency relations linking to the target words. Regarding dependency trees, when the edge type is *nsubj* or *dobj*, the direction of the edge is from predicate to subject or object. Hence, the information of the subject or object cannot flow through the predicate. Thus, we reverse the dependency edge when it links target words and its type is *nsubj* (nominal subject) or *dobj* (direct object). In addition, we remove the *root* relation because it is a self-loop, which is not helpful for our model.

3.4 Attention-Based Relational Graph Convolutional Network (ARGCN)

To encode the well-designed syntactic dependency graph, we begin from R-GCNs (Schlichtkrull et al., 2018) and extend it with a distance-aware attention mechanism. In this paper, we propose an attention-based relational graph convolutional network (ARGCN). The main purpose of our model is to consider semantic and syntactic relevance between words simultaneously.

R-GCNs (Schlichtkrull et al., 2018) updated the hidden states of nodes by aggregating node representations of their neighbours according to the edge type of their connections,

$$\mathbf{h}'_i = \sigma\left(\sum_{r\in\mathcal{R}}\sum_{j\in\mathcal{N}_i^r}\mathbf{x}_{ij,r} + \mathbf{W}_1\mathbf{h}_i\right) \tag{2}$$

$$\mathbf{x}_{ij,r} = \frac{1}{c_{i,r}}\mathbf{W}_r\mathbf{h}_j \tag{3}$$

where $\mathcal{R}$ denotes the set of relations, $\mathbf{h}_i$ is the input representation of node v_i, $\mathbf{h}'_i$ is the output representation of node v_i, $\mathcal{N}_i^r$ is the set of neighbours of v_i under relation $r \in \mathcal{R}$, $\mathbf{W}_r$ and $\mathbf{W}_1$ are trainable parameters, and $c_{i,r}$ is a problem-specific normalization constant, which is usually assigned as the number of neighbours of v_i under relation r. Moreover, σ is an element-wise activation function.

In Equation (5), each relation r corresponds to a relation-specific matrix $\mathbf{W}_r$. To reduce the parameter number, we perform a basis decomposition (Schlichtkrull et al., 2018). In particular, we set the number of bases as one:

$$\mathbf{W}_r = b_r\mathbf{W}_0 \tag{4}$$

where b_r is the coefficient depending on r. In this way, every $\mathbf{W}_r$ shares $\mathbf{W}_0$ as the basis, thereby the number of parameters is greatly reduced. On the other hand, b_r denotes the influence with respect to relation types.

In ARGCN, we introduce a distance-aware attention mechanism to enhance the power of RGCN:

$$\mathbf{x}_{ij,r} = \alpha_{ij,r}\mathbf{W}_0\mathbf{h}_j \tag{5}$$

$$\alpha_{ij,r} = \sigma(\mathbf{c}^T[b_r, \beta_{ij}]) \tag{6}$$

where β_{ij} is the attention coefficient between v_i and v_j, and $\mathbf{c}$ is a trainable vector, which can adjust the influence of the relation and the attention coefficient. σ is an activation function, and we choose to use ReLU in ARGCN layers.

We assume that the attention coefficients between two nodes are based on the features of nodes and the relative position in the sentence. First, we obtain query and key by project node features $\mathbf{h}_i$ and $\mathbf{h}_j$ by multiplying the same projection matrix $\mathbf{W}_1$. Next, we get relative positional encoding $\mathbf{p}$ by a sinusoid encoding matrix as in Dai et al. (2019).

Then, we use a shared attention mechanism to perform attention on the query, key, and relative positional encoding:

$$o_{ij} = \sigma(\mathbf{a}^T[\mathbf{W}_1\mathbf{h}_j, \mathbf{W}_1\mathbf{h}_i, \mathbf{p}]) \tag{7}$$

where **a** is a trainable vector mapping the concatenated representation to a scalar.

Finally, we normalize o_{ij} across all neighbours of v_i using the softmax function:

$$\beta_{ij} = \frac{exp(o_{ij})}{\sum\limits_{k \in \mathcal{N}_i} exp(o_{ik})} \tag{8}$$

where β_{ij} indicates the importance of v_i toward v_j with respect to the node representations and the relative position.

In addition, extending our mechanism to employ multi-head attention helps to stabilize the learning process and enhances the performance. Specifically, K independent attention mechanisms execute the transformation of Equation (5).

$$\mathbf{x}^k_{ij,r} = \alpha^k_{ij,r}\mathbf{W}^k_0\mathbf{h}_j \tag{9}$$

where $\mathbf{W}^k_0 \in \mathbb{R}^{d_j \times d_k}$, d_j is the input dimension, and d_k is the dimension of each head. Then, the output of the multi-head attention mechanism is

$$\mathbf{x}_{ij,r} = \mathbf{W}_d[\mathbf{x}^1_{ij,r}, \mathbf{x}^2_{ij,r}, ..., \mathbf{x}^K_{ij,r}] \tag{10}$$

where $\mathbf{W}_d \in \mathbb{R}^{Kd_k \times d_{j+1}}$.

Unlike Vaswani et al. (2017), who chose to use d_{j+1}/K as a dimension of each head, we set $d_k = d_{j+1}$, which leads to slight performance gains based on preliminary experiments.

We find that aspect and opinion terms often have direct or indirect relations in the graph based on the syntactic dependency tree. For example, Figure 2 shows that the relation between “service” and “quick” is direct whereas that between “service” and “great” is indirect. To capture these direct or indirect relations, we use L-layers of ARGCN, because L successive ARGCNs result in the propagation of information across the L-th order neighbour.

Moreover, with the deepening network layers, ARGCN tends to be over-smooth. In order to alleviate this problem, we add a residual connection on each ARGCN layer:

$$\mathbf{h}^{l+1}_i = \mathbf{h}^l_i + \mathbf{h}'^l_i \tag{11}$$

where $\mathbf{h}^l_i$ is the input of v_i in l-th layer of ARGCN, and $\mathbf{h}'^l_i$ is the output of v_i in l-th layer of ARGCN. Thus, $\mathbf{h}^{l+1}_i$ is the input of $(l+1)$-th layer of ARGCN.

3.5 Sequential Layer

The insufficiency of ARGCN is that it cannot encode the sequential information, which is extremely important for the TOWE task because it is defined as a sequence-labelling task. Intuitively, prediction relies on the prediction label of the words before and after the current word. Therefore, the performance of the model will not be satisfactory without capturing sequential information.

Consequently, we feed the syntactic representation extracted from L-layers of ARGCN to a BiLSTM to capture the sequential information:

$$\hat{\mathbf{h}}_i = \text{BiLSTM}(\mathbf{h}^{(L)}_i, \hat{\mathbf{h}}_{i-1}) \tag{12}$$

where $\hat{\mathbf{h}}_i$ is the concatenation of the forward and backward output vectors at time-step i.

Many other studies that used GCNs over the dependency graph (Marcheggiani and Titov, 2017; Sun et al., 2019; Wang et al., 2020) often applied LSTM to encode the sequential information, fed the obtained contextual representation to GCNs, and used them for predictions. We also attempted to first encode the sequential relationship by LSTM and then feed them to ARGCN to finally predict the labels of words. However, the performance was impaired. We believe the reason is that the sequential relationship is essential for sequence-labelling tasks. If we collect it before encoding the dependency information, it will be confused through aggregation, leading to poor performance.

3.6 Model Training

After collecting the sequential information, we simply mapped the representations to the output space with a fully connected layer and calculated the probability of the labels of words with the softmax function:

$$\hat{\mathbf{y}}_i = \text{softmax}(\mathbf{W}_{fc}\hat{\mathbf{h}}_i + \mathbf{b}_{fc}) \tag{13}$$

where $\mathbf{W}_{fc}$ and $\mathbf{b}_{fc}$ are the trainable parameters of the fully connected layer.

Next, the cross-entropy loss is defined as

$$\mathcal{L} = -\sum_{i=1}^{n}\sum_{k=0}^{2}\mathbb{I}(y_i = k)\log(\hat{y}_{ik}; \Theta) \tag{14}$$

and minimized during training. Here, the opinion word tags $\{O, B, I\}$ are correspondingly numeralized as labels $\{0, 1, 2\}$, respectively, and y_i denotes the gold label.

4 Experiments

4.1 Datasets and Metrics

Following the previous works (Fan et al., 2019; Wu et al., 2020), we evaluate the models on four benchmark datasets, including **14res**, **14lap**, **15res** and **16res**. Explicitly, the datasets **14res** and **14lap** are annotated from SemEval Challenge 2014 task 4 (Pontiki et al., 2014). The **15res** and **16res** are annotated from SemEval Challenge 2015 task 12 (Pontiki et al., 2015) and SemEval Challenge 2016 task 5 (Pontiki et al., 2016) respectively. The suffixes "**res**" and "**lap**" indicate they are collected from restaurant reviews and laptop reviews, respectively.

Datasets		#sentences	#targets
14res	Train	1627	2643
	Test	500	865
14lap	Train	1158	1634
	Test	343	482
15res	Train	754	1076
	Test	325	436
16res	Train	1079	1512
	Test	329	457

Table 1: Statistics of the four benchmark datasets.

The original SemEval challenge datasets are very popular for ABSA subtasks. However, they only contain annotations of aspect terms. Therefore, Fan et al. (2019) extended the annotation to further annotate the corresponding opinion words based on the given opinion targets and ignored the cases without explicit opinion words. Detailed statistics are shown in Table 1.

For the classification task, we adopted commonly used evaluation metrics: precision, recall, and F1-score. An extraction is considered as correct only when the opinion words from the beginning to the end are all predicted exactly as the ground truth.

4.2 Experimental Settings

For ARGCN and Target-BiLSTM, we adopted 300-dimension GloVe word embeddings (Pennington et al., 2014) as our word representations. For ARGCN-bert and Target-BiLSTM-bert, we adopted the last hidden states of the pre-trained BERT (Devlin et al., 2018) as word representations and fine-tuned it jointly. Inspired by Xu et al. (2018), we fine-tuned the GloVe vectors during training to obtain a domain-specific representation. The dimension of target embedding was 3 and 100 for our base model and GCNs-based models, respectively. We implemented our models with PyTorch (Paszke et al., 2019). We introduced 10 layers of ARGCN with 128 channels, 8 attention heads and set the hidden size of BiLSTM to 128.

We used spaCy (Honnibal and Johnson, 2015) as our dependency parser. To improve the generalization of ARGCN, dropout (Hinton et al., 2012) layers were applied after the activation with the probability of 0.5. The threshold of relative distance was set to be 3. All of the parameters were optimized by Adam optimizer (Kingma and Ba, 2014). The initial learning rate was 1×10^{-3}. We randomly split 20% of the training set as the validation set to fine-tune the hyperparameters and apply early stopping. Subsequently, we tested our models and averaged the results of 5 runs.

4.3 Compared Methods

We compare our model with several methods which can be categorized into three groups.

- **Early Solutions**: Some early solutions including rule-based methods and trivial deep learning methods are assigned to the first group. Inspired by Hu and Liu (2004) and Zhuang et al. (2006), Fan et al. (2019) proposed the Distance-rule and Dependency-rule as two representative rule-based methods. Following Liu et al. (2015) and Tang et al. (2016), Fan et al. (2019) proposed LSTM/BiLSTM and the TC-BiLSTM as some trivial deep learning methods. Besides, Fan et al. (2019) combined BiLSTM and Distance-rule method to complete TOWE in a pipelined way, which is named as Pipeline in the experiments.

- **TOWE models**: IOG is the first TOWE model proposed by Fan et al. (2019). It adopts six different positional and directional LSTMs to extract the opinion words. PE-BiLSTM is the base model of the LOTN (Wu et al., 2020). They introduced target information of TOWE by position embedding and extracted opinion words with a BiLSTM. Wu et al. (2020) proposed an effective transfer learning method LOTN to identify latent opinions from the sentiment analysis model. Next, they integrated it with the PE-BiLSTM to achieve the state-of-the-art performance in TOWE.

- **AOPE model**: Aspect-opinion pair extraction (AOPE) task which aims at extracting aspects

Models	14res			14lap			15res			16res

Table 2: Main Experimental Results(%). Comparison between our proposed models and baselines on four benchmark datasets. P, R and F1 are *precision*, *recall* and *F1-score*, respectively. The result in bold indicates that the model outperforms all of the baselines above significantly ($p < 0.01$). The results are averaged scores of 10 runs. The results of baselines are copied from the previous work (Wu et al., 2020). Noted that the experiment results of SDRN are obtained by using their released codes to train and evaluate on TOWE datasets.

and opinion expressions in pairs, is a similar task as TOWE. SDRN, which is the state-of-the-art AOPE model proposed by Chen et al. (2020), mainly consists of an opinion entity extraction unit, a relation detection unit, and a synchronization unit. The synchronization unit could enhance the mutual benefit on the opinion entity extraction unit and a relation detection unit. As a baseline, it extracts the target and opinion. Subsequently, it collect the corresponding target-opinion pairs based on the predicted relations to complete the TOWE task.

- **Base model**: To show the effectiveness of the target-aware representation, we propose our base model, Target-BiLSTM. A BiLSTM receives the target-aware representation as the input and then predicts after a fully-conneceted layer and a softmax layer.

4.4 Results and Discussion

Table 2 shows the main experimental results of the baselines and our models on four benchmark datasets. We can observe that under the same condition of using GloVe for word representation, our base model Target-BiLSTM outperforms PE-BiLSTM with large improvements ranging from 3.31% to 6.18% on F1-score. Note that PE-BiLSTM uses position embedding. Instead, Target-BiLSTM introduces target embedding, which is the evidence of the effectiveness of our target-aware representation. Moreover, it not only performs similarly with LOTN on 14res and 14lap but also significantly outperforms LOTN on 15res and 16res, which introduces a large-scale sentiment analysis dataset for transfer learning. In contrast, our base model does not require additional resources except for the pre-trained word embeddings. Besides, our full model ARGCN outperforms Target-BiLSTM by a large margin on the four datasets. Therefore, we conclude that the syntactic information ARGCN encoded over the dependency graph is helpful to TOWE. Furthermore, ARGCN significantly outperforms LOTN, with large improvements of F1-score ranging from 1.54% to 3.43%, which proves its effectiveness on the TOWE task. With a pre-trained representation model, BERT, Target-BiLSTM achieves the state-of-the-art performance by significant margins, demonstrating the power of the pre-trained language model in this task. In addition, when we apply BERT as the representation layer for ARGCN, it achieves a further state-of-the-art performance, which demonstrates the effectiveness of capturing important syntactic information for sentiment analysis.

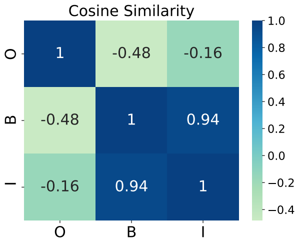

Figure 4: We train a Target-BiLSTM on 14res. After convergence, we collect the target embeddings and calculate their cosine similarities.

[‡] SDRN is an APOE model but evaluated on TOWE task.

Models	14res			14lap			15res			16res		
	P	R	F1	P	R	F1	P	R	F1	P	R	F1
R-GCN (#basis=1)	85.23	81.67	83.40	76.24	70.26	73.12	74.08	72.74	73.35	86.25	80.76	83.39
GAT	81.30	74.27	77.63	66.73	65.43	66.07	68.91	70.59	69.74	81.80	72.76	77.02
RGAT	82.99	74.37	78.44	74.38	62.96	68.19	77.67	66.33	71.55	87.18	77.71	82.18
ARGCN (original)	84.79	82.59	83.65	77.79	70.79	74.06	74.83	74.06	74.43	85.64	83.47	84.53
ARGCN	86.67	82.72	84.65	79.45	71.60	75.32	76.57	76.88	76.72	86.16	84.19	85.16

Table 3: Ablation study results (%). LSTM-ARGCN denotes the model that places the BiLSTM before ARGCN. R-GCN (#basis=1) denotes using R-GCNs with basis decomposition and the number of basis is one. ARGCN (original) denotes using original dependency tree.

4.5 Visualization on Target Embedding

We also designed an experiment to evaluate if our model can learn suitable target embeddings during training, thereby it can benefit from the target-aware representation.

Intuitively, a good target embedding should have such a property: the representation of tag "O" is significantly different from that of tags "B" and "I". However, representations of " B" and "I" are similar. However, after training, as we can observe from Figure 4, the cosine similarity between "B" and "I" is close to 1 (0.94), whereas the similarity between "B" and "O" is even smaller than 0, and that between "I" and "O" has the same property. Therefore, we conclude that our model can learn to generate suitable target embeddings during training, which confirms the effectiveness and interpretability of our target-aware representation.

4.6 Ablation Study

To evaluate the influence of each component of ARGCN, we conducted an ablation study on ARGCN. As shown in Table 3, we observe performance drops on the four datasets when replacing ARGCN layers with R-GCN layers following Equations (2) and (3), which verifies the effectiveness of employing the distance attention mechanism in ARGCN. In addition, we also find that ARGCN outperforms GAT(Veličković et al., 2018), which proves that specifying the dependency relational type is crucial for applying the dependency graph to the TOWE task. Moreover, we compared ARGCN with an ABSA model, RGAT (Busbridge et al., 2019), which is similar to our model. We observe that our ARGCN performs much better than RGAT. These results prove that in TOWE task, the approach to encode syntactic information in ARGCN is more suitable than the approach used in RGAT.

In addition, to confirm that the syntactic graph that we constructed is effective and reasonable, we compare the ARGCN over the original dependency tree and our reshaped graph. The results show that the latter model outperforms the former one, which proves the effectiveness of our reshaped syntactic dependency graph.

4.7 Model Analysis

We further analyzed the effect of the layers number of ARGCN, the number of attention heads and the threshold of relative distance in our model by using different hyper-parameters but keeping the other hyper-parameters unchanged as the experimental settings mentioned above.

Because ARGCN involves an L-layer GCN, we investigated the effect of the layers number L with the final performance of ARGCN. Basically, we varied the value of L in the set $\{2, 4, 6, 8, 10, 12\}$ and showed the corresponding F1-score of ARGCN on the 14res dataset.

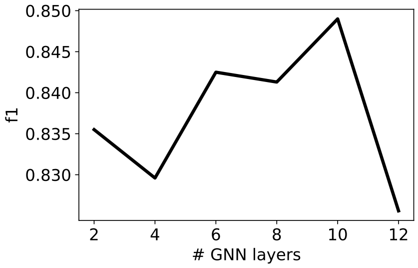

Figure 5: Effect of the number of GCN layers.

The results are illustrated in Figure 5, which shows that ARGCN achieves the best performance when $L = 10$. In this sense, our model can benefit from the increasing number of layers. However, when the number of layers is larger than 10, our model will tend to be over-smoothing which makes the performance drop dramatically.

As for the effect of the number of attention heads, we also varied the value of attention head number K in the set $\{1, 2, 4, 6, 8, 10, 12, 14\}$ and showed the corresponding F1-score of ARGCN on the 14res dataset.

Models	14res			14lap			15res			16res		
	P	R	F1	P	R	F1	P	R	F1	P	R	F1
Dependency-rule	64.57	52.72	58.04	45.09	31.57	37.14	65.49	48.88	55.98	76.03	56.19	64.62
RGCN (syntax only)	78.03	67.57	72.42	69.61	52.91	60.12	71.69	64.71	68.02	77.48	72.76	75.05
RGAT (syntax only)	78.59	61.65	69.10	61.87	45.50	52.44	68.09	58.42	62.88	74.62	65.52	69.78
ARGCN (syntax only)	78.51	71.65	74.92	68.23	56.44	61.78	74.36	65.31	69.55	82.11	72.57	77.05

Table 4: Evaluation of syntactic information (%). *Syntax only* means these models use only target embedding without word representation.

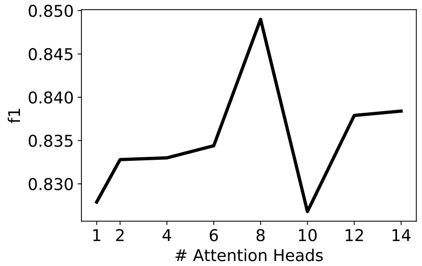

Figure 6: Effect of the number of Attention Heads.

The results are illustrated in Figure 6, which shows that ARGCN achieves the best performance when $K = 8$, which justifies the selection on the number of attention heads in the experimental settings. Comparing with the cases between $K = 1$ and $K = 8$, we found that the model with 8 attention heads performed better than that with only one attention head. This experiment demonstrated the necessity of the multi-head attention mechanism in our ARGCN.

As for the effect of threshold of relative distance, we performed experiments with different threshold D ranging from 1 to 6 and showed the corresponding F1-score of ARGCN on the 14res dataset.

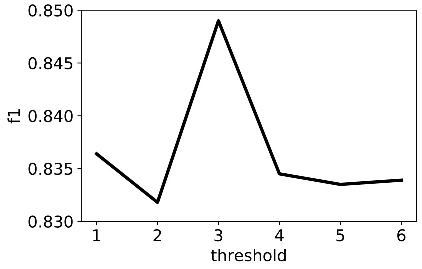

Figure 7: Effect of threshold.

The results are illustrated in Figure 7, where we observe that $D = 3$ is best value for the threshold in ARGCN.

4.8 Evaluation of syntactic information

To understand the role of syntactic information in the TOWE task and measure the ability of ARGCN to encode syntactic information, we removed word representation from our models, leaving the target embedding only. We performed some experiments on evaluating our model on the TOWE task only with syntactic information and position information. The results are shown in Table 4.

We notice that the GNN models perform better than the dependency-rule model, which indicates that the GNN models can exploit the syntactic information well from dependency graph. Furthermore, our well-designed ARGCN outperforms other GNN models including the latest one, RGAT. The reason is that ARGCN considers the relative position of words in the sentence and dependency relation type at the same time when it propagate the information.

5 Conclusions

In this paper, we proposed a target-aware representation to efficiently introduce opinion target information to our TOWE model. Moreover, we proposed ARGCN by extending the R-GCNs with a distance-aware attention mechanism. Because the sequential information is essential for such a sequence-labelling task, we captured the sequential information with BiLSTM after ARGCN layers and then completed the TOWE task. Empirical results show that our model significantly outperforms all baselines, including state-of-the-art, with large margins, which strongly proves the effectiveness of our model. The extensive analysis also demonstrated the effectiveness and necessity of all components in our model. In addition, we found that GNN model, especially a well-designed GNN model, such as ARGCN, is suitable for encoding syntactic information. We hope that these findings can be insightful for other researchers in the community.

Abstract

Detecting arguments in online interactions is useful to understand how conflicts arise and get resolved. Users often use figurative language, such as sarcasm, either as persuasive devices or to attack the opponent by an ad hominem argument. To further our understanding of the role of sarcasm in shaping the disagreement space, we present a thorough experimental setup using a corpus annotated with both argumentative moves (agree/disagree) and sarcasm. We exploit joint modeling in terms of (a) applying discrete features that are useful in detecting sarcasm to the task of argumentative relation classification (agree/disagree/none), and (b) multi-task learning for argumentative relation classification and sarcasm detection using deep learning architectures (e.g., dual Long Short-Term Memory (LSTM) with hierarchical attention and Transformer-based architectures). We demonstrate that modeling sarcasm improves the argumentative relation classification task (agree/disagree/none) in all setups.

1 Introduction

User-generated conversational data such as discussion forums provide a wealth of naturally occurring arguments. The ability to automatically detect and classify argumentative relations (e.g., agree/disagree) in threaded discussions is useful to understand how collective opinions form, how conflict arises and is resolved (van Eemeren et al., 1993; Abbott et al., 2011; Walker et al., 2012b; Misra and Walker, 2013; Ghosh et al., 2014; Rosenthal and McKeown, 2015; Stede and Schneider, 2018). Linguistic and argumentation theories have thoroughly studied the use of sarcasm in argumentation, including its effectiveness as a persuasive device or as a means to express an ad hominem fallacy (attacking the opponent instead of her/his argument) (Tindale and Gough, 1987; van Eemeren and Grootendorst, 1992; Gibbs and Izett, 2005; Averbeck, 2013). We propose an experimental setup to further our understanding of the role of sarcasm in shaping up the disagreement space in online interactions. The disagreement space, defined in the context of the dialogical perspective on argumentation, is seen as the speech acts initiating the difference of opinions that argumentation is intended to resolve (Jackson, 1992; van Eemeren et al., 1993). Our study is based on the Internet Argument Corpus (IAC) introduced by Abbott et al. (2011) that contains online discussions annotated for the presence/absence and the type of an argumentative move (agree/disagree/none) as well as the presence/absence of sarcasm. Consider the dialogue turns from IAC in Table 1, where the **current turn** (henceforth, ct) is a sarcastic response to the

Arg. Rel.	Turn Pairs
Agree	**Prior Turn:** Today, no informed creationist would deny natural selection. **Current Turn:** Seeing how this was proposed over a century and a half ago by Darwin, what took the creationists so long to catch up?
Disagree	**Prior Turn:** Personally I wouldn’t own a gun for self defense because I am just not that big of a sissy. **Current Turn:** Because taking responsibility for ones own safety is certainly a sissy thing to do?
	Prior Turn: I’m not surprised that no one on your side of the debate would correct you, but wolves and dogs are both members of the same species. The Canid species. **Current Turn:** Wow, you ’re even wrong when you get away from your precious Bible and try to sound scientific.
None	**Prior Turn:** The hand of God kept me from serious harm. Maybe He has a plan for me. **Current Turn:** You better hurry up . Are n’t you like 113 years old.

Table 1: Sarcastic turns that disagree, agree or have no argumentative relation with their prior turns.

April 19 - 23, 2021.

prior turn (henceforth, pt). These dialogue moves can be argumentative (agree/disagree) or not argumentative (none). The argumentative move can express agreement (first example) or disagreement (the second example is an undercutter, while the third example is an ad hominem attack). The fourth example, although sarcastic, it is not argumentative. It can be noticed that none of the current turns contain explicit lexical terms that could signal an argumentative relation with the prior turn. Instead, the argumentative move is being implicitly expressed using sarcasm.

We study whether modeling *sarcasm* can improve the detection and classification of *argumentative relations* in online discussions. We propose a thorough experimental setup to answer this question using feature-based machine learning approaches and deep learning models. For the former, we show that *combining* features that are useful to detect sarcasm (Joshi et al., 2015; Muresan et al., 2016; Ghosh and Muresan, 2018) with state-of-the-art argument features leads to better performance for the argumentative relation classification task (agree/disagree/none) (Section 5). For the deep learning approaches, we hypothesize that *multitask learning*, which allows representations to be shared between multiple tasks (e.g., here, the tasks of argumentative relation classification and sarcasm detection), lead to better generalizations. We investigate the impact of multitask learning for a dual Long Short-Term Memory (LSTM) Network with hierarchical attention (Ghosh et al., 2017) (Section 4.2) and BERT (Bidirectional Encoder Representations from Transformers) (Devlin et al., 2019), including an optional joint multitask learning objective with uncertainty-based weighting of task-specific losses (Kendall et al., 2018) (Section 4.3). We demonstrate that multitask learning improves the performance of the argumentative relation classification task for all settings (Section 5). We provide a detailed qualitative analysis (Section 5.1) to give insights into when and how modeling sarcasm helps. We make the code from our experiments publicly available.[1] The Internet Argument Corpus (IAC) (Walker et al., 2012b) can be found for public acess here:[2]

2 Related Work

Argument mining is a growing area of research in computational linguistics, focusing on the detection of argumentative structures in a text (see Stede and Schneider (2018) for an overview). This paper focuses on two subtasks: argumentative relation identification and classification (i.e., agree/disagree/none). Some of the earlier work on argumentative relation identification and classification has relied on feature-based machine learning models, focusing on online discussions (Abbott et al., 2011; Walker et al., 2012b; Misra and Walker, 2013; Ghosh et al., 2014; Wacholder et al., 2014) and monologues (Stab and Gurevych, 2014, 2017; Persing and Ng, 2016; Ghosh et al., 2016). Stab and Gurevych (2014) proposed a set of lexical, syntactic, semantic, and discourse features to classify them. On the same essay dataset, Nguyen and Litman (2016) utilized contextual information to improve the accuracy. Both Stab and Gurevych (2017) and Persing and Ng (2016) used Integer Linear Programming (ILP) based joint modeling to detect argument components and relations. Rosenthal and McKeown (2015) introduced sentence similarity and accommodation features, whereas Menini and Tonelli (2016) presented how entailment between text pairs can discover argumentative relations. Our argumentative features in the feature-based model are based on the above works (Section 4.1). We show that additional features that are useful in sarcasm detection (Joshi et al., 2015; Ghosh and Muresan, 2018) enhance the performance on the argumentative relation identification and classification tasks.

In addition to feature-based models, deep learning models have been recently used for these tasks. Potash et al. (2017) proposed a pointer network, and Hou and Jochim (2017) offered LSTM+Attention network to predict argument components and relations jointly, whereas (Chakrabarty et al., 2019) exploited adaptive pretraining (Gururangan et al., 2020) for BERT to identify argument relations. We use two multitask learning objectives (argumentative relation identification/classification and sarcasm detection), as our goal is to investigate whether identifying sarcasm can help in modeling the disagreement space. Majumder et al. (2019); Chauhan et al. (2020) used multitask learning for sarcasm & sentiment and sarcasm, sentiment, & emotion, respectively, where a direct link between the corresponding tasks is

---

[1] https://github.com/ritvikshrivastava/multitask_transformers
[2] https://nlds.soe.ucsc.edu/iac2

evident.

Finally, analyzing the role of sarcasm and verbal irony in argumentation has a long history in linguistics (Tindale and Gough, 1987; Gibbs and Izett, 2005; Averbeck, 2013; van Eemeren and Grootendorst, 1992). We propose joint modeling of argumentative relation detection and sarcasm detection to empirically validate sarcasm's role in shaping the disagreement space in online conversations.

While the focus of our paper is not to provide a state-of-the-art sarcasm detection model, our feature-based models, along with the deep learning models for sarcasm detection are based on state-of-the-art approaches. We implemented discrete features such as pragmatic features (González-Ibáñez et al., 2011; Muresan et al., 2016), diverse sarcasm markers (Ghosh and Muresan, 2018), and incongruity detection features (Riloff et al., 2013; Joshi et al., 2015). The LSTM models are influenced by Ghosh and Veale (2017); Ghosh et al. (2018), where the function of contextual knowledge is used to detect sarcasm. Lastly, transformer models such as BERT and RoBERTa have been used in the winning entries for the recent shared task on sarcasm detection (Ghosh et al., 2020). In our research, for both kinds of deep-learning models, the best results are obtained by using the multitask setup, showing that multitask learning indeed helps improve both tasks.

3 Data

Our $training$ and $test$ data are collected from the Internet Argument Corpus (IAC) (Walker et al., 2012a). This corpus consists of posts from conversations in online forums on a range of controversial political and social topics such as Evolution, Abortion, Gun Control, and Gay Marriage (Abbott et al., 2011, 2016). Multiple versions of IAC corpora are publicly available, and we use a particular subset, marked as IAC_{orig}, collected from Abbott et al. (2011). This consists of around 10K pairs of conversation turns (i.e., prior turn pt and the current turn ct) that were annotated using Mechanical Turk for argumentative relations (agree/disagree/none) and other characteristics such as sarcasm/non-sarcasm, respect/insult, nice/nastiness. Median Cohen's κ is 0.5 across all topics.

For agree/disagree/none relations the annotation was a scalar judgment on an 11 point scale [-5,5] where "-5" indicates a high disagreement move, "0" indicates none relation, and "5" denotes a high agreement move. We converted the scalar values to three categories: disagree (D) for values between [-5, -2], none (N) for values between [-1,1], and agree (A) for values between [2,5], where the scalar partitions ([]) follow prior work with IAC (Misra and Walker, 2013; Rosenthal and McKeown, 2015).

Arg. Rel.	Sarcasm	# of turns
A	S	315 (33%)
	NS	638 (67%)
D	S	2207 (57%)
	NS	1696 (43%)
N	S	2285 (44%)
	NS	2841 (56%)

Table 2: Dataset statistics; A (Agree), D (Disagree), N (None); S (Sarcasm), NS (Non-Sarcasm)

Each "current turn" that is part of a <pt,ct> pair is also labeled with a Sarcasm (S) or Non-Sarcasm (NS) label. Table 2 shows the data statistics in terms of argumentative relations (A/D/N) and sarcasm (S/NS). We split the dataset into $training$ (80%; 7,982 turn pairs), $test$ (10%; 999 turn pairs), and dev (10%; 999 turn pairs) sets where each set contains a proportional number of instances (i.e., 80% of 315 (=252) sarcastic turns (S) with argument relation label A (agree) appears in the training set). The dev set is used for parameter tuning.

4 Experimental Setup

We present the computational approaches to investigate whether modeling *sarcasm* can help detect argumentative relations. As our goal is to provide a comprehensive empirical investigation of sarcasm's role in argument mining rather than propose new models, we explore three separate machine learning approaches well-established for studying argumentation and figurative language. First, we implement a Logistic Regression method that exploits a combination of state-of-the-art features to detect argumentative relations as well as sarcasm (Section 4.1). Second, we present a dual LSTM architecture with hierarchical attention and its multitask learning setup (Section 4.2). Third, we discuss experiments using the pre-trained BERT models and our multitask learning architectures based on it (Section 4.3).

4.1 Logistic Regression with Discrete Features

We use a Logistic Regression (LR) model that uses both argument-relevant ($ArgF$) and sarcasm-relevant ($SarcF$) features. Unless mentioned, all features were extracted from the current turn ct.

Argument-relevant features ($ArgF$). We first evaluate the features that are reported as being useful for identifying and classifying argumentative relations: (a) *n-grams* (e.g., unigram, bigram, trigram) created based on the full vocabulary of the IAC corpus; (b) *argument lexicons*: two lists of twenty words representing agreement (e.g., "agree", "accord") and disagreement (e.g., "differ", "oppose"), respectively (Rosenthal and McKeown, 2015) (c) *sentiment lexicons* such as MPQA (Wilson et al., 2005) and opinion lexicon (Hu and Liu, 2004) to identify sentiment in the turns; (d) *hedge features*, since they are often used to mitigate speaker's commitment (Tan et al., 2016); (e) *PDTB discourse markers* because *claims* often start with discourse markers such as *therefore*, *so*. We discard markers from the temporal relation; (f) *modal verbs* because they signal the degree of certainty when expressing a claim (Stab and Gurevych, 2014); (g) *pronouns*, since they dialogically point to the previous speaker's stance; (h) *textual entailment*: captures whether a position expressed in the prior turn is accepted in the current turn (Cabrio and Villata, 2012; Menini and Tonelli, 2016)[3]; (i) *lemma overlap* to determine topical alignment between the prior and current turn (Somasundaran and Wiebe, 2010). We compute lemma overlap of noun, verbs, and adjectives between the turns, and (j) *negation* to extract explicit negation cues (e.g., "not", "don't") that often signal disagreement.

Sarcasm-relevant features ($SarcF$). As sarcasm-relevant features we use: (a) Linguistic Inquiry Word Count *(LIWC)* (Pennebaker et al., 2001) features to capture the linguistic, social, individual, and psychological processes; (b) measuring *sentiment incongruity*, that is, capturing the number of times the difference in sentiment polarity between the prior turn pt and the current turn ct occurs and number of positive and negative sentiment words in turns (Joshi et al., 2015); (c) *sarcasm markers* used by Ghosh and Muresan (2018), such as *capitalization*, *quotation marks*, *punctuation*, *exclamations* that emphasize a sense of surprisal, *tag questions*, *interjections* because they seem to undermine a literal evaluation, *hyperbole* because users frequently overstate the magnitude of an event in sarcasm, and *emoticons & emojis*, since they often emphasize the sarcastic intent.

We use *SKLL*, an open-source Python package that wraps around the Scikit-learn tool (Pedregosa et al., 2011). [4] We perform the feature-based experiment using the Logistic Regression model from Scikit-learn.

In the experimental runs, LR$_{ArgF}$ (i.e., model that uses just the $ArgF$ features) denotes the *individual* model and LR$_{ArgF+SarcF}$ (i.e., model that uses both $ArgF$ and $SarcF$ features) is the *joint* model.

4.2 Dual LSTM and Multitask Learning

LSTMs are able to learn long-term dependencies (Hochreiter and Schmidhuber, 1997) and have been shown to be effective in Natural Language Inference (NLI) research, where the task is to establish the *relationship* between multiple inputs (Rocktäschel et al., 2015). This type of architecture is often denoted as the *dual architecture* since one LSTM models the premise and the other models the hypothesis (in Recognizing Textual Entailment(RTE) tasks). Ghosh et al. (2018) used the dual LSTM architecture with hierarchical attention (HAN) (Yang et al., 2016) for sarcasm detection to model the conversation context, and we use their approach in this paper to model the current turn ct and the prior turn pt. HAN implements attention both at the word level and sentence level. The distinct characteristics of this attention is that the word/sentence-representations are weighted by measuring similarity with a word/sentence level context vector, respectively, which are randomly initialized and jointly learned during training (Yang et al., 2016). We compute the vector representation for the current turn ct and prior turn pt and concatenate vectors from the two LSTMs for the final softmax decision (i.e., A, D or N for argumentative relation detection). Henceforth, this dual LSTM architecture is denoted as $LSTM_{attn}$.

To measure the impact of *sarcasm* in argumentative relation detection, we use a multitask learning approach. Multitask learning aims to leverage useful information in multiple related tasks to im-

---

[3] We used the textual entailment toolkit (AllenNLP) (Gardner et al., 2017).

[4] https://pypi.org/project/skll/

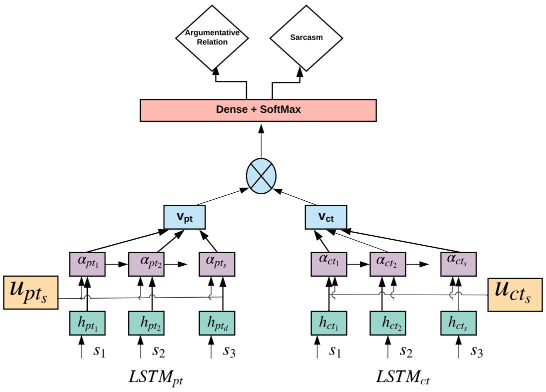

Figure 1: Sentence-level Multitask Attention Network for prior turn pt and current turn ct. Figure is inspired by Yang et al. (2016).

prove each task's performance (Caruana, 1997; Liu et al., 2019). We use a simple hard parameter sharing network. The architecture is a replica of the $LSTM_{attn}$, with a modification of employing two loss functions, one for sarcasm detection (i.e., training using the S and NS labels) and another for the argumentative relation classification task (i.e., training using the A, D, and N labels).

Figure 1 shows the high-level architecture of the dual LSTM and multitask learning ($LSTM_{MT}$). The prior turn pt (left) and the current turn ct (right) are read by two separate LSTMs (i.e., $LSTM_{pt}$ and $LSTM_{ct}$). In case of $LSTM_{MT}$ the concatenation of v_{pt} and v_{ct} is passed through a dense+Softmax layer for the MTL as shown in Figure 1. Similar to the LR models, $LSTM_{attn}$ now represents the *individual* model (i.e., predicts only the argumentative relation) whereas $LSTM_{MT}$ represents the *joint* model.

Dynamic Multitask Loss. In addition to simply adding the two losses, we also employed *dynamic weighting* of task-specific losses during the training process, based on the homoscedastic uncertainty of tasks, as proposed in Kendall et al. (2018):

$$L = \sum_t \frac{1}{2\sigma_t^2} L_t + \log \sigma_t^2 \qquad (1)$$

where L_t and σ_t depict the task-specific loss and its variance, respectively, over training instances. We denote this variation as $\text{LSTM}_{MT_{uncert}}$.

4.3 Pretrained BERT and Multitask Learning

BERT (Devlin et al., 2019), a bidirectional transformer model, has achieved state-of-the-art performance for many NLP tasks. BERT is initially trained on masked token prediction and next sentence prediction tasks over large corpora (English Wikipedia and Book Corpus). During its training, a special token "[CLS]" is added to the beginning of each training instance, and the "[SEP]" tokens are added to indicate the end of utterance(s) and separate, in case of two utterances (e.g., pt and ct). During the evaluation, the learned representation for the "[CLS]" token is processed by an additional layer with nonlinear activation. In its standard form, pre-trained BERT ("bert-base-uncased") can be used for transfer learning by fine-tuning on a downstream task, i.e., argument relation detection where training instances are labeled as A, D, and N. We denote the BERT baseline model as $BERT_{orig}$ that is fine-tuned over the $training$ partition of only the argumentative relation data (i.e., individual task training). Unless mentioned otherwise, we use the BERT predictions available via the "[CLS]" token. To this end, we propose a couple of variations in the multitask learning settings, and they are briefly described in the following sections.

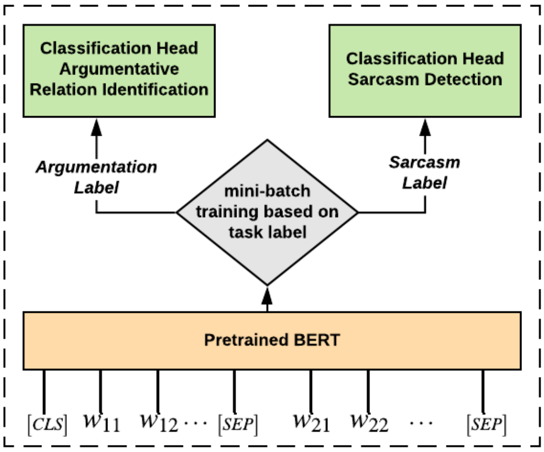

Figure 2: Alternating mini-batch training based on the task type ($BERT_{ALT}$).

Multitask Learning with BERT. The first model we use for multitask learning is denoted as $BERT_{MT}$ (i.e., BERT Multitask Learning). Here, we pass the BERT output embeddings to two classification heads - one for each task (i.e., detection of argumentative relation and sarcasm), and the relevant gold labels are passed to them. Each classification head is a linear layer (size=3 and 2 for # of labels for argumentative relation and sarcasm detection, respectively) applied on top of the pooled BERT output. The losses from these individual heads are added and propagated back through the model. This allows BERT to model the nuances of both tasks and their interdependence simultaneously.

Dynamic Loss: Similar to the LSTM architecture, here, too, we experiment with dynamic multitask loss. We denote this variation as BERT$_{MT_{uncert}}$.

Alternate Multitask Learning. We employ another multitask learning technique where we attempt to enrich the learning with fine-tuning of labeled *additional* material from the sarcasm detection task. Notably, we exploit "sarcasm V2", a sarcasm detection dataset that was also curated from the original corpus of IAC and was released by Oraby et al. (2016). We pre-process the "sarcasm V2" dataset by removing duplicates that appear in IAC_{orig} and we end up selecting 3513 $training_{v2}$ instances and 423 dev_{v2} instances balanced between S/NS categories for experiments and merged them to the sarcasm dataset ($training$ and dev, respectively) from IAC_{orig}. Note, unlike the original multitask setting, this time we have more sarcastic instances (a total of 11,495) than instances labeled with argumentative roles (7,982 instances as before) for the training purpose, while keeping the $test$ set from IAC_{orig} unchanged.

Since the $training$ data is now unequal between the two tasks of argumentative relation and sarcasm detection, we create mini-batches so that each batch consists of instances with only one task label (i.e., either argumentative labels or sarcasm labels). The batches from the two tasks are interleaved uniformly, i.e., the BERT model is only passed to one of the two tasks' specific classification heads, and the related loss is used to update the parameters in that iteration. This way, the model trains both tasks but alternates between the two tasks per mini-batch iteration while the extra batches of sarcasm data from the "sarcasm V2" dataset are managed at the end together. This model is denoted as $BERT_{ALT}$ (see Figure 2).

For brevity, all models' parameter tuning description (e.g., Logistic Regression, Dual LSTM, BERT) is in the supplemental material.

5 Results and Discussion

Table 3 presents the classification results on the $test$ set. We report F1 scores for each class (A, D and N) and Micro-F1 overall score (F1$_{micro}$) (used to account for multi-class and class imbalance).

Model	$F1_{micro}$	A	D	N
LR$_{ArgF}$	53.5	22.4	57.2	56.3
LR$_{ArgF+SarcF}$	**56.4**$^{\alpha^*}$	31.0	58.4	58.9
LSTM$_{Attn}$	51.8	28.0	49.4	59.2
LSTM$_{MT}$	53.1	30.0	53.2	56.5
LSTM$_{MT_{uncert}}$	**54.6** $^{\alpha^*}$	33.1	54.5	58.5
BERT$_{orig}$	62.2	41.8	63.3	64.4
BERT$_{MT}$	63.2	44.5	64.1	65.4
BERT$_{MT_{uncert}}$	**65.3**$^{\alpha^*}$	44.6	66.2	67.5
BERT$_{ALT}$	63.4	40.1	62.2	66.9

Table 3: Results for argumentative relation detection ($F1_{micro}$ and F1 scores/category) on the $test$ set of IAC_{orig}. $^{\alpha^*}$ depict significance on $p \leq 0.05$ (measured via Mcnemar's test) against the corresponding individual model (e.g., LR$_{ArgF}$, LSTM$_{Attn}$, BERT$_{orig}$, respectively). Highest scores per group of models are in **bold**.

The LR model using both the $SarcF$ and $ArgF$ features performs better than the model that uses $ArgF$ features alone, improving the overall performance by an absolute 2.9% F1$_{micro}$, and showing a huge impact on the agreement class (A) (8.6% absolute improvement). Table 4 shows the *top* discrete features for argumentative relation identification. From $ArgF$ features (first column), we notice discourse expansion ("particularly"), contrast ("although") and agree/disagree lexicon getting high feature weights. We also notice *pronouns* receive large feature weights because argumentative text often refers to personal stance (e.g., "you think", "I believe"). However, when analyzing $ArgF + SarcF$ features we find various sarcasm markers, such as tag questions, hyperbole, multiple punctuation, or sarcasm characteristics such as sentiment incongruity receive the highest weights.

For **LSTM models**, we see that multitask learning helps, LSTM$_{MT_{uncert}}$ showing a 2.8% improvement over the single model LSTM$_{Attn}$, which is statistically significant. Moreover, we notice that the improvement for the agree (A) and disagree (D) classes is 5.1%, with just a small reduction for the none (N) class (0.7%).

For **BERT**, we notice better results when performing multitask learning, while the best performing model is obtained from BERT$_{MT_{uncert}}$ where we experimented with the dynamic weighting of task-specific losses during the training process (Kendall et al., 2018). The performance increase is consistent across all three classes. The difference in performance among each setup is sta-

LR$_{ArgF}$	LR$_{ArgF+SarcF}$
pronouns: I. my (both A), your(s) (D); *discourse*: so, because, for (all A), incidentally, particularly, although (all D); *disagree_lexicon*: disagree, differ (both D);*agree_lexicon*: agreed (A); *entailment relation*; *negation* (D)	*pronouns*: mine, my (both A), you (D); *discourse*: then (A), though, however (both D); *modal*: will (A); *punctuation*: multiple question marks (both A and D); *tag question*: "are you", "do you" (both D); *hyperbole*: wonderful (A), nonsense, biased (both D); *LIWC dimensions*: anxiety, assent, certainty (all D); *sentiment incongruity* (D); *interj*: so, agreed (both A)

Table 4: Top discrete features from LR$_{ArgF}$ and LR$_{ArgF+SarcF}$ models, respectively. A and D depict the argumentative relations (agree and disagree) for the particular feature.

tistically significant, as shown in Table 3. Moreover, BERT$_{MT_{uncert}}$ model improves the $F1_{micro}$ by a large margin when compared to the LR and the LSTM models. However, adding more data for the auxiliary task (i.e., sarcasm detection) as presented in $BERT_{ALT}$ did not provide any significant improvement, only a 0.2 improvement of $F1_{micro}$ over $BERT_{MT}$ (however it does show improvement over the single task model). The reason could be that although "sarcasm V2"is a subset of the original IAC corpus, it was annotated by a different set of Turkers than IAC_{orig} with different annotation guidelines.

Between the three classes - A, D, and N - we observe the lowest performance on the A class. This is unsurprising, given the highly unbalanced setting of the $training$ data (A occurs less than 10% of times in the IAC_{orig}, see Table 2).

In sum, these improvements through multitask learning over single task argumentative relation detection indicate that modeling sarcasm is useful in modeling the disagreement space in online discussions. This provides an empirical justification to existing theories that study sarcasm's impact in modeling argumentation, persuasion, and argument fallacies such as ad hominem attacks. Finally, we notice that multitask learning also improves the performance on the sarcasm detection task (results are presented in the Appendix).

5.1 Qualitative Analysis

To further investigate the effect of multitask learning, we present qualitative analysis studies to:

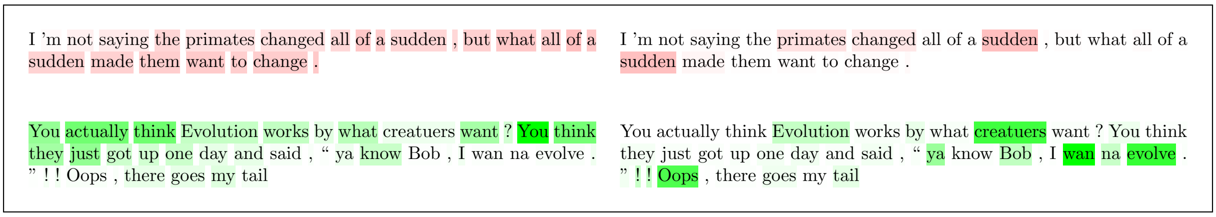
1. Understand the models' performance by looking at the turns correctly classified by the multitask models and misclassified by the corresponding individual single task model. We analyze the turns in terms of sarcastic characteristics - whether they depict incongruity, humor, or sarcasm indicators (i.e., markers).
2. Understand when both multitask and individual model made incorrect predictions.

We compare the predictions between the multitask and the individual models for different settings to address the first issue. For example, $BERT_{MT_{uncert}}$ correctly identifies 6 A, 50 D, and 60 N instances more than $BERT_{Orig}$ (out of 91, 398 and 510 instances, respectively). Two of the authors independently investigated a random sample of 100 instances ($qual$ set) chosen from the union of the $test$ instances that are correctly predicted only by the multitask models (LR$_{ArgF+SarcF}$, $LSTM_{MT_{uncert}}$, $BERT_{MT_{uncert}}$, and $BERT_{ALT}$) and not by the corresponding individual models (LR$_{ArgF}$, $LSTM_{attn}$, and $BERT_{Orig}$). For both Transformer and LSTM-based models, we explore how attention heads behave and whether common patterns exist (e.g., attending words with opposite meaning when incongruity occurs). We display the heat maps of the attention weights for a pair of prior and current turns (LSTM-based models) (Figure 3) whereas for BERT we display word-to-word attentions (Figures 4, 5, 6, 7, and 8) using visualization tools (Vig, 2019; Yang and Zhang, 2018).[5] All the examples presented in this section are argumentative moves (i.e., turns with A or D) correctly identified by our multitask learning models but wrongly predicted as none (N) by the individual models. Moreover, the multitask learning models also correctly predict that these turns are instances of sarcasm.

Incongruity between prior turn and current turn. Semantic incongruity, which can appear between conversation context pt and the current turn ct is an inherent characteristic of sarcasm (Joshi et al., 2015). This characteristic highlights the inconsistency between *expectations* and *reality*, making sarcasm or irony highly effective in persuasive communication (Gibbs and Izett, 2005).

---

[5] Clark et al. (2019) have probed different layers and attention heads in BERT to find patterns, e.g., whether a token consistently attends a fixed token in a specific layer. To avoid confusion and bias, we select attention examples from only the middle (layer=6) layer.



I 'm not saying the primates changed all of a sudden , but what all of a sudden made them want to change .

You actually think Evolution works by what creatuers want ? You think they just got up one day and said , " ya know Bob , I wan na evolve . " ! ! Oops , there goes my tail

I 'm not saying the primates changed all of a sudden , but what all of a sudden made them want to change .

You actually think Evolution works by what creatuers want ? You think they just got up one day and said , " ya know Bob , I wan na evolve . " ! ! Oops , there goes my tail

Figure 3: Attention heatmap of a particular turn pair from $LSTM_{attn}$(left) and LSTM$_{MT_{uncert}}$(right) showing higher weights on sarcasm marker such as "Oops" and "!!" for LSTM$_{MT_{uncert}}$ (disagree relation)

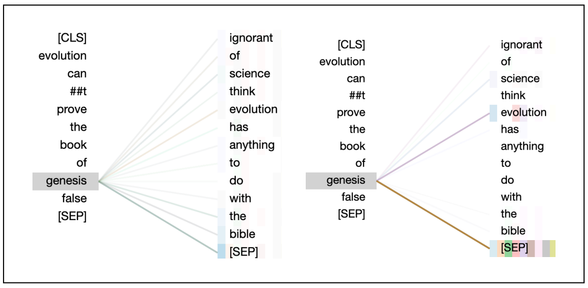


Figure 4: $BERT_{MT_{uncert}}$ (right) attending contrasting words more in word-level attention in comparison to $BERT_{Orig}$ (left) (disagree relation)

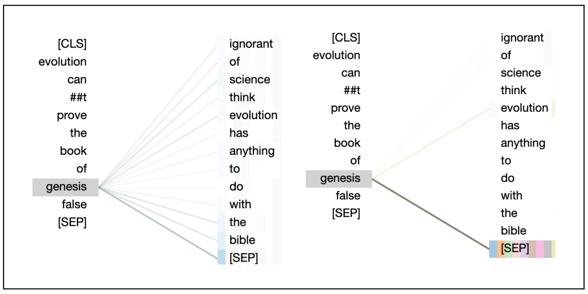

Figure 5: $BERT_{ALT}$ (right) attending only contrasting words in comparison to $BERT_{Orig}$ (left) (disagree relation). However, the strength of the contrast in the case of $BERT_{ALT}$ is lower than $BERT_{MT_{uncert}}$ for the same example turns.

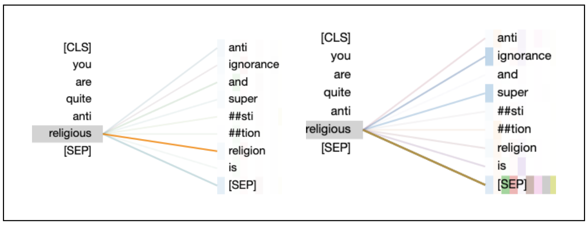

Figure 6: $BERT_{MT_{uncert}}$ (right) attending contrasting words more than $BERT_{Orig}$ (left) (disagree relation)

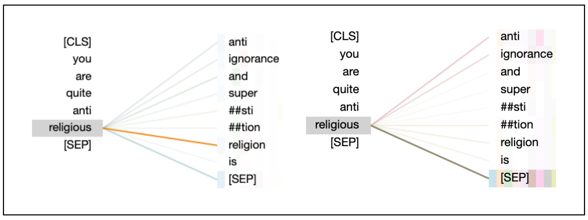

Figure 7: $BERT_{ALT}$ (right) attending only the contrasting words in comparison to $BERT_{Orig}$ (left) (disagree relation)

In the case of BERT, Figure 4 presents the turns "evolution can't prove the book of genesis false" (*pt*) ↔ "ignorant of science think evolution has anything to do with the bible" (*ct*). Here, $BERT_{MT_{uncert}}$ shows more attention between incongruous terms ("genesis" ↔ "science", "evolution") as well as to the mocking word "ignorance". Likewise, Figure 6 presents two turns "you are quite anti religious it seems" (*pt*) ↔ "anti ignorance and superstition . . . this is religion" (*ct*). We notice the word "religious" is attending "anti" and "ignorance" with high weights in case of $BERT_{MT_{uncert}}$ (from *pt* to *ct*) whereas $BERT_{Orig}$ only attends to the word "religious" from the *pt* to *ct* turn. By modeling sarcasm, the multitask learning models can better predict argumentative moves that are expressed implicitly.

We also evaluate the $BERT_{ALT}$ model for the examples presented in Figure 4 and Figure 6. Figure 5 shows that although $BERT_{ALT}$ is attending (from *pt* to *ct*) incongruous terms "genesis" ↔ "evolution", the strength of the relation (i.e., attention weight) is comparatively lower than $BERT_{MT_{uncert}}$ (See Figure 4). On the contrary, between Figure 6 and Figure 7, $BERT_{MT_{uncert}}$ model is attending multiple words in *ct* from the word "religion" in *pt*, but the $BERT_{ALT}$ model attends only two words 'anti" and "ignorance", with high weights from "religion" (*pt* to *ct*).

Humor by word repetition. Often the current turn *ct* sarcastically taunts the prior turn *pt* by word repetition and rhyme, imposing a humorous comic effect, also regarded as the phonetic style of humor (Yang et al., 2015). For the pair, "genetics

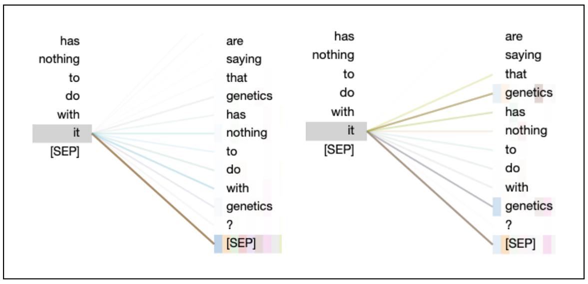

Figure 8: $BERT_{MT_{uncert}}$ (right) attending co-referenced words in a humorous example missed by the $BERT_{Orig}$ model (left) (disagree relation)

has nothing to do with it" (pt) ↔ "are saying that genetics has nothing to do with genetics?" (ct), we notice in $BERT_{MT_{uncert}}$ the token "it" in pt correctly attends to both occurrences of "genetics" in ct where the second occurrence is the co-reference of "it" (Figure 8), which is missed by the individual model $BERT_{Orig}$.

Role of sarcasm markers. Sarcasm markers are indicators that alert if an utterance is sarcastic (Attardo, 2000). While comparing the logistic regression models between LR$_{ArgF+SarcF}$ and LR$_{ArgF}$, we observe markers such as multiple punctuations ("???"), tag question ("are you"), upper case ("NOT") have received the highest features weights (Table 4). In Figure 3, while the individual model $LSTM_{attn}$ attends the words almost equally, we notice in the multitask variation several sarcasm markers such as "ya", "oops", and numerous exclamations ("!!") receive larger attention weights.

Addressing the second issue (i.e., when both multitask and single tasks models make the wrong predictions), we notice that over 100 examples of none (N) class were classified as argumentative by both $BERT_{MT_{uncert}}$ and $BERT_{Orig}$. For the none N class, one of the most common instances of wrong predictions is when the current turn ct sarcastically takes a "different stance" on a topic from pt in a narrow context but the whole turn is not argumentative. In the following example: "does he just say the opposite of everything <name> says?" (pt) ↔ "using <name> as a 180 compass is just fine by me" (ct), $BERT_{MT_{uncert}}$, $BERT_{Orig}$, LSTM$_{MT_{uncert}}$, and $LSTM_{attn}$ models make disagree D prediction (since ct is sarcastic on "<name>") where the gold label is none N. Looking closely at this pair of turns, it seems that the ct presents a case of ad hominem attack (on the person's "<name>") rather than a none relation.

In the case of argumentative turns (agree and disagree) that are wrongly classified as none by all models, we found two common patterns: the use of concessions (e.g., "it's a consideration, *but* I doubt we should be promoting this ...") and arguments with uncommitted beliefs (e.g., "it is *possible* that", "that could *probably* be", "*possibly*, I must admit").

6 Conclusion and Future Work

Linguistic and argumentation theories have studied the use of sarcasm in argumentation, including its effectiveness as a persuasive device or as a means to express an ad hominem fallacy. We present a comprehensive experimental study for argumentative relation identification and classification using sarcasm detection as an additional task. First, in discrete feature space, we show that sarcasm-related features, in addition to argument-related features, improve the accuracy of the argumentative relation identification/classification task by 3%. Next, we show that multitask learning using both a dual LSTM framework and BERT helps improve performance compared to the corresponding single model by a statistically significant margin. In both cases, the dynamic weighting of task specific losses performs best. We provide a detailed qualitative analysis by investigating a large sample manually and show what characteristics of sarcasm are attended to, which might have guided the correct prediction on the identification of the argumentative relation/classification task. In the future, we aim to study this synergy further by looking at sarcasm as well as the persuasive strategies (e.g., ethos, pathos, logos), and argument fallacies (e.g., ad hominem attack that was also noticed by Habernal et al. (2018)).

A Supplemental Material

A.1 Parameter Tuning

Logistic Regression (LR) experiment: A Logistic Regression model with L_2 penalty is employed where the class weights are proportional to the number of instances for A, D and N classes. The regularization strength C is searched over a grid using the dev data. Following values were tried for c: [.0001, .001, .01, .1, 1, 10, 100, 1000, 10000].

Dual LSTM and Multi-task Learning experiment: For LSTM networks based experiments we searched the hyper parameters over the dev set. Particularly we experimented with different mini-batch size (e.g., 8, 16, 32), dropout value (e.g., 0.3, 0.5, 0.7), number of epochs (e.g., 40, 50), hidden state of different sized-vectors (100, 300) and the Adam optimizer (learning rate of 0.01). Embeddings were generated using FastText vectors (300 dimensions) (Joulin et al., 2016). Any token occurring less than five times were replaced by a special UNK token where the UNK vector is created based on random samples from a normal (Gaussian) distribution between 0.0 and 0.17. After tuning we use the following hyper-parameters for the $test$ set: mini-batch size of 16, hidden state of size 300, number of epochs = 50, and dropout value of 0.5. Task-specific losses for the dynamic multitask version was learned during training.

BERT based models: We use the dev partition for hyperparameter tuning such as different mini-batch size (e.g., 8, 16, 32, 48), number of epochs (3, 5, 6), learning rate of 3e-5) and optimized networks with the Adam optimizer. The training partitions were fine-tuned for 5 epochs with batch size = 16. Each training epoch took between 08:46 $\sim$ 9 minutes over a K-80 GPU with 48GB vRAM.

A.2 Results on the Sarcasm Detection Task

Although improving sarcasm detection is not the focus our paper, we observe that multi-task learning improves the performance on this task as well, when compared to the single task model. We present results for the deep learning models in Table 5. The multi-task models (both for LSTM and BERT) outperform the corresponding single task models (by 6.9 F1 and 6.4 F1 for LSTM and BERT models, respectively). We note that the results on this particular dataset are much lower than on other datasets used for sarcasm detection. For example, the LSTM$_{Attn}$ which is the best model used by Ghosh et al. (2018) obtained only 52.9 F1 score on this dataset, while it obtained 70.34 F1 on Sarcasm V2 (derived also from IAC but using different annotation guidelines), 74.96 F1 on a Twitter dataset and 75.41 F1 on a Reddit dataset (Ghosh et al., 2018).

Model	Precision	Recall	F1
LSTM$_{Attn}$	52.9	52.8	52.9
LSTM$_{MT}$	59.5	59.3	**59.4**
BERT$_{orig}$	57.4	57.4	57.4
BERT$_{MT}$	61.8	61.7	**61.8**
BERT$_{MT_{uncert}}$	64.1	63.5	**64.0**

Learning Relatedness between Types with Prototypes for Relation Extraction

Lisheng Fu[*] **Ralph Grishman**

Abstract

Relation schemas are often pre-defined for each relation dataset. Relation types can be related from different datasets and have overlapping semantics. We hypothesize we can combine these datasets according to the semantic relatedness between the relation types to overcome the problem of lack of training data. It is often easy to discover the connection between relation types based on relation names or annotation guides, but hard to measure the exact similarity and take advantage of the connection between the relation types from different datasets. We propose to use prototypical examples to represent each relation type and use these examples to augment related types from a different dataset. We obtain further improvement (ACE05) with this type augmentation over a strong baseline which uses multi-task learning between datasets to obtain better feature representation for relations. We make our implementation publicly available: https://github.com/fufrank5/relatedness

1 Introduction

Relation extraction identifies specific semantic relationships between two entities within a single sentence. For example, there is a Physical.Located relationship between *George Bush* and *France* in the sentence: *George Bush* traveled to *France* on Thursday for a summit. Relation extraction is a crucial task for many applications such as knowledge base population.

Relation schemas are mostly pre-defined in existing datasets. The definition of the relation type depends on the annotation guide. There is no clear intrinsic Ontology for relation types. In practice, relation types can be created based on interests. This leaves datasets with similar, related or overlapping schemas. For example, the annotation guides for Automatic Content Extraction (ACE) 03-05 changed from year to year. The later created Entities, Relations and Events (ERE) dataset was similar in the schema, but differs in details. Because of the difficulty of annotating relations, these datasets are all small individually and hard to be utilized together.

It is not an easy task to learn relatedness between relation schemas across different datasets since there is no instance-level labels available for the relatedness. However, we can observe the connections between the relation types from different datasets based on relation names or annotation guides. We propose to simplify the relatedness as binary (related or not) and to use manual review of relation names to decide the relatedness labels. This would give the prior knowledge that one relation type in one dataset may have closer relationships to some types than the others in another dataset. Then we design a model to recognize this similarity. We propose to use prototypical examples to represent each relation type. We rank these representations higher for related types, and lower for unrelated types using a pairwise loss function. Our base model is a multi-task learning model which focuses on learning a strong encoder using multiple datasets regardless of the relation schemas. We take the step further to explore utilizing the relatedness between the relation types. Experiments on ACE05 and ERE show that it can further boost the performance, especially in the low-resource settings.

2 Related Work

Relation type dependency: There have been a few ways to model the relationships between types in a multi-label relation dataset where we can learn

---

the similarity or dependency from annotated examples. Surdeanu et al. (2012) used a two-layer hierarchical model. The object-level classifier is able to capture the label dependency, while the mention-level classifier is focused on multi-label classification. Riedel et al. (2013) used a neighborhood model to explicitly model the dependency between the labels in a matrix factorization framework. Both of models are designed to work on multi-label examples, which require annotation to capture the dependency between labels. In the recent work of neural methods for relation extraction, most of the work (Zeng et al., 2015; Lin et al., 2016; Liu et al., 2017) ignores the multi-label setting and does not explicitly model the label dependency. Ye et al. (2017), on the other hand, ranks the similarity between feature representation of the instance and the label embedding. In addition to ranking the positive classes higher than the negative ones, it ranks positive classes against each other to learn the connections between the positives classes. These methods all require annotated examples to learn the connections. In the case of relation types across different datasets, such annotation does not exist. We attempt to learn the similarity nevertheless using prototypes from each type.

Multi-task learning: Training multiple relation datasets at the same time could improve the robustness of the model and reduce annotation cost for relation extraction. (Fu et al., 2018) proposed to use a shared encoder to learn more general feature representation. We use a similar multi-task learning base model and incorporate the similarity between the relation schemas to further improve the performance.

3 Relation Model with Multi-task Learning

The majority of neural relation models (Zeng et al., 2014; Nguyen and Grishman, 2015b; Zeng et al., 2015; Lin et al., 2016) encode a sentence using a deep architecture to a vector representation followed by a softmax classifier, while the others (dos Santos et al., 2015; Ye et al., 2017) use a function to compute the score between label embedding and sentence representation. Inspired by Fu et al. (2018) where the shared encoder helps in the case of the multi-task learning, we choose the latter so that all relation types (including from different datasets) will share the whole model parameters except the label embeddings. Suppose we obtain the sentence representation $\phi(x)$ with a neural architecture. We define the label embedding as $W_l \in \mathbb{R}^D$, a D-dimension vector for each type. We compute the L_1 distance between them and learn a scoring function to estimate the scores $S_\theta(x)$ for every type:

$$S_\theta(x)_l = W_o \cdot |\phi(x) - W_l| + b_o, \tag{1}$$

where $W_o \in \mathbb{R}^D$ and $b_o \in \mathbb{R}$ are shared for all types.

We do not use the dot product (dos Santos et al., 2015; Ye et al., 2017) as the scoring function because the L_1 distance works slightly better in the multi-task learning experiments. The probability of every class is computed as the softmax output of the scores. Similar to (Fu et al., 2018), we jointly train two relation tasks at the same time with cross-entropy losses.

$$L = \lambda L_{r1} + (1 - \lambda) L_{r2}, \tag{2}$$

where L_{r1} and L_{r2} are the cross-entropy losses for the two relation tasks. λ is the hyperparameter to control the learning speed between the two tasks. This would give a strong baseline of utilizing the two datasets together.

3.1 Prototypes of Relation Types for Learning Similarity

For each relation type, we randomly select k examples (S_k) from the training set as supporting examples. We use the mean of the representations of these examples as the prototype for the relation type:

$$\bar{x}_c = \frac{1}{k} \sum_{x_i \in S_k} \phi(x_i) \tag{3}$$

These prototypes are inspired by the Prototypical Networks (Snell et al., 2017). However, in the training procedure, these supporting examples are randomly selected for every mini-batch. We have dynamic prototypes during training.

We define $S_\theta(\bar{x}_c)_l$ as the similarity score to type c for type l. We hypothesize that if the two relation types are similar in semantics, they should obtain high similarity score. Within the dataset, if the relation types in the schema are mutually exclusive to each other, then we would expect a high similarity score to itself and low scores to the other types. Across the datasets, the prototypes would obtain high scores for related types and low scores in the unrelated types. We use a pair-wise ranking loss (dos Santos et al., 2015) to learn this relatedness across the datasets.

For $l \in L$ and $c \in C$, $S_\theta(\bar{x}_c)_l$ gives the score for the similarity between the type l in the relation schema L and the type c in the relation schema C. Let $c^+ \in C$ be a class related to l and $c^- \in C$ be a class unrelated to l. The similarity scores would be $S_\theta(\bar{x}_{c^+})_l$ and $S_\theta(\bar{x}_{c^-})_l$ respectively. We define the pair-wise ranking loss as:

$$\begin{aligned} L_s = log(1 + exp(\gamma(m^+ - S_\theta(\bar{x}_{c^+})_l)) \\ + log(1 + exp(\gamma(m^- + S_\theta(\bar{x}_{c^-})_l)) \end{aligned} \tag{4}$$

m^+ and m^- are the margins and γ is the scaling factor. This loss function would push $S_\theta(\bar{x}_{c^+})_l$ higher for related type pair between c^+ and l and $S_\theta(\bar{x}_{c^-})_l$ lower for unrelated type pair between c^- and l. We manually create a relatedness matrix to state whether the two types are related or not between the types in C and L based on the definition of the relation types. For each step of training, we pick the highest scored c^- from unrelated types and lowest scored c^+ for related types corresponding to type l.

$$c^- = \underset{c \in C^-}{argmax} S_\theta(\bar{x}_c)_l \tag{5}$$

$$c^+ = \underset{c \in C^+}{argmin} S_\theta(\bar{x}_c)_l \tag{6}$$

where C^- are types unrelated to l and C^+ are types related to l. In experiments, we use looser margins ($m^+ = 0.5$, $m^- = 0.5$, $\gamma = 1.0$) compared to (dos Santos et al., 2015) as we are learning the relatedness between types rather than doing classification for individual instance. The ranking loss is jointly trained as an auxiliary task with the main relation tasks:

$$L = \lambda L_{r1} + (1 - \lambda) L_{r2} + \beta L_s, \tag{7}$$

where we use β to control the weight for learning the relatedness. If β is too large, it could disrupt the learning of main relation tasks. With appropriate weight, it could help augment the label embeddings for the relation types by considering the similarity between them.

4 Experiments

4.1 Datasets

We select two datasets with similar relation schemas in this experiment. There is overlapping of relation types between ACE05 and ERE, but the annotation guides are different in details (Aguilar et al., 2014). Thus, we can not combine the training data directly as the same type. Doing so would actually lead to worse result as it introduces more noise than benefit. The multi-task learning would be a better choice at this setting. We take a step further and try to learn the similarity between the types at the same time. There are 6 main semantic types in ACE and 5 in ERE. Manual review of the relatedness (related or not) is trivial in this case because the relation names are almost identical for related relation types. In practice, it may take a few minutes to review more complicated relation schemas, but it would cost significantly less than annotating on the instance-level in text. For preprocessing the data, we follow previous work (Gormley et al., 2015; Nguyen and Grishman, 2015a; Fu et al., 2017, 2018) on ACE05. It contains 6 domains: broadcast conversation (bc), broadcast news (bn), telephone conversation (cts), newswire (nw), usenet (un) and weblogs (wl). We use newswire as training set (bn & nw), half of bc as the development set, and the other half of bc, cts and wl as the test sets. We followed their split of documents and their split of the relation types for asymmetric relations (directionality taken into account expect for *physcial* and *person-social* types). We perform the same preprocessing for the ERE dataset, which contains documents from newswire and discussion forums. We follow the document split from (Fu et al., 2018).

4.2 Multi-task Learning Baseline

Following previous work (Nguyen and Grishman, 2015a; Fu et al., 2018), We use a similar encoder to obtain the feature representation $\phi(x)$ as our baseline. The input layer is the concatenation of word embedding, entity embedding and position embeddings. We use pretrained word2vec (Mikolov et al., 2013) as the word embedding with embedding size d_w. The entity embedding and position embeddings are randomly initialized vectors according to the entity type of the token and relative distance to the two arguments of the relation. The embedding sizes are d_e and d_p respectively. We follow previous work for these input embedding sizes as $d_w, d_e, d_p = 300, 50, 50$. It is followed by Bidirectional RNN with attention and a fully connected layer to match the size for the label embedding. We use 150 for the RNN state size

Table 2: Learning the relatedness between types (50% training).

and 200 for the label embedding size. The output of this encoder is $\phi(x)$. Then we can perform classification using the scores obtained from Equation 1.

In a mini-batch of training step, we randomly select examples from both datasets proportionally according to the dataset size so that the model can finish reading both datasets at the same time after every epoch. Because the difference of the number of examples for the two datasets in the batch, we set $\lambda = \lambda_d \frac{|D_1|}{|D_1|+|D_2|}$, where $|D_1|$ and $|D_2|$ are the number of examples for each dataset in a single batch. In a special case where the two datasets are actually split from one original dataset, we can set $\lambda_d = 1.0$, and then the two datasets are going to be learned at the same speed. In our case, we use $\lambda = 0.8$ so that the two relation tasks are roughly learning at the same speed. As the result, our multi-task model using label embedding is comparable to (Fu et al., 2018) (Table 1), which serves as a strong baseline since it is already better than training a single relation task. We obtain all our scores as the average of 10 runs to report stable results.

4.3 Learning the Relatedness between Two Relation Schemas

By learning the relatedness at the same time (Equation 4,7, $\beta = 0.001$), we obtain better re-

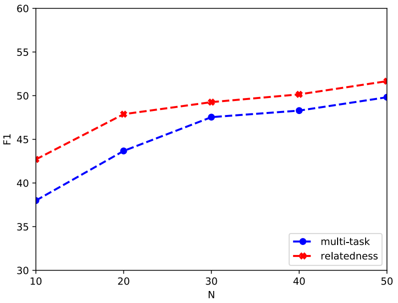

Figure 1: Low-resource setting with N examples for each positive relation type on ACE05.

sults at the full training set (Table 1). The improvement is more obvious with a smaller training set (Table 2 at 50%). The regularization in the previous work does not take the relatedness on the type-specific basis into account, which fails to obtain clear improvement over the multi-task baseline. Our method is more effective in incorporating additional knowledge from multiple sources. We also set up a low-resource setting where we only have N examples for each relation type (Figure 1 at $N = [10, 20, 30, 40, 50]$). The negatives are randomly selected according to the pos/neg ratio. We can observe larger improvement with less training data. This is also to consider the skewed data distribution in the dataset where there are far more examples for some types than the others. The k supporting prototype examples are drawn randomly at every step. We use $k = 50$ for the experiments and $k = N$ for the low-resource settings. Overall, the improvement is impressive, especially for the low-resource settings. It is also worth to note that the single task models for these low-resource settings obtain virtually zero scores without multi-task learning as there is not enough data to train the encoder. The multi-task learning between two relation tasks is better than training on a single task and more effective for a smaller training set. We now show that learning the relatedness between the types could further improve the model.

5 Conclusion

We use prototypes of relation types to learn the relatedness between them in a multi-task learning framework. With prior knowledge of relatedness between relation types, the model obtains further improvement in addition to sharing the encoder of the sentence. The prior knowledge is obtained through manual review of relation names, which costs significantly less than annotating on the instance-level in text. In this paper, we simplify the relatedness as binary. It would be interesting to further explore the relationships between relation types as a more dynamic metric.

I Beg to Differ:
A study of constructive disagreement in online conversations

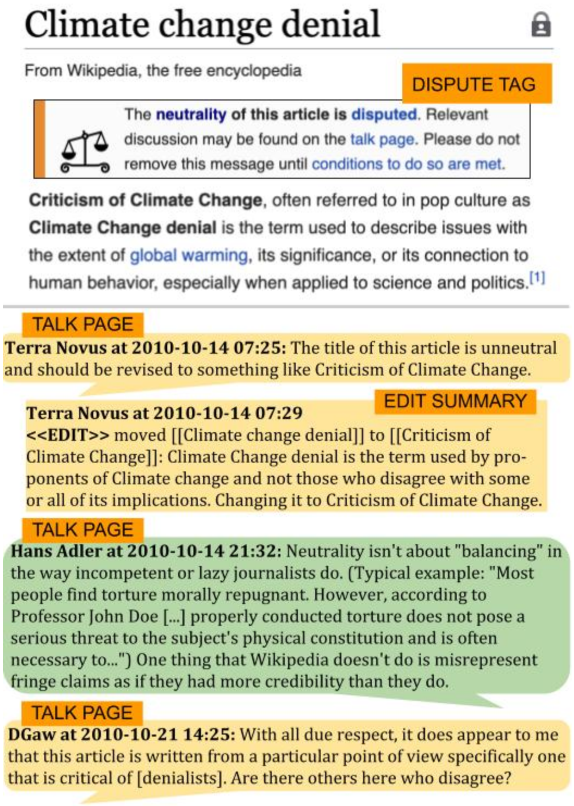
Christine De Kock and Andreas Vlachos
University of Cambridge
Department of Computer Science and Technology
`{cd700,av308}@cam.ac.uk`

Abstract

Disagreements are pervasive in human communication. In this paper we investigate what makes disagreement constructive. To this end, we construct WikiDisputes, a corpus of 7 425 Wikipedia Talk page conversations that contain content disputes, and define the task of predicting whether disagreements will be escalated to mediation by a moderator. We evaluate feature-based models with linguistic markers from previous work, and demonstrate that their performance is improved by using features that capture changes in linguistic markers throughout the conversations, as opposed to averaged values. We develop a variety of neural models and show that taking into account the structure of the conversation improves predictive accuracy, exceeding that of feature-based models. We assess our best neural model in terms of both predictive accuracy and uncertainty by evaluating its behaviour when it is only exposed to the beginning of the conversation, finding that model accuracy improves and uncertainty reduces as models are exposed to more information.

1 Introduction

Disagreements online are a familiar occurrence for any internet user. While they are often perceived as a negative phenomenon, disagreements can be useful; as is illustrated in Figure 1, disagreements can lead to an improved understanding of a topic by introducing and evaluating different perspectives. Research on online disagreements has focused on mostly negative aspects such as trolling (Cheng et al., 2017), hate speech (Waseem and Hovy, 2016), harassment (Yin et al., 2009) and personal attacks (Wulczyn et al., 2017). Recent works by Zhang et al. (2018) and Chang and Danescu-Niculescu-Mizil (2019) study conversations on Wikipedia talk pages that start out as civil but derail into personal attacks, using linguistic markers and deep learning approaches, respectively.



Climate change denial

From Wikipedia, the free encyclopedia

The **neutrality of this article is disputed**. Relevant discussion may be found on the talk page. Please do not remove this message until conditions to do so are met.

Criticism of Climate Change, often referred to in pop culture as **Climate Change denial** is the term used to describe issues with the extent of global warming, its significance, or its connection to human behavior, especially when applied to science and politics.[1]

Terra Novus at 2010-10-14 07:25: The title of this article is unneutral and should be revised to something like Criticism of Climate Change.

Terra Novus at 2010-10-14 07:29
<<EDIT>> moved [[Climate change denial]] to [[Criticism of Climate Change]]: Climate Change denial is the term used by proponents of Climate change and not those who disagree with some or all of its implications. Changing it to Criticism of Climate Change.

Hans Adler at 2010-10-14 21:32: Neutrality isn't about "balancing" in the way incompetent or lazy journalists do. (Typical example: "Most people find torture morally repugnant. However, according to Professor John Doe [...] properly conducted torture does not pose a serious threat to the subject's physical constitution and is often necessary to...") One thing that Wikipedia doesn't do is misrepresent fringe claims as if they had more credibility than they do.

DGaw at 2010-10-21 14:25: With all due respect, it does appear to me that this article is written from a particular point of view specifically one that is critical of [denialists]. Are there others here who disagree?

Figure 1: An example of a dispute on Wikipedia, showing the dispute tag on the article, talk page posts, and summaries of edits occurring during the discussion.

An alternative approach is to study good faith disagreement through debates on online platforms such as ChangeMyView (Tan et al., 2016), debate.org (Durmus and Cardie, 2019) and Kialo (Boschi et al., 2019), or formal Oxford-style debates (Zhang et al., 2016a). While this has benefits, such as readily available annotation of stances and indication of winning and losing sides, it does not mirror the way people naturally converse. For example, in formal debates, temporal and structural

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2017–2027
April 19 - 23, 2021.

constraints are imposed. Moreover, in Oxford-style debates, participants are not motivated to come to a consensus but rather to persuade an audience of a predefined stance (Zhang et al., 2016a). Finally, the task of detecting disagreement in conversations has been studied by a number of authors, e.g. Wang and Cardie (2014) and Rosenthal and McKeown (2015), without attempting to analyze it further.

We are interested instead in *constructive disagreement in an uncoerced setting*. To this end, we present `WikiDisputes`[1]; a corpus of 7 425 disagreements (totalling 99 907 utterances) mined from Wikipedia Talk pages. To construct it, we map dispute tags in the platform's edit history (shown in Figure 1) to conversations in WikiConv (Hua et al., 2018) to locate conversations that relate to content disputes. Observing that conversations are often conducted in the Talk pages and the edit summaries simultaneously, as illustrated in Figure 1, we augment the WikiConv conversations with edit summaries that occur concurrently. To investigate the factors that make a disagreement constructive, we define the task of predicting whether a dispute is eventually considered resolved by its participants, or it was escalated by them to mediation by a moderator, and therefore considered unconstructive.

We evaluate both feature-based and neural models for this task. Our findings indicate that balancing hedging and certainty plays an important role in constructive disagreements. We find that incorporating edit summaries (which have been ignored in previous work on Wikipedia discussions) improves model performance on predicting escalation. We further find that including information about the conversation structure aids model performance. We observe this in two ways. Firstly, we include gradient features, which capture changes in linguistic markers throughout the conversations as opposed to averaged values. Secondly, we experiment with adding sequential and hierarchical conversation structure to our neural models, finding that a Hierarchical Attention Network (Yang et al., 2016) provides the best performance on our task.

We further evaluate this model in terms of its predictive accuracy when exposed to the beginnings of the conversation as opposed to completed conversations, as well as its uncertainty (more details in Section 6.4). Our results indicate that model performance is reduced from a PR-AUC of 0.29 to 0.19 when exposed to only the first half of the conversation. However, this reduced model still outperforms toxicity and sentiment models predicting on full conversations. Model uncertainty decreases roughly linearly as the model is exposed to more information. We conduct a qualitative analysis of the points in the conversation where the model changes its prediction on constructiveness, finding that some markers from our feature-based models also seem to have been picked up by the neural model.

2 Dispute resolution on Wikipedia

Wikipedia relies heavily on collaboration and discussion by editors to maintain content standards, using the platform's Talk pages (Wikipedia, 2020c). Wikipedia contributors add "dispute" templates to articles (Wikipedia, 2020a) referring to a content accuracy dispute or to a violation of the platform's neutral point of view (NPOV) policy (Wikipedia, 2020b). Adding such a template to the article creates a dispute tag on the article as shown in Figure 1. Variations of these tags allow contributors to flag specific sections or phrases which relate to the issue in question, or to add details of the dispute.

All edits to Wikipedia, including the aforementioned dispute tags, are retained in the site's edit history. Revision metadata contains a description of the edit (hereafter referred to as the edit summary). As observed in Figure 1, when such edits occur while a conversation is underway, editors use the "edit summaries" to clarify their intentions in the context of the conversation.

The Wikipedia dispute resolution policy stipulates that if contributors are unable to reach a consensus through Talk page discussion, they can request mediation by a community volunteer. A prerequisite for this escalation step is proof of recent, extensive discussion on a Talk page[2].

3 WikiDisputes

Our dataset consists of three facets: disagreements on Talk pages, edit summaries, and escalation labels. Wikipedia informs users that all contributions on article or Talk pages are published publicly, and provides channels for users to permanently remove personal information that they have shared accidentally or otherwise (Wikipedia, 2020d), thus we are able to release this data to the community. In

TALK PAGE

DGaw at 2010-10-23 08:14: Hi Dmcq. A few things. 1) What is infuding? 2) The second sentence doesn't say "said to be associated", it says "has been associated". 3) Even if it did say "said to be associated", that would address a different point than my edit, the point of which is this: as written, the first sentence is making an assertion about the motives of "denialists" instead of making it clear it is those who use the term are making the assertion. If you have a better way of making the clarification, of course, that would be great too.

Dmcq at 2010-10-23 20:05: I haven't the foggiest what word I was thinking of when I wrote 'infuding'. I should take more care when writing my comments. The essential point though is that 'has been associated with' already says it is asserted by some people without fudging what the topic is about in the first place.

Figure 2: An illustration of the relationship between the revision history and Talk page conversations, using later utterances from the dispute in Figure 1. Two consecutive edits and their summaries are shown side by side.

the remainder of this section, we detail the process for obtaining the conversations, the edit summaries and the labels.

3.1 Finding disagreements

We use the Wikipedia revision history dump[3] from 1 July 2020 to find content disputes. We locate the addition of dispute templates in the article history using regular expressions that account for variations in the free text dispute templates. Using the revisions where dispute tags are added, we can also determine which user logged the dispute, the timestamp, and the article and section in dispute.

To find the related WikiConv conversation for each dispute tag, we select all conversations on the relevant article's Talk page in which the user who logged the dispute was involved. Of these candidates, the conversation closest in time to the timestamp of the dispute tag addition is selected. We filter the conversations extracted above using a number of heuristics in the pursuit of high quality samples of constructive disagreements. To ensure conversations of adequate length, we set a minimum conversation length of five utterances and 250 tokens. Based on an inspection of 100 conversations, we remove conversations of more than 50 utterances, as such conversations are often flame wars. We further include only conversations in which more than one user participated. Using this methodology, we obtain 7 425 content disputes.

Our manual inspection further indicates that the usage of the dispute tag is not entirely consistent across the platform; editors sometimes use the tag to report that they dispute some aspect of the text before discussing it, rather than to flag a currently occurring dispute in the Talk page. However, the former frequently results in a disagreement. We found that 88 out of 100 inspected examples were correctly identified disagreements, which we believe is an acceptably low error rate.

3.2 Collecting edit summaries

We show in Figure 2 two further posts from the climate dispute (continued from Figure 1), along with two edits that occurred during the course of the conversation. We note here that including the edit summaries as part of the conversation is important for understanding the conversation; without this, the reference to "infuding" in this example would be incomprehensible. We thus include all edit summaries written by users involved in the conversation, which are timestamped between the first and last utterance in the conversation.

---

[3] `https://dumps.wikimedia.org/enwiki/`

3.3 Escalation tags

For the task of inferring whether a dispute was escalated to mediation (and therefore Talk page discussion was unsuccessful), we scrape mediated cases from the Dispute Resolution Noticeboard archives and align them with WikiConv conversations.

Of the 2 520 archived mediation processes, 149 were closed as failures and 237 as successes, with the remaining 2 134 receiving "General closures". The last label is frequently assigned due to insufficient Talk page discussion. We only include accepted mediations in our dataset and thus ignore "General closures", resulting in 386 mediations.

We record the location of the disagreement to which the mediation relates, the usernames of participants and the timestamp. We use a similar alignment procedure to that described in Section 3.1 to find the relevant WikiConv conversations; except that we include the usernames of all participants listed in the mediation. During alignment, a simple match is recorded when there is exactly one conversation on the article Talk page involving all listed users (118 cases out of 386).

There are 111 cases in which no full matches occur; this sometimes happens when a participant changes their username or is participating anonymously. We manually inspect potential matches in this case. A further 67 cases have multiple matches; this happens when a participant changes their username, or is participating anonymously, or the Talk page has been archived; in this case we try to find the conversation most related to the mediation summary.

We use only the utterances which are timestamped from before the conversation was escalated and apply the same filters outlined in Section 3.1. Using this methodology, we are able to find 201 disagreements that are escalated to mediation. The complementary class label (not escalated) is assigned to the disagreements extracted using the dispute tags, for which no mediation was found.

Our classification task uses escalation as a proxy label for cases where Talk page discussion was not constructive. This relies on the assumption that non-escalated disagreements are more constructive than escalated disagreements, even though disagreements that were not escalated are not guaranteed to be successfully resolved; participants may simply not be aware of the escalation procedure, or not be willing to go through the extra effort of participating in mediation. To validate this, we annotated 35 samples from the dataset as to whether they represented constructive disagreements, and our annotations agreed with the escalation labels in 25 of these. Combined with the low estimates of antisocial behaviour on the site (Wulczyn et al., 2017), we draw the inference that the non-escalated class contains more constructive disagreements than the escalated ones. Throughout the remainder of this paper, we use these terms interchangeably.

4 Modelling constructive disagreement

4.1 Feature-based models

We develop our feature-based models using feature sets suggested in previous research on tasks related to conversational analysis. These include:

- **Politeness**: The politeness strategies from Zhang et al. (2018) as implemented in Convokit (Chang et al., 2020), which capture greetings, apologies, directness, and saying "please", etc.
- **Collaboration**: Conversation markers in collaborative discussions (Niculae and Danescu-Niculescu-Mizil, 2016), which capture the introduction and adoption of ideas, uncertainty and confidence terms, pronoun usage, and linguistic style accommodation.
- **Toxicity**: Toxicity and severe toxicity scores as estimated by the Perspective API (Wulczyn et al., 2017) and included in WikiConv (Hua et al., 2018).
- **Sentiment**: Positive and negative sentiment word counts, as per the lexicon of Liu et al. (2005) and implemented in Convokit (Chang et al., 2020).

For each feature, we calculate the average value throughout the conversation, as well as the gradient of a straight line fit of the feature value throughout the conversation. Our intuition for including this variation is that the outcome of a disagreement is likely to be influenced by a change in the language usage through the course of a conversation, which is not reflected by the mean. For instance, a disagreement might start out very politely and end impolitely, or the other way around, and would have the same mean. Logistic regression is used to infer linear relationships between the linguistic features and disagreement outcomes.

4.2 Neural models

Dialogue structure has been difficult to capture in feature based models due to sparsity. For this reason, we implement a number of neural models with increasing capacities for modelling conversation structure to assess its importance.

Averaged embeddings Our simplest variant averages the GloVe embeddings (Pennington et al., 2014) of all words in a conversation, and uses a fully connected layer for classification. It ignores both utterance hierarchy and word ordering and can be seen as a bag-of-word-embeddings approach.

LSTM Instead of averaging the GloVe embeddings, we use a bidirectional LSTM-based model (Hochreiter and Schmidhuber, 1997) to process the sequence of words in the conversation; ignoring utterance hierarchy but preserving word order.

HAN We use a Hierarchical Attention Network (HAN) (Yang et al., 2016) to model both word order and utterance hierarchy. HANs have recently been used to predict emotion in conversations (Ma et al., 2020) and are useful for capturing the structure of texts by building up utterance embeddings from word embeddings, and then constructing a conversation vector from these utterance embeddings. Given a sequence of words in an utterance, the words are first mapped to vectors through an embedding matrix (GloVe embeddings, in our case). A bidirectional LSTM layer (Hochreiter and Schmidhuber, 1997) is used to process the sequence of embeddings and calculate an embedding for each word in the context of the utterance. An attention mechanism (Bahdanau et al., 2015) is applied to these embeddings to find an utterance embedding. A similar procedure is followed to build up a conversation vector based on the utterances embeddings. This vector is then used to perform the classification. To incorporate edit summaries in a conversation, we prepend each edit summary with a special token (<EDIT>) to indicate its origin.

5 Experimental setup

An initial data analysis indicated that escalated disagreements have a median length of 16 utterances, compared to 11 for their non-escalated counterparts. While this may be an informative feature for classification, we are primarily interested in the effects of language on the conversation outcome, and therefore choose to control for this effect. We use *matching*, a technique developed for causal inference in observational studies (Rubin, 2007), also employed by Zhang et al. (2018) in the context of conversational modelling. We pair each escalated disagreement with a non-escalated disagreement of the same length in utterances, bearing in mind that the dataset is heavily imbalanced, with 7 425 non-escalated disagreements compared to 201 escalated disagreements. To retain an imbalance in the classes while conducting matching, we match every escalated disagreement with up to ten non-escalated disagreements (the actual number depending on availability) by randomly sampling without replacement from the non-escalated disagreements of the same length. Characteristics of the dataset after performing matching are shown in Table 1, with both classes having a median of 16 utterances now. Escalated disagreements have one more participant than non-escalated disagreements on average, and utterances in the escalated disagreements class are slightly shorter.

	Not escalated	**Escalated**
# Samples	1994	216
# Participants	2	3
# Utterances	16	16
Tokens per utt.	61	53

Table 1: Dataset statistics for the task of predicting escalation. Where applicable, median values are used.

We split the dataset for training as indicated in Table 2. Due to the class imbalance we use the area under the precision-recall curve (Davis and Goadrich, 2006) as metric for this task; however, for the sake of interpretability we also present the break-even F1 scores. We use a distribution-aware random class predictor as a random baseline.

Hyperparameters The logistic regression models are implemented in Scikit-Learn. We use a grid search to determine the best regularisation mode (L1 or L2) per model, evaluating C-values in [0.1,1,10,100]. The neural models are implemented in Keras, using Focal Loss (Lin et al., 2017) with Adam optimisation (Kingma and Ba, 2014) (learning rate=0.001) and Dropout ($p = 0.3$). For the HAN, we use bidirectional LSTM layers with 128 nodes in both the utterance and conversation encoders. For the LSTM model, we use only one such a layer.

Dataset	Escalated	Not escalated
Train	125	1411
Test	46	284
Validation	30	299

Table 3: Results of the escalation prediction task.

6 Results

Results are shown in Table 3. We note that generally, the neural network models perform better than the feature-based models. We discuss the PR-AUC scores of each model category below, noting that the scores from the F1 metric generally follow the same trends, but that PR-AUC is more robust in the face of imbalanced data. Furthermore, we investigate whether it is possible to predict the outcome from the beginning, how model uncertainty changes, or if there is often some inflection point in a conversation that changes the outcome.

6.1 Feature-based models

A number of our feature-based models outperforms the bag-of-words baseline, which in turn performs better than the random baseline. The toxicity and sentiment features do not perform better than the bag-of-words baseline, which indicates that these features by themselves do not capture constructiveness in disagreements. Toxicity scores were found by Zhang et al. (2016a) to be predictive of a conversation derailing, but in our case seemingly lead to the inference of spurious correlations. An explanation might be that comments which seem toxic out of context are in fact spirited discussion due to the degree of involvement of the participants; for instance, we have observed that contributors in some cases challenge others' credentials, which may seem rude in casual conversation, but can be useful in resolving a dispute.

Feature	Type	Coeff.
2nd person pronouns, $\bar{x}$	Both	+3.64
# hedging terms, $\bar{x}$	Both	-2.48
Greetings, $\bar{x}$	Politeness	+2.30
1st person pronouns, $\bar{x}$	Both	+1.91
Greetings, ∇	Politeness	-1.81
Deference, $\bar{x}$	Politeness	-1.44
3rd person pronouns, ∇	Collaboration	-1.38
# ideas adopted + certainty, $\bar{x}$	Collaboration	-1.23
Use of "by the way", $\bar{x}$	Politeness	-1.04
Certainty,∇	Collaboration	-0.92

Table 4: Ten features with the largest coefficients of the best feature-based model, which uses politeness and collaboration featuresets. Feature variations are the mean ($\bar{x}$) and gradient (∇). Positive weights are associated with the unconstructive class.

The best featuresets proposed in previous work are collaboration (Niculae and Danescu-Niculescu-Mizil, 2016), followed closely by politeness (Zhang et al., 2016a). Adding the gradient features we proposed improves performance for both, indicating that not only the presence of a marker is important, but also how its usage throughout a conversation changes. The best feature-based model is a combination of politeness and collaboration features, with a PR-AUC of 0.281 ($P < 0.05$, using a randomized permutation test).

The ten features with the largest coefficients from the combined model are shown in Table 4 in descending order or magnitude, along with their directions. Positive coefficients are associated with the escalated class, which indicates that a disagreement was not constructive.

Politeness markers such as deference and the use of "by the way" are found indicative of constructiveness, corroborating the findings of Zhang et al. (2016b). Greetings are associated with unconstructive disagreements on average, but an increase in greetings towards the end of a conversation is associated with constructiveness. An explanation of this might be that greetings can seem overly formal or indicative of tension early on, but if used later in a conversation, they indicate that new participants have entered the conversation or that more time is taken between replies. Indeed, longer gaps between replies (a feature in the collaboration featureset) are also associated with constructiveness.

The use of first and second person pronouns ("I" and "you") is associated with unconstructive disagreements, with the latter corroborating the findings of Zhang et al. (2018). This is also consistent with psychotherapy research on disagreements in relationships (e.g. Gottman and Krokoff (1989)), which emphasises avoiding 'you'-messages which might be perceived as blameful.

Hedging is associated with constructive disagreements, which corroborates the findings of Zhang et al. (2016a). An intuitive understanding of this result is that using hedging terms shows that the speaker is more open to adjusting their opinion or compromising. The certainty gradient and the adoption of new ideas with certainty are also associated with constructiveness. Niculae and Danescu-Niculescu-Mizil (2016) found no significant correlation between either certainty or hedging and successful collaboration. We attribute the observed differences in feature associations to the fact that WikiDisputes are sourced from an uncoerced setting, where users feel more invested in the outcome of a disagreement and may need to balance the use of certainty and hedging to negotiate compromises. The setting of Niculae and Danescu-Niculescu-Mizil (2016) obligates volunteers to participate in a photo geolocation game, where it is unlikely that interlocutors are as invested in the task as collaborators working on a widely read encyclopaedia.

Words associated with either class, obtained through the bag-of-words model, are shown in Appendix A. An interesting observation from this list is that citing Wikipedia policy (which is indicated with WP) is associated with escalating conversations. This practice is sometimes referred to as "Wiki-Lawyering" within the community and can signal an unwillingness to compromise.

6.2 Neural network models

The results from our neural models illustrate that incorporating structure improves predictive accuracy on our task.

The model that averages over word embeddings performs the worst; a moderate increase in performance (2%) is gained from adding sequential word processing by way of an LSTM model. Adding utterance boundary information with HAN results in a much larger improvement (11%) over the LSTM. This indicates that, while it is helpful to observe the ordering of words in a conversation, a more critical component in the case of disagreements is how words are arranged in utterances.

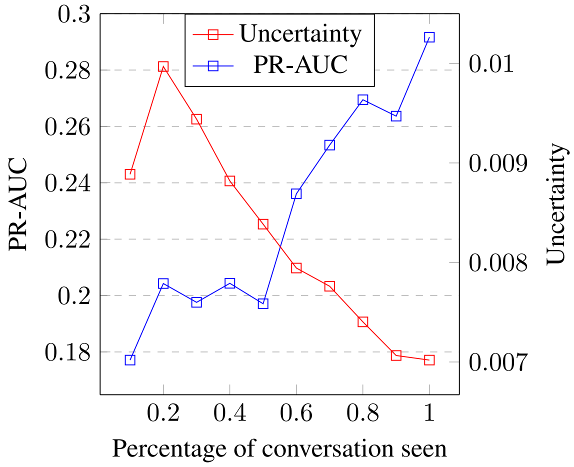

Figure 3: PR-AUC scores and uncertainty values of a HAN model when exposed to partial conversations.

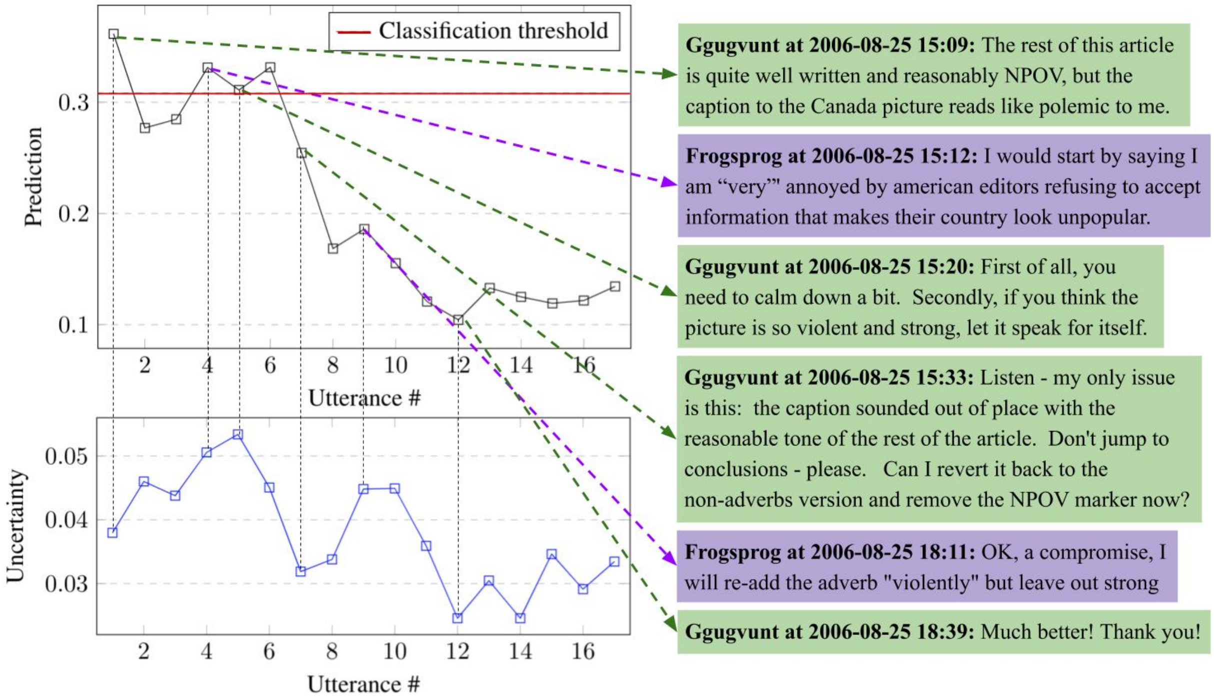
The highest scoring model, which a PR-AUC of 0.40, results from including edit summaries in the conversations ($P < 0.05$, using a randomized permutation test). This provides support for our observation that understanding some conversations requires knowledge of the edits that occurred during the conversation. However, neglecting to insert the "EDIT" token (as explained in Section 4.2) results in the PR-AUC decreasing to 0.33, which indicates that utterances sourced from edit summaries require special processing and are not completely homogeneous in the conversation.

Evaluating the predictions of this model, we observe that false positives often co-occur with heated debate. This is not unexpected, given that the positive class is contains interlocutors who feel strongly enough about their case to request mediation. The false negatives, on the other hand, contain a number of cases where it seemed as though a disagreement had been resolved, but then the argument progresses as further edits are made.

6.3 Early estimation of outcome

We are interested in how model predictions change throughout the conversation; whether it is possible to predict the outcome from the beginning, or if there is often some inflection point in a conversation that changes the outcome. Predicting the outcome of a conversation based on only a few utterances means that the model has less information for its inference; however, if models can perform well under such conditions, early intervention by a mediator could be recommended.

To evaluate model performance in such conditions, we split each disagreement into 10 buckets, chronologically (using only conversations of more than 10 utterances). We evaluate models trained on



Ggugvunt at 2006-08-25 15:09: The rest of this article is quite well written and reasonably NPOV, but the caption to the Canada picture reads like polemic to me.

Frogsprog at 2006-08-25 15:12: I would start by saying I am “very”' annoyed by american editors refusing to accept information that makes their country look unpopular.

Ggugvunt at 2006-08-25 15:20: First of all, you need to calm down a bit. Secondly, if you think the picture is so violent and strong, let it speak for itself.

Ggugvunt at 2006-08-25 15:33: Listen - my only issue is this: the caption sounded out of place with the reasonable tone of the rest of the article. Don't jump to conclusions - please. Can I revert it back to the non-adverbs version and remove the NPOV marker now?

Frogsprog at 2006-08-25 18:11: OK, a compromise, I will re-add the adverb "violently" but leave out strong

Ggugvunt at 2006-08-25 18:39: Much better! Thank you!

Figure 4: Model predictions and uncertainty throughout the course of a conversation in our dataset. The classification threshold shown is tuned on the validation set.

full conversations on these subsets to observe the change in model performance. These results are shown in Figure 3 in blue. Model performance increases from 0.198 at the midway point (0.5 bucket) to 0.292 when the full conversation has been observed, indicating that signals later in conversations are often important for predicting outcome. However, the neural model's performance when predicting on half the conversation only is still better than the toxicity and sentiment models on the complete conversations.

6.4 Uncertainty estimation

Given that this early estimation exposes the model to less information, we are interested in whether this impacts model uncertainty. We employ Monte Carlo dropout (Gal and Ghahramani, 2016) to this end. This approach calls for applying dropout before every layer of weights during both training and prediction, allowing us to sample from the distribution of predicted values for each input. Each input is evaluated multiple times (in our case, $N = 30$) and the mean and standard deviation of these predictions represent the prediction and its uncertainty.

Our results are shown in Figure 3 (in red). We note that uncertainty initially increases and then decreases monotonically. The initial increase in uncertainty could be due to a contrary position being introduced in the second utterance, in response to the introductory comment (as occurs in Figure 4). From there, the dispute is either resolved or eventually escalated, and uncertainty decreases almost linearly as the model is exposed to new data.

6.5 Identifying inflection points

Having ascertained that model accuracy improves and uncertainty decreases as a model is exposed to more information, we are interested in factors that cause the predicted class to change, and how the model predictions relate to the feature-based model coefficients. Although methods for interpreting neural network predictions exist (Ribeiro et al., 2016, 2018), these are not easily extendable to process inter-utterance dependencies as observed with the HAN. We instead analyse a conversation from our dataset to observe inflection points and what may have caused them. We show HAN model predictions and uncertainty values in Figure 4.

The HAN model initially predicts escalation, with a relatively low uncertainty value. The conversation remains confrontational for the first seven utterances with a high escalation score. There are two “I” pronouns in the second utterance and two “you” pronouns in the third utterance, which were also associated with unconstructiveness in the feature-based models. We note the use of politeness cues ("please" and "thank you" in the fourth and sixth utterances in this example), which reduces the score for escalation. The uncertainty and prediction values increase when one user proposes a compromise in utterance 9, and then decreases again in utterance 12 when the other user accepts the compromise. This feature was not explicitly modelled for in our feature-based models.

7 Conclusion

In a discussion of online disagreements by Graham (2008) (which Wikipedia references in its guidelines for resolving disputes), the author remarks that an increase in disagreements through widespread online interaction has the potential to create a surge in anger among internet users. On the other hand, as illustrated in our data, disagreements can sometimes be constructive. The success of Wikipedia shows the benefits of integrating multiple perspectives. As Hahn (2020) states, "Arguing things through is at the center of our attempts to come to accurate beliefs about the world [and] decide on a best course of action." For this reason, it is important to understand why disagreement can sometimes be constructive, and in other cases leads to conversational failure.

In this work, we investigated constructive disagreements from an NLP perspective. We have proposed a dataset of disagreements online and defined the task of predicting escalation as a proxy label for cases where disagreements were unconstructive. We analysed features that are associated with either class, and drew parallels with existing work. Using neural network models, we investigated the effect of modeling conversation structure and found that adding utterance hierarchy lead to an increase in performance. Finally, we validated our neural models by evaluating their performance and uncertainty when exposed to partial conversations. Our insights on constructive disagreements are not limited to Wikipedia and would be transferable to disagreements on other platforms. Additionally, our finding that edit summaries are an informative part of Talk page conversations should be useful for researchers who work on Wikipedia Talk pages more generally.

Abstract

To track different levels of formality in written discourse, we introduce a novel type of lexicon for the German language, with entries ordered by their degree of (in)formality. We start with a set of words extracted from traditional lexicographic resources, extend it by sentence-based similarity computations, and let crowdworkers assess the enlarged set of lexical items on a continuous informal-formal scale as a gold standard for evaluation. We submit this lexicon to an intrinsic evaluation related to the best regression models and their effect on predicting formality scores and complement our investigation by an extrinsic evaluation of formality on a German-language email corpus.

1 Introduction

The computational treatment of style in verbal communication has long been dominated by application concerns, e.g., the identification or profiling of authors in forensic linguistics (Ding et al., 2019) or the recognition of plagiarism (Alzahrani et al., 2012). This research was conducted assuming that simple lexico-statistic patterns identified by stylometric computations were sufficient to solve authorship and plagiarism assignment problems.

Despite their undisputed success in those limited fields, these studies scratched only the surface of the notion of 'style' as discussed in linguistic pragmatics (Hickey, 1993). From the many ways 'style' can be approached from a pragmatics perspective, we here focus on its inherent formality dimension, i.e., the distinction between *formal* (standard) and *informal* (colloquial) language use (for a survey, cf. Heylighen and Dewaele (1999)), with further extensions directed at the higher level of formal (e.g., elevated style) and the lower level of informal (e.g., vulgar) phrasing. Such distinctions of formality levels are crucial for the appropriateness of verbal expressions in a given discourse context.

In order to track different levels of formality in written communication, we introduce a novel type of lexicon for the German language, with entries ordered by their degree of (in)formality.[1] We start with a set of words extracted from traditional lexicographic resources, extend it by sentence-based similarity computations, and let crowdworkers assess the enlarged set of lexical items on a continuous informal-formal scale. This workflow is described in Section 3. The resulting lexicon comprising words with their respective formality scores subsequently serves as a gold standard for evaluation. In Section 4, we submit this lexicon to an intrinsic evaluation related to the best regression models and their effect on predicting formality scores, and complement our investigation by an extrinsic evaluation of formality on a German-language email corpus in Section 5.

2 Related Work

The relevance of 'style' for NLP is obvious for language output-focused core applications such as language generation (Sheikha and Inkpen, 2011; Dethlefs et al., 2014; Ficler and Goldberg, 2017), machine translation (Niu et al., 2018; Prabhumoye et al., 2018) or proper phrasing in argumentation (El Baff et al., 2020). Quite recently, the notion of 'formality style transfer' has received increasing attention, which captures the idea to generate a formal sentence given an informal one (*et vice versa*), while preserving its meaning (Shen et al., 2017; Fu et al., 2018; Rao and Tetreault, 2018; Li et al., 2018; Prabhumoye et al., 2018; Yang et al., 2018; Lample et al., 2019; Gong et al., 2019; Dai et al., 2019; Wu et al., 2019; John et al., 2019; Luo et al., 2019; Wang et al., 2019; Shang et al., 2019; Wang et al., 2020; Zhang et al., 2020; Yi et al., 2021).

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2028–2041
April 19 - 23, 2021.

Many efforts to cope with language style have been spent, however, in application niches, such as author identification or plagiarism detection. Most of the methodological contributions developed in this forensic branch are summarized under the label of *stylometrics* and have recently found their way into NLP analytics to unveil deception (Potthast et al., 2018; Pascucci et al., 2020a) or linguistic aggression (Harpalani et al., 2011; Nogueira dos Santos et al., 2018; Pascucci et al., 2020b).

The computational analysis of style according to stylometric principles, from its inception, is closely linked with *lexical frequency* counts. Typically, mostly function words (such as articles, pronouns, conjunctions, contractions, common abbreviations, hedging terms, also including punctuation marks) are assembled in small-sized dictionaries, together, if at all, with only a few content words (domain-specific nouns, verbs, adjectives). The frequency distributions resulting from counting these dictionary entries at the document or corpus level are already very beneficial for successfully dealing with disputed authorship problems (mostly for literary texts, but also for the detection of spam, fake news, or other kinds of toxic language) or uncovering plagiarism (mostly in scientific or news documents). Similar in spirit, word and sentence length criteria originating from readability metrics (Flesch-Kincaid, etc.) and several measures of vocabulary richness (e.g., type-token ratios, Yule's K and Burrow's Δ) were also incorporated into stylometric toolkits (Eder et al., 2016).

As a simple extension from these uni-grams, lexical or pseudo-lexical character *n-grams* (bi- or tri-grams, mostly) were determined and counted, as well. Slightly extending this (pseudo-)lexically focused approach by syntactic information, part-of-speech n-grams (or part-of-speech frequencies) were also considered to trace the human 'stylome', although lexical factors were found to be more relevant for style analysis than syntactic (POS sequence) patterns (van Halteren et al., 2005).

Simple frequency metrics have increasingly been complemented by various forms of lexical *association measures* (such as information gain, mutual information), and more sophisticated probabilistic models (principal component analysis (PCA), latent semantic analysis (LSA), or other types of topic models). Comprehensive lists of criteria and metrics are provided by Sheikha and Inkpen (2010); Neal et al. (2017); Ding et al. (2019).

We claim that despite their relevance for applications, such as authorship attribution and plagiarism detection, these mechanisms merely serve as easy to trace proxies for characterizing linguistic style. In our work, we will have a closer look at the style-marking semantic connotation of single lexical items as explicit carriers of linguistic formality as an important facet of language style.

A milestone for the formal definition of formality was set up by the pioneering work of Heylighen and Dewaele (1999) who defined the $\mathcal{F}$*-score*—close in spirit with the simple *lexico-statistic frequency* metrics from stylometry—as the percentage difference between deictic (article, pronouns, etc.) and non-deictic parts of speech (nouns, adjectives, etc.) in a document ($\mathcal{F}$ ranges between 0 and 100, with higher $\mathcal{F}$ indicating higher formality).[2] This document-level perspective was adapted by Lahiri et al. (2011) to sentence-level formality analysis.

A complementary *lexical* dimension for the formalization of formality was introduced by Brooke et al. (2010). They define the *formality score* for a word as a real number value in the range 1 to -1, with 1 representing an extremely formal word and -1 an extremely informal one, and assign a formality score to each lexical item based on standard word length, morphology-based features, lexical distribution criteria or association methods (LSA). Our work adheres to their way formality is scored in a formality lexicon and manually supplied seed sets are used (as starters), but differs markedly whether the lexicon is considered as a static (Brooke et al., 2010) or a dynamic resource (as we do; in a later study, Brooke and Hirst (2014) proposed a dynamic acquisition method, as well, by assigning a continuous formality score to single words based on their co-occurrence frequency with a hand-picked seed set of formal, neutral and informal words), and the way how semantic similarity is computed (LSA vs. embeddings). Further, we do not induce formality levels for a near-synonym task automatically but rather crowdsource nuances of formality for a relationally unrestricted lexical inventory from human raters.

Pavlick and Tetreault (2016) proposed a model of formality based on an empirical analysis of human formality perceptions. They apply their approach to analyze language use in online debate forums for multiple genres (news, blogs, emails,

---

[2] The $\mathcal{F}$*(ormality)*-score must not be confused with the F-score as a measure relating precision and recall.

and community question answering sites). Formality assessments are solicited via Amazon Turk (following the protocol established by Lahiri (2015)) using a 7-point Likert scale, with labels ranging from -3 (Very Informal) to 3 (Very Formal). A ridge regression classifier uses 11 different feature groups—five rarely used ones (among them WORD2VEC embeddings (Mikolov et al., 2013), parse trees, dependency tuples, and named entities) and six much more common ones (among them lower/upper casing, punctuation, readability scores, POS tags, and length-normalized formality and subjectivity scores)—to determine the formality level of sentences. Cross-genre analysis reveals that n-grams and word embeddings perform the best among all tested features (they achieve over 80% of the performance of the full classifier in all cases). This work comes closest to our approach, yet with differences in the way formality is assessed (Likert scales vs. best-worst scaling) and lexicon building is dealt with. Pavlick and Tetreault (2016) employ an acquisition method to score the formality of unseen phrases along the formal-casual dimension from scratch, as described in earlier work by Pavlick and Nenkova (2015) who use a log ratio metric based on the occurrence of phrases in various style-tagged corpora, in contrast to the embedding-based similarity model we propose.

Earlier computational models for detecting formality were proposed by Sheikha and Inkpen (2010); Peterson et al. (2011); Mosquera and Moreda (2012). The first two perform a binary classification only into formal *vs.* informal utterances, the third model classifies into four levels of (in)formality, and all of them operate at the document (as opposed to sentence) level.

3 Building a Formality-Informed Lexicon

3.1 Getting Started with VULGER

Previous work on computational lexicons (and lexicon acquisition) incorporating formality information focuses exclusively on the English language (Brooke et al., 2010; Brooke and Hirst, 2014; Pavlick and Nenkova, 2015; Pavlick and Tetreault, 2016). For German, VULGER (Eder et al., 2019)[3] constitutes a lexical resource that can be reused for such purposes to some degree. It comprises 3,300 German words scored by vulgarity/neutrality within a range of -1 (most vulgar) to $+1$ (most neutral). Accordingly, it covers the lower half of the formality spectrum quite well but completely lacks its upper half (formal up to elevated language). This study attempts to fill this gap by introducing I-FORGER, a comprehensive lexicon for *I*nformal and *For*mal *Ger*man. To acquire a lexicon covering the formal spectrum as well, we gathered formality-marked lexical entries in several ways as described in the following subsections.[4]

3.2 Input from Lexicographic Resources

As a first lexical acquisition step, we gathered lexical items from existing lexicographic resources based on their *manually* assigned categorical (in)formality tags:

Swear Words. As there is an overlap between swear words and vulgar lexicalizations, we used 500 lexical items randomly chosen from three German swear word lists[5] to feed the lower end of formality in I-FORGER.

Colloquial Items. In addition, we extracted 500 arbitrary terms marked as 'colloquial' ('ugs.' or 'umgangssprachlich,' in German) from the German slice of WIKTIONARY[6] and the German OPENTHESAURUS[7] supposed to range somewhere between vulgar and neutral on our scale.

Elevated Items. To extend the scale to the upper levels of linguistic formality, we also picked lexical items marked as 'elevated' ('geh.' or 'gehoben,' in German) from OPENTHESAURUS and WIKTIONARY yielding 1,000 additional terms (for the sake of balancing informal and formal entries in that phase). The reuse of manually curated lexicon resources (as seeds) thus follows the approach proposed by Brooke et al. (2010).

3.3 Lexicon Extension via Sentence Similarity

Given the intrinsic limitations of any manually curated lexicon resource, in the next step, we augmented I-FORGER by *automatic* means. We here suggest harvesting lexical candidates potentially carrying formality information from semantically

[7] `https://www.openthesaurus.de`

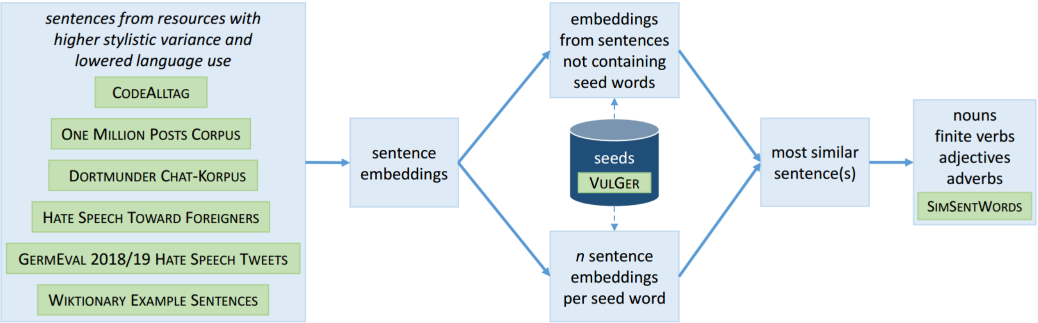

Figure 1: Generic language-independent workflow for gathering words for formality scoring approaches utilizing similar sentences (in blue) and its instantiation for our use case to acquire SIMSENTWORDS (in green)

similar sentences. This proposal goes beyond the standard way to utilize word embeddings in order to find close semantic neighbors based on the distributional hypothesis (see, e.g., Tulkens et al. (2016); Wiegand et al. (2018a) for detecting abusive lexicalizations this way). Rather than only discovering semantically related *words*, we extended our scope to semantically similar *sentences* to identify other relevant lexical candidates in the mined sentences, like an adjective modifying an offensive noun or other vulgar, yet otherwise unrelated, words in a vulgar word's context. On the flip side, this method admittedly gathers a considerable amount of noise (cf. Section 4 for a scoring approach to account for this problem).

3.3.1 Sentence Embeddings

As is well-known, BERT (Devlin et al., 2019) reaches new state-of-the-art results for various NLP problems, including semantic similarity tasks. However, finding semantically similar sentences close in vector space with BERT is computationally expensive. As a cure, Reimers and Gurevych (2019) introduced SENTENCE-BERT (SBERT), which modifies the pre-trained BERT network using siamese and triplet networks and produces semantically meaningful sentence embeddings that can be compared employing standard cosine similarity.

3.3.2 Sentence Similarity

To obtain candidate sentences for similarity computation for the German language, we employed a wide range of corpora. Our choices were guided by the requirements that these corpora should possess a high stylistic variance and contain vocabulary from the lower language register, too. We came up with:

- CODE ALLTAG[8] (Eder et al., 2020) comprising roughly 1,5M German-language emails,
- ONE MILLION POSTS CORPUS[9] (Schabus et al., 2017) containing about 1M user comments on news articles from the Austrian daily broadsheet newspaper DER STANDARD,
- DORTMUNDER CHAT KORPUS[10] (Beißwenger, 2013), with more than 140,000 German-language chats,
- HATE SPEECH TOWARDS FOREIGNERS[11] (Bretschneider and Peters, 2017), with about 6,000 posts and comments on German anti-foreign FACEBOOK pages,
- GERMEVAL 2018/19, collected for the task of identifying offensive language[12] (Wiegand et al., 2018b; Struß et al., 2019), including roughly 15,000 German-language tweets.

Using VULGER as a seed lexicon, we extracted sentences from these corpora by separating those containing VULGER entries from those that did not contain any VULGER item.[13] To further enlarge the number of sentences for each seed item, we also gathered sentences given as examples on the WIKTIONARY pages for the entries included in VULGER. From the resulting pool of sentences with seed words, we collected up to six sentences

[11] `http://www.ub-web.de/research/index.html`

[12] `https://projects.fzai.h-da.de/iggsa/data-2019`

[13] We only took 100,000 randomly chosen sentences from CODE ALLTAG and the ONE MILLION POSTS CORPUS for performance reasons.

per word. We chose them randomly but tried to take one sentence from each of the six resources to keep some balance, both formality-wise as well as genre-wise.

These sentences served as seeds for the computation of similar sentences. Like the remaining sentences not containing any seed words, they were embedded with SENTENCE TRANSFORMERS (Reimers and Gurevych, 2019) using the multilingual model supporting German (Reimers and Gurevych, 2020). Then, for all seed sentence embeddings, we calculated the most similar sentence in the remaining sentence embeddings using cosine distance (the acquisition step proper). From these most similar sentences, we gathered lemmatized nouns, finite verbs, adjectives, and adverbs, omitting named entities. An overview of the entire acquisition procedure is depicted in Figure 1.

From the resulting word list, we randomly chose 1,000 items (denoted SIMSENTWORDS, in the following) to evaluate the regression approach and the acquisition strategy of automatically gathering new words to score. As we also wanted to measure the acquisition noise, we further divided the words into 500 items manually cleansed from spelling mistakes, etc. (SIMSENTWORDS$_{cleansed}$), and left 500 as-is (SIMSENTWORDS$_{noisy}$).

3.4 I-FORGER at a Glance

Putting these pieces together, I-FORGER, the final lexicon, comprises 3,000 words, in total, with three major divisions: 1,000 terms from elevated language usage, 1,000 words, with swearwords and colloquial items joined, presumably linked to the lowered stylistic inventory, and 1,000 words that should rather occur at the lower end of our informality scale, but potentially include words from all stylistic levels (see Table 1).

Resource	# Lexical Items
ELEVATEDWORDS	1,000
SWEARWORDS	500
COLLOQUIALWORDS	500
SIMSENTWORDS	1,000
SIMSENTWORDS$_{cleansed}$	500
SIMSENTWORDS$_{noisy}$	500
Total	3,000

Table 1: Contributions from various resources for the I-FORGER lexicon

3.5 Human Assessment of I-FORGER

To establish a gold standard for subsequent evaluation, we gathered human formality assessments. For that, I-FORGER was annotated with Best-Worst-Scaling (BWS), a method that delivers high-quality annotations with only a relatively small number of annotation steps compared to standard point-interval based methods (e.g., Likert scales) for human assessment tasks. BWS also adheres to the principle that a “continuum of formality” (Heylighen and Dewaele, 1999) exists rather than n-ary categorical distinctions between formal and informal utterances (see also Lahiri et al. (2011); Brooke and Hirst (2014) for works based on degrees of formality).

BWS was introduced into NLP for emotion scaling by Kiritchenko and Mohammad (2016, 2017). Annotators are presented with n items at a time (an n-tuple, where $n > 1$, and typically $n = 4$). They then have to decide which item from the n-tuple is the *best* (highest in terms of the property of interest) and which is the *worst* (lowest in terms of the property of interest).

In our case, judges had to select the *most elevated* and the *most vulgar* terms per given n-tuple. We used the BWS tool[14] from Kiritchenko and Mohammad (2016, 2017) to generate 6,000 4-tuples for human assessment. Tuples were produced randomly under the premise that each term had to occur only once in eight different tuples and each tuple was unique.

For the annotation process proper, we used the crowdsourcing platform CLICKWORKER,[15] where we had each n-tuple assessed by five annotators (Kiritchenko and Mohammad (2016) showed that as few as 2-3 responses per tuple are sufficient to get reliable scores, at least for the assessment of sentiment.). In order to get real-valued scores from the BWS annotations, we applied COUNTS ANALYSIS (Orme, 2009)[16] and subtracted the percentage of times the term was chosen as worst from the percentage of times the term was chosen as best. Thus, we got scores between $+1$ (most formal) and -1 (most informal). We computed the split-half reliability[16] by randomly splitting the annotations of a tuple into two halves, calculating scores independently for these halves, and mea-

---

[14] `http://www.saifmohammad.com/WebPages/BestWorst.html`

[15] `https://www.clickworker.de`

[16] Again, we used the scripts from Kiritchenko and Mohammad (2016, 2017).

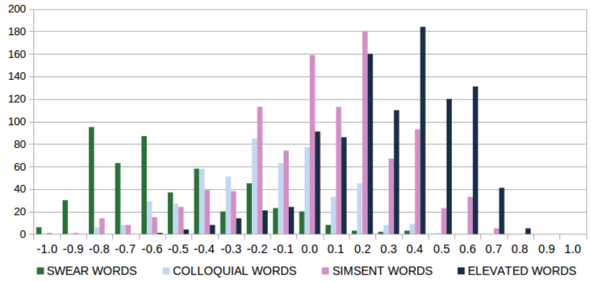

Figure 2: Distribution of scores per resource of I-ForGer

suring the correlation between the resulting two sets of scores. We got an average Spearman's ρ of $0.8954\ \ (+/-0.0030)$ over 100 trials.

Figure 2 displays the distribution of human assessed scores per resource for I-ForGer. While SwearWords and, to a lesser degree, also ColloquialWords are linked to lower scores, and ElevatedWords obtained higher scores, SimSentWords are found in the middle spreading on the entire scale of scores, also comprising a fair amount of words from the lower end of formality.

4 Intrinsic Evaluation of I-ForGer

Rather than increasing the size and thus the coverage of lexicons to improve performance on potential applications, we intend to score (unseen) words on the fly. Hence, we first evaluate the word scoring model (Section 4.1). Next, we assess the four main input streams of I-ForGer (Section 4.2) and the extension of the scale regarding formality levels (Section 4.3). Figure 3 illustrates the schematic workflow for our word scoring procedure, including (and marked in green) the three evaluation tasks.

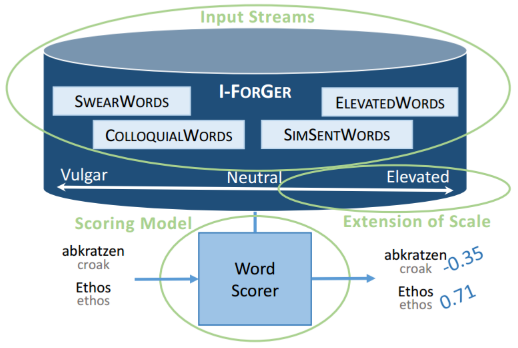

Figure 3: Overview of the word scoring workflow; parts to evaluate are marked in green

4.1 Regression Models for Word Scoring

We adopted various approaches using a seed lexicon, actually, the entries' word embeddings, as training data for regression models to automatically score new lexical items for their formality connotation (see, e.g., Li et al. (2017) and Buechel and Hahn (2018) for a similar scenario for automatic emotion induction).

As input features we decided for fastText word embeddings (Grave et al., 2018) with their own out-of-vocabulary (OOV) functionality. We found that they performed better than getting the OOV handling from BPEmb subword embeddings (Heinzerling and Strube, 2018), based on Byte Pair Encoding (BPE) (Sennrich et al., 2016), instead, or solely utilizing pure BPEmb embeddings.

We evaluated different regression models. Besides Ridge Regression,[17] which is linear regression with L_2 regularization during training, we also experimented with Densifier (Rothe et al., 2016), which learns an orthogonal transformation of the embedding space, and a modified, more robust variant of the latter, DensRay (Dufter and Schütze, 2019).[18] We ran a feed-forward neural network with one hidden layer combined with the boosting algorithm AdaBoost.R2 (Boosted FFNN) as proposed by Du and Zhang (2016).[19] Further, we tested neural networks with more than one hidden layer, namely two hidden layers with 256, 128 units ($\text{NN}_{2Hidden}$) and three hidden layers with 256, 128 and 64 units ($\text{NN}_{3Hidden}$).[20]

Table 2 depicts that Densifier and DensRay performed worse than all the others. Also, Ridge Regression yielded significantly lower results than the Boosted FFNN model. We found no difference between $\text{NN}_{2Hidden}$, $\text{NN}_{3Hidden}$ and Boosted FFNN since all three reached a strong Spearman's ρ of 0.77. As a higher number of hidden layers did not significantly improve results, we used Boosted FFNN for further processing.

---

[17] We used the scikit-learn.org implementation with the default parameters.

[18] We used their code provided on `https://github.com/pdufter/densray`.

[19] We copied their code on `https://github.com/StevenLOL/ialp2016_Shared_Task`.

[20] We used Keras in TensorFlow with the following hyperparameters: embedding/input layer with 0.2 and hidden layers with 0.5 dropout, MaxNorm weight constraint of 3, random normal weight initialization, ReLu activation, Adam optimizer, batch size of 32, mean squared error loss and 1,000 epochs with early stopping.

Model	Spearman's ρ
Ridge Regression	0.706*
Densifier	0.632*
DensRay	0.621*
NN$_{2Hidden}$	0.773
NN$_{3Hidden}$	0.771
Boosted FFNN	0.773

Table 2: Averaged Spearman's ρ for different models (10-fold cross-validation on I-ForGer); statistically significant differences (using the two-sided Wilcoxon signed-rank test on Spearman's ρ) are marked with '*' for $p < 0.005$ with respect to Boosted FFNN

4.2 Assessment of Input Streams

Table 3 pinpoints the predictability of formality for a particular input stream of I-ForGer in a 10-fold cross-validation setting. Learning scores of ColloquialWords and ElevatedWords seems harder than scoring SwearWords and SimSentWords. The lower human agreement on choosing the most elevated item supports this finding for the upper half of the formality spectrum. The data also reveal that the regression model is somewhat prone to noise since original SimSentWords$_{noisy}$ achieved much lower results than curated SimSentWords$_{cleansed}$. However, this acquisition strategy seems to be a choice worth considering for scoring approaches.

Input Stream	Spearman's ρ
SwearWords	0.593
ColloquialWords	0.409
SimSentWords	0.672
SimSentWords$_{cleansed}$	0.732
SimSentWords$_{noisy}$	0.595
ElevatedWords	0.477
I-ForGer	0.773

Table 3: Spearman's ρ for Boosted FFNN on I-ForGer with results for different input streams (10-fold cross-validation)

4.3 Assessment of Formality Scale Extension

A comparison with VulGer suggests that scoring an extended range of linguistic styles is a more difficult task, since evaluating the Boosted FFNN model on VulGer achieved a higher Spearman's ρ of 0.827 (10-fold cross-validation) than on I-ForGer (see Table 3). Nevertheless, applying a model trained on I-ForGer to VulGer gave a Spearman's ρ of 0.678, which signals evidence that I-ForGer still captures the vulgar-neutral dimension despite being trained on an extended scale with fewer words (3,000 *vs.* 3,300). It also shows that the word scoring approach *per se* indeed yields reliable results on the informal-formal dimension.

5 Extrinsic Evaluation of I-ForGer

In order to gather evidence for the value of I-ForGer in combination with the word scoring approach within a realistic use case, we ran experiments with emails, which possess a higher stylistic variability than news concerning their formality spread (Pavlick and Tetreault, 2016). Other work related to the formality of emails is typically carried out in the context of communication behavior studies in enterprises, with a focus on determining social factors (social distance, relative power, and the weight of imposition) that affect the sender's choice of formality (Peterson et al., 2011) or on the affective dimension of email exchanges (Chhaya et al., 2018) in terms of the prediction of frustration of employees from email data.

5.1 Email Corpus and Formality Gold Standard

Again using BWS and the tools from Kiritchenko and Mohammad (2016, 2017) mentioned before, we manually scored 800 German emails from CodE Alltag$_{S+d}$, a specialized, metadata-rich subset of CodE Alltag (Eder et al., 2020), for their formality. 35 annotators had to select the *most formal* email and the *most informal* email from four emails per rating step. Altogether, we had 1,600 4-tuples assessed three times. We got an average

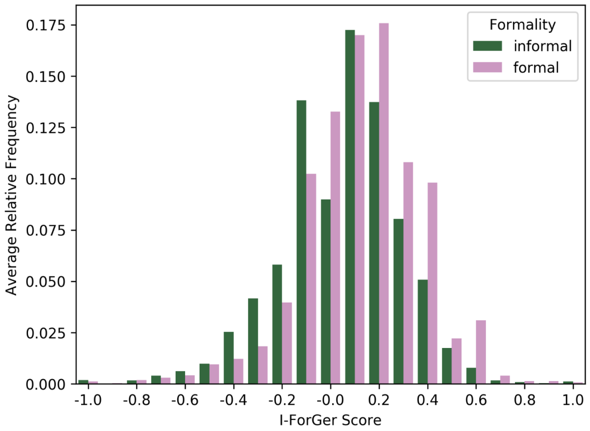

Figure 4: Distribution of I-ForGer scores for formal (with formality scores from 0 to +1) and informal emails (rated from -1 to 0)

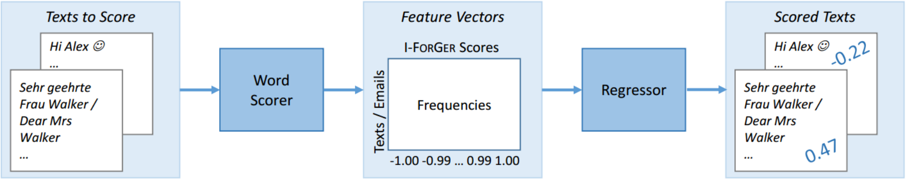

Figure 5: Overview of our workflow to score emails for formality using I-ForGer scores

Spearman's ρ of 0.9198 $(+/-0.0043)$ over 100 trials. The resulting scores on an informal-formal scale from -1 (informal) to $+1$ (formal) served as basis for our experiments.

5.2 Distribution of I-ForGer Scores

Under the assumption that formal emails include more formal words and informal emails more informal terms, we, first, examined the distribution of scores calculated for the emails' words with the Boosted FFNN model learned on I-ForGer. We split our dataset tentatively in two folds: emails with scores from -1 to 0 formed the informal part, whereas emails rated with positive numbers in a range from 0 to $+1$ were regarded as formal. Figure 4 indicates that, in comparison, informal emails indeed contain more negatively scored terms and formal emails comprise more words in the upper part of the informal-formal scale.

5.3 Formality Scoring of Emails

In the final evaluation setup, we tested whether word formality scoring works better than lexicon look-up in traditional resources and whether categorized items or continuous scores get better results. To determine the proper features for a linear regressor predicting formality scores,[21] we used a vector comprising the relative frequencies of an email's word scores as input (count per score divided by the total number of scored words). In one setting, the I-ForGer word scorer tagged (unseen) nouns, finite verbs and adjectives (Figure 5 depicts the workflow for this experiment.). In another setting, we only counted the scores of words already present in I-ForGer (without acquisition step). Besides relative score frequencies, we also tested taking the average score per document (sum of all calculated scores divided by the total number of scored words) as input feature[22] for both settings.

For a comparison of scores against pre-specified categories, we mapped the scores of I-ForGer to formality categories. We divided the scale into five distinct sections (e.g., scores between 0.6 and 1.0 form one category), assigned the respective category to each score and used a classifier instead of a linear regressor to learn the categories of new words. The relative frequencies of the categories then served as input for the linear regressor. We also experimented with ignoring OOV words and only utilizing lexicon look-up for the categorical scenario. For this setting, we exploited the *complete* pre-categorized word lists we got the Swear Words, Colloquial Words and Elevated Words from in order to increase coverage. In this way, in case of swear words, e.g., we did not only use the 500 items assembled in the I-ForGer lexicon, but used a list of more than 13,000 entries. As features instead of scores we counted the frequency of swear words, colloquial words and elevated words separately in each email and divided it by the total number of words found in the lexicons.

Table 4 summarizes our results. Scoring words based on I-ForGer yielded significantly better results than any other configuration reaching a strong Spearman's ρ of 0.728. When using the average score per document, there is still a positive correlation with the emails' formality scores. Utilizing a fixed set of lexical terms and not scoring new

Lexicon	OOV	Features	ρ
I-ForGer	Scored	counts	**0.728**
I-ForGer	Scored	average	0.587*
I-ForGer	Ignored	counts	0.446*
I-ForGer	Ignored	average	0.123*
I-ForGer$_{cat}$	Classified	counts	0.476*
Categories	Ignored	counts	0.335*

Table 4: Spearman's ρ for different configurations (10-fold cross-validation on formality scored CodE AlltaG$_{S+d}$); significance differences in respect to best model calculated with two-sided Wilcoxon signed-rank test are marked with '*' for $p < 0.005$

---

[21] We used a neural network with two hidden layers (128 and 64 units) and the same configurations in the Keras library in TensorFlow as reported for NN$_{2Hidden}$ or NN$_{3Hidden}$.

[22] Using the average scores directly to determine a correlation to the emails' formality scores gave comparable results.

words also performed better with score frequencies than using the average. However, compared to employing a word scorer for unseen words, the results for simple lexicon look-up are lower, a finding that seems to be due to the limited coverage of I-ForGer. Therefore, we can conclude that our way of scoring potentially unseen words is an effective and advantageous alternative to using fixed-size, and thus limited, lexical resources.

Employing the relative frequencies of formality categories instead of scores also yielded lower results for both settings, classifying new words (see I-ForGer$_{cat}$) and utilizing lexicon look-up with pre-categorized items (CATEGORIES). This demonstrates the benefit of a scaling approach instead of relying on coarse-grained categories.

6 Conclusion

Different levels of formality these days find increasing attention, both in methodological approaches and NLP applications. The necessity of choosing a socially appropriate tone is particularly evident in digitally mediated discourse, e.g., formal business or informal private email communication (Chhaya et al., 2018) or social media interaction via reviews, chats, or blogs (Pavlick and Tetreault, 2016; Gonzàlez Bermúdez, 2015). The increasing relevance of conversationally adequate virtual personal assistants (Shamekhi et al., 2016), chatbots (Chaves et al., 2019) and automatic procedures for smart response generation (Kannan et al., 2016) requires sensitivity on the generator's side to strike the right tone and avoid the false one. Similarly, machine translation poses special problems when expressions of (in)formality have to be adequately transferred between different languages (Niu et al., 2018). Progress in monitoring formality levels is a methodological prerequisite for several downstream applications that have to comply with users' habitual expectations or increase user satisfaction, e.g., in commercial interactions (customer service communication) (Liebrecht et al., 2020; Elsholz et al., 2019) or medical consultation (Fadhil and Schiavo, 2019).

As a methodological contribution, we here propose a lexical approach to computational style analysis based on I-ForGer, a lexicon whose (3,000) items are scaled on a continuous informal-formal spectrum. We make three new contributions to style analysis: First, a language-independent lexicon acquisition architecture employing sentence embeddings forms the basis for computing sentence similarity, thus finding formality-sensitive lexical items not contained in the seeds. Second, best-worst scaling is used for creating gold standards available for an in-depth intrinsic and extrinsic evaluation of the new lexical resource. Finally, I-ForGer stands out as the first formality-informed lexicon for the German language. This resource is available at `https://github.com/ee-2/I-ForGer`.

Despite our lexical focus, we are aware of the fact that formality is not only lexically expressed. Consequently, a lexicon-based approach has to be complemented by methods that account for non-lexicalized varieties of formality. Such forms may include syntactic variability, linguistic complexity and readability, as well as correctness of language use regarding orthography, morphology and syntax. For research on formality detection incorporating its syntactic, semantic and discourse facets, cf., e.g., Heylighen and Dewaele (1999), Li et al. (2013) or Pavlick and Tetreault (2016). These branches will also be part of our future work. Still, a (potentially) large portion of formality assessments is rooted in lexical signals, which we capture by the methodology advanced in this paper.

Abstract

This paper proposes a new task regarding event reason extraction from document-level texts. Unlike the previous causality detection task, we do not assign target events in the text but only provide structural event descriptions, and such settings accord more with practice scenarios. Moreover, we annotate a large dataset **FinReason** for evaluation, which provides **Reason**s annotation for **Fin**ancial events in company announcements. This task is challenging because the cases of multiple-events, multiple-reasons, and implicit-reasons are included. In total, FinReason contains 8,794 documents, 12,861 financial events and 11,006 reason spans. We also provide the performance of existing canonical methods in event extraction and machine reading comprehension on this task. The results show a 7 percentage point F1 score gap between the best model and human performance, and existing methods are far from resolving this problem.

Figure 1: An example of reason extraction for structural events from a document. We need to extract the textual spans from the document as reasons for the given structurally presented events. Here, we need to extract *Reason 1* and *Reason 2* for *Event 1* and *Event 2* respectively.

1 Introduction

Why does the event happen? People are always eager to find the reasons for an event. Automatically extracting the causal explanations of the given events from texts is useful and important for common users and downstream applications. For example, in the financial domain, returning the reasons of a concerned financial event in an Information Retrieval system can free analysts from reading the enormous company announcements and help investors make financial decisions.

Previous work on event causality (Do et al., 2011; Riaz and Girju, 2013; Mirza and Tonelli, 2014; Caselli and Vossen, 2017) mainly focus on the identification of causal relations between two given events that are usually presented as event trigger words. However, in reality, users may only know a particular event happened but without knowing its mention or trigger in the documents, and they just wonder the reasons for it. Therefore, we propose a new task aiming at extracting the causal explanations of the given structurally presented events from document-level texts. Specifically, a ***Structural Event*** defined here is a structural description that contains all necessary roles for an event type. Such a description can completely represent a specific happened event in reality. For example, in Figure 1, the *PLEDGE* event has four predefined roles *NAME*, *ORG*, *NUM*, *BEG* to represent an occurred *PLEDGE* event. Then, our

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2042–2048
April 19 - 23, 2021.

task is to extract the reasons of the structural events as textual spans from the document.

To investigate the solution for this challenging task, we construct a large-scale Chinese dataset **FinReason**[1]. Specifically, we automatically collect the formal financial documents with their corresponding structural events the same as Yang et al. (2018). Then, crowd workers are employed to annotate the reasons in the documents for each structural event. In order to guarantee annotation quality and high inter-annotator agreement (IAA), we set several annotation principles and define 3 types of possible causal explanations (*MOTIVATION*, *CAUSE*, *ENABLE*) as ***Reasons*** for the events in company announcements to guide annotators. Finally, there are 8,794 documents, 12,861 collected financial events, and 11,006 reason spans in total. The Cohen's kappa of annotations is 83.87%.

Moreover, to understand this task's difficulties, we regard this task as an Event Extraction (EE) or a Machine Reading Comprehension (MRC) task. We also try some canonical models, such as BiLSRM+CRF (Ma and Hovy, 2016), and BERT (Devlin et al., 2019) on this task and set benchmarks. Empirical results show that this task is challenging, and there is still an overall gap of 7pp (percentage points) in the F1 score between the best model and human performance.

2 Related Work

Much NLP research has focused on identifying causality relations from text, including knowledge bases (WordNet (Miller, 1998), FrameNet (Baker et al., 1998) and ConceptNet (Speer et al., 2017)), semantic related evaluations (SemEval-2007 task 04 (Girju et al., 2007), COPA (Roemmele et al., 2011), RED (Ikuta et al., 2014)), and event-related systems (Beamer and Girju, 2009; Do et al., 2011; Riaz and Girju, 2013; Hu and Walker, 2017; Caselli and Vossen, 2017). These work tried to identify real-world causality in lexicons or texts from different aspects. However, they have found it is difficult to agree on if a causal relationship exists in reality due to the ambiguity of causality definition. Our dataset mitigates this problem by only identifying contextual causality and do not check with reality.

In addition, plenty of work also only identify context-level causal relationships, such as general causality detection tasks PDTB (Prasad et al., 2007) and BECauSE 2.0 (Dunietz et al., 2017), and emotion causality detection task ECA (Lee et al., 2010). Some work (Radinsky et al., 2012; Mirza and Tonelli, 2014; Zhao et al., 2017) also tries to identify the causal relations between events at the contextual-level. However, our task is different because we focus on extracting the reasons for well-defined structural events, which is more close to practice scenarios.

3 Task Description and Data Collection

Task Description Our task is to extract the corresponding causal explanations for given structural events in a document. The inputs are a document with corresponding structural events described in it. The outputs are the causal text spans for the given events. For a given event in the document, there may be zero, single, or multiple causal explanations that need to be identified.

3.1 Data Collection

Event Type	Doc Count	Event Count	Reason Count	Doc Count w/ reason
Pledge	4,138	5,379	4,714	2,901 (70.11%)
O/U	2,550	4,127	3,565	2,132 (83.61%)
Lawsuit	2,106	3,355	2,727	1,438 (68.28%)
Total	8,794	12,861	11,006	6,471 (73.58%)

Table 1: Statistics of FinReason[2].

To construct this dataset, we first collect a corpus of structural events with their corresponding documents following Yang et al. (2018). The collected documents are constrained to company financial announcements, which are relatively formal documents. Such a setting could improve annotation IAA because of the logical consistency and clarity. In specific, we crawl the public company financial announcements as documents from sohu.com[3] and the structural events from eastmoney.com[4]. Since the documents are not in line with their corresponding structural events, we leverage key event items (see more details in Appendix B) matching to align them. Same as Yang et al. (2018), we assume that if the key event items of a structural event appear in a document, the document mentions the target structural event. This alignment method has a high precision of 94.5% as evaluated by Yang et al. (2018).

---

[1] `http://www.nlpr.ia.ac.cn/cip/~liukang/dataset/finreason1.html`

[2] The statistics are calculated after manual cleaning in the second step.

[3] `http://q.stock.sohu.com/index.shtml`

[4] `http://choice.eastmoney.com/`

In total, as in Table 5, we align 8,794 documents with corresponding 12,861 structural events of 3 types in financial domain, namely Pledge of Shares *(Pledge)*, Overweight and Underweight of Shares *(O/U)*, Lawsuit and Arbitration *(Lawsuit)*. To the best of our knowledge, this is the largest dataset in the event reason extraction task.

3.2 Event Reason Annotation

Annotation Principles: To construct a corresponding dataset with high IAA, we follow the two principles in the annotation. **First**, we annotate the event reasons according to the contextual expressions. We do not check with reality, even if it is obviously a false statement (*e.g., the stock market falls because of intense sunspot activity*). **Second**, we specifically define 3 types of possible causal explanations as reasons for the financial events in announcements following previous work (Trabasso et al., 1989; Van den Broek, 1990; Dunietz et al., 2015): *MOTIVATION*, *CAUSE*, *ENABLE* (see details in Appendix A). This provides a clear guideline to annotators to decide what to annotate and what not to. Because it is also ambitious to differentiate those reason types from texts (Dunietz et al., 2015), we do not require the annotators to distinguish them but just require them to confirm that the reasons annotated at least belong to one of the 3 types.

Quality Control: Besides the aforementioned 2 principles, we adopt several more rules to control data quality as follows. (1) Each member should find as many reasons for a target event as possible. (2) Each reason annotated should be as short as possible but with complete expressivity. (3) When explicit causal relation terms such as 因为 (*because*), 为了 (*in order to*) are mentioned, they should be included in the annotated reasons. (4) For each reason annotated, the annotator should confirm it by doing a *why* test (Grivaz, 2010), which means the reason should answer the question *why the event happened*.

Then, we employ crowdsourcing to annotate the reasons for each event. Specifically, 9 workers are divided into 3 teams to annotate each event type separately. Each team is trained to acquire the domain knowledge of the target event type so they can figure out the possible reasons for the events. Within each team, 2 members are responsible for annotating the reasons independently, and the 3rd member will be activated to make a judgment when 2 annotators have inconsistent annotations. Because the alignment in the first step may not be perfectly accurate, annotators are also responsible for removing those wrongly aligned cases in the annotation to maintain data quality. Finally, as shown in Table 5, there are totally 8,794 documents, 12,861 collected financial events and 11,006 annotated event reason. And, approximately 73.58% of the documents are annotated with event reason. The Cohen's kappa of IAA is 83.87%.

3.3 Task Challenges

Event Type	Multi-event Doc Count	Multi-reason Doc Count	Implicit-reason Doc Count
Pledge	796 (19.24%)	461 (11.14%)	2,845 (68.75%)
O/U	635 (24.90%)	483 (18.94%)	2,030 (79.61%)
Lawsuit	387 (18.38%)	221 (10.49%)	1,434 (68.09%)
Total	1,818 (20.67%)	1,165 (13.25%)	6,309 (71.74%)

Table 2: Three types of challenges in FinReason.

From the annotation results, we could briefly conclude that extracting the reasons for given structural events in a document is not an easy task. First, a document may mention multiple events like the 2 events in the example of Figure 1. As in Table 5, approximately 20.67% documents mention more than one events. Without event mention assignment, discriminating the corresponding reasons for different events within the same document is difficult. Second, about 13.25% of documents mention multiple reasons for an event. Finding all reasons out is also not easy. Thirdly, 71.74% of the documents mention the reason for the events in an implicit way. There are only 28.26% reasons mentioned with explicit modifiers, like 因为(because),由于(since),原因(cause),为(in order to),目的(aims to), etc. Such implicitly mentioned reasons are harder to be identified because they do not have any syntactic clue and require deep reasoning.

We regard the average performance of the two annotators with respect to the final golden standard in the test set as human performance[5]. We can see in Table 2, the human performance on the test set is in line with intuition. Compared with simple cases (Single-Event, Single-Reason, Explicit-Reason), identifying reasons in multiple-event, multiple-reason, and implicit-reason cases are more challenging.

---

[5] This setting may overestimate the actual human performance but acceptable as a performance upper bound.

4 Benchmark Settings

4.1 Evaluation Criterion

To evaluate the solution on this task, we follow a similar paradigm of SQuAD 2.0 (Rajpurkar et al., 2018) but also with several differences. In general, we get *precision/recall/f1* scores of every event in the test set and calculate the macro-average of all events as the overall performance. However, there are multiple reason cases in FinReason, and we try to evaluate the ability of multiple reasons identification. As a result, we do not fully follow SQuAD-style evaluation by selecting the best prediction but considering all predictions to avoid the systems cheating by predicting all possible causal expressions in the text. For each case, we compute the scores as follows. 1) When there is no reason annotated for an event, the prediction should be *Null* string so as to get *precision/recall/f1* scores of all 1; otherwise, all scores will be assigned 0. 2) When there is only one reason annotated for an event, we calculate the *precision/recall/f1* scores based on the overlapping strings of prediction and ground truth. 3) When there are multiple reasons for a target event, we first calculate each reason's scores with corresponding predictions as in situation 2 and then calculate the macro-average of all reasons as the final scores for the target event.

4.2 Baselines

FinReaon is a new task but similar to several existing tasks, such as event extraction (EE) or machine reading comprehension (MRC). So we apply existing canonical methods for those similar tasks on FinReason as benchmarks for future research. The selected baselines are as followed (see more details in Appendix C):

Regular Expressions (RegExp): In this setting, we regard the FinReason task as a causal sentence detection problem and employ some ad-hoc regular expressions to solve it. Specifically, we use five modifiers (因为(because),由于(since),原因(cause),为(in order to),目的(aims to)) as causal clues to detect the sentence as the reasons for an event.

BiLSTM-CRF (BiLSTM): We can take the reasons as one part of the event description and regard the task as an EE task. Similar to Yang et al. (2018), we employ a BiLSTM-CRF (Ma and Hovy, 2016) to predict the start and end positions of each reason. Specifically, We simply get the event participants in the documents via string matching between the documents and the given structural events. Such information is used as features in a BIO tagging format.

BERT-QA: We can take this task as an MRC problem if the structural event is regarded as a query and the target reason as the answer. In particular, we use templates to turn each structural event into a *why-question* and employ BERT-QA (Devlin et al., 2019) model to find the corresponding reasons.

Type	RegExp	BiLSTM	BERT-QA	Human
Pledge	19/21/20	**76/86/81**	**76**/70/73	93/94/93
O/U	20/27/23	**90/94/92**	**90**/89/89	99/99/99
Lawsuit	20/24/22	**73/73/73**	**73**/72/72	74/78/76
All	20/24/22	**80/84/82**	**80**/77/78	89/90/89

Table 3: Performance of baselines and human beings on FinReason (*precision/recall/f1*, %).

Challenges	RegExp	BiLSTM	BERT-QA	Human
Single-event	16/21/18	**86/90/88**	84/81/82	90/92/91
Multi-event	25/28/26	73/**77/75**	**74**/72/73	87/88/87
Single-reason	23/26/24	85/**86/85**	**86**/84/**85**	91/92/91
Multi-reason	8/13/10	**53/81/64**	43/41/42	76/85/80
Explicit-reason	29/32/30	**85/87/86**	**85**/83/84	90/90/90
Implicit-reason	2/4/3	54/**65/59**	**61**/58/**59**	85/90/87

Table 4: Performance for the three challenges (*precision/recall/f1*, %).

Results We split the dataset into *train/dev/test* sets with a ratio of 8:1:1 for experiments. From the results in Table 2, we can see that there is still an average of 7pp (82% vs. 89%) F1 score gap between the best model (BiLSTM) and human performance. Besides, we can see that human performance is relatively low for *Lawsuit*. This is because the reason for a lawsuit usually lies in a whole story between the plaintiff and the defendant, and it is hard to agree on the boundaries of the span. Furthermore, the BiLSTM model generally performs better than BERT-QA. The reason may be that the BiLSTM model knows the positions of event mentions by using the event BIO features, but BERT-QA only uses the structural event as the query. So it may be easier for BiLSTM to locate the correct reasons.

Besides, we also evaluate the 3 challenges on the whole test set. As from Table 2, the average F1 gap between the best model and human for the 3 challenges are 12pp, 16pp, 28pp, respectively, which is much larger than the overall average gap of 7pp. This demonstrates that the challenges are also the bottlenecks of the models to reach comparable human performance, especially the implicit cases.

5 Conclusion

In this work, we propose a dataset FinReason for a new event causality extraction task. Our experiments show that this task is still challenging for current models. Future work may consider breaking the challenging cases (multiple-events, multiple-reasons, and implicit-reasons) to achieve a more satisfying performance.

Appendices

Appendix A: Event Causality Types

We define the Event Causality Types referring to some previous work. Trabasso et al. (1989) and Van den Broek (1990) defined 4 types of narrative causality relations between events.

- *PHYSICAL*: Event A physically causes event B to happen.
- *MOTIVATIONAL*: Event A happens with B as a motivation.
- *PSYCHOLOGICAL*: Event A brings about emotions expressed in event B.
- *ENABLING*: Event A creates a state or condition for B to happen.

Dunietz et al. (2015) also defined 4 types of causal languages in texts:

- *CONSEQUENCE*: The cause naturally leads to the effect via some chain of events.
- *MOTIVATION*: Some agent perceives the cause, and therefore consciously thinks, feels, or chooses something.
- *PURPOSE*: An agent chooses the effect out of a desire to make the cause true.
- *INFERENCE*: Present the cause as evidence or justification for the effect.

However, we refer to those previous definitions, but we only define 3 types of causal explanations as **Reasons** according to our specific task and application domain. These causality types are the most common reasons for the financial events described in company announcements.

- *MOTIVATION*: The event happens with the explanation as a motivation or purpose. *e.g., He pledged the stocks aiming at providing a guarantee for self-financing.*
- *CAUSE*: The cause in the explanation naturally leads to the occurring of the event. *e.g., He sued the company because of loan disputes.*
- *ENABLE*: The explanation creates a condition or state for the event's occurrence. *e.g., He reduced his shares according to the contract.*

The reasons annotated should at least belong to one of the 3 types. However, we do not require the annotators to distinguish specific types because it is ambitious to differentiate them (Dunietz et al., 2015).

Appendix B: Event-Document Alignment

Following Yang et al. (2018), we assume that if the key items of a structured event appear in a document, then the document mentions the event. We first group those events and documents with the same Announcement Date (DATE[6]) and then use the following key items to align them:

- *Pledge*: Number of Shares (NUM), Name of Shareholder (NAME), Pledge Institution (ORG).

---

[6] The event item abbreviations are used in the corpus.

- *O/U*: Number of Shares (NUM), Name of Shareholder (NAME), Name of Shares (STOCK).
- *Lawsuit*: Plaintiff (OBG), Defendant (NAME), Court Name (ORG).

Appendix C: Model Settings

We build our baselines based on the open sources of the BiLSTM[7] and BERT-QA[8]. We do not do hyperparameter search and mainly use the default settings. Common parameters are in the Table 5:

Models	Batch Size	Learning Rate	Max Epochs	Optimizer
BiLSTM	20	$1e^{-3}$	30	Adam
BERT-QA	16	$5e^{-5}$	30	BERTAdam

Table 5: Parameters Settings.

Specifically, for BiLSTM, we use the 100-dim character embeddings[9] trained with on Chinese WiKi corpus as initial word features. For structural event embeddings, we first label back the event items to corresponding documents by string matching with BIO schema, then use the 100-dim random vectors as initial BIO features. Besides, the hidden dimension and dropout rate of the LSTM are set as 100 and 0.5, respectively. For BERT-QA, we use the *bert-base-chinese* version and choose the maximum sequence length as 512, the document stride as 128, the max query length as 64, and the max answer length as 30. We train them on two Nvidia GEFORCE GTX 1080Ti GUPs.

Moreover, we need the models to deal with the multiple-event cases. For the RegExp method, we cannot distinguish different events, so we just regard all the extracted reasons as explanations for all the events indiscriminately. For BiLSTM, we create different samples for different events from the same documents to ensure one sample just have one document with at most one event. The BERT-QA regards events as queries so it can naturally adapt to it.

Even for one event, there may be multiple reasons for it, and our models need adaptation. The RegExp is the same as before. The BiLSTM can label multiple pairs of start and end for textual spans, so it naturally adapts to multiple-reason cases. The BERT-QA can return the top k answers as reasons from the documents, and in practice, we get the best result when setting k as 1.

Abstract

In this paper, we propose to study language modelling as a multi-task problem, bringing together three strands of research: multi-task learning, linguistics, and interpretability. Based on hypotheses derived from linguistic theory, we investigate whether language models adhere to learning principles of multi-task learning during training. To showcase the idea, we analyse the generalisation behaviour of language models as they learn the linguistic concept of Negative Polarity Items (NPIs). Our experiments demonstrate that a multi-task setting naturally emerges *within* the objective of the more general task of language modelling. We argue that this insight is valuable for multi-task learning, linguistics and interpretability research and can lead to exciting new findings in all three domains.

1 Introduction

Humans are optimising their behaviour towards a multitude of objectives to reach their goals in day-to-day life. By learning many things at the same time and exploiting their commonalities, they acquire more general knowledge about the world, which in turn helps them to learn new things quicker (Perkins et al., 1992; Schwartz et al., 2005; Cormier and Hagman, 2014; Luriia, 1976). This idea of finding more general solutions through the diversification of tasks has found its way also to the machine learning community, in the field of multi-task learning (MTL) (Caruana, 1993, 1997). In MTL, multiple tasks are optimised jointly, enabling the transfer of relevant information across tasks. MTL research yields fruitful results in both application (e.g. Collobert and Weston, 2008; Collobert et al., 2011; Zhang et al., 2014; Donahue et al., 2014; Kaiser et al., 2017) and theory (e.g. Baxter, 2000; Maurer, 2006; Ando and Zhang, 2005; Argyriou et al., 2008).

However, deciding on a setup requires making many arbitrary choices. The researcher or engineer has to decide which tasks to train together (e.g. Bingel and Søgaard, 2017; Standley et al., 2020); at which hierarchy-level to allow tasks to interact (e.g. Søgaard and Goldberg, 2016); which degree of parameter sharing to employ (Ruder, 2017); which distribution of training data to employ (e.g. Luong et al., 2016), and so on. Having to make so many arbitrary choices is inconvenient for modellers, but also stands in the way of understanding the learning principles of neural models in multi-task settings. The highly constructed learning scenarios make it difficult to see whether outcomes should be attributed to one of the many a-priori decisions or to inherent properties of the learning process.

In this paper, we propose to study MTL not in a constructed, artificial scenario, but in a more natural setting. To do so, we consider the objective of *language modelling* and exploit the fact that it can be seen as a conglomerate of many different tasks. To give an example: rules of word ordering have to be learned simultaneously to rules of feature agreement and the monotonicity properties of different linguistic environments. These different tasks all need to be learned to achieve the greater goal of producing acceptable sentences, and they have to be optimised in parallel when the language model (LM) is trained. Language modelling is in that sense a *natural* multi-task learning problem with a naturally given *task hierarchy* provided by linguistic theory (see also Figure 1).

Studying language modelling as a multi-task problem has several distinct advantages. From an MTL perspective, it gives us a complete hierarchy of relevant tasks that can freely interact throughout the learning process, unconstrained by prior assumptions. We can make theoretically informed decisions about these tasks, drawing on linguistic theory. We can also deduce from linguistics how these tasks relate to each other (or, in other words, how similar they are), which in MTL is considered to be one of the crucial factors for the learn-

ing outcomes (e.g. Thrun and O'Sullivan, 1996; Passos et al., 2012). MTL has not yet been studied from this dynamic and unconstrained perspective. Then, somewhat more delicately, the extent to which models can exploit similarities hypothesised by linguistic theory can play a role in confirming or refuting specific linguistic hypotheses. Lastly, when it comes to interpretability research, applying concepts from MTL can be valuable to better understand the learning dynamics of models. By understanding how models are finding solutions, we can infer what these solutions are.

Outline In the remainder of this paper, we will first provide some basic background about MTL (§ 2.1), the subset of linguistic tasks we focus on (*Negative Polarity Items*, where we consider their different *licensing contexts* as tasks, § 2.2) and discuss some related work in interpretability (§ 2.3). Then, in § 3 and § 4, respectively, we present our approach and empirical results that showcase our idea. In § 5, we discuss our results and framework in the light of the three fields mentioned before. We conclude in § 6.

2 Background

In this paper, we aim to bring together three strands of research: MTL, linguistics and interpretability research. As a proof of concept, we focus on one specific complex subset of linguistic tasks: *licensing of Negative Polarity Items (NPIs)*. Below, we give a short overview of the most important characteristics of the three fields of interest.

2.1 Multi-task learning

In MTL, multiple tasks are learned together to enable information transfer from one task to another. If the transfer is successful, the benefits might be threefold: the model learns tasks with less training data (i.e. *more efficient*, Collobert et al., 2011; Benton et al., 2017; Kaiser et al., 2017), up to a higher final accuracy (Collobert and Weston, 2008; Kaiser et al., 2017) and in a way that better generalises to new tasks (Baxter, 2000; Collobert and Weston, 2008).

Caruana (1993, 1997) and Ruder (2017) propose several different – but related – processes that might enable positive transfer: related tasks can provide additional training examples for each other on the features they share (*statistical data amplification*), certain features might be easier to learn through one task than through another, but be useful for both of them (*eavesdropping*), and idiosyncratic features of single tasks can be averaged out, while more general features are reinforced (*attention focusing*)[1].

---

[1] For a complete list of processes please consult the original publications.

However, positive transfer is not guaranteed; It is also possible that performance *deteriorates* due to interference between different tasks, resulting in negative transfer, (Rosenstein et al., 2005; Pan and Yang, 2010; Wang et al., 2019). Whether transfer is positive depends on the *task similarity* and whether the model is able to exploit this similarity (Rosenstein et al., 2005; Thrun and O'Sullivan, 1996; Passos et al., 2012).

The main goal of MTL so far has been to avoid negative- and promote positive transfer by determining task-similarity and regulate the interactions between tasks based on these similarities. Due to its pivotal role, much research effort was spent on determining similarities of tasks and the regulation of information transfer between them (for an overview, see Zhang and Yang, 2017; Ruder, 2017). The disadvantage of these approaches is that assuming fixed tasks and regulating transfer between them based on fixed task-similarities puts large constraints on possible transfers between tasks, because it neglects the fact that learning processes are dynamic. From the perspective of the model, tasks, as well as their similarities, can change throughout the learning process. Here, we only use predefined tasks and their similarities to *analyse* the learning behaviour of the model, without constraining the learning process in any way.

2.2 Negative Polarity Items

We exemplify our idea by analysing the learning behaviour on a complex subset of linguistic tasks: the licensing of Negative Polarity Items (NPIs). The properties of NPI licensing make it an interesting and adequate subset of tasks to study, as it has a high degree of complexity, has an appropriate frequency within natural language and was previously frequently investigated in neural models.

NPIs are characterised by the property that they can only occur within the scope of certain *licensing contexts*. For instance, in the example below, the NPI '**any**' can occur in sentence (1)a., where it is in the scope of a negation, but not in sentence (1)b., where there is no licensor present.

(1) a. Bill did*n't* buy **any** books that day.
b. * Bill did buy **any** books that day.

(2) a. *Nobody* has **ever** been there.
b. * Somebody has **ever** been there.

Licensing contexts are formed on the basis of semantic properties, such as downward entailment (Fauconnier, 1975; Ladusaw, 1980), nonveridicality (Giannakidou, 2011), or scope marking (Barker, 2018). Common licensing contexts include negation, conditionals, or superlatives, and are often *triggered* by a specific expression, such as 'not' or 'nobody'.

Grasping the phenomenon of NPI licensing requires understanding of three different aspects:

1. *The class of NPIs*: there is a group of expressions that are restricted in their occurrence.
2. *Licensing contexts*: there exists a group of expressions that allow NPIs to occur.
3. *Scope and structure*: the licensing contexts have to stand in a certain structural relationship to the NPIs.

We focus on how LMs learn the second aspect by analysing how different types of licensing contexts interact and generalize throughout training. During learning they should be able to exploit their similarity in the other two aspects.

2.3 Interpretability

Interpretability research on LMs has shown that in pre-trained models, such as BERT (Devlin et al., 2019), hierarchical structure emerges throughout the layers and that this structure demonstrates parallels with linguistic theory (Peters et al., 2018; Liu et al., 2019; Tenney et al., 2019). However, the emergence of this structure has not been explicitly connected to MTL yet.

In recent years, research has shown that LMs are able to understand NPI licensing. Jumelet and Hupkes (2018) evaluate the performance of LMs on data sets containing NPI constructions extracted from large corpora, and Marvin and Linzen (2018); Wilcox et al. (2019); Warstadt and Bowman (2020) test them on artificial data sets containing template-based NPI constructions. In our own experimental setup we will utilise the extensive template-based NPI corpus of Warstadt et al. (2019).

What these approaches have in common is their focus on the performance of pretrained LMs. Our MTL approach sheds light on an unexplored aspect of NPI understanding: the learning dynamics of the model *during* training.

3 Approach

We consider two different types of experiments. First, to understand to which extent models can understand and use the similarity between different licensing contexts (our *tasks*) during learning, we exploit the effect that frequency of the different contexts has on learning. Second, we manipulate the LMs' training corpus to constrain their ability to leverage information from other licensing contexts during learning. In accordance with the MTL-literature, we expect the LMs to learn tasks more data-efficient and to a higher final accuracy if they can leverage information across contexts. Before we describe our experiments in more detail, we present our model architecture and training, the evaluation procedure of the licensing contexts, and the filter procedure we use to manipulate the training corpus.

3.1 Model

Following previous work in this area, we consider recurrent language models. We focus on unidirectional LSTM models and mirror the hyperparameter setup of Gulordava et al. (2018)[2]. We train the models on the corpus provided by the same authors[3] – a subset of the English Wikipedia – or modified versions of the same for our second experiment (see § 4.2). To track the learning process, we save models every 100 batches of training (371 model-checkpoints per epoch). For all experiments, we average performance across five random seeds.

3.2 Evaluation

To estimate the LMs' understanding of NPIs and their dependence on the different licensing contexts, we adapt the Cloze task of Warstadt et al. (2019), based on the implementation of Jumelet (2020). This task considers nine different types of licensing contexts (a list of the contexts, including examples, can be found in Table 1). For every such context, Warstadt et al. (2019) generated a large number of *minimal pair sentences*, containing correctly and incorrectly licensed NPIs. For instance, for the *adverbs* licensing context:

(3) a. A lady *rarely* **ever** thought that the children saw the boy.
b. * A lady *sometimes* **ever** thought that the children saw the boy.

Following previous work, we quantify an LM's understanding of a particular type of licensing context by computing the percentage of minimal pairs in that context for which the model correctly assigns a higher probability to the NPI in the licensing contexts than in the non-licensing contexts. I.e., in the example above, we would compare the probability the model assigns to the word *ever* in the contexts "A lady rarely" and "A lady sometimes" (see also Figure 2).

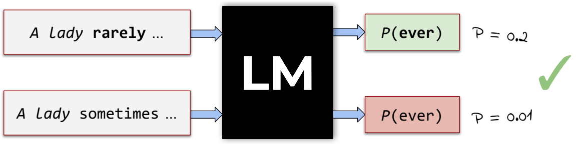

Figure 2: The NPI judgement task that is used for evaluating the LMs. A correct prediction assigns a higher probability to an NPI in a context that licenses it, based on the corpus of Warstadt et al. (2019).

3.3 Identification of NPIs in training corpus

The Warstadt et al. (2019) corpus provides us with a task to evaluate nine different context types that license NPIs. To manipulate the training corpus for our experiments we also need to identify sentences in the training corpus of the model in which these contexts actually licence NPIs. To do so, we need to locate these contexts, as well as establish that they in fact licence an NPI in a particular sentence.

We consider the nine Warstadt et al. context types, and the corresponding list of 30 expressions that are part of these contexts (e.g. the list of adverbs licensing NPIs). As for the NPIs, we consider an extensive list of 160 distinct NPIs[4], based on the collection provided by Hoeksema (2012). We then identify sentences in which an element of our NPI list is preceded by an element from our context list, ensuring that there is a dependency relation between them using the dependency parser of spaCy (Honnibal and Johnson, 2015). When there are multiple potential licensors in a sentence, we use the hierarchical distance between the licensor and the NPI in the parse tree as a heuristic to find the correct licensor. By testing this procedure on a manually labeled set of 200 randomly selected sentences with multiple licensors, we estimate that it identifies the correct among multiple licensors in around 97% of cases. In Table 1, we report examples and frequencies of the different licensing contexts in the training corpus based on this filtering scheme.

---

[2] Hyperparameters: batch size = 64, BPTT length = 35, dropout = 0.1, adaptive SGD learning rate = 20, layers = 2, hidden and embedding size = 650, epochs = 40.

[4] This list can be found in Appendix A.

Context	**Example**	**Frequency** per 100k sentences
Simple Questions	Did he **ever** do a mean thing*?*	10
Adverbs	In the present political culture, there are *hardly* **any** leaders who would avoid limelight and refuse positions of power.	23
Questions	However, various writers attribute it to Putnam, Stark, Prescott or Gridley, while others question *whether* it was said **at all** .	25
Superlative	[...] and caused the *worst* winter flooding **in decades** for river and stream valleys [...].	32
Only	[...] ”Those [students] *only* are supposed to pay **anything** who are abundantly able, or prefer to do so.	85
Conditional	In 1997 Li published a paper attempting to replicate `<unk>`’s results and showed the effect was very small, *if* it existed **at all**.	127
Quantifier	That’s *all* you’ll **ever** need.	179
Determiner negation	In spite of the `<unk>` of the disaster, *no* one was **ever** held accountable.	218
Sentential negation	It is *not* judged under **any** subjective points of view, only the clock.	712

Table 1: The nine types of licensing contexts taken from Warstadt et al. (2019), with an example and the context frequency within the training corpus.

4 Experiments and results

As a first step, we assess whether the LMs can adequately represent all nine categories of the evaluation task. To do so, we train five models on the regular training corpus, and compute their final accuracy on our nine tasks. All models show adequate performance on most contexts (see Table 2), with the exception of the simple question context. Additionally, we observe that the models achieve their accuracy surprisingly fast: already after two epochs, there are no more substantial changes in empirical error (see Figure 3). In the rest of our experiments, we therefore focus only on these first two epochs.

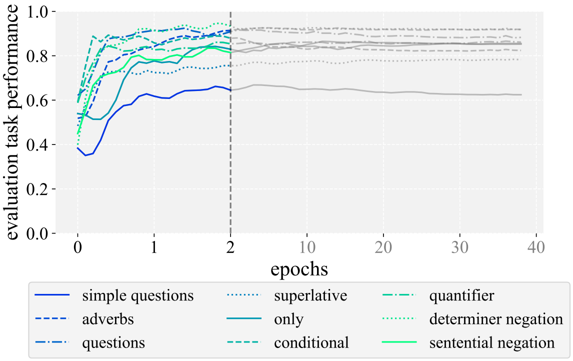

Figure 3: Average evaluation task performance. The performance rises steeply during approximately the first 2 epochs of training and afterwards levels off.

Context	**Accuracy** ± std
Simple Questions	0.62 ± 0.05
Adverbs	0.92 ± 0.01
Questions	0.88 ± 0.03
Superlative	0.78 ± 0.03
Only	0.86 ± 0.04
Conditional	0.82 ± 0.06
Quantifier	0.86 ± 0.04
Determiner negation	0.92 ± 0.05
Sentential negation	0.85 ± 0.03

Table 2: Performance of the LMs on the evaluation task after 40 epochs of training, averaged over 5 runs.

4.1 Frequency vs data efficiency

While some licensing contexts are rather common (e.g. negation), others appear scarcely as a licensor (e.g. adverbs). Therefore, throughout the learning process, the LMs encounter many instances of the more frequent contexts before they see an example of an infrequent context. If LMs were able to leverage information across contexts, less frequent contexts should thus have more prior established NPI-understanding that they can bootstrap from. Consequently, the LMs should require fewer training examples to learn less frequent contexts than they need to learn more frequent contexts. In other words, the LM should be more *data efficient* for these infrequent contexts.

In our first experiment, we use this hypothesised relationship between frequency and data efficiency to assess whether LMs can exploit the similarities between different licensing contexts. To be able to compare across different contexts, we quantify the data efficiency of an LM for a particular context as the number of examples the LM needs to observe until it reaches 95% of its final accuracy for that context.[5] To make this measure more robust, we first apply a Savitzky–Golay noise-filter to the learning curve (degree of polynomial = 1, window size = 25; Savitzky and Golay 1964).

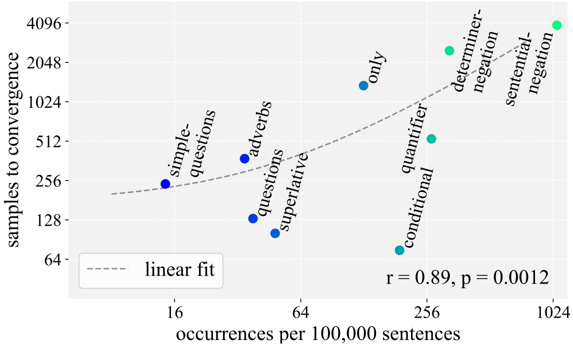

Figure 4: Data efficiency of nine different licensing contexts plotted against their frequency, averaged over five runs. The data efficiency is quantified as number of training examples the model needs to observe to achieve 95% of the trained-out performance.

We compute the data efficiency of the trained LMs for all nine contexts and compute the correlation between a context's frequency and the model's data efficiency with respect to that context. In Figure 4, we plot the average data efficiency of each context against the frequency of that context, as well as the linear fit that relates these two variables. The experiment demonstrates a strong relationship between the data efficiency and frequency of a respective context: $r = .89$, $p < .05$. Hence, the less frequent a licensing context is, the fewer examples are needed for the model to learn it, from which we conclude that the model is indeed able to transfer knowledge from previously acquired knowledge.

4.2 Transfer from general knowledge

While the presented relationship between frequency and data efficiency demonstrates that LMs can leverage previously learned information to learn less frequent licensing contexts, it does not unequivocally show that it leverages information from *other NPI contexts*. After all, when a less frequent context is encountered, the LM has not only had the opportunity to acquire prior knowledge about NPIs, it has also simply seen more language in general. In other words, the LM may meanwhile also have acquired more *general language knowledge*, which may help it to more quickly learn a less frequent licensing context. In our second experiment, we isolate transfer from general language knowledge and transfer from previously observed NPIs by training LMs on *single-context* corpora.

Single-context corpora *Single-context corpora* contain NPIs licensed only by a single context. LMs trained on these corpora can thus not transfer knowledge acquired from other licensing contexts, as these are not present in the training data. By comparing the data efficiency of contexts between LMs trained on all-context and single-context corpora, we can thus infer how much of the increase of data efficiency for lower-frequent contexts is due to leveraging information from other contexts.

To create our nine single-context corpora, we use the procedure described in § 3.3 to identify all sentences containing NPIs licensed by our nine contexts. For every context, we then create a corpus in which all sentences containing other contexts licensing NPIs are replaced by a neutral sentence of the same length, sampled from the rest of the corpus. During this replacement procedure, the ordering and composition of the corpus remained otherwise intact.

When we compare the learning of single-context with all-context models, we cannot rely on the previously used data-efficiency metric from Experiment 4.1. The data-efficiency measure is bound to how quickly the model reaches its final accuracy and accordingly benefits when its final accuracy decreases. As we expect the final accuracy to be lower in the single context models, comparing only data-efficiencies between models is likely to be uninformative.[6]. In this experiment, as explained below, we instead consider the area between the curves (AbC).

Area between Curves (AbC) *Area between Curves* (AbC) incorporates both data efficiency and accuracy: for every context, we calculate the area between the all-contexts and single-context learning curves until the point in time where they both have reached 95% of their final accuracy. The larger this area is, the more impactful it is to remove

---

[5] The *more* data efficient, the *lower* this number thus is.

[6] Consider, for instance, the extreme case in which an LM does not learn a particular context at all anymore in the single-context condition, as indicated by a chance accuracy of 0.5. Because it is not learning anything, the model would arrive at its maximum accuracy before having seen any examples, resulting in a data efficiency of 0.

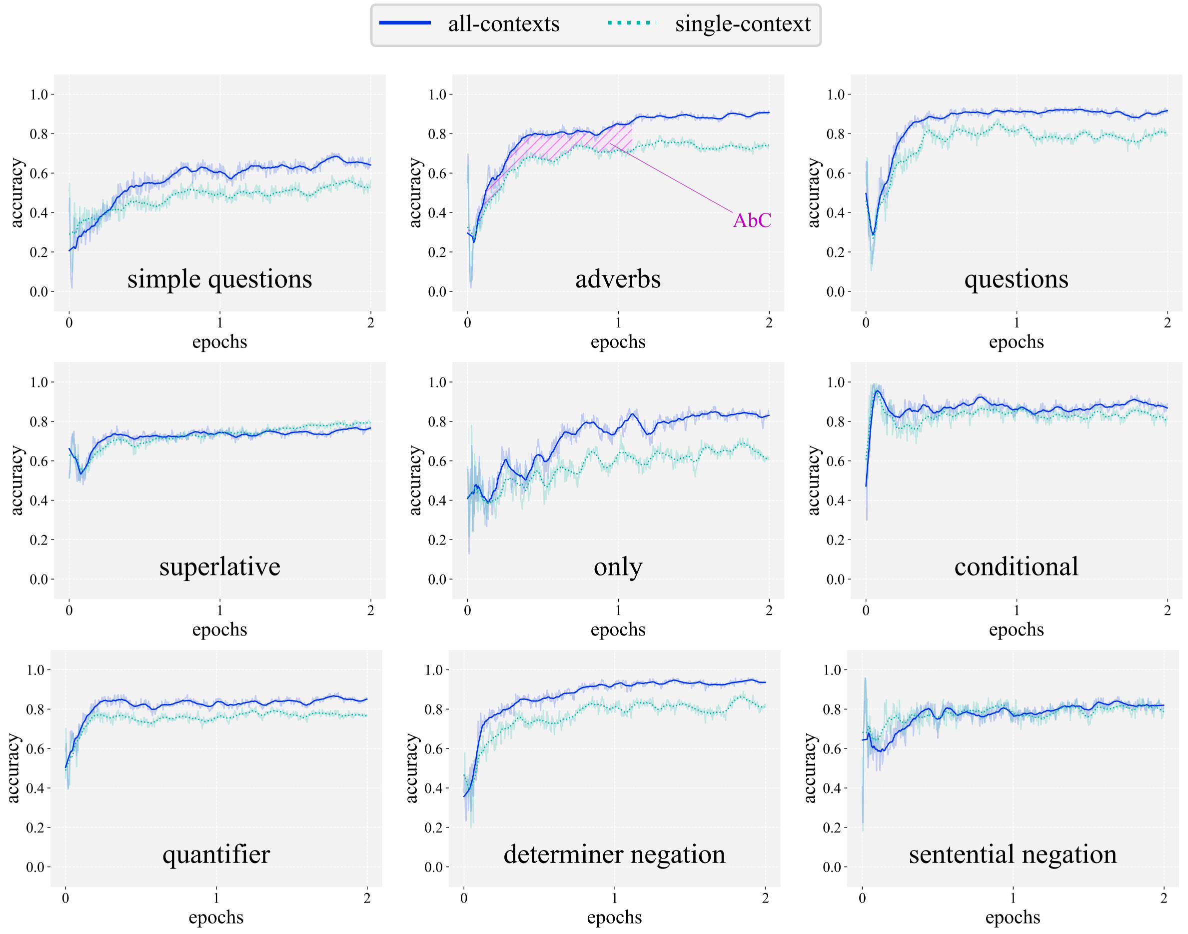

Figure 5: The LMs performance on different licensing contexts for the first two epochs of training. We obtained these curves by evaluating all models at all 730 training-checkpoints on the evaluation task.

all other NPI contexts, and the more the model leveraged from these contexts. The learning curves of all contexts, along with an illustration of the AbC-measure, can be found in Figure 5.

As a first interesting observation, we see that for seven of the nine contexts, the all-contexts model learns faster and achieves higher final performance.[7] Both frequent and infrequent contexts thus benefit from information acquired by other licensing contexts, in terms of both data-efficiency and final accuracy.

This positive transfer can also be seen in Figure 6, where we plot the AbC for all licensing contexts against their frequency. This plot also confirms the relationship found in our previous experiments: the less frequent a context is, the more it benefits from other NPIs ($r = .76$, $p < .05$).

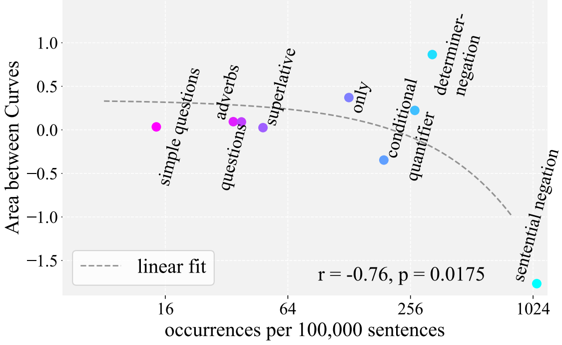

Figure 6: Normalised AbC for all licensing contexts until convergence of both contexts to 95% accuracy. AbC > 0 indicates a better performance of the all-context model and vice versa.

5 Discussion

In this paper, we studied language modelling as a multi-task problem. We show that neural language models can find and exploit similarity between the different language construction rules that we deduced from linguistic theory and that their transfer

---

[7] A one-sided Welch's test confirms that the calculated AbCs are overall different from zero: $t = 2.61$, $p < .05$.

behaviour mirrors the generalisation behaviour in traditionally constructed MTL settings. In this section, we now reflect on how our setup and results contribute to the three different areas that we mentioned in the introduction: MTL, linguistics and interpretability research.

5.1 Multi-task learning research

Studying LMs as multi-task learners, we observe several phenomena known from traditional MTL: when trained in parallel, similar (sub)tasks are learned more efficiently (compare Collobert et al., 2011; Kaiser et al., 2017), and with higher accuracy (Collobert and Weston, 2008; Kaiser et al., 2017), and this effect is stronger for less frequent tasks (Benton et al., 2017; Kaiser et al., 2017).

Our study differs in one crucial aspect from previous research on MTL: it looks at learning dynamics *within* one, larger, natural task instead of between tasks defined by the modeller. As a consequence, the learning process itself is not constrained through a priori decisions concerning task selection, or how tasks should be optimised together. In our scenario, contrary to traditional MTL, we use tasks and their hypothesised similarity only to *analyse* the learning process of the language model, not to inform its training. As such, our natural setting allows to study traditional MTL phenomena, such as data amplification, eavesdropping, and attention focusing, independent of arbitrary decisions regarding task selection and optimisation. This knowledge can then be transferred to scenarios in which more control over the selection of tasks may be required.

5.2 Interpretability research

A second field where we believe studying language models as multi-task learners can contribute, is the field of interpretability. On a more basic level, our paper confirms previous findings in interpretability that LMs are able to adequately model NPIs (Jumelet and Hupkes, 2018; Wilcox et al., 2019; Marvin and Linzen, 2018). We add to this literature by *explicitly* showing that LMs are connecting different types of contexts together through their learning behaviour. Contrary to previous work, we are tapping the learning process itself as a source of information to better understand the inner workings of these models.

Traditional concepts from MTL, such as the earlier mentioned explanations of Caruana (1993) and Ruder (2017) (§ 2.1) are valuable to better understanding what models are learning and how. For instance, when we observe that the solution of models improves when more varied NPI material is presented (our single- versus all-context experiment), MTL can aid to formulate concrete hypotheses about *why* this is the case. This, in turn, can help us improve our understanding of the solutions that are learned by the model. For instance, we find that the single-context models usually level-off on a lower accuracy-level than the all-context model (see Figure 5). This is not merely explainable by the amount of data, as we continue to add training examples in either case. The difference between models instead appears to be due to the variety of the training data. The idea of *attention focusing* (Caruana, 1993, 1997; Ruder, 2017) helps us to understand what is going on: by being trained on more varied NPI material, the model can better sort out which features are relevant and which ones are instead idiosyncrasies correlated with specific contexts. Such hypotheses can then help inform further experiments, that investigate – for example – which features specifically are better learned through attention focusing.

5.3 Linguistics research

Finally, we believe that studying language models as multi-task learners can also contribute to the field of linguistics. In our study, we show that LMs can find and exploit similarities between linguistically defined concepts. Turning things around, this generalisation behaviour of models can also be seen as a confirmation of the linguistic task hierarchy that we assumed from the start. The language modelling objective is unconstrained by linguistic theory and therefore does not necessarily have to find the same solutions as linguistics. Similarity derived from the learning behaviour of language models might therefore be used as a tool to work on more disputed ideas in linguistics and to form new hypotheses in linguistic theory. While the linguistic insights that can be drawn from the current study are relatively limited, they do provide a proof of concept for future work: we show that domain knowledge and learning behaviour of neural models can be connected.

6 Conclusion

In the current study we explored the possibility to use multi-task learning as a framework to study learning behaviour *within* a task. To this end we considered LMs as multi-task learners and investigated how they learn the task-cluster of NPI-licensing. We find that LMs pick up on similarities that we assume from linguistic theory and exploit them to learn similar language constructions with less data and to a higher accuracy. Especially less frequent tasks benefit from this effect.

These results resemble positive transfer in 'traditional' MTL. We lined out the possible benefits that our study may have for MTL research, interpretability and linguistics. From here there are many directions for future work: targeting less comprehensively researched areas in linguistics to add empirical data to otherwise usually theoretical linguistic discussions, investigating the change of internal representations in place of the behavioural measure used here to more precisely describe the learning process, or applying the approach to other high-level tasks in other modalities obeying other knowledge domains are just few of theses possibilities.

Acknowledgments

We thank the anonymous reviewers; the COLT-group at UPF for the discussions and their useful feedback; the participants of the EviL-seminars, and especially Emmanuel Dupoux, for inspiration; and Laura Castro Moreno for her help with the graphic designs. Further, LW thanks the Department of Translation and Language Sciences at the University Pompeu Fabra for funding.

Abstract

Conversational systems enable numerous valuable applications, and question-answering is an important component underlying many of these. However, conversational question-answering remains challenging due to the lack of realistic, domain-specific training data. Inspired by this bottleneck, we focus on conversational question generation as a means to generate synthetic conversations for training and evaluation purposes. We present a number of novel strategies to improve conversational flow and accommodate varying question types and overall fluidity. Specifically, we design *ChainCQG* as a two-stage architecture that learns question-answer representations across multiple dialogue turns using a flow propagation training strategy. *ChainCQG* significantly outperforms both answer-aware and answer-unaware SOTA baselines (e.g., up to 48% BLEU-1 improvement). Additionally, our model is able to generate different types of questions, with improved fluidity and coreference alignment.

1 Introduction

Conversational systems are important in many real-world applications, including personal assistants, educational tutors (Winkler et al., 2020), customer service (El Asri et al., 2017; Budzianowski et al., 2018), and increasingly, entertainment. A key component of these systems is the ability to interpret a search query and retrieve information from different sources as naturally and efficiently as possible. In analogous human interactions, such a search generally occurs through conversation. In this context, a conversation consists of a sequence of dialogue turns during which the search objective becomes clearer over time. The applications mentioned above could benefit greatly from this type of multi-turn interaction, enabling conversational agents to accurately predict intent, request additional information, and better understand ambiguous followup questions and comments. In an applied setting, meaningful and natural conversations are important features of virtual entities as a means to establish trust and improve usability.

Here, we are motivated by the challenging task of conversational question answering (CQA). Current open-source datasets such as CoQA (Reddy et al., 2019) and QuAC (Choi et al., 2018) provide strong baselines for this task. However, these datasets have limited applicability in practical settings, because 1) they are created from domain-agnostic source material, and 2) they do not necessarily consider the full diversity of question types and vernacular that may be encountered in natural dialogue. Creating realistic, domain-specific datasets to train CQA models is notoriously costly and time-consuming. As such, we focus on the related task of question generation as a means to generate synthetic conversational questions and subsequently, create new datasets or augment existing ones. This will ultimately enable training CQA models in closed-loop, simulation environments, as well as allow machines to initiate dialogue and engage in information-seeking behavior.

While QA models have been studied previously (Zhu et al., 2018; Huang et al., 2019; Yeh and Chen, 2019; Chen et al., 2020; Ju et al., 2019; Ohsugi et al., 2019)), the QG task, which is the focus of this paper, has received less attention. QG models in the answer-unaware setting aim to predict a question given the source passage, while in the answer-aware setting, the target answer and rationale are included as inputs as well. Most QG-related literature has focused on single-turn question generation using question-answer datasets such as SQuAD (Rajpurkar et al., 2016), and other textual sources like Wikipedia articles (Du and Cardie, 2018).

Conversational Question Generation (CQG)

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2061–2070
April 19 - 23, 2021.

proves more challenging than single-turn QG as the questions are often highly ambiguous on their own, forcing the model to learn a deeper understanding of the context surrounding the passage text and dialogue history (Pan et al., 2019). Most CQG studies have generated questions using only the passage and dialogue history as inputs (i.e., answer-unaware) (Pan et al., 2019; Qi et al., 2020; Nakanishi et al., 2019; Wang et al., 2018). Answer-aware CQG models, on the other hand, generate questions based on the target answer, as well as dialogue history and passage. Although answer-aware CQG models seek to improve the generated conversation flow, current answer-aware QG models suffer from issues including inaccurate coreference alignment, dialogue inconsistencies, incorrect grammar and the inability to generate many different types of questions (e.g. yes/no, factoid, explanation).

In this paper, we introduce *ChainCQG*, a Conversational QG model that achieves improved performance by jointly learning the representations of questions and answers sequentially, across multiple dialogue turns. To this end, we outline a two-stage architecture, inspired by the approach discussed in Wu et al. (2019) and Gu et al. (2020), where two language models are used to simulate user and system in a response generation task. Our *ChainCQG* model is trained end-to-end, resulting in high-quality questions, while reducing computational cost by using shared parameters across both models. Using an answer-aware strategy grounds each turn of QG by jointly encoding the passage with the target answer rationale, increasing accuracy of the generated question types and further aligning coreferences between dialogue turns. We evaluate our approach using the inverted CoQA dataset (Reddy et al., 2019), which is a large-scale CQA dataset that we re-purposed for question generation. Our model outperforms existing SOTA CFNet (Gao et al., 2019) and ReDR (Pan et al., 2019) by a large margin on automatic evaluation metrics, and shows improved results on human evaluation metrics as well. More information about the baselines will be discussed in Section 2.

In summary, the main contributions of this paper are threefold [1]:

- The *ChainCQG* two-stage architecture is introduced with answer-aware input encoding, and it is an end-to-end model which is able to fluently generate different types of questions and achieve high consistency with the target answers.
- We demonstrate a flow propagation-based training method to learn question-answer representations across multiple dialogue spans.
- *ChainCQG* sets the new SOTA results on the answer-aware CQG task with robust human evaluation results.

The remainder of the paper is structured as follows: First, we discuss related work and how our approach is distinguished from previous methods (in Section 2). Then, we discuss the *ChainCQG* framework and preprocessing steps (in Section 3). Next, we describe our experiments, datasets and metrics, and evaluation results (in Section 4). Finally, we discuss conclusions, future work and the ethical issues (in Sections 5 and 6).

2 Related Work

In this section, we first explore previous approaches to question generation and then discuss outstanding research challenges in conversational question generation.

2.1 Single-turn Question Generation

Single-turn question generation has been the focus of extensive research. Two of the main categories in QG are answer-unaware and answer-aware. The former category generates the question without knowledge of the answer and solely based on the passage; whereas, the latter takes both passage and answer as inputs. Traditional approaches for answer-unaware QG include two main steps: content selection and question generation (Du and Cardie, 2017; Subramanian et al., 2018). Some of the more recent approaches utilize sequence-to-sequence (seq2seq) models for end-to-end question generation using Transformer-based architectures (Scialom et al., 2019). Various techniques have been used for improving the generated questions, including contextualized word embeddings (Scialom et al., 2019), question type usage and copying mechanism (Wu et al., 2020), and typed decoders (Wang et al., 2018).

To enable answer-aware question generation, the input passage is augmented with information describing the answer. For example, the passage can be concatenated with the answer positions and

---

[1] Code available at `https://github.com/searchableai/ChainCQG.`

lexical features (e.g., part-of-speech (POS) and named entity (NER)) to form the encoder input of a seq2seq model (Zhou et al., 2017). Jointly modelling the unstructured passage and the structured answer-relevant relation has been suggested for improving question generation as well (Li et al., 2019). Additional techniques have been proposed to solve various answer-aware QG challenges, including poor performance on long passages (Zhao et al., 2018) and the bias of repeating the terms in the target answer within the generated question (Kim et al., 2019).

2.2 Conversational Question Generation

Compared to single-turn QG, conversational (i.e., multi-turn) QG is less frequently explored in the literature. Further, it is more difficult as it requires a deeper understanding of the context and the dialogue history. Previous work mostly focused on answer-unaware CQG (Pan et al., 2019; Qi et al., 2020; Nakanishi et al., 2019; Wang et al., 2018). Specifically, Pan et al. (2019) proposed an encoder-decoder framework, ReDR, for answer-agnostic CQG, which is fine-tuned using feedback from an independent question-answer model. However, in this setting, maintaining conversational flow and consistency between dialogue turns is a primary challenge.

In this paper, we focus on answer-aware question generation. By grounding the generated question with the target answer rationale in each turn, this approach seeks to improve conversational flow and question-answer consistency. Within answer-aware CQG, (Gao et al., 2019) introduced the current SOTA, CFNet, which combined an auxiliary coreference alignment module with a copy mechanism and dialogue flow embedding. As will be described (in Section 4), we compare our model to answer-aware, CFNet (Gao et al., 2019), and answer-unaware, ReDR (Pan et al., 2019), SOTA baselines. As a practical note, in real-world applications, answer-aware QG systems may be augmented with an Answer Generation (AG) model to form an answer-unaware model that predicts the next conversational question-answer pair jointly. Discussing this AG model is out of the scope of this paper and will be the focus of future work.

3 The *ChainCQG* Framework

ChainCQG learns the question-answer representations jointly using two modules: Answer Encoding (AE) and Question Generation (QG). Encoding the answer based on the passage and dialogue history improves the answer understanding within the QG module, which in turn improves the generated questions. In the rest of this section, we provide a description of the input pre-processing steps, the general CQG problem formulation, and the AE and QG modules.

3.1 Task Definition

The conversational QG task in this paper aims to predict the next question given the passage (P), target answer (A_n) and history of the dialogue preceding the n$^{\text{th}}$ turn, (H_n). We also consider the answer rationale in each turn, and annotate the passage with the target answer rationale span, which we denote as P_{HL_n}. Mathematically, given the annotated passage (P_{HL_n}), target answer (A_n), and dialogue history ($H_n = ((Q_1, A_1), (Q_2, A_2), ..., (Q_{n-1}, A_{n-1}))$), the QG task predicts the next question Q_n. This task can be defined explicitly as generating a question, $\hat{Q}$, where:

$$\hat{Q} = \underset{Q_n}{argmax} Prob(Q_n | P_{HL_n}, A_n, H_n). \quad (1)$$

3.2 Input Preprocessing

In this Section, we briefly describe the processing steps necessary to prepare the input data. Specifically, we take the following approach:

1. We first create n sub-dialogues based on the full dialogue, with the i-th sub-dialogue starting from the first turn and finishing with the i-th turn, i.e., $SD_1 = \{\{Q_1, A_1\}\}$, $SD_2 = \{\{Q_1, A_1\}, \{Q_2, A_2\}\}$, ..., $SD_n = \{\{Q_1, A_1\}, \{Q_2, A_2\}, ..., \{Q_n, A_n\}\}$.

2. For the i-th sub-dialogue, we use a highlight token, [HL], to denote the answer rationale in the passage corresponding to the answer in the i-th turn, which serves as additional context for the target answer.

3. For each sub-dialogue, i, the passage (with the highlighted token corresponding to the i-th turn) is concatenated with the first answer (i.e., A_1) by a SEP token. We denote the concatenation as A^*.

4. We then reverse the order of the answers and questions in the sub-dialogues (e.g., {A1, Q1} instead of {Q1, A1}). The reason behind this

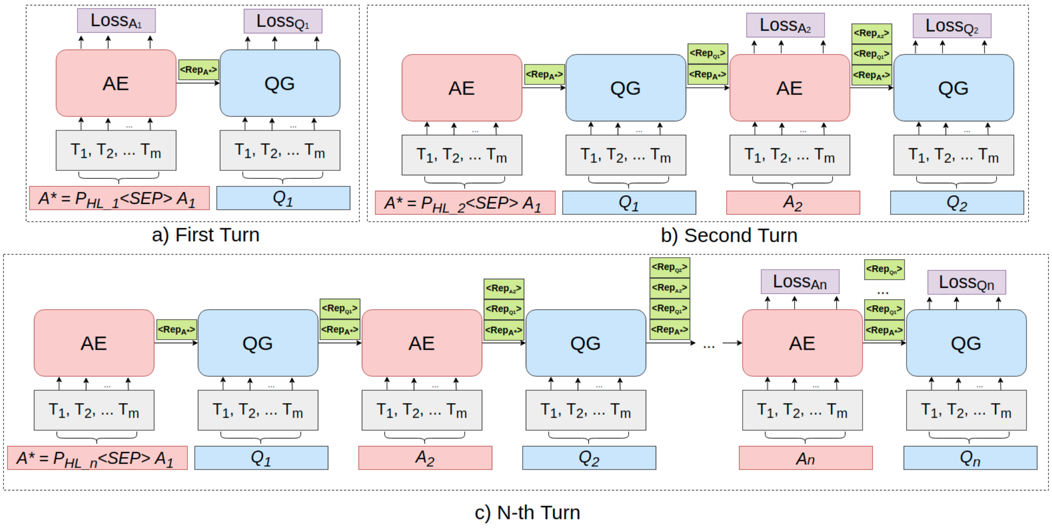

Figure 1: Main structure of *ChainCQG*. Each QA turn in the dialogue span is trained with a separate conversational flow that contains all previous dialogue turns. Answer Encoder and Question Generator modules iteratively generate and share answer and question representations across multiple dialogue turns.

step is to align the input sequence with the natural order of the QG task, where the questions come after the answers. We examine the effects of this ordering scheme in later ablation studies.

3.3 Answer Encoding and Question Generation Modules

In this paper, we use GPT-2 (Radford et al., 2019) to represent both the AE and QG modules described above. Specifically, the AE model is used to learn the representation of the passage and answer in each turn, and the QG model is used to learn the representation of the dialogue history and generate the next question in the conversation. The AE and QG models communicate via the models' hidden states, which are the K and V values when using GPT. K and V values together form a contexual representation for the entire conversation history.

3.4 Flow Propagation-Based Training

To improve the conversational flow of the CQG, we introduce a sequential training process. Figure 1 shows the main structure. To make it more concrete, let us consider a dialogue of n turns ($\{\{Q_1, A_1\}, \{Q_2, A_2\}, ..., \{Q_n, A_n\}\ \}$). The forward propagation process iterates through all previous turns and finally estimates the loss values for A_n and Q_n. In this process, we pass the GPT-based (K, V) representation forward to the next module, which accumulates the representations of each previous turn, with the original highlighted passage as reference. For each sub-dialogue, we only update the loss from the answer and question in the last turn since the highlighted span specifies the information for the last turn. For a sub-dialog of n turns, the loss is calculated as

$$Loss = Loss_{A_n} + Loss_{Q_n} \tag{2}$$

where

$$Loss_{A_n} = CE(A_n, P_{A_n}) \tag{3}$$

and

$$Loss_{Q_n} = CE(Q_n, P_{Q_n}) \tag{4}$$

CE refers to the cross-entropy loss from a target sentence. The parameters of the model are updated by backpropagating the aggregated loss values. By considering the encoding of the previous turns for estimating the loss and increasingly considering various sub-dialogues, the flow propagation-based training improves the conversational flow of the CQG.

4 Experiments

4.1 Dataset

We conduct experiments on the CoQA dataset (Reddy et al., 2019), which is a large-scale conversational question answering dataset composed of 8k conversations with 127k question-answer pairs collected via Amazon Mechanical Turk. Each dialogue turn also contains the supporting rationale for each answer. A number of different question types are present, as documented in the original paper, including Yes/No, explanation (i.e. How?, Why?), and factoid (i.e. What? When? Where? How much?). Yes/No and explanation questions, alongside the overall conversational language, make this an exceedingly challenging dataset for CQG. Since the private test set is not available, we conduct experiments on the training set and the dev set. We randomly sample 10% from the original training set to form the test set, and keep the original dev set unchanged. We conduct our experiments with a training set with 97783 examples, dev set with 7983 examples and test set with 10846 examples. We report the performance on the test set.

4.2 Implementation Details

We use both $\text{GPT}_{\text{small}}$ and $\text{GPT}_{\text{medium}}$ in all experiments. For baselines, we consider ReDR, the SOTA method in answer-unaware CQG, and CFNet, the SOTA method in answer-aware CQG. We also implemented two SOTA pre-training generation models, T5 and BART. They utilize all our preprocessing methods and training skills except the AE/QG modules. We used T5_{large} (770M) and $\text{BART}_{\text{large}}$ (400M), which are comparable with *ChainCQG*-M in terms of parameter size.

We initialize *ChainCQG* with the open sourced GPT-2 parameters (Radford et al., 2019). We apply AdamW optimizer (Loshchilov and Hutter, 2019), and the warmup ratio is set to 0.1. The learning rate is tuned between 2e-5 and 5e-5. The dropout ratio is set to be 0.1. We decode questions by nucleus sampling (Holtzman et al., 2020) with top-p as 0.2, top-k as 400, and temperature as 0.7.

4.3 Evaluation Metric

Our main objectives when evaluating our model are quality of the generated questions and performance on our task goal (e.g., asking conversational questions that are consistent with the target answers). To this end, we first examine a set of automated metrics. Then, to ensure robustness, we evaluate and discuss a set of human-based metrics.

4.3.1 Automated Metrics

To evaluate our question generation approach, we aim to show that it is 1) grammatically and semantically correct and 2) able to achieve the task objectives. To achieve the first goal, we compute automatic metrics with respect to the ground truth questions. We report multiple commonly used metrics, including BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Banerjee and Lavie, 2005), and perplexity (Clarkson and Robinson, 1999). BertScore (Zhang* et al., 2020) and MoverScore (Zhao et al., 2019) are recently proposed metrics that utilize a large pre-trained model to evaluate the generation quality at the semantic level. We use both of these to evaluate the semantic similarity between the generated question and the reference question. Since two questions could express similar meaning with low lexical overlap, these two semantic-level metric could also show important information about the question quality.

4.3.2 Human Evaluation Metrics and Procedure

In this section, we discuss the metrics used for human evaluation. Human evaluation provides additional support for the approach and the robustness of automatic evaluation. Specifically, we use answerability and fluency to measure the quality of the generated questions in relation to the context. We have used Mechanical Turk for this evaluation.

In the context of answer-aware question generation, **Answer Consistency** describes whether the generated questions result in the correct answers (Celikyilmaz et al., 2020). To measure this metric, we provide the passage and the answer, and ask the evaluators whether the generated question is consistent with the answer (i.e., 1 for consistent and 0 for inconsistent). **Fluency** measures the quality of the generated questions and accounts for criteria such as grammar, spelling, choice of words, and style (Du et al., 2017). To measure this metric, we provide the generated question and ask the human evaluator whether the language in the generated question is fluent. We consider three categories of errors: grammar/spelling mistakes, missing entity names, and mismatched pronouns. Based on these categories, we assign 2 for cases with no mistake in any of the categories, 1 for cases with maximum of one mistake in any of the mentioned categories, and 0 for cases with one or more mistakes in each one of the categories. We scale the fluency score to (0,1) by maximum evaluation scores.

4.4 Main Results

The *ChainCQG* model architecture is evaluated alongside two SOTA baselines (ReDR, CFNet) on a number of automatic metrics, including BLEU (1-4), METEOR, ROUGE-L, MoverScore, and BERTScore. More information about these metrics and baselines was presented in Section 4.3.

Model	B1	B2	B3	B4	M	RL	BS	MS
ReDR	27.58	7.81	2.83	1.35	12.15	34.05	87.14	7.62
CFNet	38.24	22.60	16.11	12.23	25.75	43.25	91.25	25.92
BART-large	49.41	30.57	19.40	12.34	35.78	46.88	92.55	31.89
T5-large	50.83	32.64	20.81	13.84	37.08	48.67	92.86	33.91
ChainCQG-M	**53.15**	**35.31**	**23.31**	**15.78**	**40.15**	**50.98**	**93.14**	**36.40**
ChainCQG-S	49.26	31.06	20.24	12.11	33.26	46.23	92.53	32.82

Table 1: Automated Metric Evaluation Results.

These scores seek to evaluate the lexical overlap, and to some degree, the semantic similarity, between generated and ground truth questions within each dialogue turn. We also train two QG models based on pretrained Transformer seq2seq architectures (BART-large (Lewis et al., 2020), T5-large (Raffel et al., 2020)) using all elements of the *ChainCQG* methodology except the question-answer representation sharing mechanism used in *ChainCQG* model. Instead, the target answer is the direct input to the model, concatenated with the passage and dialogue history.

4.4.1 Automated Metrics Results

Results of all models and baselines are shown in Table 1. In the top row of this Table, P is the perplexity, B1-4 are BLEU 1 through BLEU 4, M is METEOR, RL is ROUGE-L, BS is the BERTScore, and MS is MoverScore. In the first column, ChainCQG-M and ChainCQG-S refer to two version of our approach using medium and small GPT-2. Major observations are listed below:

The top performing *ChainCQG* model, composed of two GPT-2 Medium modules, improves upon all baselines by a considerable margin and across all the considered metrics. In addition, it also outperforms the T5-large, which has more parameters, by a large margin. This suggests that the *ChainCQG* learns a better representation using the AE-QG structure, with less parameters than the T5. We improve upon the current answer-aware CQG SOTA, CFNet, on each metric as well. Note that with our methods, T5-large and BART-large also outperforms the SOTA methods. T5-large is the next best performing model, trailing *ChainCQG* by at least two points on all metrics except BERTScore, which shows a narrower margin of improvement.

4.4.2 Human Evaluation Results

It is well-known that automatic evaluation metrics do not always correlate with human judgement in conversational generation tasks (Celikyilmaz et al., 2020). Especially in the context of CQG, there is a many-to-one relationship between questions and their target answers and dialogue contexts, and token-based metrics are inherently unable to measure the similarity between such sequences with low degrees of lexical overlap. As a recourse, we also assess our model performance on a number of human evaluation metrics described in a previous section: Answer Consistency and Fluidity. These metrics cover an important cross-section of human judgement, which is not represented in the automatic metrics. Specifically, we seek to quantify the naturalness and consistency of *ChainCQG* results within each dialogue span. Table 2 shows the performance of our models and baselines on these metrics.

Model	Consistency	Fluency
CFNet	0.710	0.439
BART	0.792	0.482
T5	0.757	0.462
ChainCQG-M	**0.817**	**0.548**

Table 2: Human Evaluation Results.

4.5 Results Discussion

Overall, both standalone QG models using BART and T5, as well as *ChainCQG* outperformed the SOTA baseline, CFNet, on both metrics, while the *ChainCQG* model achieved the best performance of all models on both metrics. The Answer Consistency roughly indicates that the question types were better aligned with the target answer and dialogue history, than the baseline, while the Fluency metric points to improvements in factors like grammar, coreference alignment, and dialogue flow. Together with the Automatic Metrics, these results support our finding that the *ChainCQG* model is able to learn to produce conversational dialogue that is well aligned with the CoQA dataset, both lexically and semantically, and more robust in general.

The improvement over single CQG seq2seq models like T5 demonstrates the success of learning joint question-answer representations and using the encoding of the latter to inform the QG module. We present a more complete analysis of error and ablation studies in the following sections. The answer-aware QG strategy is also validated here, as shown by the significant improvement of every answer-aware model over the answer-unaware (ReDR) baseline. Finally, the comparison of *ChainCQG* to the current answer-aware QG SOTA, CFNet, demonstrates the importance of the question-answer representation and encoding scheme in our model. While CFNet incorporates tactical model components to improve the quality of CQG along specific dimensions, such as coreference and dialogue flow, our model is able to flexibly learn the progression of questions without the need for architectural components that target specific dialogue features. Another important point is that CFNet excluded all Yes/No questions from their analysis, as they proved difficult to reliably generate. Our model not only achieves SOTA performance, but is also able to natively generate every question type present in the dataset. Moreover, we notice that our model shows improved coreference alignment ability when generating questions with complex and entangled dialog history.

4.6 Ablation Study

Our ablation study aims to understand the effectiveness of various design choices in the *ChainCQG* approach outlined (in Section 3.3). In all ablation experiments, the reference model is the *ChainCQG* model, combining the AE and QG modules. Results of this analysis are shown in Table 3. We have applied the following ablations:

4.6.1 Removing the dialogue history

Here, we evaluate the effect of the flow propagation training scheme. Table 3 shows that removing the dialogue history, and consequently, any notion of dialogue flow, reduces performance across all the metrics (e.g., approximately 14% for both small and medium versions). These results match the intuition that dialogue history provides essential context to correctly handle coreferences and natural transitions.

4.6.2 Removing the answer rationale highlight tokens

To evaluate the effect of grounding the generated questions in the relevant passage text, we remove the answer rationale highlight tokens from the input passage. The results in Table 3 show that this ablation decreases performance in all the metrics. For example, removing the highlight reduces BLEU-1 for the medium GPT from 53.15 to 47.07 (approximately 11% reduction). We conclude that the highlighted tokens ground the model in the relevant passage information, providing essential context while focusing the scope of the question.

4.6.3 Changing the order of the questions and answers

As discussed in Section 3.2, we have used the AQ order instead of QA in our input encoding. Here, we evaluate the effect of such ordering. As Table 3 shows, reversing the order of the question and answers results in a performance reduction of approximately 5% in the BLEU-1 score for the medium GPT model. This shows that the AQ order is a more natural structure for dialogue flow propagation, since answers precede the generated question in each turn.

4.6.4 Removing the AE module

As discussed in Sections 1 and 3.3, by including the AE module, we aim to address the challenge of expressing the representations of questions and answers over multiple dialogue turns. Here, we remove the AE module to validate the effect of this modelling choice. The results in Table 3 show that removing the AE module reduces the performance of the model by 3% and 8% in the BLEU-1 score for the medium and small GPT models, respectively. This indicates that propagating the question-answer representations across dialogue turns produces rich temporal representations that improve the fidelity of dialogue flow.

4.7 Error Analysis

In order to better understand the performance differentiation between our model and baselines considered here, we inspected some samples of generated questions with poor quality. While the SOTA baseline, CFNet, neglected all Yes/No questions completely, our model is overall, very successful at generating this type, alongside others such as factoid and explanation. However, Yes/No questions

Model	P	B1	B2	B3	B4	M	RL	BS	MS
ChainCQG-M	7.04	53.15	35.31	23.31	15.78	40.15	50.98	93.14	36.40
ChainCQG-S	9.55	49.26	31.06	20.24	12.11	33.26	46.23	92.53	32.82
M w/o history	9.13	45.53	28.35	18.31	11.27	30.35	40.45	92.54	27.59
S w/o history	11.1	42.54	25.63	14.91	8.01	27.73	39.23	91.03	24.30
M w/o highlight	7.83	47.07	30.63	20.54	12.91	32.56	43.63	92.36	31.50
S w/o highlight	11.09	43.63	25.74	17.14	10.54	27.73	40.43	91.23	24.82
M w/o AQ order	7.43	50.23	33.65	21.43	14.08	37.35	48.88	92.94	34.73

Table 3: Ablation Study Results.

can still be problematic when the answer context includes many potential targets, each of which could be satisfied by a consistent Yes/No question. We also find that in minority cases, *ChainCQG* cannot handle questions requiring complex logic or reasoning to arrive at the target answer. We hypothesize that a more powerful pre-training model could alleviate this issue. Also, the *ChainCQG* model sometimes includes additional details related to the answer, not contained in the gold question, which results in slightly more verbose, though consistent, questions.

5 Discussion and Ethical Issues

The results presented here demonstrate the efficacy of modern Transformer-based architectures, and specifically *ChainCQG*, in producing conversational questions on a challenging dataset. While answer-aware QG is our focus here, we plan to expand this in future work to include answer-unaware and open-ended QG, multi-task NLG involving QA, and domain-specific dialogue simulation. The flexibility of the *ChainCQG* architecture lends itself well to each of these problems, as representations from different inputs and tasks can be shared easily between modules.

As for the practical implications of our QG work, a number of applications mentioned in previous sections could immediately take advantage of QG features, either for training QA models or generating user-facing questions. In the former setting, generation models, such as *ChainCQG*, risk polluting the training dataset with examples that are noisy or inconsistent with the target answers, which can cause undesirable effects at inference time. In the latter setting, generation models may suffer from bias based on the questions available for training, which may lead to misrepresentation of application domains and individual users. Additional work is required to understand the extent of these issues in real-world applications, and identify corrective measures to ensure model robustness and diversified training distributions.

6 Conclusion

In this paper, we introduce *ChainCQG*, an answer-aware Conversational Question Generation model that outperforms all baselines on both automatic and human evaluation metrics on the inverted CoQA dataset (e.g., BLEU-1 improvement of 48% and 28% with GPT medium compared to ReDR and CFNet, respectively). We have designed a two-stage GPT-2-based architecture that jointly learns passage and dialogue history representations via a flow propagation training method. *ChainCQG* produces high-quality questions in multi-turn dialogue, addressing previous SOTA issues such as question type fidelity, question-answer inconsistency and coreference misalignment. Finally, we have performed and presented extensive ablation studies for various aspects of our approach.

Abstract

When training a model on referential dialogue guessing games, the best model is usually chosen based on its task success. We show that in the popular end-to-end approach, this choice prevents the model from learning to generate linguistically richer dialogues, since the acquisition of language proficiency takes longer than learning the guessing task. By comparing models playing different games (GuessWhat, GuessWhich, and Mutual Friends), we show that this discrepancy is model- and task-agnostic. We investigate whether and when better language quality could lead to higher task success. We show that in GuessWhat, models could increase their accuracy if they learn to ground, encode, and decode also words that do not occur frequently in the training set.

1 Introduction

A good dialogue model should generate utterances that are indistinguishable from human dialogues (Liu et al., 2016; Li et al., 2017). This holds for both chit-chat, open-domain, and task-oriented dialogues. While chit-chat dialogue systems are usually evaluated by analysing the quality of their dialogues (Lowe et al., 2017; See et al., 2019), task-oriented dialogue models are evaluated on their task success and it is common practice to choose the best model based only on the task success metric. We explore whether this choice prevents the system from learning better linguistic skills.

Important progress has been made on the development of such conversational agents. The boost is mostly due to the introduction of the encoder-decoder framework (Sutskever et al., 2014) which allows learning directly from raw data to both understand and generate utterances. The framework has been found to be promising both for chit-chat (Vinyals and Le, 2015) and task-oriented dialogues (Lewis et al., 2017), and it has been further extended to develop agents that can communicate through natural language about visual content (Mostafazadeh et al., 2017; Das et al., 2017a; de Vries et al., 2017). Several dialogue tasks have been proposed as *referential guessing games* in which an agent (the Q-bot) asks questions to another agent (the A-bot) and has to guess the referent (e.g., a specific object depicted in the image) they have been speaking about (de Vries et al., 2017; Das et al., 2017b; He et al., 2017; Haber et al., 2019; Ilinykh et al., 2019; Udagawa and Aizawa, 2019). We are interested in understanding the interplay between the learning processes behind these two sub-tasks: generating questions and guessing the referent.

Shekhar et al. (2019) have compared models on GuessWhat and have shown that task success (TS) does not correlate with the quality of machine-generated dialogues. First of all, we check whether this result is task-agnostic by carrying out a comparative analysis of models playing different referential games. We choose a task in which visual grounding happens during question generation (GuessWhat, de Vries et al. 2017); a task in which it happens only in the guessing phase (GuessWhich, Das et al. 2017b), and a task that is only based on language (MutualFriends, He et al. 2017). We introduce a linguistic metric, Linguistic Divergence (LD), that, by assembling various metrics used in the literature (Shekhar et al., 2019; Murahari et al., 2019; van Miltenburg et al., 2019), measures how much the language generated by computational models differs, on the surface level, from the one used by humans. We consider LD to be a proxy of the quality of machine-generated dialogues.

For each task, we compare State-Of-The-Art (SOTA) models against their TS and LD. In the

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2071–2082
April 19 - 23, 2021.

core part of the paper, we study the relationship between the learning process behind TS and LD by comparing model performance across epochs and by downsizing the training set. Finally, we study whether and when a lower LD (i.e., the generated dialogues are more similar to humans) could help reach a higher TS.

Our results confirm that models performing similarly on TS differ quite a lot on their conversational skills, as claimed in Shekhar et al. (2019) for models evaluated on the GuessWhat game. Furthermore, we show that:

- SOTA models are much faster in achieving high performance on the guessing task compared to reaching a high dialogue quality (i.e., low LD). Hence, choosing the best model on task success prevents the model from reaching better conversational skills;
- SOTA models mostly use very frequent words; this limited vocabulary is sufficient for succeeding in a high number of games;
- in GusseWhat, a higher TS could be reached if the model learns to use also less frequent words.

2 Related Work

Task-oriented models can be evaluated based on their task success, but this is not enough to know whether the generated dialogues are human-like. The development of quantitative metrics to evaluate the quality of dialogues generated by conversational agents is a difficult challenge (Liu et al., 2016), and it is under investigation for chit-chat dialogue systems. For instance, Guo et al. (2017) study topic diversity in the conversational flow, which is rather important in chit-chat and open-domain dialogues, but less so for task-oriented ones; Kannan and Vinyals (2016), Li et al. (2017), Bruni and Fernández (2017) propose to use adversarial evaluation, whereas Lowe et al. (2017), See et al. (2019), and Hashimoto et al. (2019) propose automatic systems that build upon human evaluation. All these efforts are still preliminary and are not easily employable for new datasets or new models. Since no standard and unique metric has been proposed to evaluate the quality of task-oriented (grounded) conversational dialogues, we consider a mixture of metrics used independently in various studies, and we provide a comparative analysis across models and tasks based on the same set of linguistic metrics.

Neural Networks have been shown to generate text that sounds unnatural due to the presence of repeated utterances, poor vocabulary, and inconsistency in word usage (Ray et al., 2019). Various improvements have been proposed to mitigate these weaknesses. To prevent the decoder from choosing words based simply on their frequency, Li et al. (2019) replace its maximum likelihood estimation objective, while others change the sampling search strategy (Holtzman et al., 2020; Wu et al., 2019; See et al., 2019); these changes aim to reduce the number of repeated questions, to increase the variety of words and their distribution. Attempts have been made to provide the conversational models with a reasoning module based on Bayesian inference (Abbasnejad et al., 2019) or Rational Speech Act (Shuklar et al., 2019) frameworks that should lead to more informative and coherent questions. Here, we do not propose new models, but rather aim to better understand the strengths and weaknesses of current models.

3 Games and Metrics

Our focus is on task-oriented dialogues. We consider a task that relies on grounding language into vision during question generation, i.e. GuessWhat (de Vries et al., 2017), a task that requires grounding only at the guessing phase, i.e. GuessWhich (Das et al., 2017b), and a task based only on language, i.e. MutualFriends, (He et al., 2017).

Games As illustrated by the snippets reported in Table 1, the three tasks also differ in the flexibility of the dialogues: GuessWhat and GuessWhich are both based on rigid turns in which an agent asks questions and the other answers, whereas MutualFriends has free-form dialogues. Moreover, GuessWhat consists only of Yes/No questions, while in GuessWhich this constraint does not apply. Relevant statistics of the three datasets are summarized in Table 1.

GuessWhat (de Vries et al., 2017) is an asymmetric game.[1] A Questioner (Q-Bot) has to ask Yes/No questions to guess which is the target object among a set of maximum 20 candidates; while asking questions, it sees the image containing the

---

	#dialogues training	 testing	Vocab. size	#candidates	#turns	Examples
GuessWhat	108K	23K	4900	3-20	1-10	***A***: Is it a person? ***B***: No. ***A***: Is it a dog? ***B***: Yes. [***A*** guesses the target object]
GuessWhich	120K	2K	11321	2K	10	***A***: What color is the car? ***B***: Blue. ***A***: Who is driving it? ***B***: A man. [***A*** guesses the target image]
MutualFriends	8K	1K	5325	5-12	2-46	***A***: My friends work at Google. ***B***: None of mine do. [***A*** and ***B*** select a friend]

Table 1: Salient statistics of the human dialogues in the three data sets under consideration in this work. The last column reports samples of dialogues exchanged between two agents (A and B).

candidate objects and it has access to the dialogue history. The Answerer (A-Bot), who knows which is the target, provides the answers. The two bots learn to speak about the image by being trained on human dialogues, which have been collected by letting humans play the game. Humans could stop asking questions at any time (human dialogues contain on average 5.2 question-answer pairs), while models have to ask a fixed number of questions (8 in the setting we have considered).

GuessWhich (Das et al., 2017b) is also an asymmetric game. Unlike the task described above, the Q-Bot has to ask questions without seeing the candidate images, but it has access to captions describing the images. Q-Bot can ask any type of question; the target image has to be selected among 2K candidates at the end of the dialogue. The A-Bot instead sees both the caption and the target image. Human dialogues are from the VisDial dataset[2] and were collected as chit-chat dialogues (Das et al., 2017a). Both humans and models have to ask exactly 10 questions.

MutualFriends (He et al., 2017) is a symmetric game based only on text: two agents, each given a private list of friends described by a set of attributes/labels, try to identify their mutual friend based on the friend's attributes.

Metrics: Since we are interested in the interplay between the downstream task and the quality of the generated dialogues, we consider two types of metrics.

Task Success: We use the task success (TS) metrics used in the literature to evaluate models against these tasks, namely accuracy (ACC) for GuessWhat and MutualFriends, and Mean Percentile Rank (MPR) for GuessWhich. The latter is computed from the mean rank position (MR) of the target image among all the candidates. An MPR of e.g., 96% means that, on average, the target image is closer to the one chosen by the model than the 96% of the candidate images. Hence, in the VisDial test set with 2K candidates, 96% MPR corresponds to an MR of 80, and a difference of $\pm$ 1% MPR corresponds to $\mp$ 20 mean rank. The task success chance levels are: 5% accuracy (GuessWhat), 50% MPR (GuessWhich) and 11.76% accuracy (MutualFriends).

Linguistic metrics: It has been shown that the quality of the dialogues generated by computational agents is not satisfactory. The main weaknesses of these models consist of poor lexical diversity, a high number of repetitions, and the use of a limited vocabulary. To evaluate the quality of the generated dialogues (defined as the closeness to human dialogues according to surface-level cues), we use several metrics that have been proposed in the literature. As in He et al. (2017), we compute *unigram entropy (H)*, which measures the entropy of unique unigrams in the generated dialogues normalized by the total number of tokens used by the model. From Murahari et al. (2019), we take the *Mutual Overlap (MO)* metric, which evaluates the question diversity within a dialogue by computing the average of the BLEU-4 score obtained by comparing each question with the other questions within the same dialogue.[3]

---

[2] VisDial is available from `https://visualdialog.org/data`.

[3] A high number of novel questions and low mutual overlap cannot be taken per se as a sign of high quality of the dialogues: a model could ask a question never seen in training or with very little overlap with the other questions but completely out of scope. To rule out this possibility, we compute the cosine similarity of each question marked as novel and with a low mutual overlap with the dialogue they occur in, and compare it with the similarity between the latter and

Moreover, following Shekhar et al. (2019), we report the percentage of games with *one question repeated verbatim (GRQ)* within a dialogue. Finally, we compare models with respect to their ability on lexical acquisition by calculating the *Global Recall (GR)* introduced by van Miltenburg et al. (2019) to evaluate image captioning: it is defined as the overall percentage of learnable words (from the training set) that the models recall (use) during generation. Furthermore, taking inspiration from the Local Recall introduced in the same work, we propose a similar metric tailored to dialogues, i.e., *Local Recall-d (LRd)*, which measures how many content words the generated dialogue shares with the corresponding human dialogue for the same game. Given a human dialogue D_h about an image and a generated dialogue D_g about the same image, we compute LRd as the normalized lexical overlap (considering only content words) between D_h and D_g.

We sum up all these linguistic metrics used in the literature so far into one which we take as a proxy of the quality of dialogues: it shows the *linguistic divergence (LD)* of the dialogues generated by a model from human dialogues. To this end, we normalize each metric so that all values lie between 0 and 1: 0 stands for human performance for the "lower is better" metrics and 1 stands for human performance for "higher is better" metrics. We compute LD by averaging all the scaled values V for each model; we take $1 - V$ for "higher is better" metrics to obtain a "divergence" value. All the metrics are equally weighted. By definition, LD is 0 for human dialogues. LD captures three main surface-level aspects: overall vocabulary usage (H, GR), diversity of questions/phrases within a dialogue (MO, GRQ), and similarity of content word usage with respect to human dialogues (LRd). There could be some correlation between metrics capturing similar aspects of language quality, but this does not affect the validity of the proposed LD metric.

4 Models

For both visual dialogue games, GuessWhat and GuessWhich, supervised learning has been compared with other learning paradigms. After the introduction of the supervised baseline model (de Vries et al., 2017), several models have been proposed for GuessWhat. They exploit either reinforcement learning (Sang-Woo et al., 2019; Zhang et al., 2018b,a; Zhao and Tresp, 2018; Gan et al., 2019; Pang and Wang, 2020) or cooperative learning (Shekhar et al., 2019; Pang and Wang, 2020); in both cases, the model is first trained with the supervised learning regime and then the new paradigm is applied. This two-step process has been shown to reach higher task success than the supervised approach. For GuessWhich, after the supervised model introduced in Das et al. (2017a), new models based on reinforcement learning have been proposed, too (Das et al., 2017b; Murahari et al., 2019; Zhou et al., 2019), but their task success is comparable if not lower than the one achieved by using only supervised learning (see Testoni et al. 2019). Below, we briefly describe the models we have compared in our analysis. For each task, we have chosen generative models trained with different learning paradigms and for which the code is available; for each paradigm, we have tried to choose the best performing ones or those that obtain a task success near to state-of-the art and could help better understand the interplay between task success and dialogue quality.

GuessWhat We use the A-Bot introduced in de Vries et al. (2017), which is trained in a supervised learning (SL) fashion. For the Q-Bot, we compare models based on different learning paradigms: supervised and cooperative learning (GDSE-SL and GDSE-CL, respectively) proposed in Shekhar et al. (2019) and reinforcement learning (RL) proposed in Strub et al. (2017). In RL, the reinforce paradigm used aims at optimizing the task accuracy of the game. Besides using different learning paradigms, these models differ in their architecture. In particular, while in RL the Question Generator (QGen) and the Guesser are trained independently, in GDSE a common visually-grounded dialogue state encoder is used and the two modules are trained jointly. In both cases, the Guesser receives as input the candidate object's categories and their spatial coordinates, and during training it is updated only at the end of the dialogue.[4]

---

random questions taken from other dialogues. Embeddings are obtained by using Universal Sentence Encoder-USE (Cer et al., 2018). We found that novel and low-MO questions are more similar to their dialogue than the random ones, confirming the effectiveness of these metrics.

[4] The code of the A-Bot and of RL is available at https://github.com/GuessWhatGame/guesswhat. The code of GDSE at: https://github.com/shekharRavi/

GuessWhich We use the A-Bot introduced in Das et al. (2017b). For the Q-bot, we compare Diverse (Murahari et al., 2019) and ReCap (Testoni et al., 2019). Diverse and ReCap have similar architectures: several encoders incrementally process the linguistic inputs to produce the dialogue hidden state. This state is used to condition a decoder that generates a new question at each turn, and a guesser that is trained to produce the visual representation of the target image through a feature regression module. The two models differ in the encoders used and in the training paradigm. While Diverse encodes the caption together with the dialogue history through a Hierarchical LSTM, ReCap has two independent LSTMs that produce the linguistic features of the caption and of the dialogue history, merged together to produce the dialogue hidden state. Secondly, in Diverse, an auxiliary objective on the dialogue state embedding (Huber loss) is used to incentivize the bot to ask more diverse questions with respect to the immediate previous turn. In ReCap, the Guesser sees the ground-truth image only at the end of the game while in Diverse the Guesser is updated at each turn. ReCap has been trained only by SL, Diverse both by SL (D-SL) and SL plus RL (D-RL). Further details can be found in the respective papers (Murahari et al., 2019; Testoni et al., 2019).[5]

MutualFriends We evaluate the model proposed in He et al. (2017), DynoNet (Dynamic Knowledge Graph Network), in which entities are structured as a knowledge graph and the utterance generation is driven by an attention mechanism over the node embeddings of such graph. The model is trained via supervised learning and at test time it plays with itself. DynoNet consists of three components: a dynamic knowledge graph (which represents the agent's private KB and shared dialogue history as a graph), and two LSTMs that map the graph embedding over the nodes and generate utterances or guess the entity.[6]

5 Experiments and Results

Shekhar et al. (2019) has shown that in GuessWhat task success (TS) does not correlate with the quality of the dialogues. First of all, we check to what extent this result is task and model agnostic by taking GuessWhat, GuessWhich and MutualFriends as case-studies and compare the behaviour of the models described above.

First, we evaluate the impact of the number of epochs and the size of the training set; then, we study whether and when a lower LD could help to reach a higher TS.

5.1 Task Success and Linguistic Divergence

We evaluate all models described above, in their supervised, cooperative, or reinforcement learning version, aiming to test whether some patterns can be found irrespectively of the model and data explored. Our results confirm what has been shown in Shekhar et al. (2019) for GuessWhat: **TS does not correlate with the quality of the generated dialogues**; models with similar TS generate dialogues that vary greatly with respect to the linguistic metrics. We run a Spearman's analysis and found a very weak correlation between LD and TS (coefficient < 0.15, p-value < 0.05). Our comparison across tasks shows that both in GuessWhich and in GuessWhat the vocabulary used by humans while playing the games in the training and testing set is rather similar (resp., 91% and 84% of words are in common between training and testing sets). Yet in both visual tasks models reach an LRd of around 42%. Specifically, the average mean rank of words they fail to use is 7000 (over 11321) for GuessWhich and 3016 (over 4900) for GuessWhat. **Hence, models mostly use very frequent words.** Details on the metrics for each task and model are reported in Table 2.

5.2 Learning Processes behind TS and LD

We aim to understand the relation between TS and LD. To this end, we compare the two metrics during the training processes across epochs and by downsizing the training set. For each task, we consider the models trained in a SL fashion since those trained with other paradigms build on them. Hence, we focus on ReCap, GDSE-SL, and DynoNet.

Comparison Across Epochs We study for *how long* a model has to be trained to reach its best performance on guessing the target referent and

Table 2: Comparative analysis of different models on several tasks and datasets.TS: task success. GR: global recall. LRd: local recall. MO: mutual overlap. GRQ: games with repeated questions. H: unigram entropy. LD: linguistic divergence. ↑: higher is better. ↓: lower is better.

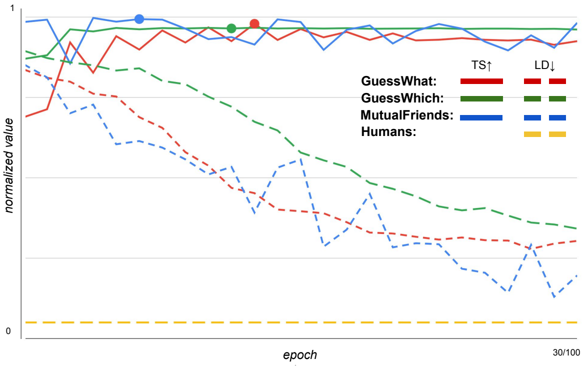

Figure 1: Comparison of Task Success (TS, solid lines) and Linguistic Divergence (LD, dashed lines) for GDSE-SL (GuessWhat, trained for 100 epochs), ReCap (GuessWhich, trained for 100 epochs), DynoNet (MutualFriends, trained for 30 epochs); Humans LD lower-bound metric in yellow. The LD of the generated dialogues keeps decreasing (moving close to human level) even though we no longer notice improvements in TS, whose highest value is reached well before (marked by bullets).

generating human-like dialogues. Figure 1 reports the TS and the LD of three models trained on the three tasks under examination. Each line is normalized w.r.t the highest value for each metric, so that it is possible to see different trends on the same plot. As we can see from the figure, the highest TS (marked by bullets) is reached earlier in GuessWhich and in MutualFriends than in GuessWhat. More interestingly, for all the tasks, the LD of the generated dialogues keeps decreasing (moving close to human level) even though we no longer notice improvements in TS, whose highest value is reached well before. Figure 2 (solid lines) reports the details of the linguistic metrics used to compute LD. We see that for all tasks a high entropy is reached already after a few epochs; this means that though the number of words used is small, models learn to distribute their use well. All the other metrics improve through the epochs quite a lot. For MutualFriends, we do not compute MO and GRQ since the model trained on it, DynoNet, asks questions referring to different attributes and hence, by design, it generates very few repetitions. From the results of this first experiment, it emerges fairly clearly that in all referential games we have considered, **models learn to perform well on the task quite quickly.** On the one hand, this means that **choosing the best model purely on the basis of its TS prevents the model from developing better linguistic skills**, on the other hand, that **the higher quality of the dialogues does not help reach a higher TS.** This result holds in all cases despite the target being an entity in a graph described by linguistic attributes (MutualFriends), an object (GuessWhat) or an image (GuessWhich).

Comparison by Downsizing the Training Set To understand whether the relation between TS and LD is related to the size of the training set, we compare models trained on datasets of decreasing size. We evaluate the models by training them with 50% and 25% of the standard GuessWhat and GuessWhich datasets. For MutualFriends, we have not run the downsizing analysis since the dataset is too small. For readability reasons, in Figure 2 we report only the results obtained with the 25% setting since they represent the observed pattern well enough. The y-axis reports the metrics scaled between 0 and 1. In GuessWhich the TS (yellow lines) does not decrease by downsizing the dataset: when using just 25% of the full dataset (dotted line) it gets very close to the highest MPR obtained by the model trained on the full dataset (solid line) already after the first 5 epochs. Interestingly, the linguistic metrics do not get worse ei-

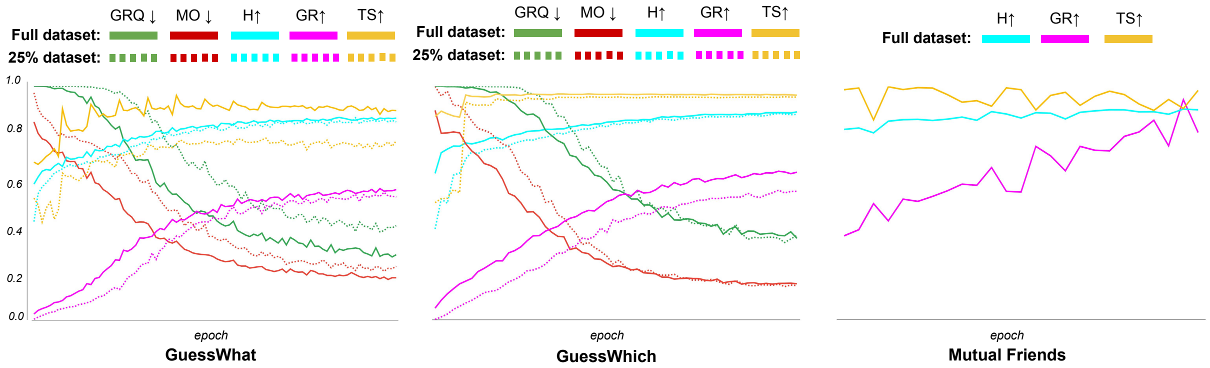

Figure 2: Comparison across epochs and by downsizing the training data using the following metrics: Task Success (TS), Games with Repeated Questions (GRQ), Mutual Overlap (MO), Unigram Entropy (H) and Global Recall (GR); all metrics are scaled between 0 and 1 (y-axis). **Left:** GDSE-SL on GuessWhat. **Middle**: ReCap on GuessWhich. **Right**: DynoNet on MutualFriends. Downsizing the training data has a higher impact, both for TS and some linguistic metrics, in GuessWhat than in GuessWhich. Among the linguistic metrics, entropy is the most stable and GR increases through the epochs in all tasks. For readability, we have not reported Local Recall-d since its pattern is very close to GR. The dataset of MutualFriends is too small to analyse the effect of downsizing it.

ther, with the only exception of GR. However, in GuessWhat the TS decreases when downsizing the training data (again, yellow solid vs. dotted lines) and dialogues quality is affected too (with the exception of entropy and GR). This result shows that **in GuessWhat *how well* the model learns to ground language plays an important role and affects the TS.** In the next experiment, we aim to further understand the difference between the two visual tasks and when LD could impact TS in GuessWhat.

5.3 When Could Language Quality Impact Task Success?

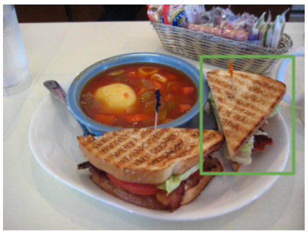
First of all, we check the extent to which the dialogue is used by the Guesser module to pick the correct target. Secondly, we evaluate whether the quality of the dialogues could lead to higher task success. Finally, we pinpoint when a lower LD could contribute to succeed in the task.

The role of the dialogues on TS We run a by-turn evaluation checking whether the information incrementally gained through the dialogue brings increased performance. We evaluate ReCap on GuessWhich and GDSE-SL on GuessWhat. We find that the performance of ReCap is flat across the dialogue turns, confirming results reported in Murahari et al. (2019) for other models. Instead, the performance of GDSE-SL keeps on increasing at each turn from the beginning till the end of the dialogue, though the increase in the first 3 turns is higher than in the later ones (details in Appendix A). **This suggests that in GuessWhich the role of the dialogue is rather limited.** This might be due to the highly informative image caption that GuessWhich models receive together with the dialogue to solve the guessing task (Testoni et al., 2019). Instead, in **GuessWhat dialogues do play a major role in the guessing task**. Hence, we focus on this dataset to understand whether and when the quality of the dialogue could lead to a higher task success.

Impact of the quality of dialogues on TS To check whether the Guesser could profit from dialogues of better quality, we evaluate GDSE-SL using human dialogues. When given human dialogues, the model reaches an accuracy of 60.6%, which is +8.5% higher than the one it achieves with the dialogues generated by its decoder (52.1%). One hypothesis could be that this higher TS is due to the mistakes produced by the A-bot when using instead the generated dialogues, but this is not the case: we have evaluated the model when receiving human questions paired with the A-bot's answers for each question and the accuracy drops of only 2.5%. This experiment suggests that **a lower LD could indeed lead to a higher TS.**

The role of less frequent words As we have observed above, models mostly use very frequent words. Here, we aim to understand to what extent this penalizes GuessWhat models. In this dataset, more than half (55%) of the words in the vocabulary are used less than 15 times in the training set. We refer to this set of words as "*rare*" words: most

Human dialogues		Generated dialogues	
Questioner	**Answerer**	**Questioner**	**Answerer**
1. Is it a man?	No	1. Is it a person?	No
2. Is it food?	Yes	2. Is it food?	Yes
3. Is *pancake*?	No	3. Is it pizza?	Yes
4. Is egg?	Yes	4. Is it the pizza in front?	Yes
		5. . . .	
$\leadsto$ **model suceeds guessing**		$\leadsto$ **model fails guessing**	



Human dialogues		Generated dialogues	
Questioner	**Answerer**	**Questioner**	**Answerer**
1.Is it edible?	Yes	1. Is it food?	Yes
2.Is it a sandwich?	Yes	2. Is it a sandwich?	Yes
3. Does it have an orange *toothpick* in it?	Yes	3. Is it on the right?	Yes
		. . .	
$\leadsto$ **model fails guessing**		$\leadsto$ **model succeeds guessing**	

Figure 3: Examples of GuessWhat games in which humans use "rare" words (rare words in italic) and the corresponding generated dialogues. The failure of the model could be due to the inability to generate (top) or to encode (bottom) rare words.

Figure 4: In GuessWhat, longer human dialogues contain more rare words, more distractors and more distractors of the same category of the target object.

of them are nouns (79%) or verbs (11%) (e.g., "*feline*", "*forest*", "*compute*", "*highlight*").

We check whether there is a relation between rare words and difficult games. Human dialogue length is a good proxy of the difficulty of the games, both for humans and models. Figure 4 illustrates some statistics about human dialogues: games for which humans ask more questions are about images with a higher number of distractors, with a higher number of distractors of the same category of the target, and with a higher number of "rare" words. In 10% of the games in the test set, humans have used at least one rare word. These dialogues are longer than those that do not contain rare words (resp., 7.8 vs. 4.7 turns on average). Interestingly, the accuracy of the model on these games is lower than the overall accuracy: -13.8% (48.7% vs. 62.5%) when evaluating it with human dialogues and -8.3% (45% vs. 53.3%) when using the dialogues generated by the model itself. Moreover, the accuracy reached by the model in the latter setting is lower when comparing games for which humans have used a higher number of rare words. Overall, we found that 65% of the rare words in the human test set show up in games that the model is not able to solve correctly.

Figure 3 shows some examples of games in which humans have used a rare word. It illustrates the human vs. generated dialogue and whether the model succeeds in guessing the target object when receiving the former or the latter. The failure of the model in guessing the target object could be due to its inability to generate or encode rare words. The example on top shows that if the model fails to generate an appropriate word (e.g. the rare word "*pancake*") this can have a domino effect on the next words and the next questions it generates. On the other hand, the model can fail to encode rare words, e.g., "*toothpick*" in Figure 3-bottom. The inability to generate rare words could be mitigated by developing dialogue strategies that produce less natural but still informative dialogues. For instance, in the example at the bottom, the model avoids using "*toothpick*" by asking a spatial question ("*Is it on the right?*") which is rather informative for the Guesser since it has the coordinates of each candidate object. These observations show that current models fail to properly ground and use *rare words* and suggest that, in some contexts, **the use of only frequent words could be behind the failure in reaching the communication goal.**

6 Conclusion

Our work highlights the different complexity of two sub-tasks involved in referential guessing (visual) games: guessing the target and asking questions. We have shown that while learning to win the game can be reached in a rather short time (with a few epochs), learning to generate rich human-like dialogues takes much longer. This holds for all three tasks and models we have scrutinized independently of the size of the vocabulary, the task, and the learning paradigm used. Therefore, choosing the best model only on the base of the task success could prevent the model from generating more human-like dialogues. We have shown that in GuessWhich decreasing the size of the training set does not bring a drop in either TS (task success, higher is better) or in LD (linguistic divergence, lower is better) and, moreover, the dialogues play a minor role on TS. Instead, for GuessWhat, decreasing the size of the training dataset brings a decrease in TS and an increase in LD, and, through dialogues, models accumulate information to succeed in the task. Hence, we have focused our in-depth analysis on GuessWhat. Furthermore, we have investigated whether and when higher language quality could lead to higher task success. We have shown that if models are given human dialogues, they can reach a higher TS. Hence, LD could boost TS. We have shown that this boost could help more in difficult games, i.e. those for which humans ask longer dialogues. These games contain images with more distractors and humans use less frequent words while playing them. Hence, we claim that in GuessWhat models could increase their accuracy if they learn to ground, encode and decode words that do not occur frequently occur in the training set.

In the paper, we propose the LD metric that, despite its limitations (i.e., being based only on surface cues) represents a proxy of the quality of dialogues. We believe LD effectively captures the most common deficiencies of current models and it allows a straightforward comparison between different models. As future work, LD can be used as a training signal to improve the quality of generated dialogues. Moreover, a comparison between human quality judgments and LD may shed some light on the strengths and weaknesses of this metric. Further work is needed to design new metrics that capture more fine-grained phenomena and better evaluate the quality of generated dialogues.

A Appendix A

Figure 5 reports the token frequency curve for human dialogues and generated dialogues on the GuessWhat test set (Zipf's law). Human dialogues are clearly more rich and diverse compared to generated dialogues.

Figure 6 and Figure 7 show the per-turn accuracy of GDSE-SL for GuessWhat and ReCap for GuessWhich, respectively. For GuessWhat, we report the simple task accuracy on the game, while for GuessWhich we use the Mean Percentile Rank; please refer to the main paper for additional details. For GuessWhat, the accuracy keeps increasing while new turns are given as input to the model. For GuessWhich, on the other hand, the Mean Percentile Rank (MPR) is pretty stable after very few turns and it is already high at turn 0, i.e. when only the caption is provided without any dialogue history.

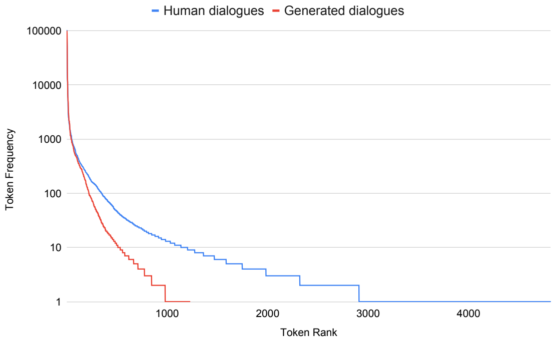

Figure 5: Token frequency plot (Zipf's Law curve) for human vs. generated dialogues

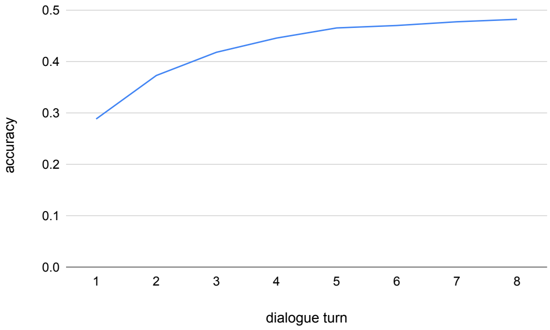

Figure 6: GDSE-SL per-turn accuracy on the GuessWhat game.

Abstract

Abusive language in online discourse negatively affects a large number of social media users. Many computational methods have been proposed to address this issue of online abuse. The existing work, however, tends to focus on detecting the more explicit forms of abuse leaving the subtler forms of abuse largely untouched. Our work addresses this gap by making three core contributions. First, inspired by the theory of impoliteness, we propose a novel task of detecting a subtler form of abuse, namely *unpalatable questions*. Second, we publish a context-aware dataset for the task using data from a diverse set of Reddit communities. Third, we implement a wide array of learning models and also investigate the benefits of incorporating conversational context into computational models. Our results show that modeling subtle abuse is feasible but difficult due to the language involved being highly nuanced and context-sensitive. We hope that future research in the field will address such subtle forms of abuse since their harm currently passes unnoticed through existing detection systems.

1 Introduction

Abusive language and other antisocial behaviour is omnipresent in online discourse. According to a recent survey, 41% of Americans have personally experienced some form of online harassment (Duggan, 2017). To counter abusive behaviour online, different social media platforms implement their own mechanisms such as content moderation, muting or blocking users from posting etc. It is, however, infeasible to *manually* moderate online communities due to the sheer enormity of content produced every day – Twitter, for example, receives over 500 million tweets per day. Manual moderation in such a scenario would require humans to read millions of tweets daily which would take an impractical amount of time and other resources. Consequently, many computational models have been proposed by the Natural Language Processing (NLP) community to detect online abuse and facilitate automatic content moderation.

Abuse is an umbrella term which can cover several types of negative expressions. There exists a plethora of abuse detection studies employing different terminology: personal attacks (Wulczyn et al., 2017), bullying (Dadvar et al., 2013; Chatzakou et al., 2017), hate speech (Warner and Hirschberg, 2012; Davidson et al., 2017; Djuric et al., 2015; Gao and Huang, 2017), nastiness (Samghabadi et al., 2017), harassment (Golbeck et al., 2017; Yin et al., 2009), hostility (Liu et al., 2018), racism or sexism (Waseem and Hovy, 2016), abusive language (Nobata et al., 2016), aggression (Caines et al., 2018), and others. However, extant work in abuse detection has largely focused on detecting overt abuse ignoring the more subtle forms of abuse which can be just as damaging. This is also noted in a recent survey calling on the NLP community to rethink and expand what constitutes abuse (Jurgens et al., 2019).

In this work, we make three contributions to address this gap in the literature. First, inspired from the theory of linguistic impoliteness, we propose a novel task of detecting a subtler form of abuse called *unpalatable questions* (UQ). It is one of the conventionalized impoliteness formulae introduced by Culpeper (2010). We define the UQ task as detecting a negatively phrased question designed to antagonise its recipient in online discourse.

Second, we collect, annotate, and make publicly available a context-aware dataset for the UQ task.[1] The data comes from a diverse set of online communities (or *subreddits*) on the popular social media site Reddit. Most existing datasets used in abuse

---

[1] We make our dataset and code publicly available at https://github.com/networkdynamics/unpalatable-questions.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2083–2099
April 19 - 23, 2021.

detection (Wulczyn et al., 2017; Waseem and Hovy, 2016; Davidson et al., 2017; Founta et al., 2018; Golbeck et al., 2017) only include annotations for stand-alone comments or tweets. In comparison, we explicitly consider conversational context during annotation and preserve contextual information in our dataset (see Section 4.4 for a detailed comparison).

A major limitation of existing abuse detection studies – also pointed out in (Castelle, 2018; Mishra et al., 2019; Gao and Huang, 2017) – is that a comment is treated as a single-utterance in isolation, ignoring any conversational context provided by other comments in the discussion. This is problematic since abuse is inherently contextual, and it becomes a major issue when working with subtler forms of abuse such as unpalatable questions. To this end, our third contribution is that we implement a wide array of learning models to detect unpalatable questions and investigate the benefits of incorporating conversational context in our computational models.

2 What is an Unpalatable Question?

We adopt the term *unpalatable question* (UQ) from the conventionalised impoliteness formulae introduced by Culpeper (2010). Although Culpeper did not formally define UQ, several examples were laid out: ‘why do you make my life impossible?’, ‘which lie are you telling me?’, ‘what’s gone wrong now?’. We find that UQs tend to be rhetorical in nature in that they are usually asked not to elicit an answer but to make a point. In particular, they have a close resemblance to *epiplexis*: a type of rhetorical question which is asked not to elicit information but to reproach, upbraid, or rebuke (Zimmerman, 2005). This can be seen in the examples listed in Table 1, where the questions are asked to shame the interlocutor for adopting a particular point of view and are often insults asked as questions. For our task, we define an *unpalatable question* as a negatively phrased question designed to antagonise its recipient.

Why UQ? Jurgens et al. (2019) outline a spectrum of abusive behaviour highlighting that existing work only focuses on overt abuse ignoring both the subtler forms and extreme behaviours. As can be seen in Figure 1, our task of detecting a subtler form of abuse is a step towards addressing this gap. Moreover, studies in linguistics show that being asked an unpalatable question puts the recipient in a vulnerable position to receive further verbal attacks (Bousfield, 2007; Wijayanto et al., 2017).

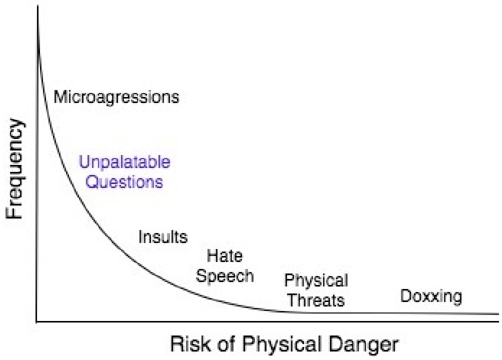

Figure 1: This figure, taken from (Jurgens et al., 2019), illustrates where *unpalatable questions* fit in a hypothetical spectrum of online abuse.

3 Further Related Work

3.1 Abusive Language Detection

Work on abuse detection has studied specific types of abuse using several feature-based and deep learning approaches. One of the earliest studies was by Yin et al. (2009) employing SVM to detect ‘personal insult harassment’ using TF-IDF values for words and sentiment-based features. Using a similar but enhanced set of features, Davidson et al. (2017) implement Logistic Regression and SVM to detect hate speech and offensive language on Twitter. Warner and Hirschberg (2012) use a template-based strategy to extract features from text and a linear-SVM to detect hate speech with a focus on anti-semitic language. Djuric et al. (2015) report an AUC of 80% using Logistic Regression with $paragraph2vec$ which outperformed standard bag-of-words approaches. Nobata et al. (2016) also use word2vec and comment2vec as one of their features to detect ‘abusive language’ which, in their work, encompasses hate speech, profanity and derogatory language. Wulczyn et al. (2017) implement a multilayer perceptron with word and character n-grams to detect personal attacks on Wikipedia and report an AUC of 96.5%.

In recent years, deep learning techniques have been widely adopted to detect online abuse. Pavlopoulos et al. (2017) show that RNN with GRU cells outperform the original classifier on detecting personal attacks (Wulczyn et al., 2017). Park and Fung (2017) propose a Hybrid-CNN that uses both word-level and character-level CNNs to detect hate speech on Twitter. Aken et al. (2018) utilise

So no article, right? Thought not.	*Oh, your brain stopped functioning at that?* Well then, I'll repeat myself. The abstract is enough, the article, you can find it yourself. I'm not going to waste my time.

Table 1: Examples of unpalatable questions from our annotated dataset.

CNN, bi-directional LSTM and GRU initialised with pre-trained word embeddings and report a f1-score of 78.3% and AUC of 98.3%. Gunasekara and Nejadgholi (2018) implement a Light Gradient Boosting Machine stacking model where they combine two bidirectional-LSTM based architectures and report an AUC of 98.6%. Finally, some studies also incorporate user-level context in their models. Mishra et al. (2018) report improvements in performance by incorporating author embedding features using $node2vec$ on community graphs of Twitter users. Dadvar et al. (2013) employs both user-based features and standard content-based features to detect bullying on YouTube. There are other studies that employ user-based features to detect aggression (Chatzakou et al., 2017) and hate speech (Gao and Huang, 2017).

3.2 Linguistic Impoliteness

Long before detecting online abuse gained attention, there had been significant research on linguistic impoliteness. The most notable contribution in this field is by Culpeper (1996) who introduced his theory of impoliteness as a parallel to Brown and Levinson (1987)'s politeness theory. Impoliteness is defined as the use of strategies to attack the interlocutor's *face* – a persona that one presents in a conversation (Goffman, 1967) – and create social disruption (Culpeper, 1996). More recently, Culpeper (2010) offered conventionalized impoliteness formulae for English derived from his corpora that consisted of phone calls, 'exploitative' TV shows, army training documentaries etc. He identified candidates for impoliteness and grouped them according to structural commonalities:[2]

- *Insults*: you f*cking moron; you disgust me
- *Pointed criticisms*: this was absolutely terrible
- *Unpalatable questions*: why do you make my life impossible?
- *Dismissals*: piss off; get lost
- *Threats*: I'm gonna beat the sh*t out of you if you don't [X]

3.3 Rhetorical Questions

Rhetorical questions are defined as sentences "that have the form of a question but serve as a statement" (Anzilotti, 1982). Since unpalatable questions tend to be rhetorical in nature, we present a brief overview of the literature on rhetorical question detection in social media.

One of the first studies was on Twitter data by Li et al. (2011) where they distinguish 'qweets' – tweets that ask for some information – from other interrogative tweets including rhetorical questions. They implement SVM using a set of different hand-crafted features. Bhattasali et al. (2015) use bag of n-grams to detect rhetorical questions in the Switchboard Dialogue Corpus. Their best-performing model achieved a F1-score of 0.53 by incorporating both preceding and subsequent text. Using questions from Twitter and Debate Forums, Oraby et al. (2017) implement SVM and LSTM to detect rhetorical questions, and further distinguish between sarcastic rhetorical questions and other questions. There exists other studies modeling rhetorical questions that draw inspiration from linguistic theories behind the motivations of users to post rhetorical questions (Ranganath et al., 2016, 2018). A general consensus in these studies is that rhetorical questions are hard to accurately classify due to their syntactic similarity to regular questions.

4 Data

The aim is to detect unpalatable questions in online discourse. For this, we construct a dataset using comments from Reddit and annotate them

---

[2] See (Culpeper, 2010) for a complete list and additional examples of each form.

for whether they contain an unpalatable question or not. We also preserve conversational context in the dataset by including the preceding comment in the discussion; therefore, our data consists of (pc_i, r_i, y_i) tuples denoting the preceding comment, reply[3] (or main comment), and the corresponding label respectively. The task is formulated as a binary classification problem where $y_i = 1$ indicates that the main comment r_i contains an unpalatable question.

We collect data from a diverse set of 15 online communities (or *subreddits*) belonging to different genres: politics, sports, hate and toxic.[4] The subreddits were carefully selected to prevent the dataset from being heavily skewed towards *not unpalatable* samples since these topics are more likely to involve opinionated and antagonistic discussions.

4.1 Question Filter

A challenge during data collection was to filter out comments that did not contain a question. We experiment with two approaches: (1) simple rule-based approach where we tokenize the comment and extract sentences that end with a '?', and (2) parsing-based approach where we first generate constituent parse trees using Stanford CoreNLP (Manning et al., 2014) and then identify questions using clause-level Penn Treebank Tags.[5]

Performance Comparison. We manually annotated a random sample of 300 Reddit comments for the presence of questions. There were a total of 81 questions out of which 74 contained a '?'. Although the parsing-based approach achieved a high precision, it missed out on several questions due to the low accuracy of the parser on noisy social media text. On the other hand, the simpler rule-based approach achieved a much higher recall and only missed out on the 7 samples that did not contain a '?'. Given the high disparity in performance, we decided to use the rule-based approach as our question filter. Although a potential data limitation, it is an acceptable design decision given that 91% of questions in our random sample were explicitly phrased using a '?'. This simple '?' heuristic has also been successfully used for identifying questions in other social media studies (Zhao and Mei, 2013; Ranganath et al., 2016; Paul et al., 2011).

	Confidence **0.6**	 **0.8**	 **1.0**	*Total*
Unpalatable	879	585	453	1917
Not Unpalatable	1324	2386	5282	8992
Total	2203	2971	5735	10,909

Table 2: Distribution of confidence scores in the annotated dataset.

4.2 Crowdsourcing

We use Amazon Mechanical Turk for crowdsourcing our data annotations. The coders were shown the *main comment* and also the *preceding comment* for context. They were asked to label the main comment for whether it contained an unpalatable question or not. Each comment in our dataset is labeled by at least five different coders.

Quality Control. Since coders can sometimes be unreliable at labeling abusive content (Nobata et al., 2016), we employ three measures to ensure high quality annotations. First, we were able to provide high-quality training to our coders through the use of clear instructions that laid out detailed tips, examples, and counter examples.[6] Second, we allowed only qualified coders to contribute to the task – they were required to achieve a perfect score on a quiz which had a total of 10 questions. Third, we inserted secret test questions throughout our task to address the issue of spam responses (Kittur et al., 2008). The coders were disqualified and blocked if their accuracy on the test questions fell below our predefined threshold of 90%.

4.3 Data Description

We aggregated the five annotations by taking the majority as the final label – a data sample is considered *unpalatable* if at least 3 coders labeled it as *unpalatable*. In order to not lose useful information, we added a *confidence* dimension to the dataset which is the ratio of the number of annotations with the majority label and the total number of annotators: *confidence* $\in \{0.6, 0.8, 1.0\}$. As can be seen in Table 2, 1,917 (17.5%) comments contain an *unpalatable* question, and the remaining 82.5% of comments do not. It is interesting to note the distribution of confidence scores across the two labels. Annotators seem to be much more confident

---

[3] Note that we use the term *main comment* and *reply* interchangeably.

[4] See Appendix A for the complete list of subreddits.

[5] https://gist.github.com/nlothian/9240750

[6] This was done through multiple in-house annotation rounds where we improved the instructions at each step. See Appendix B for the instructions shown to the coders.

for *not unpalatable* samples: 58% of samples correspond to a confidence score of 1.0 as compared to 25% for *unpalatable* samples. Following a similar trend, 45% of comments labeled *unpalatable* have a confidence score of 0.6 as compared to only 14% for *not unpalatable* samples. This highlights the nuanced nature and complexity associated with identifying unpalatable questions.

Annotator Agreement. We compute two measures of inter-annotator reliability: (1) Cohen's Kappa, and (2) Krippendorff's alpha. Our data achieved a Kappa score of 0.82 against a random sample of 150 comments manually annotated by the authors. Out of 150 comments, there were a total of 8 instances of disagreement – 7 out of which had a confidence score of 0.6. Next, we compute Krippendorff's α which is used when there are multiple coders annotating overlapping but different sets of comments (Krippendorff, 2004). Our data achieved an $\alpha = 0.39$ which is in-line with other abuse detection work that used crowdsourcing (Wulczyn et al., 2017; Cheng et al., 2015).

4.4 Comparison with Existing Datasets

As previously discussed, most datasets used for abuse detection contain annotations only for standalone comments in isolation. This is problematic since offensiveness can highly depend on the context. Castelle (2018) shows how their learning models failed (F1 = 0.3) on a StackOverflow dataset that required contextual enrichment to determine the offensiveness of a comment – a majority of comments, that were originally flagged as offensive, were not considered offensive by their coders. This is because the dataset lacked interactional context which was available to StackOverflow users when they originally flagged it as offensive.

We are aware of the following existing datasets that include contextual information:[7]

- Karan and Šnajder (2019) published a large dataset of 400k comments from Wikipedia including complete discussion threads. However, a major limitation of their data is that the labels are generated automatically using an existing toxicity classifier.[8] This implies that their labels would not be accurate for comments where the original toxicity classifier itself fails. In comparison, we perform manual annotation where our coders explicitly consider interactional context.
- Liu et al. (2018) published a dataset of 30,987 comments from Instagram annotated for *hostility*. The coders were shown an Instagram post and all comments in the thread. However, their data collection is biased (intentionally) towards teenagers and is filtered by certain keywords, eg: profanities, emojis. In comparison, our dataset involves a random sample of comments from a diverse set of subreddits without the use of any keyword-filtering.
- Gao and Huang (2017) released a dataset of 10 complete discussion threads from Fox News. The data includes additional contextual information in the form of user screen name, other comments in the thread, and title of the news article. However, their dataset is much smaller with only 1,528 comments and includes only two annotations per comment. In comparison, we use at least five annotations for each of the 10,909 comments in our dataset.

5 Methodology

In this section, we introduce our methodology for detecting unpalatable questions.

5.1 Traditional Machine Learning

We implement Logistic Regression[9] using a diverse set of features:

- **N-grams**: We use TF-IDF values for word unigrams, bigrams, and trigrams. We also utilise character trigrams, 4-grams, and 5-grams.
- **Embeddings**: We experiment with several pre-trained 300-dimensional embeddings: word2vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), and Fasttext (Bojanowski et al., 2017). In addition, we trained a word2vec model[10] from scratch on Reddit using Gensim (Řehůřek and Sojka, 2010).
- **Writing Style**: This category captures writing style of the comment and includes the following features: total number of words,

---

[7] Additionally, Zhang et al. (2018) released a dataset to *pre-emptively* detect toxic comments given all preceding comments in the discussion focusing on "personal attacks."

[8] http://www.perspectiveapi.com

[9] Note that additional experiments with SVM yielded similar results (not shown here).

[10] Specifically, we train the continuous bag-of-words (CBOW) architecture on all of Reddit data from 2016.

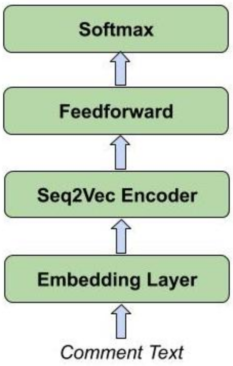

Figure 2: The skeletal architecture for our deep learning models.

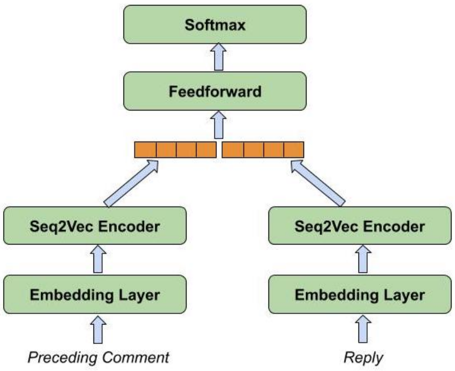

Figure 3: The skeletal architecture for our deep learning models that incorporate interactional context.

capital words, question marks, exclamation marks and second person pronouns.

- **Lexicon-based**: This category includes three features computed using pre-defined lexicons:
  - We compute the number of non-English words by comparing against NLTK words (Loper and Bird, 2002) and Enchant's dictionary.[11]
  - We compute the number of toxic words using a lexicon compiled from different sources: list of bad words released by Google[12] and lexicons released by other studies (Chandrasekharan et al., 2017; Davidson et al., 2017).
  - Empath (Fast et al., 2016) provides a set of 200 built-in validated categories for analysing text. We hand-picked a set of 15 relevant categories, for example: aggression, disgust, hate, shame etc.
- **Sentiment**: We use the *positive*, *negative*, and *neutral* sentiment scores returned by VADER, a rule-based sentiment analyser built for social media text (Hutto and Gilbert, 2014).

To build feature vectors, we experiment with the features in isolation as well as several combinations of these feature categories. The feature vectors along with the corresponding labels y_i are then fed to the learning algorithm, which is implemented using scikit-learn (Pedregosa et al., 2011).

5.2 Deep Learning

Deep learning models have been successfully used in many abuse detection studies (Pavlopoulos et al., 2017; Park and Fung, 2017; Aken et al., 2018). In this work, we implement a number of deep learning models – both CNN and RNN-based – using the architecture shown in Figure 2. We use pre-trained GloVe embeddings for the embedding layer.[13] An encoder is responsible for condensing a sequence of word vectors to a single vector. We experiment with a number of neural networks for the encoder: CNN, LSTM, Bidirectional LSTM, and Stacked Bidirectional LSTM.

ELMo. For the embedding layer, we also experiment with deep contextualized ELMo (Peters et al., 2018) representations[14] as an alternative to using GloVe embeddings. The encoder layer here can be either a CNN, LSTM, Bi-LSTM, or Stacked Bi-LSTM.

Dense Hybrid. We also implement deep learning models that utilise the various hand-engineered features discussed in Section 5.1. For this, we compute a 'dense' feature vector using those feature categories, and concatenate it with the neural encoder's output. This combined vector is then fed to a fully-connected feedforward neural network followed by a softmax layer.

Implementation details. All models are implemented using AllenNLP (Gardner et al., 2017), an open-source deep learning library for NLP. The training objective is weighted cross entropy loss, and Adam optimizer (Kingma and Ba, 2014) is used for learning network weights. Additionally, early stopping is implemented to terminate training of the neural network once the loss stops improving on a set-aside validation set.

5.3 Incorporating Conversational Context

Since humans can better comprehend a comment with reference to its context, we wanted to investigate the benefits of incorporating conversational context in the learning models. For traditional machine learning models, we concatenate the feature vectors for the preceding comment pc_i and main comment r_i which is then fed to the learning algorithm. For deep learning models, we first vectorize the preceding comment pc_i and the main comment r_i using the same encoder pipeline. The two vectors are then concatenated and fed to a feedforward neural network (Figure 3). In the LSTM-based models, the final hidden states of the pc_i and r_i pipeline are concatenated. For CNN, the output of the max pooling layers of the pc_i and r_i pipeline are concatenated.

In addition to simple concatenation, we experiment with additional heuristics to model context inspired from the task of Natural Language Inference (NLI). Specifically, we used a CNN encoder to vectorize the context pc_i and main comment r_i. They are then combined using three-heuristics: (1) concatenation, (2) element-wise product, and (3) element-wise difference (Mou et al., 2016).

6 Experiments and Results

We conduct experiments across two dimensions:

1. **Confidence Score:** We hypothesize that the models would exhibit better performance on data samples which were easier for the coders to annotate. To test this, we experiment with two scenarios:
    - *All-Data*: we use the complete dataset.
    - *High-Agreement-Data*: we use data samples corresponding to *confidence* $= 1.0$.
2. **Text Input:** To investigate the benefits of including contextual information, we experiment with three input scenarios:
    - *Question Text Only*: we only provide the question text as input.
    - *Reply Text*: we provide the full text of the main comment as input.
    - *Reply Text + Comment Text*: In addition to the main comment, we also provide the preceding comment text as input.

We evaluate our computational models on several classification metrics: precision, recall, F1-score, and Area under Receiver Operating Characteristic curve (AUROC) and Precision-Recall curve (AUPRC). All reported values are averaged over stratified five-fold cross-validation runs. The empirical results on *All-Data* and *High-Agreement-Data* are presented in Table 3 and Table 4 respectively.[15]

---

[15] We only display the top-performing traditional and deep learning models here. The complete list of all results is available in Appendix C.

7 Discussion

Among traditional learning algorithms, a combination of simple word unigrams, bigrams, and trigrams achieves the best F1-score of 0.44. Adding other hand-engineered features to $word(1,3)$ results in a better precision and AUPRC. As expected, deep learning models outperform traditional machine learning algorithms for both *All-Data* and *High-Agreement-Data* scenarios. In particular, CNN models perform much better than LSTM models. This is evident from Tables 3 and 4 where the best-CNN model outperforms the best-LSTM model by a 3-point and 5-point increase in F1-score respectively. We observe improvements with using contextualized ELMo embeddings as opposed to static GloVe embeddings for both scenarios. Moreover, the addition of dense hand-engineered feature vector further improves the F1-score to 0.532. Finally, our hypothesis, that it would be easier for the models to classify if it was easier for the humans, holds true in that there is a considerable improvement in the F1-score (15 points) for *High-Agreement-Data*.

Despite the performance gains observed with using more sophisticated deep learning models, the performance is still poor to be used for any practical applications. This is not surprising given how linguistically nuanced our dataset is and the complexity associated with abusive language detection on noisy social media text (Nobata et al., 2016). Specifically, learning models struggle to deal with *implicit* abuse – language which does not immediately convey abuse (Waseem et al., 2017). Aken et al. (2018) find that their toxicity classifier fails on data where there were instances of sarcasm, toxicity without employing swear words, and rhetorical questions. We qualitatively examined a random sample of hundred *unpalatable* samples from our dataset, and found that 65% do not contain swear words and 20% involve sarcasm. Similarly, from a random sample of hundred mis-classified *unpalatable* samples, 72% do not contain swear words and 30% involve sarcasm. Moreover, since unpalatable questions are rhetorical in nature, it is not surprising that learning models performed relatively poorly on the task.

Context. Our assumption was that models would benefit from conversational context since humans find it easier to determine the offensiveness of a comment when provided with some context. It is, however, evident from our empirical results that incorporating context through providing the preceding comment to the model did not improve performance for both traditional machine learning and deep learning models. This finding is consistent with other studies that attempt to incorporate interactional context into their models (Karan and Šnajder, 2019; Lee et al., 2018). We believe that effectively incorporating deeper context, as opposed to just the preceding comment, using more sophisticated methods such as hierarchical neural networks might help improve performance.

Evaluation Metrics. Mishra et al. (2019) observe a problematic trend with several abuse detection studies using AUROC for evaluation. This is not ideal since ROC plots can be deceptive when dealing with imbalanced classification scenarios (Saito and Rehmsmeier, 2015). Since most abuse detection datasets tend to be heavily skewed towards non-abusive samples, this can lead to misleadingly optimistic values for AUROC (also observed in Tables 3 and 4). A better alternative is to report AUPRC which is more robust to imbalanced data since it evaluates the fraction of true positives among positive predictions at different thresholds (Saito and Rehmsmeier, 2015).

8 Conclusion

In this work, we addressed an important gap in the abuse detection literature by introducing a novel task of detecting unpalatable questions. We also released a context-rich dataset for the task and implemented a number of learning models to automatically detect unpalatable questions. Our results show that it is difficult to model subtle abuse due to the language being nuanced and context-sensitive. This calls for advancements in natural language understanding methods that can identify such implicit signals and take pragmatic context into account. We hope that future research would explore other forms of abuse and draw inspiration from related fields such as linguistic impoliteness. Detecting abuse – both overt and subtle – on the Internet would help enhance user's experience online and facilitate civil and productive discussions.

A Data Collection

We collect data from a diverse set of 15 Reddit communities (or *subreddits*) belonging to different genres:

- **Politics**:

  - r/The_Donald
  - r/politics
  - r/PoliticalDiscussion
  - r/Conservative

- **Sports**:
  - r/nfl
  - r/sports
  - r/nba
  - r/hockey

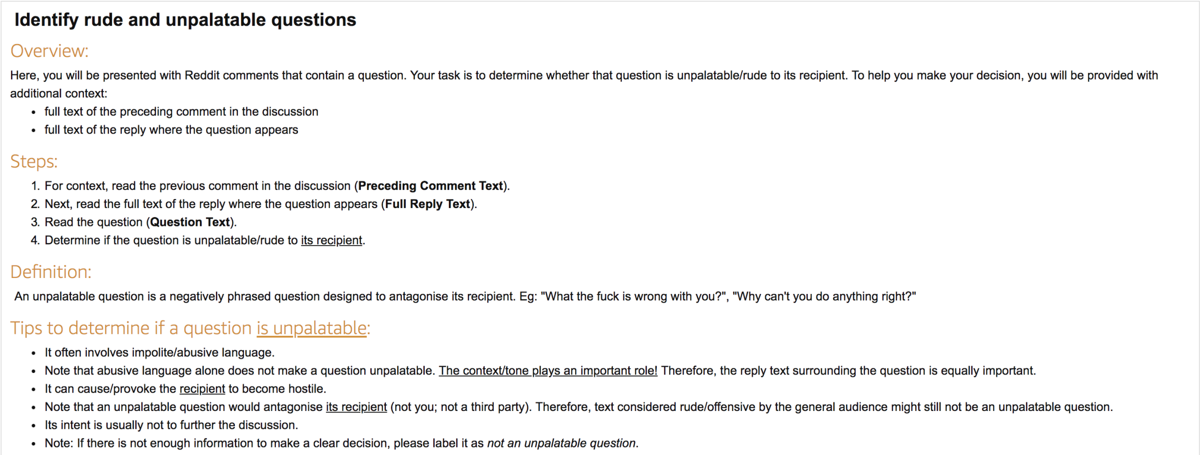
- **Hate and Toxic**:
  - r/cringepics
  - r/cringe
  - r/4chan
  - r/CringeAnarchy
  - r/KotakuInAction
  - r/ImGoingToHellForThis
  - r/TumblrInAction

B Crowdsourcing Instructions

The instructions provided to Amazon Mechanical Turk coders are shown in Figure 4 and Figure 5.

C Results

The complete list of results for the *All-Data* scenario are shown in Table 5 (deep learning models) and Table 7 (traditional machine learning models). Next, the complete list of results for the *High-Agreement-Data* scenario are shown in Table 6 (deep learning models) and Table 8 (traditional machine learning models).



Identify rude and unpalatable questions

Overview:

Here, you will be presented with Reddit comments that contain a question. Your task is to determine whether that question is unpalatable/rude to its recipient. To help you make your decision, you will be provided with additional context:

- full text of the preceding comment in the discussion
- full text of the reply where the question appears

Steps:

1. For context, read the previous comment in the discussion (**Preceding Comment Text**).
2. Next, read the full text of the reply where the question appears (**Full Reply Text**).
3. Read the question (**Question Text**).
4. Determine if the question is unpalatable/rude to its recipient.

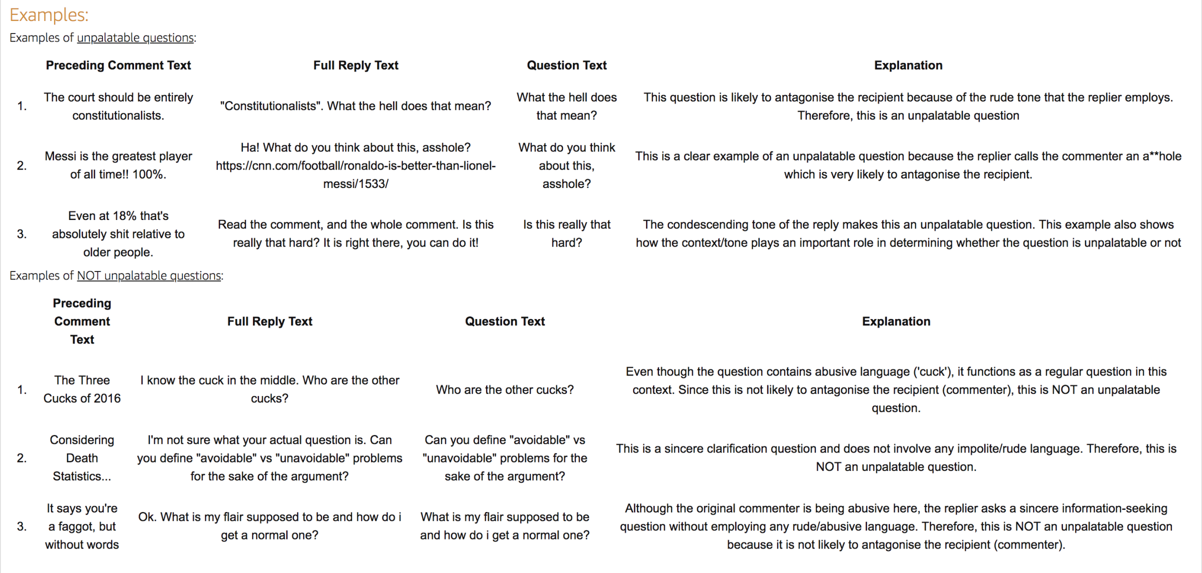
Definition:

An unpalatable question is a negatively phrased question designed to antagonise its recipient. Eg: "What the fuck is wrong with you?", "Why can't you do anything right?"

Tips to determine if a question is unpalatable:

- It often involves impolite/abusive language.
- Note that abusive language alone does not make a question unpalatable. The context/tone plays an important role! Therefore, the reply text surrounding the question is equally important.
- It can cause/provoke the recipient to become hostile.
- Note that an unpalatable question would antagonise its recipient (not you; not a third party). Therefore, text considered rude/offensive by the general audience might still not be an unpalatable question.
- Its intent is usually not to further the discussion.
- Note: If there is not enough information to make a clear decision, please label it as *not an unpalatable question*.

Figure 4: Instructions for the crowdsourcing task as seen by Mechanical Turk Workers.



Examples:

Examples of unpalatable questions:

	Preceding Comment Text	Full Reply Text	Question Text	Explanation
1.	The court should be entirely constitutionalists.	"Constitutionalists". What the hell does that mean?	What the hell does that mean?	This question is likely to antagonise the recipient because of the rude tone that the replier employs. Therefore, this is an unpalatable question
2.	Messi is the greatest player of all time!! 100%.	Ha! What do you think about this, asshole? https://cnn.com/football/ronaldo-is-better-than-lionel-messi/1533/	What do you think about this, asshole?	This is a clear example of an unpalatable question because the replier calls the commenter an a**hole which is very likely to antagonise the recipient.
3.	Even at 18% that's absolutely shit relative to older people.	Read the comment, and the whole comment. Is this really that hard? It is right there, you can do it!	Is this really that hard?	The condescending tone of the reply makes this an unpalatable question. This example also shows how the context/tone plays an important role in determining whether the question is unpalatable or not

Examples of NOT unpalatable questions:

	Preceding Comment Text	Full Reply Text	Question Text	Explanation
1.	The Three Cucks of 2016	I know the cuck in the middle. Who are the other cucks?	Who are the other cucks?	Even though the question contains abusive language ('cuck'), it functions as a regular question in this context. Since this is not likely to antagonise the recipient (commenter), this is NOT an unpalatable question.
2.	Considering Death Statistics...	I'm not sure what your actual question is. Can you define "avoidable" vs "unavoidable" problems for the sake of the argument?	Can you define "avoidable" vs "unavoidable" problems for the sake of the argument?	This is a sincere clarification question and does not involve any impolite/rude language. Therefore, this is NOT an unpalatable question.
3.	It says you're a faggot, but without words	Ok. What is my flair supposed to be and how do i get a normal one?	What is my flair supposed to be and how do i get a normal one?	Although the original commenter is being abusive here, the replier asks a sincere information-seeking question without employing any rude/abusive language. Therefore, this is NOT an unpalatable question because it is not likely to antagonise the recipient (commenter).

Abstract

We study a search-based paraphrase generation scheme where candidate paraphrases are generated by iterated transformations from the original sentence and evaluated in terms of syntax quality, semantic distance, and lexical distance. The semantic distance is derived from BERT, and the lexical quality is based on GPT2 perplexity. To solve this multi-objective search problem, we propose two algorithms: *Monte-Carlo Tree Search For Paraphrase Generation* (MCPG) and *Pareto Tree Search* (PTS). We provide an extensive set of experiments on 5 datasets with a rigorous reproduction and validation for several state-of-the-art paraphrase generation algorithms. These experiments show that, although being non explicitly supervised, our algorithms perform well against these baselines.

1 Introduction

Paraphrase generation, *i.e.* the transformation of a sentence into a well-formed but lexically different one while preserving its original meaning, is a fundamental task of NLP. Its ability to provide diversity and coverage finds applications in several domains like question answering (McKeown, 1979; Harabagiu and Hickl, 2006), machine-translation (Callison-Burch et al., 2006), dialog systems (Yan et al., 2016), privacy (Gröndahl and Asokan, 2019a) or adversarial learning (Iyyer et al., 2018).

The formal definition of paraphrase may vary according to the targeted application and the tolerance we set along several axes, including the *semantic distance* from the source that we want to minimize, the *quality of the syntax*, and the *lexical distance* from the source that we want to maximize to ensure diversity.

The available aligned paraphrase corpora are often biased toward specific problems like *question answering* or *image captioning*. For instance, a transformer or a seq2seq model trained on a question answering corpus will typically turn any input sentence into a question. With the lack of generic aligned datasets, it remains challenging to train generic paraphrase models in a supervised manner.

On the other hand, with the availability of large-scale non-supervised language models like BERT and GPT2, the assessment of a given candidate paraphrase in terms of *semantic distance* from its source and *lexical quality* has become much more tractable.

Leveraging from these metrics, we propose to cast the paraphrase generation task as a multi-criteria search problem. We use PPDB 2.0 (Pavlick et al., 2015), a large-scale database of rewriting rules derived from bilingual corpora, to potentially generate billions of 'naive' candidate paraphrases by edition from the source sentence. To sort the good candidates efficiently from the others, we experiment with two search algorithms. The first one, called *Monte-Carlo Paraphrase Generation* (MCPG), is a variant of the *Monte-Carlo Tree Search* algorithm (MCTS) (Kocsis and Szepesvári, 2006; Gelly and Silver, 2007; Chevelu et al., 2009). The MCTS algorithm is famous for its successes on mastering the – highly combinatorial – game of Go (Gelly and Silver, 2007; Silver et al., 2016).

The second one is a novel search algorithm that we call *Pareto Tree Search* (PTS). In contrast to MCTS which is a single-criterion search algorithm, we designed PTS to retrieve an approximation of the whole Pareto optimal set. This allows for more flexibility on paraphrase generation where the balance between *semantic distance*, *syntax quality*, and *lexical distance* is hard to tune *a priori*. Another difference between MCPG and PTS is that PTS uses a randomized breadth-first exploration policy which proves to be more efficient on this problem.

The main contribution of this article is a study on search-based paraphrase generation through the

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2100–2111
April 19 - 23, 2021.

Source sentence :	he is speaking on june 14 .
PPDB rule	**Edited sentence**
is → is found	he is found speaking on june 14 .
is speaking → 's talking	he 's talking on june 14 .
speaking → speak now	he is speak now on june 14 .
14 → 14th	he is speaking on june 14th .

Table 1: PPDB rules applied to a source sentence

sieve of three criteria: semantic similarity, syntax quality, and lexical distance. We propose and evaluate two search algorithms: MCPG and PTS. We also provide an extensive set of experiments on English datasets with a rigorous reproduction and validation methodology for several state-of-the-art paraphrase generation algorithms.

This article is organized as follows: The candidate paraphrase generation scheme is presented in Section 2. In Section 3, we develop the different criteria we use to qualify correct paraphrases. The two search algorithms (MCPG and PTS) are described in Section 4. Section 5 gives a survey on other state-of-the-art paraphrase generation algorithms. The comparisons with non-supervised and supervised baselines are presented in Section 6 where the methodology is discussed in Section 6.3. We conclude by a data-augmentation experiment in Section 6.6.

2 Paraphrase generation scheme

We model paraphrase generation as a sequence of editions and transformations from a source sentence into its paraphrase. In this work, we only consider local transformations, *i.e.* replacement of certain words or group of words by others that have the same or similar meanings, but the method we propose should work with more sophisticated transformations as well.

The *Paraphrase Database* (PPDB) (Ganitkevitch et al., 2013; Pavlick et al., 2015) is a large collection of scored paraphrase rules that was automatically constructed from various bilingual corpora using a pivot alignment method (Callison-Burch, 2008). The database is divided into increasingly large and decreasingly accurate subsets[1]. We used the XL subset, and we removed the rules labeled as "`Independent`". This left us with a set of 5.5 million rewriting rules. We give some examples of these rules in Table 1.

By iteratively applying the rules from a source sentence like the one in Table 1, we obtain a vast lattice of candidate paraphrases. Some of these candidates like "*he's* ***talking*** *on june 14*" are well-formed, but many are syntactically broken, like "*he is* ***speak now*** *on june 14*".

The number of rules that apply depends on the source sentence's size and the words it contains. For instance, on the MSRPARAPHRASE dataset (see section 6.2), sentences are quite long and the median number of PPDB-XL rules that apply is around 450. After two rewriting steps, the median number of candidates is around 10^5, and by iterative rewriting, we quickly reach a number of paraphrase candidates that is greater than 10^8.

3 Paraphrase selection criteria

As it depends on the type of text we consider that may be spoken or written, casual or formal; it is not easy to define a *universal semantic distance* or a *universal scale of well formed syntax*. However, recent advances in NLP with neural networks like BERT and GPT2 trained on huge corpora have led to the development of metrics that can act as good proxies for these ideal notions.

For the semantic distance, a quick experiment confirms that the BERT score (Zhang et al., 2019a) performs well on difficult paraphrase identification tasks. The BERT score is an F1-measure over an alignment of the BERT contextual word embeddings of each of the sentences. To assess the sensitivity of this score, we computed the Area Under the ROC curve (AUC) on QQP and PAWS, two difficult paraphrase identification corpora (Kornél Csernai, 2017; Zhang et al., 2019b). On QQP, we obtained 75.2% and on PAWS, we obtained 67.0%. The PAWS corpus being designed to trick paraphrase identification classifiers, 67.0% is a reasonable performance. We hence opted for the BERT score between the source sentence and paraphrase candidate (denoted BERT$_{S}$) as our semantic score.

Regarding the syntax quality, the perplexity of GPT2 (Radford et al., 2019) is a good ranking criterion. Although, as illustrated in Table 2, in some cases, a rule-based spell-checker may detect errors that GPT2 would miss (but the reverse is also true). We hence opted for GPT2 as a primary criterion for syntax quality, combined with the LANGUAGETOOL spell-checker (Naber, 2003) that we only used on a second stage for performance reasons.

The lexical distance is important to ensure the

---

[1] PPDB is available on `http://paraphrase.org`, and a python interface is available here `https://github.com/erickrf/ppdb`

diversity of the produced paraphrases. It is however simple to handle. Some authors use the BLEU surface metric (Miao et al., 2018a), we opted here for the normalized character-level Levenshtein edition distance.

The balance between these criteria is difficult to obtain. Table 2 illustrates their impact on a sentence taken from the train set of MSRPARAPHRASE. The candidate examples in this table underline the tough dilemma between maximizing the semantic similarity (safe and conservative policy) and maximizing the lexical distance (risk-prone). The third and fourth examples underline the utility of the spell-checker: some low-perplexity examples are ill-formed. On the second part of the table, we printed the sentences chosen by our two models: MCPG and PTS.

4 Searching algorithms

Searching for good paraphrases in the large lattice of candidates generated by PPDB is a costly task. We propose two algorithms that share a similar structure: an outer loop explores the lattice at different depths, while an inner loop explores the candidates at each depth. Both algorithms are anytime: they return the best solutions found so far when the time or space budget is depleted.

4.1 MCPG: Monte-Carlo tree search for Paraphrase Generation

Following the idea of Chevelu et al. (2009), we used *Monte-Carlo Tree Search* (MCTS) to explore the PPDB lattice. The three key ingredients of MCTS are: a *bandit* policy at each node of a search-tree to select the most promising paths, randomized roll-outs to estimate the quality of these paths, and back-propagation of rewards along the paths to update the bandit. We opted here for a randomized bandit policy called EXP3 (Auer et al., 2002). The MCTS algorithm being not designed for multi-objective problems, we needed to combine semantic similarity BERT_S, syntax correctness GPT2 and surface diversity Lev_S into a single criterion. We opted for the following polynomial:

$$\alpha \cdot \text{BERT}_\text{S} + \beta \cdot \text{Lev}_\text{S} \cdot \text{BERT}_\text{S} - \gamma \cdot \text{GPT2} \quad (1)$$

where the product $\text{Lev}_\text{S} \cdot \text{BERT}_\text{S}$ is intended to avoid a trivial maximization of the score by applying a lot of editions to the source sentence. After a few experiments on train sets, we tuned empirically the weights to $\alpha = 3, \beta = 0.5$ and $\gamma = 0.025$ in order to obtain a balance as the one described in Table 2.

4.2 PTS: Pareto Tree Search in the paraphrase lattice

We observed two drawbacks for MCTS.

First, it was designed for combinatorial problems like Go where the evaluation is only possible on the leaves of the search tree. This is not the case for paraphrase generation where the neural models can evaluate any rewriting step and where rewriting from good candidates is more likely to provide good paraphrases than rewriting from bad ones. Secondly, it has been designed for single criterion search which requires fixing the balance between criteria definitively before any paraphrase search begins. This is not very flexible, and it becomes painful when we want to generate sets of candidates.

By plotting the distributions of the scores like on Figure 1, we noticed that most of the candidates were dominated in the Pareto sense: it was possible to eliminate most of the candidates without any hyper-parameter tuning. Hence, we adapted MCPG to explore the paraphrase lattice and recover an approximation of the Pareto front, postponing the balance between criteria as a quick post-optimization stage. This led us to the PTS algorithm described as pseudo-code in Table 3.

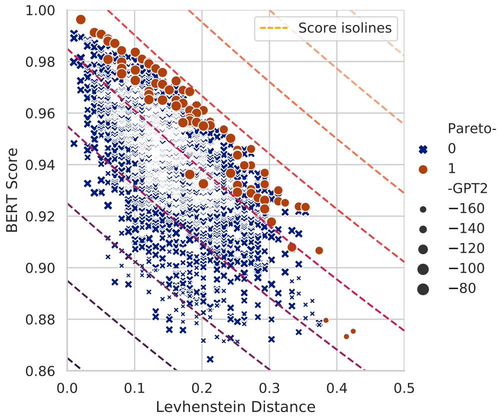

Figure 1: The cloud of candidates generated from the sample of Table 2. The optima of any positive combination of BERT score, normalized Levenshtein distance, and GPT2 perplexity belong to the Pareto front (orange dots). We plotted the projections of MCPG combined score (1) with dashed isolines. The BERT score and Levenshtein distance being clearly anti-correlated, the balance between these two criteria is difficult to tune.

Source	the agency could not say when the tape was made , though the voice says he is speaking on june 14 .

Policy	Candidate Sentence	BERT_S	GPT2	Lev_S	Errs
high BERT conservative	the agency could not say when the tape was made , though the voice says he is talking on june 14 .	**0.99**	4.23	0.04	0
high Lev risk prone	the organizations and agencies could just 'm saying whenever the tape-based was provided presentation there are , however the express opinions informed that he was found talking pertaining end-june fourteen .	0.60	7.83	**1.0**	0
high GPT2 bad syntax	the agencies was not able say when the tape been given currently undertaking though the voice indicated he talking on june 14 .	0.82	**7.10**	0.55	2
spell & grammar errors	the organisation are incapable of 're saying when the tape is set out , despite the fact that the voice just said he have a conversation on june 14 .	0.73	5.49	0.79	**2**
balanced	the organization could not say when the tape was made , although the voice indicates that he is talking on june 14 .	0.95	4.34	0.28	0
MCPG output	the organization could not say when the tape was made , though the voice indicates that he is talking on june 14 .	0.96	4.36	0.26	0
PTS output	the agency could not say when the tape was made , although the voice says he is speaking on june 14 .	1.00	4.17	0.02	0
Target	the agency could put no exact date on the tape , though the voice says he is speaking on june 14 .	0.87	4.77	0.22	0

Table 2: An example of a source sentence sampled from the MSRPARAPHRASE train set with some representative candidates from its PPDB rewriting graph. For each of the candidates, we computed the BERT score with respect to the source (BERT_S), the normalized GPT2 perplexity (GPT2), the Levenshtein distance from the source sentence (Lev_S), and the number of spell and grammar errors detected (Errs). The PPDB editions are highlighted in green. The detected spell and grammar errors are highlighted in purple. The first candidate maximizes the semantic similarity (BERT score) and is very conservative. The second one maximizes the surface diversity (Lev_S) and takes a lot of risks. The third one shows an ill-formed paraphrase candidate. The fourth candidate emphasizes the utility of the spell-checker. The last candidate, on the fifth row, achieves our equilibrium goal. We show on a second part, the paraphrases generated by our models MCPG an PTS, and on a third part, we give the reference paraphrase from the dataset.

```
function PTS(input_sentence)
    candidates ← REWRITE(input_sentence)
    depth ← 1
    while time/space $<$ budget do
        while time/space $<$ layer-budget do
            batch ← SAMPLE(candidates)
            scored ← scored $\cup$ NN.SCORES(batch)
        end while
        layer_front_set ← PARETO-FRONT(scored)
        candidates ← REWRITE(layer_front_set)
        depth ← depth + 1
    end while
    return PARETO-FRONT(all scored nodes)
end function
```

5 Related work

Rule-based and statistical approaches Following the path of machine translation, the paraphrase generation literature first evolved from laboriously handcrafted linguistic rules (McKeown, 1979; Meteer and Shaked, 1988; Chandrasekar and Srinivas, 1997; Carroll et al., 1999) to more automatic and data-driven rules extraction methods (Callison-Burch et al., 2006; Madnani and Dorr, 2010). Like in machine translation, phrase-level substitution rules can be extracted by sub-sentence alignment algorithms from parallel corpora (Brown et al., 1993). Building such a dedicated corpus being a long and costly task, one usually transforms other corpora through a "pivot representation" (Barzilay and McKeown, 2001; Callison-Burch et al., 2006; Ganitkevitch et al., 2013; Chen et al., 2015). The weakness of these approaches is that phrase-level rewriting rules alone are not able to build coherent sentences. A typical data-driven paraphrase generator used to be a mixture of potentially noisy handcrafted and data-driven rewriting rules coupled with a score that had to be optimized in real-time through dynamic programming. However, dynamic programming methods like *Viterbi* are constrained by the requirement of a score that decomposes into a sum of word-level or phrase-level criteria (Xu et al., 2016). Some attempts were made to relax this constraint with search-based approaches (Chevelu et al., 2009; Daumé et al., 2009), but the global optimized criteria were simplistic, and the obtained solutions were not suitable for practical deployment.

Supervised encoder-decoder approaches Like machine translation, paraphrase generation benefited from deep neural networks and evolved to efficient end-to-end architectures that can both learn to align and translate (Bahdanau et al., 2016; Vaswani et al., 2017). Several papers like (Prakash et al., 2016a; Cao et al., 2017) set the paraphrase generation task as a supervised sequence-to-sequence problem. As confirmed by our experiments in Section 6.4, this approach is efficient for specific types of paraphrases. It is also able to produce relatively long-range transformations, but it requires huge and high-quality sentence-level aligned datasets for training.

The paraphrase generation literature mostly reports results on MSCOCO (Chen et al., 2015) and QQP (Kornél Csernai, 2017) datasets which are built respectively from image captions and semi-duplicate questions. These datasets are very specific: MSCOCO is strongly biased toward image description sentences, and QQP is dedicated to questions. The Transformer model we trained on QQP typically transforms any input into a question. For instance, from "He is speaking on june 14." it gives "Who is speaking on june 14?".

Generative and hybrid approaches Recent approaches rely on conditional generative models like CVAE to allow the generation of paraphrase sets and palliate the lack of supervision data (Gupta et al., 2018; Yang et al., 2019a; Roy and Grangier, 2019; An and Liu, 2019). Others make use of CGANs combined with reinforcement learning (Li et al., 2018; Wang and Lee, 2018). Witteveen and Andrews (2019) propose to simply fine-tune a large non-supervised model like GPT2.

Recent text-generation architectures like the one proposed in (Moryossef et al., 2019; Fu et al., 2019) make a clear separation between a rule-based planning phase and the neural realization. A similar idea was tested by Huang et al. (2019) where PPDB rules are used to control the decoder of a CVAE.

Search-based approaches Search-based methods regained interest in the text generation community for several reasons, including the need for flexibility and the fact that with deep neural-networks, the search evaluation criteria have become more reliable. These methods are often slower than auto-regressive text generation methods, but it is always possible to distillate the models into faster ones like we do in Section 6.6. In (Gröndahl and Asokan, 2019b) they deployed a search-based policy for style imitation, Schwartz and Wolter (2018) and Kumagai et al. (2016) both used MCTS for text generation. Following the same trend, Miao et al. (2018a) proposed to use Metropolis-Hasting sampling (Metropolis et al., 2004) for constrained sentence generation in an algorithm called CGMH.

Starting from the source sentence, the CGMH algorithm samples a sequence of sentences by using local editions: word replacement, deletion, and insertion. For paraphrase generation, CGMH constraints the sentence generation using a matching function that combines a measure of semantic similarity and a measure of English fluency. This model is therefore directly comparable with our MCPG and PTS approaches.

6 Experiments

The evaluation metrics and datasets are described respectively in Section 6.1 and 6.2. We paid attention to set up a rigorous validation protocol for our experiments. The reproducibility and methodology issues that we faced are discussed in Section 6.3. We compare our model with state-of-the-art supervised methods and with CGMH, another search-based algorithm. The technical details on these algorithms are developed in Section 6.4. The results are detailed in Section 6.5.

6.1 Evaluation metrics

We rely on standard machine translation metrics that compare the generated paraphrase to one or several ground-truth references (Olive et al., 2011). We report surface metrics BLEU and TER and semantic metrics METEOR and BERT[2], the average BERT score of the generated sentence with respect to the reference sentences[3].

6.2 Evaluation datasets

Table 4 gives a summary of the datasets we used. On one hand, we have large datasets like MSCOCO or OPUSPARCUS (OPUSPAR.) that are noisy and very specific. On the other hand, we have MSR-PARAPHRASE (MSRPARA.), a high-quality but small human-labeled dataset.

---

[2] This is the same metric, but this usage of BERT score against **reference** must not be confused with the BERT score against **source** ($BERT_S$) that we use in (1).

[3] We used the scripts from `github.com/jhclark/multeval` and `github.com/Tiiiger/bert_score`. For the BERT score we used 'bert-base-uncased_L8_no-idf_version=0.1.2'

Corpus	**Size**	**Len**	**B>0.75**	**L<0.25**	**PPDB@1**	**PPDB@3**
MSCOCO	$2.4 \cdot 10^6$	11	**13.6%**	0.6%	119	$7.4 \cdot 10^4$
MSRPARA.	$7.8 \cdot 10^3$	23	81.8%	18.3%	454	$\mathbf{7.0 \cdot 10^6}$
OPUSPAR.	$4.2 \cdot 10^7$	6	36.0%	0.5%	113	$1.5 \cdot 10^4$
PAWS	$3.6 \cdot 10^5$	20	**100%**	**65.6%**	289	$1.3 \cdot 10^6$
QQP	$1.5 \cdot 10^5$	10	64.1%	21.8%	141	$1.3 \cdot 10^5$

Table 4: **Datasets statistics**. 'Size' is the number of instances. 'Len' is the median number of words per sentence. We also report a rough distribution of the BERT score (B) and the Levenshtein distance (L) computed on the corpora paraphrases pairs. The 'PPDB@x' columns give the median number of candidates that PPDB-XL generates from one sentence respectively at one and three rewriting steps. The size of the PPDB rewriting lattice is correlated to the length of sentences.

Model applied on MSCOCO	$BLEU \uparrow$
RESIDUAL LSTM (Fu et al., 2020)	23.7
LBOW-TOPK (Fu et al., 2020)	25.3
RESIDUAL LSTM (Prakash et al., 2016a)	37.0
VAE-SVG-EQ (Gupta et al., 2017)	39.6
TRANSFORMER (Egonmwan and Chali, 2019b)	41.8
TRANSSEQ (Egonmwan and Chali, 2019b)	44.5

Model applied on QQP	$BLEU \uparrow$
RESIDUAL LSTM (Fu et al., 2020)	24.9
CGMH (Miao et al., 2018a) - *weakly-supervised*	18.8
LBOW-TOPK (Fu et al., 2020)	26.2
VAE-SVG-EQ (Gupta et al., 2017)	37.1
TRANSFORMER (Egonmwan and Chali, 2019b)	39.0
TRANSSEQ (Egonmwan and Chali, 2019b)	39.8

Table 5: Inconsistent BLEU scores as reported in several articles on paraphrase generation.

The MSCOCO-2017 set (Chen et al., 2015) contains image captions, assuming that captions associated with the same picture are paraphrases. The strengths of MSCOCO are its size and the fact that each source sentence is associated with four reference paraphrases. However, the sentences are biased towards a descriptive style, and the quality of the paraphrases is often questionable.

The OPUSPARCUS dataset (Creutz, 2018) has been extracted from movies and TV shows subtitles. It contains mostly informal dialogues.

Quora Question Pairs dataset (QQP) (Kornél Csernai, 2017) is a paraphrase identification corpus dedicated to question-answering systems. The MSRPARAPHRASE dataset (Dolan and Brockett, 2005) is mostly build with pieces of news. The sentences of this corpus are quite long. It is a small but high-quality paraphrase identification corpus that was labeled by humans. PAWS$_{wiki}$ (PAWS) (Zhang et al., 2019b; Yang et al., 2019b) is a paraphrase identification corpus that contains several lexically-similar but hard-to-classify pairs like "*Flights to Florida from New York*" and "*Flights from Florida to New York*".

6.3 Methodology and reproducibility issues

In the paraphrase generation literature, most of the papers report results on MSCOCO and QQP corpora. In table 5, we provide the BLEU scores as reported in (Prakash et al., 2016b; Gupta et al., 2017; Fu et al., 2019; Miao et al., 2018b) and (Egonmwan and Chali, 2019a). However, even if the dataset names coincide, and even if each evaluation methodology is correct on its own, the discrepancies between methodologies render these values impossible to compare with each other.

The strange gap between the residual LSTM performance of (Prakash et al., 2016b) and the one reported in (Fu et al., 2019) can be explained by the fact that the first one is using the 2014 version of MSCOCO while the other is using 2017 version. But we also found several other issues: differences in test sets splits, different strategies for sentence length shrinking (or pruning), different vocabulary size, and tokenization strategies.

Regarding the sentence lengths, Prakash et al. (2016b) and Gupta et al. (2017) shrunk all sentences to 15 words. Fu et al. (2019) set the maximum length to 16 while Egonmwan and Chali (2019a) set it to 15 and 10 respectively for the input and target sentences. Knowing that roughly 56% (resp. 5%) of MSCOCO target sentences are strictly longer than 10 (resp. 15) words, these small changes can have a great impact on the results. The vocabulary considered also differs. Fu et al. (2019) used a vocabulary of 8k and 11k tokens from the train sets of QQP and MSCOCO respectively, whereas Egonmwan and Chali (2019a) had a vocabulary of approximately 15k words that was constructed on both the train and test sets.

The scripts used to compute metrics did also differ from one paper to another, and it is known that BLEU scores can vary wildly with different parameterizations (Post, 2018).

We used the code when available and otherwise, we tried as much as possible to reproduce the models of the literature faithfully. This allowed us to have the exact same preprocessing, training and testing pipeline for all our experiments. As a side effect, it gives a grounded benchmark between the methods that we could test.

6.4 Baseline systems implementation

In the next subsections, we present the re-implemented encoder-decoder neural networks architectures and the weakly-supervised paraphrase generator used as baselines in our experiments.

Supervised paraphrase generators As supervised baselines, we trained three neural network architectures that were previously reported to achieve good results on MSCOCO and QQP, in particular, the Seq2Seq architecture, a *Residual* LSTM architecture (Prakash et al., 2016b) and a TRANSFORMER model (Egonmwan and Chali, 2019a). We extended the experiments to the other aligned corpora: MSRPARAPHRASE, OPUSPARCUS and PAWS.

To be more precise, we trained a 4-layers LSTM Seq2Seq with a bidirectional encoder and decoder using attention. This architecture is reported as SEQ2SEQ in the results. We trained a 4-layer Residual LSTM Seq2Seq as introduced by Prakash et al. (2016b) and reproduced by Fu et al. (2019). This architecture is reported as RESIDUAL LSTM in the results. The results we obtained with this model are close to the ones reported by Fu et al. (2019).

Finally, we trained a TRANSFORMER using the *transformer_base* hyper-parameters set from (Vaswani et al., 2017). This architecture is reported as TRANSFORMER BASE in the results.

For all the encoder-decoder experiments, we used the *fairseq* framework (Ott et al., 2019) that implements the SEQ2SEQ and TRANSFORMER architectures. We added our own implementation of the RESIDUAL LSTM architecture.

For preprocessing, we used Moses tokenizer and subword segmentation following Sennrich et al. (2016b) and using the subword-nmt library . The maximum sentence length is set to 1024 tokens which the default setting in *fairseq*. For decoding, we did a beam search with a beam of size 5.

Weakly-supervised paraphrase generator For the weakly-supervised strategy CGMH introduced by Miao et al. (2018b) we used the official code. We managed to reproduce their results on QQP. On our test set we achieve a BLEU score of 22.5 while they reported 18.8. We then extended the experiment to other datasets and metrics.

6.5 Results

Table 6 summarizes the results of the comparison of our models, supervised encoder-decoder neural networks and the weakly-supervised method CGMH. Overall, these results are mixed: it is however important to keep in mind that contrary to the supervised baselines which are retrained for each dataset, the parameters of the CGMH, MCPG and PTS models are left unchanged.

On the MSCOCO and QQP datasets, the supervised baselines achieve clearly better results, but MCPG and PTS achieve better results on OPUSPARCUS and PAWS except with the BERT score for which the TRANSFORMER model achieves similar results. On MSRPARAPHRASE, the encoder-decoder neural networks models perform poorly. This result can be explained by the small number of training examples available on this corpus (See Table 4). On the weakly-supervised side, MCPG and PTS models outperform the CGMH baseline on all corpora except on the MSCOCO dataset where the results are similar.

These results prove that even without a specialized training sets, generic search-based methods are competitive for paraphrase generation. However, it is a fact that encoder-decoder networks have excellent performances for text generation and have the potential to generate more complex paraphrases than those obtained by simple local transformations as in our models.

Training a general – all-purpose – paraphrase generation network would require a huge volume of data. And there is yet much less aligned corpora available for paraphrase than for translation.

6.6 Data-augmentation experiment

In order to get the best of both worlds, one option is to enrich the training set of a TRANSFORMER with the results of a search-based method.

To test this idea, we used our models to augment the MSRPARAPHRASE training set. For that purpose we created new pairs of paraphrases from unused sentences of MSRPARAPHRASE (the pairs labeled as “not paraphrases”) using MCPG and PTS. We then trained a new supervised TRANSFORMER models on the augmented training sets.

Having no guarantee that our models generate syntactically perfect sentences, we inverted the pairs, thus taking the generated paraphrases as input and the dataset’s sentences as output. This trick, called *back-translation*, forces the target model to generate correct sentences (Sennrich et al., 2016a; Edunov et al., 2018).

We report the results of this experiment in Table 7. The models trained with the augmented

Corpus	**Model**	*BLEU* ↑	*TER* ↓	*METEOR* ↑	*BERT* ↑
MSCOCO	SEQ2SEQ	**27.5**	**62.3**	**24.3**	0.76
	RESIDUAL LSTM	**26.9**	63.3	**24.2**	0.76

	MCPG	**39.3**	52.4	**37.2**	**0.81**
	PTS	**40.3**	**48.4**	36.1	**0.80**

Table 6: **Experiments summary.** Symbol '↑' means that higher value is better. Significantly best values are marked in bold. MCPG and PTS outperform state-of-the-art models on OPUSPAR., PAWS and MSRPARA.. Contrary to the supervised baselines, the parameters of the MCPG and PTS models are left unchanged for each dataset.

Train set	*BLEU*	*TER*	*METEOR*	*BERT*
ORIG.	20.7	76.7	21.6	**0.65**
ORIG. + MCPG	**25.3**	**69.6**	24.5	0.63
ORIG. + PTS	25.3	71.1	**24.6**	0.63

Table 7: **Data-augmentation experiment summary**. We trained a TRANSFORMER base model on three versions of the MSRPARAPHRASE set: the original train set (ORIG) and the original train set extended by paraphrasing other sentences from the same distribution with the MCPG (ORIG + MCPG) and PTS (ORIG + PTS) models.

training sets achieved a significant performance gain on BLEU, TER and METEOR.

7 Conclusion

We experimented with two search-based approaches for paraphrase generation. These approaches are pragmatic and flexible. Being generic, our approaches did not overfit on small datasets. We performed extensive experiments with a rigorous evaluation methodology that we applied both on our algorithms and on the other related methods that we tried to reproduce faithfully. These experiments confirm that our two methods, namely MCPG and PTS, are comparable to supervised state-of-the-art baselines despite being less tightly supervised. When compared with CGMH, another search-based and weakly-supervised method, our algorithms proved to be faster and more efficient.

We plan to refine the scoring with deep reinforcement learning techniques and enrich the edition rules with more sophisticated patterns like phrase permutations. Our search algorithms remain slow for a real-time deployment: the current versions are better suited as an offline model for data augmentation. The experiment of Section 6.6 confirms that this application of search-based methods is a promising research avenue. A planning-then-realization hybridization like the one proposed by Moryossef et al. (2019) and Fu et al. (2019) could also be considered for further works.

Word Alignment by Fine-tuning Embeddings on Parallel Corpora

Zi-Yi Dou, Graham Neubig
Language Technologies Institute, Carnegie Mellon University
{zdou,gneubig}@cs.cmu.edu

Abstract

Word alignment over parallel corpora has a wide variety of applications, including learning translation lexicons, cross-lingual transfer of language processing tools, and automatic evaluation or analysis of translation outputs. The great majority of past work on word alignment has worked by performing unsupervised learning on parallel text. Recently, however, other work has demonstrated that pre-trained contextualized word embeddings derived from multilingually trained language models (LMs) prove an attractive alternative, achieving competitive results on the word alignment task even in the absence of explicit training on parallel data. In this paper, we examine methods to marry the two approaches: leveraging pre-trained LMs but fine-tuning them on parallel text with objectives designed to improve alignment quality, and proposing methods to effectively extract alignments from these fine-tuned models. We perform experiments on five language pairs and demonstrate that our model can consistently outperform previous state-of-the-art models of all varieties. In addition, we demonstrate that we are able to train multilingual word aligners that can obtain robust performance on different language pairs. Our aligner, **AWESOME** (**A**ligning **W**ord **E**mbedding **S**paces **O**f **M**ultilingual **E**ncoders), with pre-trained models is available at `https://github.com/neulab/awesome-align`.

1 Introduction

Word alignment is a useful tool to tackle a variety of natural language processing (NLP) tasks, including learning translation lexicons (Ammar et al., 2016; Cao et al., 2019), cross-lingual transfer of language processing tools (Yarowsky et al., 2001; Padó and Lapata, 2009; Tiedemann, 2014; Agić et al., 2016; Mayhew et al., 2017; Nicolai and Yarowsky, 2019), semantic parsing (Herzig and Berant, 2018) and speech recognition (Xu et al., 2019). In particular, word alignment plays a crucial role in many machine translation (MT) related methods, including guiding learned attention (Liu et al., 2016), incorporating lexicons during decoding (Arthur et al., 2016), domain adaptation (Hu et al., 2019), unsupervised MT (Ren et al., 2020) and automatic evaluation or analysis of translation models (Bau et al., 2018; Stanovsky et al., 2019; Neubig et al., 2019; Wang et al., 2020). However, with neural networks advancing the state of the arts in almost every field of NLP, tools developed based on the 30-year-old IBM word-based translation models (Brown et al., 1993), such as GIZA++ (Och and Ney, 2003) or fast-align (Dyer et al., 2013), remain popular choices for word alignment tasks.

One alternative to using statistical word-based translation models to learn alignments would be to instead train state-of-the-art neural machine translation (NMT) models on parallel corpora, and extract alignments therefrom, as examined by Luong et al. (2015); Garg et al. (2019); Zenkel et al. (2020). However, these methods have two disadvantages (also shared with more traditional alignment methods): (1) they are directional and the source and target side are treated differently and (2) they cannot easily take advantage of large-scale contextualized

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2112–2128
April 19 - 23, 2021.

word embeddings derived from language models (LMs) multilingually trained on monolingual corpora (Devlin et al., 2019; Lample and Conneau, 2019; Conneau et al., 2020), which have proven useful in other cross-lingual transfer settings (Libovický et al., 2019; Hu et al., 2020b). In the field of word alignment, Sabet et al. (2020) have recently proposed methods to align words using multilingual contextualized embeddings and achieve good performance even in the absence of explicit training on parallel data, suggesting that these are an attractive alternative for neural word alignment.

In this paper, we investigate if we can combine the best of the two lines of approaches. Concretely, we leverage pre-trained LMs and fine-tune them on parallel text with not only LM-based objectives, but also unsupervised objectives over the parallel corpus designed to improve alignment quality. Specifically, we propose a self-training objective, which encourages aligned words to have further closer contextualized representations, and a parallel sentence identification objective, which enables the model to bring parallel sentences' representations closer to each other. In addition, we propose to effectively extract alignments from these fine-tuned models using probability thresholding or optimal transport.

We perform experiments on five different language pairs and demonstrate that our model can achieve state-of-the-art performance on all of them. In analysis, we find that these approaches also generate more aligned contextualized representations after fine-tuning (see Figure 1 as an example) and we can incorporate supervised signals within our paradigm. Importantly, we show that it is possible to train multilingual word aligners that can obtain robust performance even in zero-shot settings, making them a valuable tool that can be used out-of-the-box with good performance over a wide variety of language pairs.

2 Methods

Formally, the task of word alignment can be defined as: given a sentence $\mathbf{x} = \langle x_1, \cdots, x_n \rangle$ in the source language and its corresponding parallel sentence $\mathbf{y} = \langle y_1, \cdots, y_m \rangle$ in the target language, a word aligner needs to find a set of pairs of source and target words:

$$A = \{\langle x_i, y_j \rangle : x_i \in \mathbf{x}, y_j \in \mathbf{y}\},$$

where for each word pair $\langle x_i, y_j \rangle$, x_i and y_j are semantically similar to each other within the context of the sentence.

In the following paragraphs, we will first illustrate how we extract alignments from contextualized word embeddings, then describe our objectives designed to improve alignment quality.

2.1 Extracting Alignments from Embeddings

Contextualized word embedding models such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) represent words using continuous vectors calculated in context, and have achieved impressive performance on a diverse array of NLP tasks. Multilingually trained word embedding models such as multilingual BERT can generate contextualized embeddings across different languages. These models can be used to extract contextualized word embeddings $h_{\mathbf{x}} = \langle h_{x_1}, \cdots, h_{x_n} \rangle$ and $h_{\mathbf{y}} = \langle h_{y_1}, \cdots, h_{y_m} \rangle$ for each pair of parallel sentences $\mathbf{x}$ and $\mathbf{y}$. Specifically, this is done by extracting the hidden states of the i-th layer of the model, where i is an empirically-chosen hyper-parameter. Given these contextualized word embeddings, we propose two methods to calculate unidirectional alignment scores based on probability simplexes and optimal transport. We then turn these alignment scores into alignment matrices and reconcile alignments in the forward and backward directions.

Probability Thresholding. In this method, for each word in the source/target sentence, we calculate a value on the probability simplex for each word in the aligned target/source sentence, and then select all values that exceed a particular threshold as "aligned" words. Concretely, taking inspiration from attention mechanisms (Bahdanau et al., 2015; Vaswani et al., 2017), we take the contextualized embeddings $h_{\mathbf{x}}$ and $h_{\mathbf{y}}$ and compute the dot products between them and get the similarity matrix:

$$S = h_{\mathbf{x}} h_{\mathbf{y}}^T.$$

Then, we apply a normalization function $\mathcal{N}$ to convert the similarity matrix into values on the probability simplex $S_{\mathbf{xy}} = \mathcal{N}(S)$, and treat $S_{\mathbf{xy}}$ as the source-to-target alignment matrix. In this paper, we propose to use *softmax* and a sparse variant α-entmax (Peters et al., 2019) to do the normalization. Compared with the *softmax* function, α-entmax can produce sparse alignments for any $\alpha > 1$ and assign non-zero probability to a short

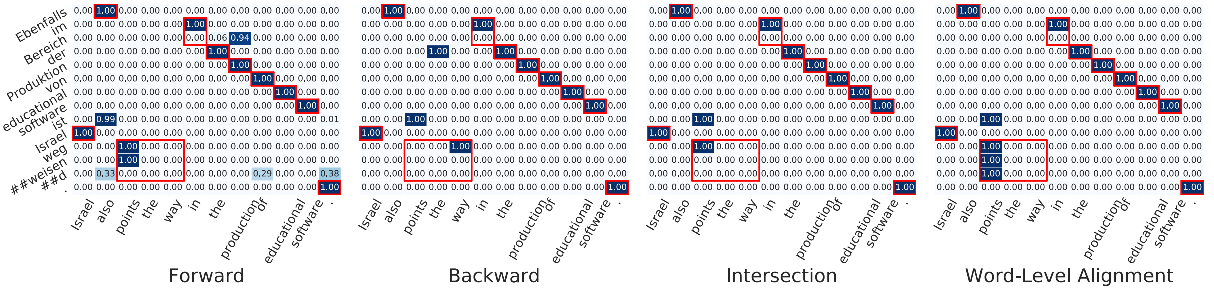

Figure 2: Extracting word alignments from multilingual BERT using probability thresholding (*softmax*). Red boxes denote the gold alignments.

list of plausible word pairs, where a higher α will lead to a more sparse alignment.

Optimal Transport. The goal of optimal transport (Monge, 1781; Cuturi, 2013) is to find a mapping that moves probability from one distribution to another, which can be used to find an optimal matching of similar words between two sequences (Kusner et al., 2015). Formally, in a discrete optimal transport problem, we are given two point sets $\{x_i\}_{i=1}^n$ and $\{y_j\}_{j=1}^m$ associated with their probability distributions $p_{\mathbf{x}}$ and $p_{\mathbf{y}}$ where $\sum_i p_{x_i} = 1$ and $\sum_j p_{y_j} = 1$. Also, a function $C(x_i, y_j)$ defines the cost of moving point x_i to y_j. The goal of optimal transport is to find a mapping that moves probability mass from $\{x_i\}_{i=1}^n$ to $\{y_j\}_{j=1}^m$ and the total cost of moving the mass between points is minimized. In other words, it finds the transition matrix $S_{\mathbf{xy}}$ that minimizes:

$$\sum_{i,j} C(x_i, y_j) S_{\mathbf{xy}_{ij}}, \qquad (1)$$

where $S_{\mathbf{xy}} \mathbf{1}_m = p_{\mathbf{x}}$ and $S_{\mathbf{xy}}^T \mathbf{1}_n = p_{\mathbf{y}}$. The resulting transition matrix is self-normalized and sparse (Swanson et al., 2020), making it appealing alternative towards extracting alignments from word embeddings.

In this paper, we propose to adapt optimal transport techniques to the task of word alignment. Concretely, we treat the parallel sentences $\mathbf{x}$ and $\mathbf{y}$ as two point sets and assume each word is uniformly distributed. The cost function is obtained by computing the pairwise distance (e.g. cosine distance) between $h_{\mathbf{x}}$ and $h_{\mathbf{y}}$, and all the distance values are scaled to [0, 1] with min-max normalization. The optimal transition matrix $S_{\mathbf{xy}}$ to Equation 1 can be calculated using the Sinkhorn-Knopp matrix scaling algorithm (Sinkhorn and Knopp, 1967). If the value of $S_{\mathbf{xy}_{ij}}$ is high, x_i and y_j are likely to have similar semantics and values that exceed a particular threshold will be considered as "aligned".

Extracting Bidirectional Alignments. After we obtain both the source-to-target and target-to-source alignment probability matrices $S_{\mathbf{xy}}$ and $S_{\mathbf{yx}}$ using the previous methods, we can deduce the final alignment matrix by taking the intersection of the two matrices:

$$A = (S_{\mathbf{xy}} > c) * (S_{\mathbf{yx}}^T > c),$$

where c is a threshold and $A_{ij} = 1$ means x_i and y_j are aligned.

Note that growing heuristics such as *grow-diag-final* (Och and Ney, 2000; Koehn et al., 2005) that are popular in statistical word aligners can also be applied in our alignment extraction algorithms, and we will demonstrate the effect of these heuristics in the experiment section.

Handling Subwords. Subword segmentation techniques (Sennrich et al., 2016; Kudo and Richardson, 2018) are widely used in training LMs, thus the above alignment extraction methods can only produce alignments on the subword level. To convert them to word alignments, we follow previous work (Sabet et al., 2020; Zenkel et al., 2020) and consider two words to be aligned if any of their subwords are aligned. Figure 2 shows a concrete example of how we extract word-level alignments from a pre-trained embedding model.

2.2 Fine-tuning Contextualized Embeddings for Word Alignment

While language models can be used to produce reasonable word alignments even without any fine-tuning (Sabet et al., 2020), we propose objectives that further improve their alignment ability if we have access to parallel data.

Masked Language Modeling (MLM). Gururangan et al. (2020) suggest that we can gain improvements in downstream tasks by further pretraining LMs on the task datasets. Therefore, we propose to fine-tune the LMs with a masked language modeling objective on both the source and target side of parallel corpora. Specifically, given a pair of parallel sentences $\mathbf{x}$ and $\mathbf{y}$, we choose 15% of the token positions randomly for both $\mathbf{x}$ and $\mathbf{y}$, and for each chosen token, we replace it with (1) the `[MASK]` token 80% of the time (2) a random token 10% of the time and (3) unchanged 10% of the time. The model is trained to reconstruct the original tokens given the masked sentences $\mathbf{x}^{mask}$ and $\mathbf{y}^{mask}$:

$$L_{MLM} = \log p(\mathbf{x}|\mathbf{x}^{mask}) + \log p(\mathbf{y}|\mathbf{y}^{mask}). \quad (2)$$

Translation Language Modeling (TLM). The MLM objective only requires monolingual data and the model cannot make direct connections between parallel sentences. To solve the issue, similarly to Lample and Conneau (2019), we concatenate parallel sentences $\mathbf{x}$ and $\mathbf{y}$ and perform MLM on the concatenated data. Compared with MLM, the translation language modeling (TLM) objective enable the model to align the source and target representations. Different from Lample and Conneau (2019), we feed source and target sentences twice in different orders instead of resetting the positions of target sentences:

$$\begin{aligned} L_{TLM} &= \log p([\mathbf{x};\mathbf{y}]|[\mathbf{x}^{mask};\mathbf{y}^{mask}]) \\ &+ \log p([\mathbf{y};\mathbf{x}]|[\mathbf{y}^{mask};\mathbf{x}^{mask}]). \end{aligned} \quad (3)$$

Self-training Objective (SO). We also propose a self-training objective for fine-tuning LMs which is similar to the EM algorithm used in the IBM models and the agreement constraints in Tamura et al. (2014). Specifically, at each training step, we first use our alignment extraction methods (described in Section 2.1) to extract the alignment A for $\mathbf{x}$ and $\mathbf{y}$, then maximize the following objective:

$$L_{SO} = \sum_{i,j} A_{ij} \frac{1}{2}\left(\frac{S_{\mathbf{xy}_{ij}}}{n} + \frac{S_{\mathbf{yx}_{ij}}}{m}\right). \quad (4)$$

Intuitively, this objective encourages words aligned in the first pass of alignment to have further closer contextualized representations. In addition, because of the intersection operation during extraction, the self-training objective can ideally reduce spurious alignments and encourage the source-to-target and target-to-source alignments to be symmetrical to each other by exploiting their agreement (Liang et al., 2006).

#Test Sents.	508	447	248	582	450

Table 1: Statistics of datasets.

Parallel Sentence Identification (PSI). We also propose a contrastive parallel sentence identification loss that attempts to make parallel sentences more similar than mismatched sentence pairs (Liu and Sun, 2015; Legrand et al., 2016). This encourages the overall alignments of embeddings on both word and sentence level to be closer together. Concretely, we randomly select a pair of parallel or non-parallel sentences $\langle \mathbf{x}', \mathbf{y}' \rangle$ from the training data with equal probability. Then, the model is required to predict whether the two sampled sentences are parallel or not. The representation of the first `[CLS]` token is fed into a multi-layer perceptron to output a prediction score $s(\mathbf{x}', \mathbf{y}')$. Denoting the binary label as l, the objective function can be written as:

$$L_{PSI} = l \log s(\mathbf{x}', \mathbf{y}') + (1-l)\log(1 - s(\mathbf{x}', \mathbf{y}')). \quad (5)$$

Consistency Optimization (CO). While the self-training objective can potentially improve the symmetricity between forward and backward alignments, following previous work on machine translation and multilingual representation learning (Cohn et al., 2016; Zhang et al., 2019; Hu et al., 2020a), we use an objective to explicitly encourage the consistency between the two alignment matrices. Specifically, we maximize the trace of $S_{\mathbf{xy}}^{\mathrm{T}} S_{\mathbf{yx}}$:

$$L_{CO} = -\frac{\mathrm{trace}(S_{\mathbf{xy}}^{\mathrm{T}} S_{\mathbf{yx}})}{\min(m, n)}. \quad (6)$$

Our Final Objective. In summary, our training objective is a combination of the proposed objectives and we train the model with them jointly at each training step:

$$L = L_{MLM} + L_{TLM} + L_{SO} + L_{PSI} + \beta L_{CO},$$

where β is set to 0 or 1 in our experiments.

3 Experiments

In this section, we first present our main results, then conduct several ablation studies and analyses of our models.

3.1 Setup

Datasets. We perform experiments on five different language pairs, namely German-English (De-En), French-English (Fr-En), Romanian-English (Ro-En), Japanese-English (Ja-En) and Chinese-English (Zh-En). For the De-En, Fr-En, Ro-En datasets, we follow the experimental setting of previous work (Zenkel et al., 2019; Garg et al., 2019; Zenkel et al., 2020). The training and test data for Ro-En and Fr-En are provided by Mihalcea and Pedersen (2003). The Ro-En training data are also augmented by the Europarl v8 corpus (Koehn, 2005). For the De-En data, the Europarl v7 corpus is used as training data and the gold alignments are provided by Vilar et al. (2006). The Ja-En dataset is obtained from the Kyoto Free Translation Task (KFTT) word alignment data (Neubig, 2011), and the Japanese sentences are tokenized with the KyTea tokenizer (Neubig et al., 2011). The Zh-En dataset is obtained from the TsinghuaAligner website[1]. We treat their evaluation set as the training data and use the test set in Liu and Sun (2015). The De-En, En-Fr, Zh-En datasets contain the distinction between sure and possible alignment links. The statistics of these datasets are shown in Table 1. We use the Ja-En development set to tune the hyper-parameters.

Baselines. We compare our models with:

- fast_align (Dyer et al., 2013): a popular statistical word aligner which is a simple, fast reparameterization of IBM Model 2.
- eflomal (Östling and Tiedemann, 2016): an efficient statistical word aligner using a Bayesian model with Markov Chain Monte Carlo (MCMC) inference.
- GIZA++ (Och and Ney, 2003; Gao and Vogel, 2008): an implementation of IBM models. Following previous work (Zenkel et al., 2020), we use five iterations each for Model 1, the HMM model, Model 3 and Model 4.
- SimAlign (Sabet et al., 2020): a BERT-based word aligner that is not fine-tuned on any parallel data. The authors propose three alignment extraction methods and we implement their IterMax model with default parameters.
- Zenkel et al. (2020) and Chen et al. (2020): two state-of-the-art neural word aligners based on MT models.

---

[1] `http://nlp.csai.tsinghua.edu.cn/~ly/systems/TsinghuaAligner/TsinghuaAligner.html`

Implementation Details. Our main results are obtained by using the probability thresholding method on the contextualized embeddings in the 8-th layer of multilingual BERT-Base (mBERT; Devlin et al. (2019)) and we will discuss this choice in our ablation studies. We use the AdamW optimizer (Loshchilov and Hutter, 2019) with a learning rate of 2e-5 and the batch size is set to 8. Following Peters et al. (2019), we set α to 1.5 for α-entmax. The threshold c is set to 0 for α-entmax and 0.001 for *softmax* and optimal transport. Unless otherwise stated, β is set to 0. We mainly evaluate the model performance using Alignment Error Rate (AER).

3.2 Main Results

We first train our model on each individual language pair, then investigate if it is possible to train multilingual word aligners.

Bilingual Model Performance. From Table 2, we can see that our *softmax* model can achieve consistent improvements over the baseline models, demonstrating the effectiveness of our proposed method. Surprisingly, directly extracting alignments from mBERT (the *w/o fine-tuning* setting) can already achieve better performance than the popular statistical word aligner GIZA++ on 4 out of 5 settings, especially in the Zh-En setting where the size of parallel data is small.

Multilingual Model Performance. We also randomly sample 200k parallel sentence pairs from each language pair (except for Zh-En where we take all of its 40k parallel sentences) and concatenate them together to train multilingual word aligners. As shown in Table 2, the multilingually trained word aligners can achieve further improvements and they consistently outperform our bilingual word aligners and all the baselines even though the size of training data for each individual language pair is smaller. The results demonstrate that we can indeed obtain a neural word aligner that has state-of-the-art and robust performance across different language pairs. We also test the performance of our consistency optimization objective in this setting. We can see that incorporating this objective (β=1) can significantly improve the model performance on Ro-En, while it also deteriorates the Ja-En and Zh-En performance by a non-negligible margin. We find that this is because the CO objective can significantly improve the alignment recall while sacrificing the precisions, and our Ro-En dataset tends to favor models with high recall and the Ja-En and Zh-En datasets have an opposite tendency.

	Component	De-En	Fr-En	Ro-En	Ja-En	Zh-En	Speed
Prob.	*softmax*	**17.4**	**5.6**	**27.9**	**45.6**	**18.1**	**33.22**
	α-entmax	18.1	**5.6**	29.0	46.3	18.4	32.36
OT	Cosine	24.4	15.7	33.7	54.0	31.1	3.36
	Dot Product	25.4	17.1	34.1	54.2	30.9	3.82
	Euclidean	20.7	15.1	33.3	53.2	29.8	3.05

Table 3: Comparisons of probability thresholding (Prob.) and optimal transport (OT) for alignment extraction. We try both *softmax* and α-entmax for probability thresholding and different cost functions for optimal transport. We measure both the extraction speed (#sentences/seconds) and the alignment quality (AER) on five language pairs, namely German-English (De-En), French-English (Fr-En), Romanian-English (Ro-En), Japanese-English (Ja-En), and Chinese-English (Zh-En). The best scores are in **bold**.

Zero-Shot Performance. In this paragraph, we want to find out how our models perform on language pairs that it has never seen during training. To this end, for each language pair, we train our model with data of all the other language pairs and test its performance on the target language pair. Results in Table 2 demonstrate that training our models with parallel data on *other* language pairs can still improve the model performance on the target language pair. This is a very important result, as it indicates that our model can be used as a off-the-shelf tool for multilingual word alignment for any language supported by the underlying embeddings, *regardless of whether parallel data has been used for training or not*.

3.3 Ablation Studies

In this part, we compare the performance of different alignment extraction methods, pre-trained embedding models and training objectives.

Alignment Extraction Methods. We first compare the performance of our two proposed alignment extraction methods, namely the probability thresholding and optimal transport techniques. We use the representations of the 8-th layer of mBERT following Sabet et al. (2020).

As shown in Table 3, probability thresholding methods can consistently outperform optimal transport by a large margin on the five language pairs. In addition, probability thresholding methods are much faster than optimal transport. *softmax* is marginally better than α-entmax, yet one advantage of α-entmax is that we do not need to manually set

Model	Layer	De-En	Fr-En	Zh-En
mBERT	7	18.7	6.1	19.1
	8	**17.4**	**5.6**	***18.1***
	9	18.8	6.1	20.1
XLM-15 (MLM)	4	21.1	6.8	**25.3**
	5	**20.4**	**6.1**	26.1
	6	23.2	7.7	33.3
XLM-15 (MLM+TLM)	4	16.4	4.9	**18.6**
	5	***16.2***	***4.7***	23.7
	6	18.8	5.7	26.2
XLM-100 (MLM)	7	20.5	8.5	30.8
	8	**19.8**	**8.2**	**28.6**
	9	19.9	8.8	29.3
XLM-R	5	24.4	10.3	33.2
	6	**23.1**	**9.2**	30.7
	7	24.7	11.5	**28.1**

Table 4: Comparisons of different LMs in terms of AER. We extract alignments using *softmax* and take representations from different layers of LMs. The best scores for each individual model are in **bold** and the overall best scores are in ***italicized bold***.

the threshold. Therefore, we use both *softmax* and α-entmax to obtain the main results.

Pre-trained Embedding Models. In this paragraph, we investigate the performance of three different types of pre-trained embedding models, including mBERT, XLM (Lample and Conneau, 2019) and XLM-R (Conneau et al., 2020). For XLM, we have tried its three released models: 1) XLM-15 (MLM) pre-trained with MLM and supports 15 languages; 2) XLM-15 (MLM+TLM) pre-trained with both the MLM and TLM objectives and supports 15 languages; 3) XLM-100 (MLM) pre-trained with MLM and supports 100 languages. We use *softmax* to extract the alignments.

Because XLM-15 does not support Japanese or Romanian, we only report the performance on the three other language pairs in Table 4. We take representations from different layers and report the performance of the best three layers. We can see that while XLM-15 (MLM+TLM) can achieve the best performance on De-En and Fr-En, the best layer is not consistent across language pairs. On the other hand, the optimal configurations for mBERT are consistent across language pairs. In addition, considering mBERT supports many more languages than XLM-15 (MLM+TLM), we will use mBERT in the following sections.

Training Objectives. We also conduct ablation studies on each of our training objectives. We can see from Table 5 that the self-training objective can best improve the model performance. Also, the translation language modeling and parallel sentence identification objectives can marginally benefit the model. The masked language modeling objective, on the other hand, cannot always improve the model and can sometimes even deteriorate the model performance, possibly because the TLM objective already provides the model with sufficient supervision signals.

3.4 Analysis

We conduct several analyses to better understand our models. Unless otherwise stated, we perform experiments on the *softmax* model using mBERT.

Incorporating Supervised Signals. We investigate if our models can benefit from supervised signals. If we have access to word-level gold labels for word alignment, we can simply utilize them in our self-training objectives. Specifically, we can set A_{ij} in Equation 4 to 1 if and only if they are aligned. In our experimental settings, we have gold labels for all the Zh-En sentences and 653 sentences from the Ja-En development set. Table 6 demonstrates that training our models with as few as 653 labeled sentences can dramatically improve the alignment quality, and combining labeled and unlabeled parallel data can further improve the model performance. This analysis demonstrate the generality of our models as they can also be applied in semi-supervised settings.

Growing Heuristics. As stated in Section 2.1, because our alignment extraction methods essentially take the intersection of forward and backward alignments, growing heuristics can also be applied in our settings. The main motivation of growing heuristics is to improve the recall of the resulting alignments. While effective in statistical word aligners, as shown in Table 7, the growing heuristics only improve our alignment extraction method on the vanilla mBERT model in the Ro-En setting while degrading the model performance on all the other language pairs. After fine-tuning, the growing heuristics can only hurt the model performance, possibly because the self-training objective encourages the forward and backward alignments to be symmetrical. Based on these results, we do not adopt the growing heuristics in our models.

Annotation Projection. Word alignment has been a useful tool in cross-lingual annotation projection (Yarowsky et al., 2001; Nicolai and Yarowsky, 2019). Therefore, it would be inter-

Table 8: Our model is also effective in an annotation projection setting where we train a BERT-based NER model on English data and test it on Spanish data. The best scores are in **bold**.

esting to see if our model can be beneficial in these settings. To this end, we evaluate our model and baselines on cross-lingual named entity recognition (NER). We train a BERT-based NER model on the CoNLL 2003 English data (Tjong Kim Sang and De Meulder, 2003) and test it on the CoNLL 2002 Spanish data (Tjong Kim Sang, 2002). We use Google Translate to translate Spanish test set into English, predict the labels using the NER model, then project the labels from English to Spanish using word aligners. From Table 8, we can see that our model is also better than baselines in this setting, demonstrating its usefulness in cross-lingual annotation projection.

Sentence-Level Representation Transfer. We also test if the aligned representations are beneficial for sentence-level cross-lingual transfer. In doing so, we perform experiments on XNLI (Conneau et al., 2018), which evaluates cross-lingual sentence representations in 15 languages on the task of natural language inference (NLI). We train our models with the provided 10k parallel data on the 15 languages, fine-tune our model on the English NLI data, then test its performance on other languages. As shown in Table 9, our model can outperform the baseline, indicating the aligned word representations can also be helpful for sentence-level cross-lingual transfer.

Table 9: Results of mBERT and our fine-tuned model on XNLI (Conneau et al., 2018). Our objectives can improve the model cross-lingual transfer ability. "*" denotes significant differences using paired bootstrapping ($p<0.05$) .

Alignment Examples. We also conduct qualitative analyses as shown in Figure 1, 2 and 3. After fine-tuning, the learned contextualized representations are more aligned, as the cosine distances between semantically similar words become closer, and the extracted alignments are more accurate. More examples are shown in Appendix B.

4 Related Work

Based on the IBM translation models (Brown et al., 1993), many statistical word aligners have been proposed (Vogel et al., 1996; Östling and Tiedemann, 2016), including the current most popular tools GIZA++ (Och and Ney, 2000, 2003; Gao and Vogel, 2008) and fast_align (Dyer et al., 2013).

Recently, there is a resurgence of interest in neural word alignment (Tamura et al., 2014; Alkhouli et al., 2018). Based on NMT models trained on parallel corpora, researchers have proposed several methods to extract alignments from them (Luong et al., 2015; Zenkel et al., 2019; Garg et al., 2019; Li et al., 2019) and successfully build an end-to-end neural model that can outperform statistical tools (Zenkel et al., 2020). However, there is an inherent discrepancy between translation and word alignment: translation models are directional and the source and target side are treated differently, while word alignment is a non-directional task. Therefore, certain adaptations are required for translation models to perform word alignment.

Another disadvantage of MT-based word aligners is that they cannot easily utilize contextualized embeddings. Using learned representations to improve word alignment have been investigated (Sabet et al., 2016; Pourdamghani et al., 2018). Recently, pre-trained LMs (Peters et al., 2018; Devlin et al., 2019; Brown et al., 2020) have proven to be useful in cross-lingual transfer (Libovickỳ et al., 2019; Hu et al., 2020b). In word alignment, Sabet et al. (2020) propose effective methods to extract alignments from multilingual LMs without explicit training on parallel data. In this work, we propose better alignment extraction methods and combine the best of the two worlds by fine-tuning contextualized embeddings on parallel data.

There are also work on supervised neural word alignment (Stengel-Eskin et al., 2019; Nagata et al., 2020). However, supervised data are not always accessible, making their methods inapplicable in many scenarios. In this paper, we demonstrate that our model can incorporate supervised signals if available and perform semi-supervised learning, which is a more realistic and general setting.

Some work on bilingual lexicon induction also share similar general ideas with ours. For example, Zhang et al. (2017) minimize the earth mover's distance to match the embedding distributions from different languages. Similarly, Grave et al. (2019) present an algorithm to align point clouds with Procrustes (Schönemann, 1966) in Wasserstein distance for unsupervised embedding alignment.

5 Discussion and Conclusion

We present a neural word aligner that achieves state-of-the-art performance on five diverse language pairs and obtains robust performance in zero-shot settings. We propose to fine-tune multilingual embeddings with objectives suitable for word alignment and develop two alignment extraction methods. We also demonstrate its applications in semi-supervised settings. We hope our word aligner can be a tool that can be used out-of-the-box with good performance over various language pairs. Future directions include designing better training objectives and experimenting on more language pairs.

Also, note that we mainly evaluate our word aligners using AER following previous work, which has certain limitations. For example, it may not be well-correlated with statistical machine translation performance Fraser and Marcu (2007) and different types of alignments can be suitable for different tasks or conditions (Lambert et al., 2012; Stymne et al., 2014). Although we have evaluated models in annotation projection and cross-lingual transfer settings, alternative metrics (Tiedemann, 2005; Søgaard and Wu, 2009; Ahrenberg, 2010) are also worth considering in the future.

Ours-Supervised	87.2	**89.8**	**88.5**

Table 10: Our model is also effective in monolingual alignment settings.

A Implementation Details

We use the AdamW optimizer (Loshchilov and Hutter, 2019) with a learning rate of 2e-5 and the batch size is set to 8. Following Peters et al. (2019), we set α to 1.5 for α-entmax. The threshold c is set to 0 for α-entmax and 0.001 for *softmax* and optimal transport. We train our models on one 2080 Ti for one epoch and it takes 3 to 24 hours for the model to converge depending on the size of the dataset. We evaluate the model performance using Alignment Error Rate (AER).

B Analysis

In this section, we conduct more analyses of our models.

Monolingual Alignment. We also investigate how our models perform in monolingual alignment settings. Previous methods (MacCartney et al., 2008; Yao et al., 2013a,b; Sultan et al., 2014) typically exploit external resources such as WordNet to tackle the problem. As shown in Table 10, mBERT can outperform previous methods in terms of recall and F_1 without any fine-tuning. Our multilingually fine-tuned model can achieve better recall and slightly better F_1 score than the vanilla mBERT model, and fine-tuning our model with supervised signals can achieve further improvements.

Sensitivity Analysis. We also conduct a sensitivity analysis on the threshold c for our *softmax* alignment extraction method. As shown in Table 11, our method is relatively robust to this threshold. In particular, after fine-tuning, the AERs change within 0.5% when varying the threshold.

Comparisons with IterMax. IterMax is the best alignment extraction method in SimAlign (Sabet et al., 2020). The results in the main paper have demonstrated that our alignment extraction methods are able to outperform IterMax. In Figure 4, we can see that the IterMax algorithm tends to sacrifice precision for a small improvements in recall, while our model can generate more accurate alignments.

Model	c.	De-En	Fr-En	Ro-En	Ja-En	Zh-En
mBERT	1e-6	17.3	6.0	27.2	45.2	18.9
	1e-5	17.3	5.9	27.4	45.1	18.6
	1e-4	17.3	5.7	27.6	45.3	18.3
	1e-3	17.4	5.6	27.9	45.6	18.1
	1e-2	17.7	5.6	28.4	45.8	18.2
	1e-1	18.1	5.6	28.9	46.3	18.3
	5e-1	18.4	5.6	29.5	47.0	18.7
Ours-Multilingual	1e-6	15.4	4.6	22.7	38.2	14.1
	1e-5	15.4	4.5	22.7	38.1	14.0
	1e-4	15.3	4.5	22.6	37.9	13.9
	1e-3	15.3	4.4	22.6	37.9	13.8
	1e-2	15.3	4.3	22.7	37.9	13.8
	1e-1	15.4	4.3	22.8	38.0	13.8
	5e-1	15.4	4.2	23.0	38.2	13.9

Table 11: Our *softmax* alignment extraction method is relatively robust to the threshold c.

Ablation Studies on Training Objectives. Table 12 presents more ablation studies on our training objectives. We can see that the self training objective is the most effective one, with the translation language modeling objective being the second and the parallel sentence identification objective being the third. The masked language modeling objective can sometimes hurt the model performance, possibly because of the translation language modeling objective.

Experiments on More Language Pairs. We also test our alignment extraction methods on other language pairs following the setting of Sabet et al. (2020) without fine-tuning as shown in Table 13.[2]

More Qualitative Examples. In addition to the examples provided in the main text, we also present some randomly sampled samples in Figure 5. We can clearly see that our model learns more aligned representations than the baseline model.

Abstract

Many types of distributional word embeddings (weakly) encode linguistic regularities as directions (the difference between *jump* and *jumped* will be in a similar direction to that of *walk* and *walked*, and so on). Several attempts have been made to explain this fact. We respond to Allen and Hospedales' recent (ICML, 2019) theoretical explanation, which claims that word2vec and GloVe will encode linguistic regularities whenever a specific relation of *paraphrase* holds between the four words involved in the regularity. We demonstrate that the explanation does not go through: the paraphrase relations needed under this explanation do not hold empirically.

1 Introduction

The study of linguistic regularities in distributional word embeddings—that the difference vector calculated between the vectors *jump* and *jumped* shows a similar direction to that of *walk* and *walked*, and so on—has been both stimulating and controversial. While a number of such regularities appear to hold, across a number of different kinds of embeddings, the standard 3COSADD analogy test used to measure the presence of these regularities has come under fire for confounding analogical regularities with unrelated properties of semantic embeddings. It is thus important to note that several papers have proposed theoretical explanations for why linguistic regularities *should* hold in distributional word embeddings. Particularly in light of the controversies over linguistic regularities, it is important to examine the soundness of these arguments.

Allen and Hospedales (2019) develop such an explanation by linking the semantic definition of an analogy to *paraphrases.* In the sense of Gittens et al. (2017), paraphrases are sets of words which are semantically and distributionally closely equivalent to another word or set of words—for example, *king* may be paraphrased by $\{$*man*, *royal*$\}$. Allen and Hospedales argue that the standard analogy criterion, that *king* - *man* + *woman* = *queen*, is equivalent to a criterion whereby $\{$*king*, *woman*$\}$ paraphrases $\{$*man*, *queen*$\}$. With this in mind, it becomes possible to rewrite the arithmetic analogy criterion in terms of vectors encoding the pointwise mutual information (PMI) between words and their contexts, and to decompose the error in the analogy equality into several components, including a *paraphrase error* term measuring the degree to which the critical paraphrase holds. Making use of an assumption that the word2vec embedding is a linear transformation of the PMI matrix, they argue that results in terms of PMI apply to word vectors. Thus, under their explanation, a major part of success on an analogy $a - a^* + b^* = b$ is due to a, b^* and a^*, b being close distributional paraphrases.

We first review the literature on the analogy test itself, underlining known pitfalls which any explanation of linguistic regularities must navigate. We then show empirically that the relation between the PMI matrix and word2vec embeddings is to some degree linear, which may be enough to satisfy the assumption of Allen and Hospedales (2019). We further examine the proposed decomposition into error terms. We demonstrate that, empirically, these error terms tend to be undefined due to data sparseness, undermining their explanatory force. Most importantly, examining a number of analogies which pass the standard test, we show that the critical paraphrase error term is, contrary to the proposed explanation, very large.[1]

2 Related work

Early works proposing explanations of the analogical properties of word embeddings include Mikolov et al. (2013b) and Pennington et al. (2014). A geometrical explanation is proposed by Arora et al. (2016), but this explanation relies on very strong preconditions, notably, that the word vectors be distributed uniformly in space. Ethayarajh et al. (2019) also propose an explanation, providing a link between the PMI and the norm of word embeddings. However, as pointed out by Allen and Hospedales (2019), this explanation, too, rests on strong assumptions. Notably, the words involved in the analogy are required to be coplanar, a property that seems unlikely in light of the lack of parallelism we discuss in the next section.

3 Issues with the test

Issues have arisen with the standard way of measuring linguistic analogies. Levy and Goldberg (2014a), Vylomova et al. (2016), Rogers et al. (2017), and Fournier et al. (2020) all demonstrate that the standard 3CosAdd measure conflates several very different properties of embeddings, simultaneously measuring not only the directional regularities suggested by typical illustrations of vectors in a parallelogram, but also the similarity of individual matched pairs such as *king, man*, as well as the global arrangement of vectors in semantic fields, such as *king, queen, prince, …* versus *man, woman, child, …* in distinct regions of the space. These issues undermine the construct validity of the standard analogy test. This conflation of properties explains certain pathological behaviours of the test (Linzen, 2016; Rogers et al., 2017). In spite of these issues, Fournier et al. (2020) demonstrate, using alternative measures, that linguistic regularities are nevertheless coded by directional similarities. This parallelism is weak, with directions tending to be closer, in the absolute, to being orthogonal than to being parallel, but is present above chance level (unmatched word pairs).

Thus, before turning to Allen and Hospedales (2019), one of a number of theoretical attempts to explain performance on the 3CosAdd objective, we underscore that such demonstrations run the risk of explaining properties of the test which may be of secondary interest, or, conversely, of placing undue emphasis on the role of directional regularities, which have been shown to play only a small role in success on 3CosAdd.

4 Explaining analogies through paraphrases

For a word w_i and a word c_j which can appear in the context of w_i, the pairwise mutual information $PMI(w_i, c_j)$ is defined as $\log \frac{p(w_i,c_j)}{p(w_i)p(c_j)}$. As shown by Levy and Goldberg (2014b), skip-gram word2vec with negative sampling factorizes the PMI: PMI $\approx W^\top \cdot C$, with W and C the word and context embedding matrices of a word2vec model.

For two pairs of words (a, a^*) and (b, b^*) from the same semantic relation, the standard arithmetic analogy test criterion is that $a - a^* + b^* = b$. Writing $\mathcal{W} = \{a, b^*\}, \mathcal{W}_* = \{a^*, b\}$, and $\mathbf{PMI}_x$ the PMI vector of x, Allen and Hospedales (2019) show that is possible to rewrite the arithmetic analogy formula with PMI vectors, and to decompose the error in the equality into five terms as follows:

$$\begin{aligned}\mathbf{PMI}_{b^*} =& \mathbf{PMI}_b + \mathbf{PMI}_{a^*} - \mathbf{PMI}_a \\ &+ \underbrace{\rho^{\mathcal{W},\mathcal{W}_*}}_{\text{Paraphrase error}} + \underbrace{\sigma^{\mathcal{W}} - \sigma^{\mathcal{W}_*}}_{\text{Conditional dependence error}} \\ &+ \underbrace{(\tau^{\mathcal{W}} - \tau^{\mathcal{W}_*})\mathbf{1}}_{\text{Mutual dependence error}}\end{aligned} \tag{1}$$

The error terms are vectors of length $|\mathcal{V}|$ (vocabulary size), with each element j defined as:

$$\begin{aligned}\rho^{\mathcal{W},\mathcal{W}_*} &= \log \frac{p(c_j|\mathcal{W}_*)}{p(c_j|\mathcal{W})} \\ \sigma^{\mathcal{W}} &= \log \frac{p(\mathcal{W}|c_j)}{\prod_{\mathcal{W}} p(w_i|c_j)} \\ \tau^{\mathcal{W}} &= \log \frac{p(\mathcal{W})}{\prod_{\mathcal{W}} p(w_i)}\end{aligned} \tag{2}$$

The authors claim that these terms can be embedded linearly into a word2vec embedding space by multiplying them by the Moore-Penrose pseudo-inverse $C^\dagger$ of the context matrix C. Then with $\mathbf{w}_x$ the word2vec embedding of x, $C^\dagger \cdot \mathbf{PMI}_x \approx \mathbf{w}_x$. Thus we get the final decomposition:

$$\begin{aligned}\mathbf{w}_{b^*} =& \mathbf{w}_b + \mathbf{w}_{a^*} - \mathbf{w}_a + \\ & C^\dagger \left(\rho^{\mathcal{W},\mathcal{W}_*} + \sigma^{\mathcal{W}} - \sigma^{\mathcal{W}_*} - (\tau^{\mathcal{W}} - \tau^{\mathcal{W}_*})\mathbf{1}\right)\end{aligned} \tag{3}$$

The paraphrase error term is claimed to be small for successful analogies. Elaborating on the notation, $\mathcal{W}$ is taken to paraphrase $\mathcal{W}_*$ if, wherever all $w \in \mathcal{W}$ appear together, we observe the same distribution of surrounding words as for $\mathcal{W}_*$. The paraphrase error assesses the similarity of the distributions of words in the context of $\mathcal{W}$ (all words in $\mathcal{W}$ appearing together) versus $\mathcal{W}_*$.

5 Linearity of the link between PMI and word2vec

Though it is true that there is a relation between the word2vec matrices $W^\top \cdot C$ and the PMI matrix, in practice the link is more complicated than simple linear matrix factorization, due in part to the training tricks described in Mikolov et al. (2013a). The result of Allen and Hospedales (2019) requires that the embedding from PMI vectors to word2vec embeddings be "linear enough" for $C^\dagger\cdot$ PMI to approximate W.

To assess this, we use the *text8* corpus [2] both to train word2vec embeddings [3] and to estimate a PMI matrix. We replace infinite values in the PMI matrix by 0. In Figure 1a, we show the distribution of the Pearson correlation coefficient (assessing the presence of a linear relation) between the word2vec embedding and the corresponding row of $C^\dagger\cdot$ PMI for the top ten thousand words in the corpus. As can be seen from the figure, the correlation tends to be between 0.5 and 0.8. For instance in Figure 1b, the word2vec embedding for *king* is plotted against the row of $C^\dagger\cdot$ PMI corresponding to *king*.

While the relation is not perfectly linear—many words have a correlation of around 0.55, far lower than that of *king*—the empirical relations shown here leave open the possibility that it may indeed be "sufficiently linear" to be taken for granted. However, while linearity is necessary for the result of Allen and Hospedales (2019) to go through, it is not sufficient. In the next section, we assess the critical question of whether the paraphrase error is small enough to serve as an explanation for the success of linguistic analogies.

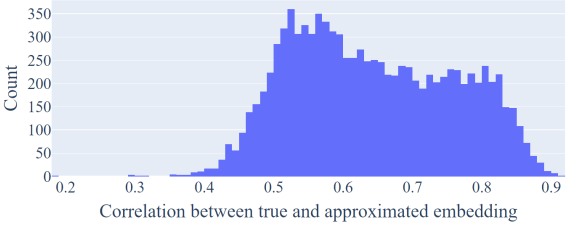

Figure 1a: Histogram of the Pearson correlations between true and approximated word2vec embeddings for the top ten thousand words in the *text8* corpus. The mean value is 0.643 and the variance is 0.014.

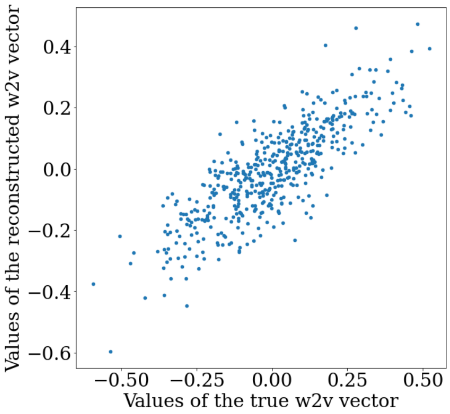

Figure 1b: Plot of the values of the word2vec embedding for *king*, versus coefficients for the row of $C^\dagger\cdot$ PMI corresponding to *king*, for word2vec matrices trained on the same corpus (*text8*). The Pearson correlation is one of the best possible at 0.825.

6 Empirical analysis of the error terms

We now seek to examine the proposed explanation by calculating the proposed error terms empirically. However, in practice, many of the terms are undefined, since they rely on cooccurrences unattested in practical corpora. The most extreme situation occurs when the two words of a paraphrase $\mathcal{W} = \{w_1, w_2\}$ are *never* present in the same context window in the corpus. We found that only 16% of the paraphrase sets associated with the BATS analogy set (Gladkova et al., 2016)—for example, *king, woman*—were present together in the *text8* corpus in a context window of length five. We refer to such paraphrase sets as "well-defined" with respect to the corpus. The problem of zero co-occurrence counts was anticipated by Allen and Hospedales (2019), who propose to restrict their analysis to the case where the context window is sufficiently large that all relevant terms are well defined. We stress that our trained word2vec vectors are also trained with a context window of five, and yield expected levels of performance on the BATS analogy test, despite having access to little training data on which to model co-occurrences such as *king, woman*, *queen, man*, and so on.

At a minimum, if the proposed explanation holds, the cases for which the error terms are empirically well-defined should show signs of the paraphrase

Table 2: For an analogy equivalent to two paraphrases $\mathcal{W}$ and $\mathcal{W}_*$, the rank of $\mathcal{W}_*$ in the list of the closest paraphrases to $\mathcal{W}$ with respect to the L2 norm of the paraphrase error vector. 7762K means a rank of 7762000, rounded to the nearest thousand.

error being relatively small. We now detail how we implemented the error terms in cases for which they were well-defined. We count co-occurrences $N(w_i, w_j, w_k)$ in *text8* for all triplets of words w_i, w_j, w_k, with w_k at the center of the context window, and $W = \{w_i, w_j\}$ any paraphrase, both occurring anywhere within a context window of width five. We restrict analysis to the ten thousand most frequent word types w_i and w_j, yielding 10^8 possible paraphrases.[4] We use the relative frequencies as estimators of $p(w_k|\{w_i, w_j\})$ and $p(\{w_i, w_j\}|w_k)$, and marginalize to obtain $p(w_i|w_k)$, $p(\{w_i, w_j\})$ and $p(w_k)$. The error terms follow. Since this can still lead to ill-defined elements, we replace $log(+\infty)$ and $log(0)$ by $+/-log(\epsilon)$, with $\epsilon = 10^{-15}$ (within reason, the value of ϵ is immaterial). We also replace $log(0/0)$ with 0.

Table 1 shows the mean and median values of the L2 norms of the paraphrase error vectors across several categories of the BATS dataset. We compare them with the sum of the four dependence error terms (the dependence error reflects statistical dependencies within $\mathcal{W}$ and $\mathcal{W}_*$ irrelevant to the analogy), as well as the sum of all five error terms (equal to the difference between the PMI of $\mathcal{W}$ and $\mathcal{W}_*$).The paraphrase error is indeed smaller than the other error terms. However, as we now show, the paraphrase error is not small *enough* to contribute substantially to the success of analogies.[5]

Take the norm of the paraphrase error vector ρ as a measure of the divergence in the PMI between two paraphrases. For an analogy with associated paraphrases $\mathcal{W}$ and $\mathcal{W}_*$, we assess how many paraphrases are closer to $\mathcal{W}$ than to $\mathcal{W}_*$ by calculating the rank of the norm of $\rho^{\mathcal{W},\mathcal{W}_*}$ among all $\rho^{\mathcal{W},\mathcal{X}}$, where $\mathcal{X}$ spans over all pairs of words constructible from the top ten thousand most frequent words in the corpus. To do so, we define a Paraphrase Conditional Information matrix (PCI). For $W_{ij} = \{w_i, w_j\}$ and w_k, we define $PCI(l_{ij}, k)$, the value at column l_{ij} and row k to be $log(p(W_{ij}|w_k))$, where with l_{ij} is a unique index associate with tuple (i, j). We compute only the positive PCI, to obtain a sparse matrix. The difference between two PCI columns is a paraphrase error vector, and their Euclidean distance is the norm of the paraphrase error.

We now compute, for each analogy, the distance between the PCI column of $\mathcal{W}$ and every other column (paraphrase) of the PCI matrix. We calculate the rank of the true analogy pair $\mathcal{W}_*$. Given that the analogy test generally succeeds in picking out b as being the most similar to $a - a^* + b^*$ out of the entire vocabulary (modulo Linzen 2016), we would expect that, for successful analogies, the paraphrase error for the true analogy would be among the highest, if small paraphrase error were the explanation for success. Table 2 displays the mean of this rank within each BATS category. The rank is extremely low (in the millions), making the paraphrase error in true analogies far too high to be the explanation for their success.[6]

---

[4] w_k is allowed to vary over all of the types included in the training for word2vec, of which there are 71290. Thus, for each paraphrase, the error vectors have 71290 elements, one for each vocabulary word.

[5] We note also that the error values seem relatively consistent between categories, while success on the analogy test varies differ greatly between categories.

[6] Limiting the search to the paraphrases composed by at least one of the words of W_* still results in a very low rank

7 Conclusion

Recent work has shown that, in spite of the standard analogy test's confound with simple vector similarity, distributional word vectors genuinely do encode linguistic regularities as directional regularities above and beyond vector similarity (Fournier et al., 2020), further research is warranted into the mechanisms by which distributional word embeddings come to show these regularities. However, the analysis of analogies as paraphrases does not hold up as an explanation of performance on the analogy test—nor would an explanation of performance on the 3COSADD analogy test be a satisfying result, since the test is not a useful measure to begin with.

Abstract

Guessing games are a prototypical instance of the "learning by interacting" paradigm. This work investigates how well an artificial agent can benefit from playing guessing games when later asked to perform on novel NLP downstream tasks such as Visual Question Answering (VQA). We propose two ways to exploit playing guessing games: 1) a supervised learning scenario in which the agent learns to mimic successful guessing games and 2) a novel way for an agent to play by itself, called Self-play via Iterated Experience Learning (SPIEL). We evaluate the ability of both procedures to generalise: an in-domain evaluation shows an increased accuracy (+7.79) compared with competitors on the evaluation suite CompGuessWhat?!; a transfer evaluation shows improved performance for VQA on the TDIUC dataset in terms of harmonic average accuracy (+5.31) thanks to more fine-grained object representations learned via SPIEL.

1 Background & Related Work

Learning a language requires interacting with both the environment and other agents (Bisk et al., 2020). Language games represent one common example of this (Wittgenstein et al., 1953), as seen by the important role of play in L1 child language acquisition (Hainey et al., 2016) as well as L2 learners (Godwin-Jones, 2014).

Among the language games defined in the literature (Steels, 2015), *guessing games* represent the first step in a curriculum for language learning. For example, in GuessWhat?! (de Vries et al., 2017), two agents interact with each other: a *Questioner* generates questions aimed at finding a hidden object in the scene and an *Oracle*, aware of the target object, answers the questions supporting the Questioner in playing the game. Different from other language games (Das et al., 2017), guessing games have a specific goal which represents a clear incentive for learning. In addition, they require that the *Questioner* masters both natural language generation and understanding with a focus on object categories and attributes. For humans, concepts learned in this way are generic and generalisable to new tasks and domains where grounded reasoning is important (Hampton, 1979). However, *how well can AI agents generalise with concepts acquired from visual guessing games?*

The literature has not explored if representations built from self-play are transferable, focusing instead on large scale self-supervised learning. For instance, large scale image captioning datasets have been used to train multi-modal Transformers (Lu et al., 2019; Li et al., 2019; Tan and Bansal, 2019; Chen et al., 2019). Multi-task learning (Lu et al., 2020) has been used to leverage the diversity of training signals provided combining datasets, but only for discriminative tasks. While some dialogue work (Cogswell et al., 2020) aims to bootstrap a conversing agent from VQA datasets, most work on GuessWhat?! (de Vries et al., 2017; Shekhar et al., 2019; Strub et al., 2017) has designed bespoke models for the task, ignoring the utility of this dataset for other Vision+Language tasks.

We propose self-play as a mechanism for learning general grounded representations. We seed our approach with the *GuessWhat?!* corpus of questions and objects, and demonstrate how to generalise to other downstream tasks. We propose two different strategies to exploit these data. First, a supervised learning phase is undertaken to learn a Questioner and Oracle model able to play guessing games. Second, the trained agents can be used to play guessing games on images requiring only object annotations as supervision. We show that an agent trained on GuessWhat?! dialogues can use self-play to adapt to new and harder tasks. Specifically, we investigate models' gener-

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2135–2144
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

alisation performance and quality of the learned representations on the CompGuessWhat?! benchmark (Suglia et al., 2020), a more extensive evaluation suite for GuessWhat?!. Furthermore, we study how the learned representation help solve VQA on the dataset TDIUC (Kafle and Kanan, 2017). We show overall comparable performance with state-of-the-art models and improvements for specific question types that require object attribute information to be answered correctly.

2 Methodology

Our proposed transfer/fine-tuning procedure requires a training set of guessing games D_g from which we learn a Questioner Q and an Oracle O via supervised learning. Given a set of images $\mathcal{I}$, it is possible to use the trained models Q and O to run the self-play procedure for n epochs obtaining the model Q^n. Finally, given a downstream task t and an associated dataset $\mathcal{D}_t$ based on images from $\mathcal{I}$, we use Q^n's parameters as initialisation for the training procedure on $\mathcal{D}_t$.

To apply this procedure, both the *Questioner* and the *Oracle* require a *multi-modal encoder* Γ able to generate d-dimensional representations for the textual tokens $\mathbf{h}_t$, for the objects $\mathbf{h}_o$, as well as fusing the visual and textual modalities in a representation of the current context $\mathbf{h}_c$. After the self-play procedure, only the encoder Γ of the model Q^n is used in the fine-tuning process on the downstream task t using the dataset $\mathcal{D}_t$. It is important to underline that the presented self-play procedure does not depend on a specific implementation of the multi-modal encoder Γ. A possible implementation is presented in Section 2.4 and it is used in the experimental evaluation of this paper.

2.1 Oracle design

The Oracle task is cast as a Visual Question Answering (VQA) task conditioned on the image I, the current question q and on the target object $\hat{o}$. We follow common practice in vocabulary-based VQA (Antol et al., 2015) and we treat the problem as a multi-class classification task over the classes $\{Yes, No, N/A\}$. We use $\mathbf{h}_c$ as input to a multi-layer feedforward neural network to obtain a probability distribution over the label set.

2.2 Questioner design

The Questioner must play two roles: question generation and target object prediction (de Vries et al., 2017). It is beneficial to jointly learn the two tasks because the representations learned by each task are complementary. In addition, they better encode attributes, which favours better generalisation to unseen object categories (Suglia et al., 2020).

To solve the two specific tasks in a multi-task fashion, we design two different heads on top of the shared encoder Γ: 1) the *guesser head*, produces a probability distribution over every object o_i using the encoded representations $\mathbf{h}_{o_i}$ passed through an MLP; 2) the *generator head*, a multi-modal decoder, also implemented as an MLP, which predicts a probability distribution over the vocabulary V given the context representation generated by Γ.

We include two losses in our model: 1) the negative log-likelihood of the probability associated by the guesser head with the target object $\hat{o}$ (Shekhar et al., 2019); 2) a sequence-to-sequence cross-entropy loss (Sutskever et al., 2014) for the generated question tokens. Unlike previous work that trains a separate module to learn to stop (Shekhar et al., 2018), we add a special token `[STOP]` to the input data so that it learns when to stop more efficiently as part of the question generation task.

Training an agent to solve tasks of different complexity and size is challenging. The procedure presented in (Shekhar et al., 2019) alternates between tasks, updating the hardest task more often. For this technique, finding the right schedule is cumbersome and requires fine-tuning. We rely on a more systematic training procedure based on random dataset-proportional batch sampling inspired by (Sanh et al., 2019). This represents a hard-parameter sharing multi-task training procedure that avoids interference between tasks and favours a more stable training, which mitigates catastrophic forgetting (French, 1999).

2.3 Self-Play via Iterated Experience Learning (SPIEL)

Inspired by iterated learning (Kirby et al., 2014), we design a process by which the Questioner learns from games previously generated by other instances of the Questioner agent. We call our training procedure *Self-play via Iterated Experience Learning* (SPIEL).

In SPIEL, described in Algorithm 1, we assume access to a set of images $\mathcal{I}$ and the bounding boxes $\mathcal{O}_I$ of the objects therein.[1] In every gameplay, there

---

[1] Object annotations intended as either gold bounding boxes or predicted bounding boxes from an object detector.

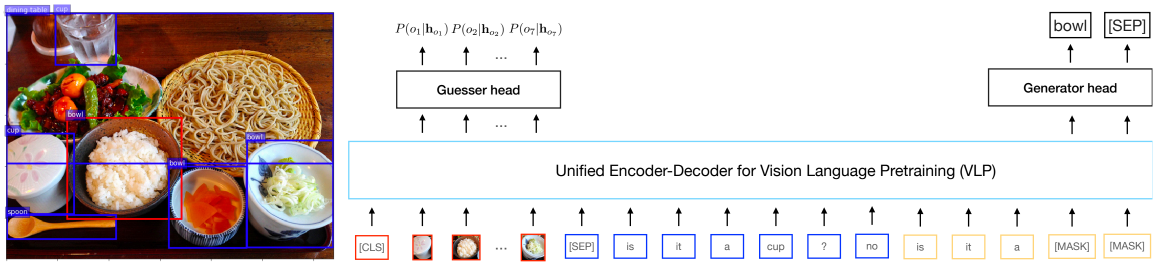

Figure 1: We use the single-stream VLP model as a backbone multi-modal encoder for our task. The visual features tokens (marked in red) are the FastRCNN features associated with the objects in the image, the history tokens (marked in blue) and the tokens to be generated (marked in yellow) are given in input to the model. A *Guesser head* uses the learned contextual object representations to generate a probability distribution over the objects $P(o_i|\mathbf{h}_{o_i})$, whereas the *Generator head* is used to incrementally predict the masked tokens.

Algorithm 1 SPIEL: Self-Play via Iterated Experience Learning

```
procedure SELF_PLAY($Q_0, O, \mathcal{I}, n$)
    $\mathcal{D}_q \leftarrow$ READ_GOLD_GAMES()
    $\mathcal{E}_g \leftarrow []$                    ▷ Initialise the experience buffer
    for $e \leftarrow 1, n$ do
        ▷ Interactive phase
        $Q \leftarrow Q^e$                         ▷ load latest weights
        $\mathcal{G}^e \leftarrow$ GENERATE_GAMES($\mathcal{I}$)
        $\mathcal{G}^e \leftarrow$ PLAY_GAMES($Q, O, \mathcal{G}^e$)
        APPEND($\mathcal{E}_g, \mathcal{G}^e$)
        $\mathcal{D}^e_g \leftarrow []$
        ▷ Transmission phase
        for $i \leftarrow 0, len(\mathcal{E}_g)$ do
            $g \leftarrow \mathcal{E}_g[i]$             ▷ Priority to the latest games
            if IS_VALID_GAME($g$) then
                APPEND($\mathcal{D}^e_g, g$)
            if LEN($\mathcal{D}^e_g$) == LEN($\mathcal{D}_q$) then break
        ▷ Learning phase
        $Q^{e+1} \leftarrow$ TRAIN($Q, \mathcal{D}_q, \mathcal{D}^e_g$)
```

is a Questioner Q and an Oracle O, initialised with agents Q^0 and O, respectively, that were trained with Supervised Learning using gold successful dialogues.[2] We consider every iteration e of the algorithm as a *self-play* epoch. In a single self-play epoch, we alternate 3 phases:

Interactive phase: the agents play guessing games with novel combinations of image and target object. The generated dialogue can be successful if the predicted target object is equal to the target object. Every played dialogue is stored in an experience buffer $\mathcal{E}_g$.

Transmission phase: in this phase the datasets for the multi-task learning procedure for the Questioner are created. The generator head dataset $\mathcal{D}_q$ is fixed in advance while the dataset for the guesser head $\mathcal{D}^e_g$ is created from the experience buffer $\mathcal{E}_g$ by selecting the *unique* and *valid* dialogues.

Learning phase: the same multi-task learning procedure used in the supervised learning phase is used to fine-tune the Questioner parameters using the datasets $\mathcal{D}^e_g$ and $\mathcal{D}_q$ collected for the current epoch e. This procedure is repeated n times or until a halting condition is reached (e.g. early stopping based on validation metric).

See Appendix A.1 for implementation details. At the end of the SPIEL procedure, we obtain the model Q^n whose parameters can be reused in other tasks. Particularly, we use the parameters of Q^n's shared encoder Γ as initialisation for the fine-tuning on the downstream task t using dataset $\mathcal{D}_t$.

2.4 Implementation

We implement a shared multi-modal encoder Γ using VLP (Zhou et al., 2020), a single-stream multi-modal Transformer for captioning depicted in Figure 1. During the GuessWhat?! fine-tuning, we extend VLP by including dialogue context in the input together with the features associated with the objects in the image. We learn two new segment ids to represent the question/answer exchanges in the dialogue, as described in (Wolf et al., 2019). The question is generated by incrementally replacing `[MASK]` tokens until the end of sequence is generated. See Appendix A.2 for more details. SPIEL training is run on a set of images $\mathcal{I}$ from GuessWhat?! and TDIUC dataset with corresponding object annotations. We make sure that GuessWhat?! test images are not contained in $\mathcal{I}$. This is not an issue for TDIUC test images because the downstream task annotations (QA pairs) are not used by the model during this phase. Once the model has been trained with SPIEL, we use the parameters of the shared encoder Γ as a backbone for a VQA model that is fine-tuned on the TDIUC dataset.

---

[2] The Oracle is fixed during this learning procedure.

3 Experimental Evaluation

To assess the generality of our learned representations, we include two evaluation paradigms: 1) *in-domain evaluation* and 2) *transfer evaluation*. We evaluate several variants of our model: 1) VLP-SL: VLP-based model trained on GuessWhat?! data using multi-task learning; 2) SPIEL-gs: VLP-SL model fine-tuned with our SPIEL procedure where the generator head uses only gold successful games (gs); 3) SPIEL-gm: same as 2) but both successful and failed gold games are used by the generator head. In both SPIEL variants, the guesser head is trained using failed and successful generated games because it is important for the guesser head to be exposed to both types of signal to learn a more robust policy. We decided to investigate the two variants SPIEL-gs and SPIEL-gm to get more insights about the effect that successful and failed games have on the generator head ability to produce effective dialogues.

3.1 In-domain evaluation

We use the CompGuessWhat?! evaluation suite (Suglia et al., 2020) to assess the ability of the Questioner to play guessing games and learn visually grounded representations in the process. It complements an evaluation based only on gameplay accuracy (de Vries et al., 2017) with 2 auxiliary tasks: target object 1) attribute-prediction expressed in terms of abstract attributes (A), situated-attributes (SO), abstract+situated attributes (AS), and location attributes (L); 2) zero-shot gameplay with near-domain accuracy (ND) and out-of-domain accuracy (OD). Table 1 shows the comparison with previous state-of-the-art models on this benchmark such as de Vries et al. (2017) (DV-⋆) and Shekhar et al. (2019) (GDSE-⋆). VLP-SL has a greater advantage in terms of representation power compared to previous models. This is reflected in all the tasks of the CompGuessWhat?! evaluation. Particularly, we see better performance even for the zero-shot gameplay (ND: +5.6, OD: +15.2). This is because VLP associates a vector of probabilities that represents a distribution over the VisualGenome object classes with every object. This helps VLP to cope with the issue of unseen objects and helps the model to generalise. Learning to play is key to gameplay performance, leading to an increase of +4.4 over VLP-SL and +7.9 over GDSE-CL. In this setup, the difference between the versions SPIEL-gs and SPIEL-gm is very minimal (0.1). However, when analysed in more detail, we can see that training the questioner with gold successful data only improves attribute prediction while using mixed data improves overall generalisation in the zero-shot evaluation.

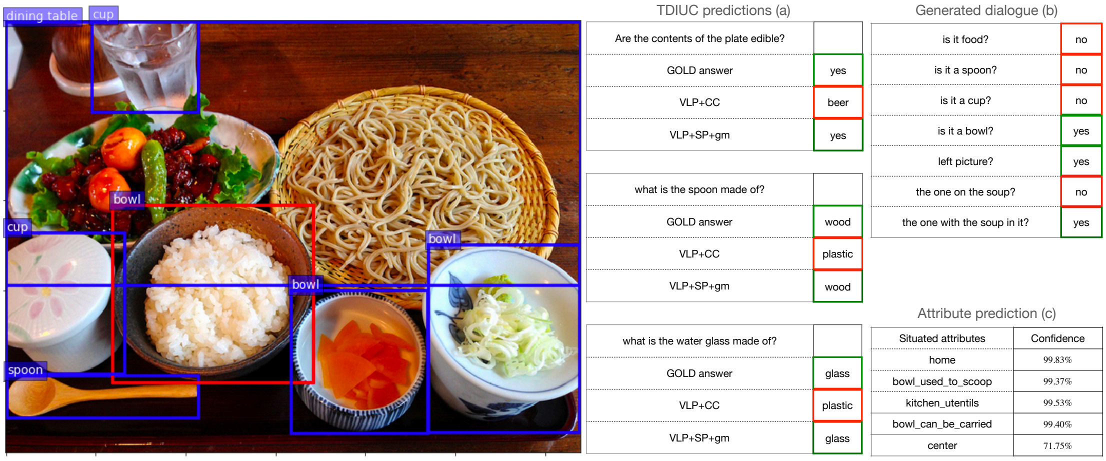
		Attribute Pred.				ZShot		Score
Models	Acc.	A	SO	AS	L	ND	OD	
Random	15.8	15.1	0.1	7.8	2.8	16.8	18.6	13.3
DV-SL	41.5	46.8	39.1	48.5	42.7	31.3	28.4	38.5
DV-RL	53.5	45.2	38.9	47.2	43.5	43.9	38.7	46.2
GDSE-SL	49.1	59.9	47.6	60.1	48.3	29.8	22.3	43.0
GDSE-CL	59.8	59.5	47.6	59.8	48.1	43.4	29.8	50.1
VLP-SL	59.5	59.2	48.2	59.7	49.3	49.0	45.0	53.5
SPIEL-gs	64.1	**61.3**	**49.6**	**61.6**	**51.1**	54.9	51.9	57.8
SPIEL-gm	**64.6**	60.8	48.3	59.5	51.0	**55.3**	**52.9**	**57.9**

Table 1: F1 scores for attribute prediction and accuracies for zero-shot evaluation on CompGuessWhat?!.

3.2 Transfer evaluation

For the transfer evaluation, we use the VQA dataset TDIUC (Kafle and Kanan, 2017). It provides a finer-grained way to assess the quality of the representations learned by our guessing game transfer technique in terms of several question types including object categories and their attributes. Specifically, we were interested in improving on the following question types: 1) Positional reasoning; 2) Counting; 3) Object presence; 4) Utility/Affordances; 5) Attribute; 6) Color; and 7) Object recognition. TDIUC is evaluated using the arithmetic mean accuracy per question type (A-MPT), as well as the harmonic mean (H-MPT) that better captures the skewed question-type distribution. In Table 2, we report a comparison between variants trained on guessing games data (VLP+SL and SPIEL-⋆), the original model VLP trained on Conceptual Captions (VLP+CC) and other state-of-the-art models *specifically* designed for the VQA task such as MUREL (Cadene et al., 2019), RAU (Noh and Han, 2016), NMN (Andreas et al., 2016), MCB-⋆ (Fukui et al., 2016). The full set of results is available in the Appendix, Table 4.

Among them, MUREL achieves the best scores across the board, due to a custom iterative reasoning mechanism and a non-linear fusion module. However, all our models have a more balanced overall performance which results in better harmonic means (H-MPT, +5 points over MUREL). Specifically, this improvement is favoured by an increase in accuracy on the *Utility/Affordances* ques-



TDIUC predictions (a)

Are the contents of the plate edible?	
GOLD answer	yes
VLP+CC	beer
VLP+SP+gm	yes

what is the spoon made of?	
GOLD answer	wood
VLP+CC	plastic
VLP+SP+gm	wood

what is the water glass made of?	
GOLD answer	glass
VLP+CC	plastic
VLP+SP+gm	glass

Generated dialogue (b)

is it food?	no
is it a spoon?	no
is it a cup?	no
is it a bowl?	yes
left picture?	yes
the one on the soup?	no
the one with the soup in it?	yes

Attribute prediction (c)

Situated attributes	Confidence
home	99.83%
bowl_used_to_scoop	99.37%
kitchen_utentils	99.53%
bowl_can_be_carried	99.40%
center	71.75%

Figure 2: We show the ability of the model to play guessing games with the *bowl* as target object (highlighted in *red*). Given the generated dialogue, we use the probing classifier trained for CompGuessWhat?! to predict the *bowl*'s attributes. Predictions on TDIUC questions associated with the current image are reported as well.

tion type (+20.7). As shown by the attribute prediction in the CompGuessWhat?! and depicted in Figure 2 (c), our models learn better representations than competitors specifically for abstract attributes among which there are object affordances. Particularly, we can see how it is able to understand that certain objects can *contain* things (e.g. "the one with the soup in it?"), that objects have specific functions (e.g. "are the contents of the plate edible?") or that they have specific properties (e.g. "a spoon is made of wood").

The effectiveness of the proposed fine-tuning procedure is confirmed by the improved performance across all the question types compared to our baseline `VLP+CC`. Models such as `MUREL` and `MCB-*` equipped with specific VQA modules have an advantage on specific question (e.g., positional reasoning) compared to VLP that relies only on BERT self-attention layers (Devlin et al., 2019). In addition, when comparing the two SPIEL variants, a similar trend showed in the in-domain evaluation can be observed. Particularly, `SPIEL-gm` benefits from being exposed to more language data coming from successful and failed guessing games.

MODEL	POSITION	COUNT	PRESENCE	AFFORD.	ATTR.	COLOR	RECOG.	A-MPT	H-MPT
`RAU`	35.3	48.4	94.4	31.6	56.5	66.9	86.1	67.8	59.0
`NMN`	27.9	49.2	92.5	25.2	47.7	54.9	82.0	62.6	51.9

Table 2: Results for the transfer evaluation on TDIUC. The models are divided in two categories: (top) Models specifically designed for VQA and (bottom) our VLP-based implementations. We report only the question types that we believe will benefit from the guessing games fine-tuning procedure. For the full set of results please refer to Appendix, Table 4.

4 Conclusions

In this work, we verified that representations learned while playing guessing games can be transferred to other downstream tasks such as VQA. We presented two ways of learning from guessing games data namely multi-task learning and SPIEL. Models using SPIEL performed better both on in-domain evaluation on CompGuessWhat?! as well as on the transfer task TDIUC. Our self-play procedure was able to learn useful and finer-grained object representations such as object affordances, thus demonstrating that *learning to guess helps learning to ground.*

The current study showed how we can apply the SPIEL training procedure to a VQA dataset such as TDIUC. We believe that this work can be extended to other datasets because the SPIEL procedure only requires a set of images and associated object bounding boxes. These could be either gold or generated by a trained object detector therefore classifying guessing games as a *holistic self-training procedure* for multi-modal datasets.

A Appendices

A.1 Self-Play via Iterated Experience Learning (SPIEL)

Learning to replicate gold dialogues is not enough to play successfully. High performance in gameplay can be achieved only when the agents start playing the game and are exposed to their own mistakes. Reinforcement Learning (Strub et al., 2017) or Collaborative Learning (Shekhar et al., 2019) are possible approaches to tackle this problem.

Inspired by iterated learning (Kirby et al., 2014), we design a process by which "the gameplay arises in one instance of the questioner through induction on the basis of observations of gameplay in other questioner agents who acquired that gameplay capability in the same way". Therefore, we call our procedure *Self-play via Iterated Experience Learning* (SPIEL).

In this setup, we assume we have access to a set of images $\mathcal{I}$ and for each image I we have object bounding boxes $\mathcal{O}_I$. The SP training procedure, showed in Figure 1, can be described as follows. We assume that there is a Questioner agent Q and an Oracle agent O. At the beginning of the procedure they are initialised with agents Q^0 and O, respectively, trained with Supervised Learning using gold successful dialogues [3]. We consider every iteration e of the algorithm as a *self-play* epoch. In a single self-play epoch we alternate 3 phases: 1) *interactive* phase: the agents play guessing games with novel combinations of image and target object; 2) *transmission* phase: the questioner creates new datasets from the dialogues generated over the epochs; 3) *learning* phase: multi-task learning is used to fine-tune the Questioner parameters using the datasets collected for the current epoch.

A.1.1 Interactive phase

We start the interactive phase by first sampling a set of reference games $\mathcal{G}^e$ which consists of pairs $(I, \hat{o})$ where $I \in \mathcal{I}$ and $\hat{o}$ is the target object sampled at random from the object annotations $\mathcal{O}_I$. The agents Q^e and O play the games $\mathcal{G}^e$ and accumulate the generated experiences. During this phase, the questioner agent is using the most updated weights generated at epoch $e-1$. It generates questions by nucleus sampling (Holtzman et al., 2019) from the probability distribution over the vocabulary learned by the generator head. When the `[STOP]` token is sampled, the guesser head, conditioned on the dialogue generated so far, selects the object $\tilde{o}$ with the highest probability. A game is *successful* if the predicted object $\tilde{o}$ is equal to the target object $\hat{o}$.

A.1.2 Transmission phase

For every epoch e, in the transmission phase, we create the datasets $\mathcal{D}_q$ and $\mathcal{D}_g$ for the questioner and guesser heads, respectively, used in the learning phase for the questioner parameters update.

Questioner experience buffer To make sure that the questioner does not experience *language drift* (Lee et al., 2019), we consider a fixed dataset $\mathcal{D}_q$ composed of dialogues generated by humans contained in the GuessWhat?! training data. The shared encoder Γ benefits from this data too because it is still exposed to human generated language, which guarantees better generalisation.

Guesser experience buffer The Guesser should learn from its own mistakes – therefore we use generated dialogues for the model updates (de Vries et al., 2017; Shekhar et al., 2019). Inspired by Prioritised Experience Replay (Schaul et al., 2015), we create the experience buffer for the guesser $\mathcal{E}_g^e$ by accumulating all the *unique* and *valid* dialogues generated until epoch e. We consider a dialogue *unique* if $\mathcal{D}_g^e$ does not contain another dialogue with the same encoding [4]. In addition, we consider a dialogue *valid* if it does not contain repeated questions. We cap the number of dialogues in $\mathcal{D}_g^e$ so that it matches the number of experiences in $\mathcal{D}_q$. This is done so that during the multi-task training procedure there is an equal number of dialogues for each task from which the agent will learn.

A.1.3 Learning phase

In this phase, we use the same multi-task training procedure that was used during the supervised learning phase. We update the Questioner parameters using the dialogues collected in $\mathcal{D}_q$ and $\mathcal{D}_g^e$. The updated parameters resulting from this step will be used for the self-play epoch $e+1$.

A.2 VLP implementation

A.2.1 Multi-modal encoder

To implement the agents in our guessing games, we rely on VLP, a single-stream multi-modal model (Zhou et al., 2020) that jointly learns visual and language representations using Conceptual Captions (CC) dataset (Sharma et al., 2018). The input starts with a classification token (`[CLS]`), followed by a series of K visual tokens, a separation token (`[SEP]`) divides the *dialogue* sequence from the visual and from the sequence of *tokens to be generated*. In a guessing game, we represent the reference image I as a set of image regions extracted from an off-the-shelf object detector $\{r_1, r_2, \ldots, r_K\}$. Following (Zhou et al., 2020), each region r_i is represented by linear transformation of a feature vector $f \in \mathbb{R}^{d_n}$, region class probabilities $c \in \mathbb{R}^{d_c}$ and region geometric information $g \in \mathbb{R}^{d_o}$ where $d_o = 5$ consists of four values for top left and bottom right corner coordinates of the region bounding box (normalized between 0 and 1) and one value for its relative area (i.e., ratio of the bounding box area to the image area, also between 0 and 1). The Questioner models uses at most 36 predicted bounding boxes from FastRCNN while the Guesser is using features generated by FastRCNN for gold bounding boxes. We use a specific segment id s_v for every region.

For the language part, we use Wordpiece embeddings (Wu et al., 2016). In particular, we flatten the turns of the dialogue context as a sequence of

---

[3] The Oracle is fixed during this learning procedure.

[4] The encoding of a dialogue is the SHA-256 hash associated with its sequence of tokens.

tokens. However, to allow the model to differentiate between question and answer tokens, following (Wolf et al., 2019), we rely on novel segment ids (s_u,s_a). The VLP's hidden state of the `[CLS]` token is used as context representation $\mathbf{h}_c$.

A.2.2 Oracle design

The implementation of the Oracle follows the one presented in the original VLP paper to solve the VQA task (Zhou et al., 2020). Particularly, the model predicts a probability distribution over the possible answers by using a multi-layer feed-forward neural network that receives in input the element-wise product between the hidden state associated with the `[CLS]` token and the hidden state associated with target object. The model is optimised by minimising the cross-entropy loss using as training dataset the question/answer pairs in the successful GuessWhat?! training dialogues.

A.2.3 Questioner design

We rely on the VLP ability to generate captions for the question generation task. In particular, we provide in input to the model: 1) predicted FastR-CNN visual features following (Zhou et al., 2020); 2) dialogue generated so far as a flattened sequence of tokens; 3) question to be generated. We use another segment id s_q to allow the model to differentiate what is the input and which are the tokens to be generated. Following (Dong et al., 2019), we make sure that the attention mask for tokens of the question to be generated are masked so that the token at timestep t is not allowed to attend to the future tokens (*seq2seq attention mask*). For this specific model, we use the masked language modelling objective (Devlin et al., 2019) casting the task as multi-modal masked language modelling.

A.3 GuessWhat?! evaluation

Oracle evaluation We report the test accuracy for the Oracle of 82.22%. The baseline model used by all the other is 78.5% (de Vries et al., 2017).

Guesser evaluation We report in Table 3 the accuracy of the guesser in predicting the target object when gold dialogues are given in input. We compare this model with several baselines reported in (de Vries et al., 2017) (first block), more sophisticated methods such as `ParallelAttention` (Zhuang et al., 2018) and `GDSE-*` (Shekhar et al., 2019) (second block) as well as other Transformer-based models such as VILBERT (Lu et al., 2020) (third block).

Model	Accuracy
Human	90.80%
Random	17.10%
LSTM	61.30%
HRED	61%
LSTM+VGG	60.50%
HRED+VGG	60.40%
ParallelAttention	63.40%
GDSE-SL	62.96%
GDSE-CL	59.79%
VILBERT	65.69%
VLP-SL	69.30%
SPIEL-gs	**71.80%**
SPIEL-gm	71.70%

A Unified Feature Representation for Lexical Connotations

Abstract

Ideological attitudes and stance are often expressed through subtle meanings of words and phrases. Understanding these *connotations* is critical to recognizing the cultural and emotional perspectives of the speaker. In this paper, we use distant labeling to create a new lexical resource representing connotation aspects for nouns and adjectives. Our analysis shows that it aligns well with human judgments. Additionally, we present a method for creating lexical representations that capture connotations within the embedding space and show that using the embeddings provides a statistically significant improvement on the task of stance detection when data is limited.

1 Introduction

Expressions of ideological attitudes are widespread in today's online world, influencing how we perceive and react to events and people on a daily basis. These attitudes are often expressed through subtle expressions or associations (Somasundaran and Wiebe, 2010; Murakami and Putra, 2010). For example, the sentence "the people opposed gun control" conveys no information about the author's opinion. However, by adding just one word, "the *selfish* people opposed gun control", the author can convey their stance on both gun control (against) and the people who support it (not valuable and disliked). Discerning such subtle meaning is crucial for fully understanding and recognizing the hidden influences behind everyday content.

Recent studies in NLP have begun to examine these hidden influences through framing in social media and news (Asur and Huberman, 2010; Hartmann et al., 2019; Klenner, 2017) and style detection in hyperpartisan news (Potthast et al., 2018). Lexical connotations provide a method to study these influences, including stance, in more detail.

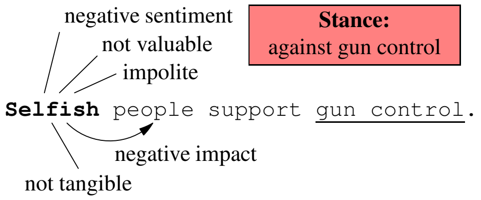

Figure 1: Connotations of the word "selfish" and the resulting implied stance on the topic "gun control".

Connotations are implied cultural and emotional associations for words that augment their literal meanings (Carpuat, 2015; Feng et al., 2011). Connotation values are *associated* with a phrase (e.g., fear is associated with "cancer") (Feng et al., 2011) and capture a range of nuances, such as whether a phrase is an insult or implies value (see Figure 1).

In this paper, we define six new fine-grained connotation aspects for nouns and adjectives, filling a gap in the literature on connotation lexica, which has focused on verbs (Sap et al., 2017; Rashkin et al., 2016, 2017), and coarse-grained polarity (Feng et al., 2011; Kang et al., 2014). We create a new distantly labeled English lexicon that maps nouns and adjectives to our six aspects and show that it aligns well with human judgments. In addition, we show that our lexicon confirms existing hypotheses about subtle semantic differences between synonyms.

We then learn a single connotation embedding space for words from all parts of speech, combining our lexicon with existing verb lexica and contributing to the literature on unifying lexica (Hoyle et al., 2019). Intrinsic evaluation shows that our embedding space captures clusters of connotatively-similar words. In addition, our embedding model can generate representations for new words without the numerous training examples required by standard word-embedding methods. Finally, we show that our connotation embeddings improve performance on stance detection, particularly in a

low-resource setting.

Our contributions are as follows: (1) we create a new connotation lexicon and show that it aligns well with human judgments, (2) we train a connotation feature embedding for all parts of speech and show that it captures connotations within the embedding space, and (3) we show the connotation embeddings improve stance detection when data is limited. Our resources are available: `https://github.com/emilyallaway/connotation-embedding`.

2 Related Work

Studies of connotation build upon the literature examining subtle language nuances, including good and bad effects of verbs (Choi and Wiebe, 2014), evoked sentiments and emotions (Mohammad et al., 2013a; Mohammad and Turney, 2010; Mohammad, 2018b), multi-dimensional sentiment (Whissell, 2009; Mohammad, 2018a; Whissell, 1989), offensiveness (Klenner et al., 2018), and psycho-sociological properties of words (Stone and Hunt, 1963; Tausczik and Pennebaker, 2009). Work explicitly on connotations has focused primarily on detailed aspects for verbs (Rashkin et al., 2016, 2017; Sap et al., 2017; Klenner, 2017) or single polarities for many parts of speech (Feng et al., 2011, 2013; Kang et al., 2014). One exception is the work of Field et al. (2019), which extends limited detailed connotation dimensions from verbs to nouns within the context of certain verbs. Our work is unique in directly defining detailed aspects for nouns and adjectives.

Early work on stance detection applied topic-specific models to various genres, including online debate forums (Sridhar et al., 2015; Somasundaran and Wiebe, 2010; Murakami and Putra, 2010; Hasan and Ng, 2013, 2014) and student essays (Faulkner, 2014). More recent studies have used a single model for many topics to predict stance in Tweets (Mohammad et al., 2016; Augenstein et al., 2016; Xu et al., 2018) and as part of the fact extraction and verification pipeline (Conforti et al., 2018; Ghanem et al., 2018; Riedel et al., 2017; Hanselowski et al., 2018). Klenner et al. (2017) explore the relationship between connotations and stance through verb frames. In contrast, our work studies stance using connotation representations from a learned joint embedding space for words from all parts of speech. Recently, Webson et al. (2020) examine representations of political ideology as connotations and its use in information retrieval. Representation learning has been used for stance detection of online debates by Li et al. (2018), who develop a joint representation of the text and the authors. Our work, however, uses a representation of word connotations and does not use any author information (a strong feature in fully-supervised datasets but which may not be available in real-world settings).

3 Connotation Lexicon

We build a connotation lexicon for nouns and adjectives by defining six new aspects of connotation. We take inspiration from verb connotation frames and their extensions (Rashkin et al., 2016; Sap et al., 2017), which define aspects of connotation in terms of the agent and theme of transitive verbs. Rashkin et al. (2016) define six aspects of connotation for verbs (entities', writer's, and reader's perspectives, effect, value, and mental state) in connotation frames (e.g., "suffer" $\rightsquigarrow$ negative effect on the agent) and Sap et al. (2017) extend these aspects to include power and agency.

We first define the six new aspects of connotation for nouns and adjectives (§3.1) in our work, then we describe our distant labeling procedure (§3.2) and human evaluation of the final lexicon (§3.3).

3.1 Definitions

We use w to indicate a word and w' to indicate the person, thing or attribute signified by w.

For each w, we define (1) **Social Value**: whether w' is considered valuable by society, (2) **Politeness** *(Polite)*: whether w is a socially polite term, (3) **Impact** whether w' has an impact on society (or the thing modified by w if w is an adjective), (4) **Factuality** *(Fact)*: whether w' is tangible, (5) **Sentiment** *(Sent)*: the sentiment polarity of w, and (6) **Emotional association** *(Emo)*: the emotions associated with w'. We show examples in Table 1.

(1) Social Value includes both the value of objects or concepts and the social status and power of people or people-referring nouns (e.g., occupations). "Sociocultural pragmatic reasoning" (Colston and Katz, 2005) about such factors is crucial for understanding language such as connotations.

Initial work on connotation polarity lexica recognized the important role of *Social Value* in overall connotation by defining a 'positive' connotation for objects and concepts that people value (Feng et al., 2011). Later work made this idea more explicit

Aspect	Lexicon	Example Rules	Examples
Social Value	GI	Authoritative power → valuable Related to failure → not valuable	`attorney` ⇝ valuable (+) `aimless` ⇝ not valuable (-)
Politeness	GI	Gain of respect → polite Loss of affection → impolite	`commendable` ⇝ polite (+) `alienation` ⇝ impolite (-)
Impact	GI	Virtue → positive Loss of well-being → negative	`adept` ⇝ positive impact (+) `shock` ⇝ negative impact (-)
Factuality	DAL	Imagery(w) $> \theta_F \rightarrow$ factual Imagery(w) $< -\theta_F \rightarrow$ not factual	`rocky` ⇝ factual (+) `tradition` ⇝ not factual(-)
Sentiment	CWN	$v > \theta_S \rightarrow$ positive $v < -\theta_S \rightarrow$ negative	`song` ⇝ positive (+) `cancerous` ⇝ negative (-)
Emotional Association	NRC	emotions $E \subseteq$ {anger, joy, fear, trust, anticipation, sadness, disgust, surprise}	`snake` ⇝ {disgust, fear} `effective` ⇝ {trust}

Table 1: Example mappings from existing lexica to our connotation aspects. GI: Harvard General Inquirer, DAL: Dictionary of Affect in Language, CWN: Connotation WordNet, and NRC: NRC Emotion Lexicon. Scores for imagery, Imagery(w), and sentiment, v, are real-valued.

by defining 'Value' for transitive verb arguments in connotation frames. More recently 'power' and 'agency', components of *Social Value*, have been defined for verbs in connotation frames and for nouns in context (Field et al., 2019) and have been used to analyze bias and framing in a variety of texts, illustrating the applications and importance of *Social Value* in connotations.

(2) Politeness follows the definition of Lakoff (1973) in noting words that make the addressee feel good but also includes notions of formality. These notions have been previously studied within the context of politeness as a set of behaviors and linguistic cues (Brown and Levinson, 1987; Danescu-Niculescu-Mizil et al., 2013; Aubakirova and Bansal, 2016). We focus on purely lexical distinctions because how one comprehends these distinctions affects one's "attitude towards the speaker ... or some issue" as well as whether one feels insulted by the exchange (Colston and Katz, 2005). This aspect of perspective is a component of verb connotation frames and we extend it to nouns and adjectives in our lexicon through *Politeness*.

(3) Impact and effect have been studied in verb connotation frames and other verb lexica (Choi and Wiebe, 2014), capturing notions of implicit benefit or harm on the arguments of the verb. We extend this idea to nouns and adjectives by observing that while they do not directly have arguments, nouns (e.g. "democracy") often impact society and adjectives (e.g. "sick") impact the nouns they modify. Thus, we define *Impact* in this way.

(4) Factuality captures whether words correspond to real-world objects or attributes, following the sense of Saurí and Pustejovsky (2009). Klenner and Clematide (2016) argue that the factuality of events is crucial for understanding sentiment inferences. Building upon this, Klenner et al. (2017) use factuality as a key component of German verb connotations and of applying those connotations to analyze stance and sides in German Facebook posts. Imagery, as an "indicator of abstraction" (Whissell, 2009), also models a similar attribute to event factuality for all parts of speech. Given its importance, we include a notion of *Factuality* for nouns and adjectives as aspect of connotations.

(5) Sentiment polarity has been used to convey overall connotations since the early work on connotation lexica (Feng et al., 2011, 2013; Kang et al., 2014). As such, we deem it important to include this polarity in our lexicon.

(6) Emotional Associations for words can be strong, persisting long after they are formed and improving the recall of memories triggered by those words (Rubin, 2006). Emotions are also impacted when people process non-literal meaning (Colston and Katz, 2005). To fully understand what a piece of text is trying to convey, it is important to understand what emotional associations exist in the text. For example, news headlines often aim to evoke strong emotions in their readers (Mohammad and Turney, 2013). To capture this, we include *Emotional Association* as an aspect of connotation.

3.2 Labeling Connotations

We use distant labeling to build our lexicon, since complete manual annotation of a lexical resource is

	Social Val	*Polite*	*Impact*	*Fact*	*Sent*
%+	32.1	10.5	14.8	19.0	56.8
%−	15.5	1.0	13.3	67.2	33.1

Table 2: Class distributions of fully-labeled words in the connotation lexicon.

a lengthy and costly process. Although crowdsourcing can lessen these burdens, the results are often unreliable with low inter-annotator agreement and, for this reason, many lexical resources are automatically created (Mohammad, 2012; Mohammad et al., 2013b; Kang et al., 2014). Following these researchers, we automatically generate our lexicon by combining several existing lexica.

To generate our lexicon, we map dimensions from existing lexica to connotation aspects (see Table 1). We use dimensions from the Harvard General Inquirer (Stone and Hunt, 1963) for *Social Value*, *Politeness*, and *Impact*. For *Factuality* we map the real-valued 'Imagery' dimension, Imagery(w), from the revised Dictionary of Affect in Language (Whissell, 2009) into distinct classes. For *Sentiment* we directly use the polarity v from Connotation WordNet (Kang et al., 2014) and for *Emotional Association* we use the eight Plutchik emotions (Plutchik, 2001) from the NRC Emotion Lexicon (Mohammad and Turney, 2013) (see appendix B for full rules).

The labels are word-sense-independent, following other automatically generated lexica, such as the Sentiment140 lexicon (Mohammad et al., 2013b), which do not treat word sense. In addition, sense-level annotations are not available for all lexica in our distant labeling method and therefore sense-level connotations would require both extensive manual annotation and automated word-sense disambiguation, introducing cost and additional noise. As a result, we use sense-level distinctions (e.g., in the Harvard General Inquirer) when available and combine the labels for an aspect across senses to obtain the final connotation aspect label. These aggregate aspect labels represent a word's connotative potential, rather than exact value

Our resulting lexicon has $7,578$ words fully-labeled for all aspects, with an additional $\sim$93k words labeled only for some aspects (e.g., only *Sentiment*), resulting in $100,176$ words total. For each non-emotion aspect, we have a label $l \in \{-1, 0, 1\}$. For *Emotional Association*, each of the eight emotions has label $l \in \{0, 1\}$.

Aspect	**Avg** κ	**Avg % Agree**	**Lex % Agree**	**Lex % NC**
Social Value	.699	88.9	68.6	92.6
Politeness	.381	56.6	59.4	95.1
Impact	.630	87.6	73.7	94.6
Factuality	.675	86.3	58.0	77.7
Average	.596	87.9	64.2	90.0

Table 3: Lexicon annotation results. Fleiss' κ and % agreement are averaged across nouns and adjectives. Lex % is agreement between annotators and the lexicon. NC indicates non-conflicting value agreement.

We find that many aspects exhibit uneven class distributions (e.g., 10.5% of words are polite and only 1% are impolite) (see Table 2). For emotions, we calculate the class distribution using the number of fully-labeled words with at least one associated emotion ($1,373$ words or 18%). For these $1,373$ words, the average number of associated emotions is $\sim$2. Our distributions are similar to previous work on verb connotations, where distributions range from 1.4% to 20.2% for the smallest class (Rashkin et al., 2016).

3.3 Evaluation of the Lexical Resource

Human Evaluation

We evaluate the quality of the lexicon by creating a gold-labeled set and comparing the labels created with distant supervision against the human labels. We ask nine NLP researchers[1] to annotate 350 words (175 nouns, 175 adjectives) for *Social Value, Politeness, Impact* and *Factuality*. We do not annotate *Sentiment* or *Emotional Association*, since these labels come directly from existing lexica.

Annotators are given a word w, along with its definitions (for all senses) and related words, and annotate connotation independent of word sense. This setup mimics the input to the representation learning models in §4. The average Fleiss' κ across nouns and adjectives is 0.60 (see Table 3), indicating substantial agreement. We select as the final annotator label, the majority vote.

We find that the distantly labeled lexicon agrees with human annotators the majority of the time (on average 64.2% or Cohen's $\kappa = 0.368$ (Cohen, 1988)). If we consider *non-conflicting value agreement* (NC), the lexicon agreement with humans rises to 90%, where NC agreement is defined as: the pairs (+, neutral) and (−, neutral) agree but

---

[1] native English speakers at Columbia University

Aspect	**Same Connotation**	**Different Connotation**
Social Value	(=) `hurry` vs. `rush` (+) `fantastic` vs. `wonderful`	`sentence` (=) vs. `condemnation` (-) `relentless` (-) vs. `persistent` (+)
Politeness	(-) `disgrace` vs. `shame` (+) `humble` vs. `modest`	`gentleman` (+) vs. `man` (=) `preposterous` (=) vs. `ridiculous` (-)
Impact	(-) `weariness` vs. `fatigue` (+) `rightful` vs. `lawful`	`fire` (=) vs. `burning` (-) `supporting` (+) vs. `suffering` (-)
Factuality	(+) `daytime` vs. `day` (-) `dire` vs. `terrible`	`post` (+) vs. `position` (=) `protection` (-) vs. `security` (=)
Sentiment	(+) `wonderous` vs. `marvelous` (-) `commotion` vs. `disturbance`	`giddy` (=) vs. `dizzy` (+) `moving` (=) vs. `striking` (+)
Emotional Association	(trust) `wise` vs. `smarter` (sadness) `flaw` vs. `disturbance`	`dire` (fear, sadness) vs. `terrible` (fear,sadness,disgust)

Table 4: Synonym examples from the lexicon. = indicates neutral or neither.

(+,−) does not. This shows that the lexicon and humans rarely select opposite values and instead disagree on neutral vs. non-neutral.

Looking closer at disagreements between neutral and non-neutral, we see that most result from human annotators selecting a non-neutral label. That is, the lexicon makes fewer distinctions between neutral and non-neutral than humans; humans select a non-neutral value 68% of the time, compared to 56% in the lexicon. Despite this tendency towards neutral, the lexicon aligns with human judgments, agreeing the majority of the time and rarely providing a value opposite to humans.

Synonym Analysis

We also evaluate the ability of our lexicon to capture subtle semantic differences between words using lexical paraphrases (synonyms). In the paraphrase literature, it has been argued that paraphrases actually differ in many ways, including in connotations (Bhagat and Hovy, 2013). In fact, Clark (1992) proposes that absolute synonymy between linguistic forms does not exist. With this in mind, we hypothesize that our connotation lexicon should differentiate between lexical paraphrases.

To test this, we select synonym paraphrase pairs from lexical PPDB (Pavlick et al., 2015) where one element in the pair is in the Wordnet synset of the other [2]. We find that out of the 2216 resulting pairs where both words are in our lexicon, 74.3% have connotations that differ in some aspect. Many words agree on *Sentiment* (67.5% the same), following the intuition that two synonyms likely have the same sentiment but differ in more fine-grained ways. Other pairs agree on *Politeness* (76.1% the same), resulting from the extreme class imbalance for this aspect (88.5% neutral). However, the lexicon does still capture differences along these dimensions, for example in terms of formality (e.g., “gentleman” vs. “man”).

Looking more closely, we find that many times agreements along a particular dimension accurately represent synonyms that differ along other dimensions. For example, “weariness” and “fatigue” both have a negative *Impact*, but “weariness” is associated with *sadness* and “fatigue” is not.

On the other hand, the majority of differences across almost all aspects (79% on average) are between neutral and non-neutral polarities within a synonym pair, for example, between “position” (possibly tangible) and “post” (tangible), from *Factuality*. This confirms the intuition that synonyms often do not have opposing connotation values, although examples do exist (e.g., the *Social Value* of “relentless” vs. “persistent”) (see Table 4). As a whole, our analysis confirms our hypothesis and the claims of Clark (1992) about synonymy.

4 Connotation Embedding

4.1 Methods

Using our connotation lexicon, we train a dense connotation feature representation for words from all parts of speech. We combine three lexica (our lexicon and two verb lexica) into a single vector space, making connotations easier to use as model input and providing a single representation method for the connotations of any word.

We design a novel multi-task learning model that

---

[2] `https://wordnet.princeton.edu/`

jointly predicts all of the connotation labels for a word w, from a learned representation v_w. Each task is to predict the label for exactly one connotation aspect: the 6 aspects in §3.2 for nouns and adjectives and the 11 aspects in CFs+ (connotation frames and their extension to power and agency) for verbs (Rashkin et al., 2016; Sap et al., 2017).

To learn a representation for w we encode dictionary definitions of the word w and words related to w (e.g., synonyms, hypernyms) in a single vector, which we then use to predict connotation labels. We use definitions and related words since linguists have argued that definitions and related words convey a word's meaning (Guralnik, 1958).

Let w be a word with part of speech t. The input to the connotation encoding model is then: (1) a set of dictionary definitions D_{w^t} and (2) a set of words related to w^t, R_{w^t}. We use multiple definitions to capture multiple senses of w^t. To emphasize more prevalent senses of w^t, we use similar repeated definitions for the same sense, collected from multiple sources. From D_{w^t} and R_{w^t}, the encoder produces a connotation feature embedding $v_{w^t} \in \mathbb{R}^d$ of dimension $d = 300$. Then we use v_{w^t} to predict the label ℓ_a for connotation aspect a (see Figure 2).

4.1.1 Encoding Models

For a word w^t, the input to our encoder is $d_{w^t} = [d^1_{w^t}; d^2_{w^t}; ...; d^N_{w^t}] \in \mathbb{R}^{Nd_{in}}$, the sequence of fixed pre-trained token embeddings for concatenated definitions in D_{w^t}. Then we take as our embedding the normalized final hidden state from a BiLSTM, a standard architecture for text encoding: $v_{w^t} = \frac{h_{w^t}}{\|h_{w^t}\|}$, where $h_{w^t} = \text{BiLSTM}(d_{w^t})$ and $h_{w^t} \in \mathbb{R}^{2H}$ is the concatenation of the last forward and backward hidden states (model **CE**).

As a variation of our model, we apply scaled dot-product attention (Vaswani et al., 2017) over the related words R_{w^t}, using h_{w^t} as the attention query, to obtain v_{w^t}. Then we add the result to h_{w^t} before normalizing (model **CE+R**).

4.1.2 Label Classifier

For each connotation aspect, we train a separate linear layer plus softmax with the input $[v_{w^t}; e_{w^t}]$, where e_{w^t} is the pre-trained embedding for w^t. For the non-emotion aspects, the layer has three target classes $\{-1, 0, 1\}$ for most aspects (four classes for the 'power' and 'agency' verb aspects) and we predict the label with highest output probability. For emotions, we do multi-label classification by thresholding the output probabilities for each emotion dimension with a fixed $\theta \in \mathbb{R}$. We include e_{w^t} in the predictor input to encourage v_{w^t} to model connotation information that is complementary to the information present in pre-trained embeddings.

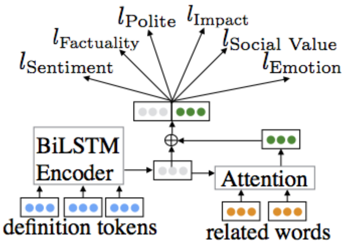

Figure 2: Connotation embedding modeling in §4.1.

4.1.3 Learning

For each non-emotion connotation aspect a (e.g., *Impact*) we calculate the weighted cross-entropy loss $\mathcal{L}^a$. For *Emo* we calculate the one-versus-all cross-entropy loss on each of the eight emotions, $\mathcal{L}^{Emo}_i$ for $1 \leq i \leq 8$, and their sum is $\mathcal{L}^{Emo}$.

In our multi-task joint learning framework **(J)**, we minimize the weighted sum of $\mathcal{L}^a$ across all connotation aspects. We also experiment with training a separate encoding model for each connotation aspect a that minimizes $\mathcal{L}^a$ **(S)**.

4.1.4 Baselines and Models

For each baseline, we implement one classifier per connotation aspect, or, for *Emo*, one classifier for each emotion. Following Rashkin et al. (2016) we implement a Logistic Regression classifier trained on the 300-dimensional pre-trained word embedding for w using the standard L-BFGS optimization algorithm and sample re-weighting (`LR`). We also implement a majority class baseline (`Maj`).

We present three variations of our model: (i) trained jointly for all parts of speech and all connotation aspects (`CE(J)`), (ii) trained on each aspect individually with related word attention (`CE+R(S)`), and (iii) trained jointly on all parts of speech and all connotation aspects with related word attention (`CE+R(J)`).

4.2 Connotation Prediction

4.2.1 Data and Parameters

For nouns and adjectives, we train using the aspects described in §3 (6 aspects). For verbs, we train on 9 aspects[3] from Rashkin et al. (2016) as well as 'power' and 'agency' from Sap et al. (2017)

---

[3] perspective of the writer on the agent/theme, perspective of the agent on the theme, effect on/value/ state of entities

Verb Avg	.222	.553	.489	.521	.520
All Avg	.251	.568	.524	.548	.547

Table 5: Macro-averaged F1 for connotation prediction on the test set, averaged across aspects. N/Aj indicates noun and adjective.

(11 aspects total). We split our connotation lexicon (§3) into train (60%), development (20%) and test (20%). For the verb CFs+, we preserve the originally published data splits where possible. We move words only to ensure that all parts of speech for a word are in the same split (e.g., 'evil' both as a noun and adj is in the dev set).

We collect dictionary definitions and related words from all seven dictionaries available on the Wordnik API[4]. These are extracted for each word and part-of-speech pair. We preprocess definitions by removing stopwords, punctuation, and the word itself. We use pre-trained Concept-Net numberbatch embeddings (Speer et al., 2016).

4.2.2 Results

Label Prediction

We present results on the connotation prediction task to check the quality of our representation learning system. Given dictionary definitions and related words, we predict the labels from our lexicon (§3) and CFs+ (see Table 5).

First, we observe that joint learning (models `(J)`) improves over training representations individually (`CE+R(S)`). We hypothesize that joint learning provides regularization across all aspects. Second, we compare joint learning with (`CE+R(J)`) and without (`CE(J)` related words to the strong `LR` baseline. We find that the model with related words (`CE+R(J)`) is statistically indistinguishable from the baseline[5] (for $p \leq 0.05$). In contrast, our model without related words (`CE(J)`) is significantly worse than the `LR` baseline for one aspect (see Appendix D for aspect-level results). Thus we conclude that related words are beneficial for learning connotations.

Overall, our approach provides a single unified feature representation for the lexical connotations of all parts of speech, without any loss in label prediction performance. Specifically, our best representation learning model (`CE+R(J)`) has comparable label prediction performance to a strong baseline (`LR`), a baseline that does not learn any kind of representation. We use `CE+R(J)` to generate connotation embeddings that we use in all further evaluation.

Observations

Our connotation representation learning model presents several advantages. Since the model uses dictionary definitions, we can generate representations for slang words (e.g., "gucci" meaning "really good"), where knowledge-base entries (e.g., in Concept-Net) do not capture the slang meaning. For example, in our connotation embedding space, the nearest neighbors of "gucci" include words related to the slang connotations (e.g., "beneficial" – positive impact, not factual), whereas neighbors in a pre-trained word embedding space are specific to the fashion meaning and connotations (e.g., "buy", "italy", "textile"). Along with slang, our model can also generate representations for new or rare words (e.g., "merchantile") that don't have a pre-trained word representation.

5 Experiments

5.1 Intrinsic Evaluation

To evaluate the connotation embedding space, we look at the 50 nearest neighbors, by Euclidean distance, of every word in our training and development sets. We find that neighbors in the connotation embedding space are more closely related based on the connotation label than in the pre-trained embedding space.

Looking at example nearest neighbors (Table 6) we see that nearest neighbors in the pre-trained embedding space include antonyms (e.g., "inability" is close to "ability") and topically related words (e.g., "merry" is close to "wives"), while in the connotation space, neighbors often share connotation labels even though they may be topically or denotatively unrelated. For example, "slug" (noun) is close to many *impolite* but otherwise unrelated words (e.g., "shove", "murder", "scum") in the connotation embedding space while in the pre-trained space "slug" is close to topically related (e.g., "bug") but *polite* words. Therefore, we can see that words with similar connotations are placed closer together than in the pre-trained semantic space.

To quantify the semantic differences, we measure neighbor-cluster connotation label purity.

---

[5] We use an approximate randomization test

Aspect	**Word**	**Conn Only**	**Both**	**Word Only**
Social Value	ability (+)	service, imagination, worth, practical	NONE	lack, inability, enough, difficult
Polite	slug (-)	bang, shove, murder, scum	NONE	quote, bug, exception, reference
Impact	merry (+)	glee, exhilaration, pretty, prosperous	cheery, genial, joyful, fun, merriment, jolly joy, delightful, cheerful	amiable, wonderful, crazy, wives

Table 6: Examples of nearest neighbors in the connotation embedding space (Conn Only), the pre-trained word embedding space (Word Only) and all top 50 nearest neighbors in both spaces (Both). NONE indicats no overlap.

	c	***Social Val***	***Polite***	***Impact***
$r_c^{a(C)}$	+	21.27	2640.14	47.49
	-	5.88	50.00	33.33
$r_c^{a(P)}$	+	4.70	43.71	4.73
	-	2.38	0.54	8.33

Table 7: Select cluster connotation purity ratios.

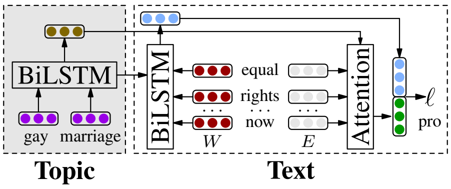

Figure 3: Stance models `BiC+`E; $E \in \{C, W, R\}$.

Specifically, for each connotation aspect a (e.g., *Social Value*) and each non-neutral label c (e.g., valuable (+)), we calculate $r_c^{a(C)}$: the average ratio of words with label c to label $-c$ in the set of nearest neighbors of all words with label c for aspect a. We compare it against the same ratio for the nearest neighbors selected using the same pre-trained word embeddings as in §4.2, denoted $r_c^{a(P)}$.

We find that across connotation aspects, these ratios are higher for the learned connotation embeddings, compared to pre-trained embeddings. For example, $r_+^{\textit{Social Val}(C)} = 21.27$ but $r_+^{\textit{Social Val}(P)} = 4.70$ (see Table 7). This shows the connotation embeddings reshape the pre-trained semantic space.

5.2 Extrinsic Evaluation

We further evaluate our connotation embeddings using the stance detection task, hypothesizing they will lead to improvement. Given a text on a topic (e.g., "gun control"), the task is to predict the stance (pro/con/neutral) towards the topic (see Figure 1).

5.2.1 Methods and Experiments

Models

As a baseline architecture, we implement the bidirectional conditional encoding model (Augenstein et al., 2016). This model encodes a text as h_T with a BiLSTM, conditioned on a separate topic encoding h_P, and predicts stance from h_T (`BiC`). We include connotation embeddings through scaled dot-product attention over the noun, adjective, and verb embeddings from the text, with h_P as the query (see Figure 3). We experiment with three types of embeddings in the attention: pre-trained word embeddings (`BiC+W`), our connotation embeddings (`BiC+C`), and randomly initialized embeddings (`BiC+R`), as a baseline to measure the importance of attention. We also implement a Bag-of-Word-Vectors baseline (`BoWV`), encoding the text and topic as separate BoW vectors and passing their concatenation to a Logistic Regression classifier.

Data and Parameters

We use the Internet Argument Corpus (Abbott et al., 2016): $\sim$59k posts from online debate forums. Of the 16 total topics, four are large (*L*, with $> 7k$ ex each), five are medium (*M*, with $\sim 2k$ ex each), and seven are small (*S*, with 30-300 ex each).

Since not every text will take a position on every topic, we automatically generate 'neutral' examples for the data. To do this, we sample a pro/con example and then assign it a new (different) topic, randomly sampled from the original topic distribution. We split the data into train, development, and test such that no posts by one author are in multiple splits and preprocess the data by removing stopwords and punctuation and lowercasing.

Stance is topic-dependent and as a result, models require numerous training examples for each individual topic. However, many examples are not always available for every topic. Since there are hundreds of thousands of potential topics, the vast majority of which will have very few examples, our goal is to build models that exhibit strong performance across all topics, regardless of size.

	All Data	Trunc Train	Trunc All
BoWV	.3587	.3473	.3613
BiC	.5677	.5151	.5244
BiC+R	.5282	.5260	.5128
BiC+W	.5650	.5384	.5421
BiC+C	.5613	.5579*	.5562*

Table 8: Stance detection macro-averaged F1 on the test set. * indicates significance ($p < 0.01$) between `BiC+C` and `BiC+W`.

Therefore, we experiment with three data scenarios: (i) training and evaluating using all the data (`All Data`), (ii) truncating each topic in training to *M* size (at most $2k$ examples) and evaluating using all data (`Trunc Train`), and (iii) truncating each topic to *M* size in training and in evaluation (`Trunc All`), so that topics have the same frequency for both training and evaluation.

5.2.2 Results

We find that when using all of the training data, the pre-trained embeddings and our connotation embeddings perform comparably (significance level $p = 0.3$). Note that both the connotation and pre-trained embeddings outperform the random embeddings in all scenarios, showing that the architecture difference is not the only reason for improvement when adding embeddings. We find that in both scenarios where data is limited per topic (`Trunc Train` and `Trunc All`), the connotation embeddings improve significantly over the pre-trained word embeddings. In fact, the same trend is visible across varying numbers of training examples (see Figure 4). Our results demonstrate that the connotation information is useful for detecting stance when data is limited.

We find further evidence that the connotation embeddings (`BiC+C`) make the model robust to loss of training data when we look at the results on the individual topic level. Namely, in setting `Trunc Train`, `BiC+C` has a significant improvement (with $p < 0.05$) over `BiC+W` on six topics, including four of the *M* and truncated *L* topics. In fact, for the four *M*/*L* topics, the average per-topic decrease in F1 for `BiC+C` is $1/4$ that of `BiC+W`. These per-topic results further highlight the robustness of `BiC+C` when training data is restricted.

We conclude that connotation embeddings improve stance performance when training data is limited, suggesting they can be used in future work that generalizes stance models to topics with no training data (i.e. most topics).

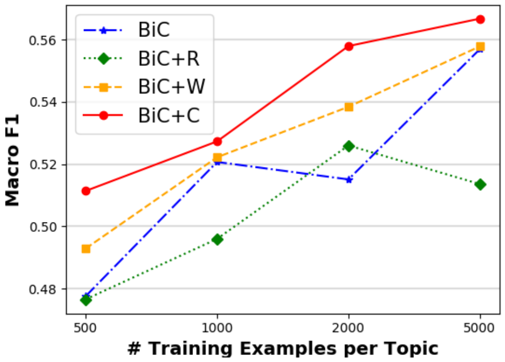

Figure 4: Stance F1 on the test set as number of training examples per topic varies.

6 Conclusion

We create a new lexicon with six new connotation aspects for nouns and adjectives that aligns well with human judgments. We also show that the lexicon confirms hypotheses about semantic divergences between synonyms. We then use our lexicon to train a unified connotation representation for words from all parts of speech, yielding an embedding space that captures more connotative information than pre-trained word embeddings.

We evaluate our connotation representations on stance detection. Since the stance detection tasks encountered in real life concern a very large number of topics, zero-shot and few-shot stance detection are important subtasks. We show that models using our connotation representations are well suited for few-shot stance detection and may also generalize well to zero-shot settings.

In future work, we plan to explore the relationships between connotations, context, and word sense, as well as adapting our methods to learn multi-lingual connotation representations that accurately capture cultural and linguistic variations.

A Overview

The data and software are provided as supplementary material her: `https://github.com/connotationembeddingteam/connotation-embedding`.

B Connotation Labeling

We construct labels for our connotation lexicon (§3) using categories from the following existing resources: *HGI* – the Harvard General Inquirer (Stone and Hunt, 1963), *DAL* – the revised Dictionary of Affect in Language (Whissell, 2009), *CWN* – Connotation WordNet (Kang et al., 2014), and *NRCEmoLex* – the NRC Emotion Lexicon (Mohammad and Turney, 2013).

The HGI consists of 183 psycho-sociological categories. Each lexical entry ($\sim 11k$ total) is tagged with a non-zero number of categories. Different senses (noted through brief definitions) and parts-of-speech for the same word have separate entries. The available categories include valence (i.e., positive and negative), words related to a particular entity or social structure (e.g., institutions, communication), and value judgements (e.g., concern with respect).

The DAL consists of $\sim 8k$ words with scores for 3 categories: pleasantness, activation, and imagery. Word entries include inflection but do not explicitly mark part-of-speech. CWN is a lexicon of connotation polarity scores (ranging from 0 to 1) for $\sim 180k$ words, explicitly marked for part of speech. Finally, NRCEmoLex consists of word entries marked for any number the eight Plutchik emotions (anticipation, joy, trust, fear, surprise, sadness, disgust, anger) as well as positive and negative sentiment. Two versions of the lexicon are available: with and without sense level distinctions. Neither version includes explicit information on part-of-speech, and so we infer part-of-speech using the words provided to distinguish different senses.

We provide the complete distant labeling rules for each of the connotation aspects in Table 9 (see `http://www.wjh.harvard.edu/~inquirer/homecat.htm` for complete information on abbreviations). Within each connotation aspect, we determine the connotation polarity using the additional categories: *Positiv, Negativ, Strong, Weak, Hostile, Submit, Active* and *Power*.

Aspect	**General Inquirer Categories**
Social Value	PowGain, PowLoss, PowEnds, PowCon, PowCoop, PowAuPt, PowPt, PowAuth, PowOth, RcEthic, RcRelig, RcGain, RcEnds, RcLoss, Virtue, Vice, WltPt WltTran, WltOth, Food, Object, Doctrin, Academ, Work, NatrObj, Vehicle, Econ@, Goal, EnlPt, EnlOth, EnlLoss, SklPt, SklAsth, SklOth, Exprsv, Legal, COLL, Means MeansLw, Fail, Solve, EndsLw, Try, WlbPhys, WlbGain, WlbPt, WlbLoss, WlbPsyc, Quality, SocRel
Politeness	RspGain, RspLoss, RspOth, AffGain, AffLoss, AffOth, WlbPt, SklPt, EnlPt, Relig, WltPt, Polit, HU, Milit, Legal, Academ, Doctrin
Impact	PosAff, Pleasur, Pain, NegAff, Anomie, NotLw, Vice, Virtue, RcGain, RcLoss, RspLoss, RcEthic, RspOth, WlbPysc, RcEnds, EnlOth, WlbGain, RspGain, EnlGain, EnlEnds, EnlPt, WlbLoss, WlbPt, EnlLoss, SklOth, WlbPhys, Try, Goal, Work
Factuality	$v = \begin{cases} -1 & \text{if } x \leq -0.25 \\ 1 & \text{if } x \geq 0.25 \\ 0 & \text{otherwise} \end{cases}$ where x is the Imagery score normalized to $[-1, 1]$.
Sentiment	$v = \begin{cases} -1 & \text{if } x \leq -0.25 \\ 1 & \text{if } x \geq 0.25 \\ 0 & \text{otherwise} \end{cases}$ where x is the sentiment score normalized to $[-1, 1]$.

Table 9: Categories from the Harvard General Inquirer used in distant labeling connotations.

Aspect	**Avg Cohen's κ**
Social Value	0.526
Politeness	0.186
Impact	0.595
Factuality	0.164
Average	0.368

Table 10: Cohen's κ for agreement between the connotation lexicon and human annotators.

C Analysis of the Connotation Lexicon

In this section, we provide further analysis of the connotation lexicon as exemplification of its content and properties.

C.1 Human Evaluation

We show the instructions provided to annotators for the manual labeling of samples from the connotation lexicon in §3.3 (see Figures 5 and 6).

We include Cohen's $kappa$ score for agreement between the lexicon and human annotators for individual connotation aspects in Table 10.

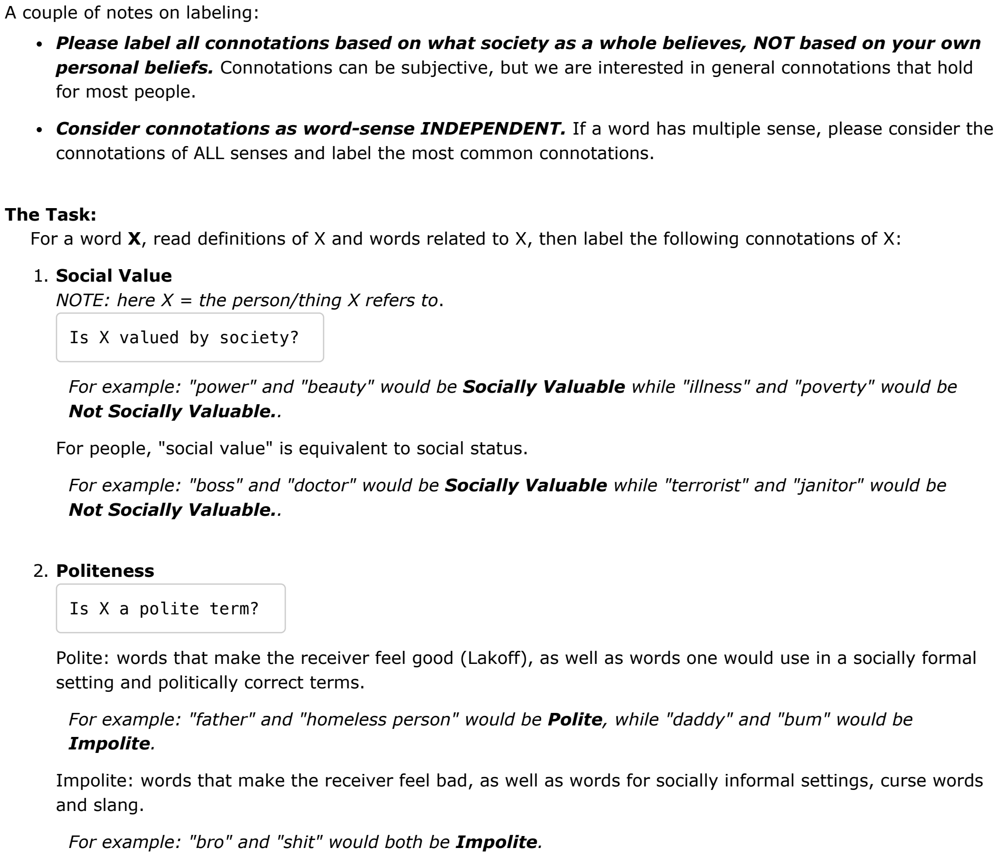
C.2 Gender Bias Analysis

Connotations have been used to study gender bias in movie scripts (Sap et al., 2017) and online media (Field et al., 2019). Here we use our connotation lexicon to analyze gender bias in two new domains: celebrity news (Celebrity) and student reviews of computer science professors (Professors).

We use existing datasets for these domains and the accompanying methodology of Chang and McKeown (2019) to infer word-level gender associations. Then, for the gender-associated words that are in our lexicon, for each connotation aspect and domain, we examine the percentage of positive and negative polarity words and find that these quantify known trends in gender-biased portrayals.

In the Celebrity domain, *Factuality* highlights the tendency of news media to focus on physical characteristics of female celebrities (Selby, 2014). More words with positive *Factuality* polarity (tangible concepts and attributes) are associated with women and more words with negative polarity (abstract concepts and attributes) are associated with men. For example, women are described as "beautiful" and "slim", while men are described as "political" and "presidential". In fact, even many of the not tangible female-associated words still align with physical attributes (e.g., "chic"), further emphasizing the biased portrayal.

We also find that in the Professors domain, patterns in *Social Value* and *Impact* agree with the observations of Chang and McKeown (2019) and with social science literature that finds male teachers are praised more than female teachers for being experts (both socially valuable and positively impacting society). For example, men are associated with posi-



A couple of notes on labeling:

- ***Please label all connotations based on what society as a whole believes, NOT based on your own personal beliefs.*** Connotations can be subjective, but we are interested in general connotations that hold for most people.
- ***Consider connotations as word-sense INDEPENDENT.*** If a word has multiple sense, please consider the connotations of ALL senses and label the most common connotations.

The Task:

For a word **X**, read definitions of X and words related to X, then label the following connotations of X:

1. **Social Value**

   NOTE: here X = the person/thing X refers to.

   `Is X valued by society?`

   *For example: "power" and "beauty" would be **Socially Valuable** while "illness" and "poverty" would be **Not Socially Valuable.**.*

   For people, "social value" is equivalent to social status.

   *For example: "boss" and "doctor" would be **Socially Valuable** while "terrorist" and "janitor" would be **Not Socially Valuable.**.*

2. **Politeness**

   `Is X a polite term?`

   Polite: words that make the receiver feel good (Lakoff), as well as words one would use in a socially formal setting and politically correct terms.

   *For example: "father" and "homeless person" would be **Polite**, while "daddy" and "bum" would be **Impolite**.*

   Impolite: words that make the receiver feel bad, as well as words for socially informal settings, curse words and slang.

   *For example: "bro" and "shit" would both be **Impolite**.*

Figure 5: First part of annotator instructions for connotation labeling in §3.3.

tive *Social Value* (socially valuable) words such as "knowledge" and "experience", while women are relatively less often associated with the same type of words.

Finally, in the Celebrity domain we find our lexicon reflects the coverage in the media of recent sexual harassment allegations against male celebrities. Namely, women are associated with more positive *Social Value* words and men are associated with many more negative *Social Value* words (see Table 11). Overall, our results quantitatively validate previous observations and known patterns of gender bias.

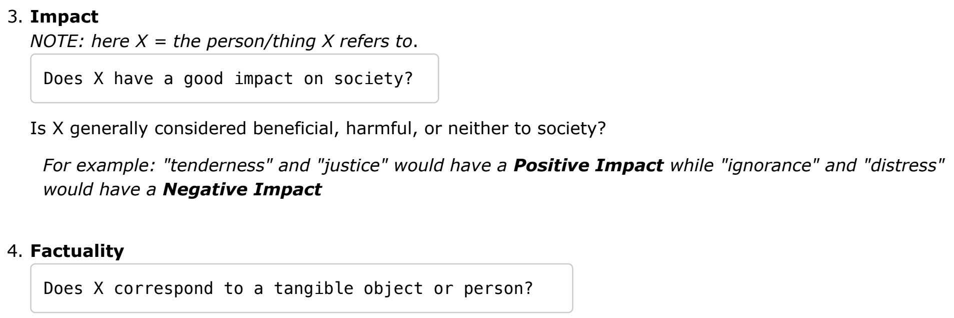
Aspect	Pol	F:M	Examples
Fact	+	54:27	F: beautiful, slim M: actor, film
	−	26:39	F: style, chic M: apology, political
Social Value	+	39:27	F: beauty, body, gold M: attempt, evidence
	−	3:24	F: blue, dancer, party M: abuse, allegation

Table 11: Gender bias examples in the Celebrity news domain. Pol is Polarity (tangible(+) vs. not tangible(−) and valuable (+) vs. not valuable (−)). F:M shows percent of female-associated words to percent of male-associated.

D Connotation Modeling

D.1 Data

We use dictionary definitions extracted from all available dictionaries on the Wordnik API: American Heritage Dictionary, CMU Pronouncing Dictionary, Macmillan Dictionary, Wiktionary, Webster's Dictionary, and WordNet. For labels, we use six aspects (see §3): *Social Value*, *Politeness*, *Impact*, *Factuality*, *Sentiment*, and *Emotional Association*. For verbs we use 11 aspects: perspective of the writer on the theme *P(wt)* and agent *P(wa)*, perspective of the agent on the theme *P(at)*, effect on the theme *E(t)* and agent *E(a)*, value of the theme *V(t)* and agent *V(a)*, mental state of the theme *S(t)* and agent *S(a)*, power, and agency.



3. **Impact**

NOTE: here X = the person/thing X refers to.

`Does X have a good impact on society?`

Is X generally considered beneficial, harmful, or neither to society?

For example: "tenderness" and "justice" would have a ***Positive Impact*** *while "ignorance" and "distress" would have a* ***Negative Impact***

4. **Factuality**

`Does X correspond to a tangible object or person?`

Figure 6: Second part of annotator instructions for connotation labeling in §3.3.

D.2 Hyperparameters

All models are trained with hidden size $H = 150$, number of definition words $N = 42$, number of related words $|R_{w^t}| = 20$ and dropout of 0.5 to prevent overfitting. For emotion prediction we set $\theta = 0.5$. We use Concept-Net numberbatch embeddings (Speer et al., 2016) because we find empirically that these outperform other pre-trained embeddings (GloVe and dependency-based embeddings (Levy and Goldberg, 2014)) on the development set.

We tune our only hyperparameters on the development set: the weights λ_a for the contribution of each loss term $\mathcal{L}^a$ to the total loss $\sum_a \lambda_a \mathcal{L}^a$ (see 4.1.3). We experiment with 10 manually selected weight combinations, where each $\lambda_a \in (0, 5)$. We find that the optimal weights are:

- $\lambda_a = 0.3$ for $a \in \{SocialVal, Impact, V(t), V(a), power, agency\}$
- $\lambda_a = 0.167$ for $a \in \{Fact, Sent\}$
- $\lambda_a = 1.0$ for $a \in \{P(wt), P(wa), P(at), E(t), E(a), S(t), S(a)\}$
- $\lambda_a = 0.5$ for $a = Polite$
- $\lambda_a = 3.0$ for $a = Emo$

Additionally, we compute expected validation performance (Dodge et al., 2019) on each connotation aspect individually (see Table 12).

D.3 Training

We optimize using Adam (Kingma and Ba, 2014) with learning rate 0.001 and minibatch-size of 64 for 80 epochs with early stopping. We optimize the parameters W^a, b^a for each noun and adjective aspect a separately from the parameters for each verb aspect a, allowing both to update the parameters of the definition encoder, and attention layer.

dle part are medium sized, and topics in the lower part are small sized.

E.2 Training Details

We split the data 60% train, 20% development, and 20% test. We train our models using pre-trained 100-dimensional word embeddings from GloVe (Pennington et al., 2014), as these are comparable to and more time-efficient than larger word embeddings. We use a hidden size of 60, dropout of 0.5, and train for 70 epochs with early stopping on the development set. We optimize Adam with learning rate 0.001 and minibatch-size of 64 on the cross-entropy loss. Our hyperparameters are set following Augenstein et al. (2016).

When truncating to medium size in §5.2, we truncate train topics to at most 2000 examples (`Trunc Train` and `Trunc All`) and development and test topics to at most 600 examples (`Trunc All`).

Topic	**# Ex**	**# C**	**# P**	**# N**

E.3 Topic Stance Analysis

We present a detailed analysis of the results of the models `BiC+W` and `BiC+C` on the stance detection on individual topics. First, we find that when the models are trained with all of the data (All Data), there are statistically significant differences on only two topics, one of which is very small (see Table 15a). This is further evidence that the models are comparable in this setting.

We then find that when trained with truncated training data (see §5.2 for details) (`Trunc Train`), `BiC+C` improves over `BiC+W` on six topics, including four of the medium or truncated large topics (see Table 15b). When trained and evaluated with truncated data (`Trunc All`), `BiC+W` and `BiC+C` have statistically significant improvements over each other on the same number of topics (two each) but `BiC+C` is significantly better overall (see

Table 15c). These results further show that connotations help to learn stance when data is limited.

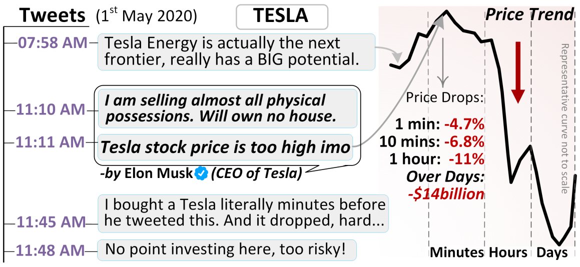
Abstract

Designing profitable trading strategies is complex as stock movements are highly stochastic; the market is influenced by large volumes of noisy data across diverse information sources like news and social media. Prior work mostly treats stock movement prediction as a regression or classification task and is not directly optimized towards profit-making. Further, they do not model the fine-grain temporal irregularities in the release of vast volumes of text that the market responds to quickly. Building on these limitations, we propose a novel hierarchical, learning to rank approach that uses textual data to make time-aware predictions for ranking stocks based on expected profit. Our approach outperforms state-of-the-art methods by over 8% in terms of cumulative profit and risk-adjusted returns in trading simulations on two benchmarks: English tweets and Chinese financial news spanning two major stock indexes and four global markets. Through ablative and qualitative analyses, we build the case for our method as a tool for daily stock trading.

1 Introduction

The stock market, a financial ecosystem involving quantitative trading and investing, observed a market capitalization exceeding $US 60 trillion as of 2019.[1] Stock trading presents lucrative opportunities for investors to utilize the market as a platform for investing funds and maximizing profits. However, making profitable investment decisions is challenging due to the market's volatile and rapid-changing nature (Adam et al., 2016; Foucault et al., 2016). Research at the intersection of natural language processing (NLP) and finance presents encouraging prospects in stock prediction (Jiang, 2020). Conventional work forecasts future trends by modeling numerical historic stock data (Lu et al., 2009; Bao et al., 2017). However, price signals alone can not capture market surprises, news, and company announcements. Such events, often reported across financial news and social media, have shown to influence market dynamics (Laakkonen, 2004). As shown in Figure 1, prices immediately react to breaking news about the related company. Such reactions conform to the Efficient Market Hypothesis (EMH), which states that financial markets are *informationally efficient* and prices reflect all available information (Malkiel, 1989).



07:58 AM – Tesla Energy is actually the next frontier, really has a BIG potential.

11:10 AM – *I am selling almost all physical possessions. Will own no house.*

11:11 AM – *Tesla stock price is too high imo*

-by Elon Musk *(CEO of Tesla)*

11:45 AM – I bought a Tesla literally minutes before he tweeted this. And it dropped, hard...

11:48 AM – No point investing here, too risky!

Figure 1: Here, we study how Tesla's tweets influence investors' opinions about the company and impact its stock price trend. The first tweet shows positive opinions, and we observe a rise in prices. Later, the tweets made by the CEO *rapidly* lead to drastic price drops within minutes. Further, without a sequential context, it gets challenging to understand the tweets that follow.

The abundance of stock affecting information across news and Twitter helps investors analyze market trends and inspires the adoption of NLP to study the interplay between textual data and stock prices (Xu and Cohen, 2018; Oliveira et al., 2017). However, unlike structured numerical data, analyzing natural language poses various challenges. First, analyzing individual tweets or news headlines may not be informative enough. They often exhibit a sequential context-dependency, where analyzing them together can provide a greater unified context,

---

*Equal contribution.

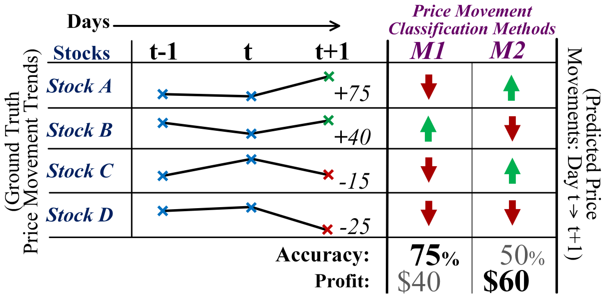

Figure 2: More accurate methods M_1 (higher accuracy) may not always be more profitable than less accurate methods M_2 (lower accuracy). Profit is gained by selling stocks having ⬆ prediction for price movement from trading day t to t+1.

as shown in Figure 1. Despite the success of recurrent neural networks (RNNs) in modeling such a sequential context (§2), a critical drawback is that they assume all text to be equally spaced in time, ignoring the inherent dynamic timing irregularities of social media and news. Timing plays a critical role as stock markets rapidly react to new information (Foucault et al., 2016), leading to significant price changes within minutes, as shown in Figure 1. Scholtus et al. (2014) show that reacting one second slower than other market participants can lead to a loss in thousands of dollars. Further, not each text holds the potential to influence stock prices, texts have a *diverse influence* on stock prices based on their content, such as breaking news or tweets from a reliable source, as opposed to noise like vague comments as shown in Figure 1. These observations mandate the need to factor in the *time-aware dependencies* and *diverse influence* in analyzing online natural language data for stock trading.

Despite profitability being the prime objective of trading, NLP methods for stock prediction (Xu and Cohen, 2018; Hu et al., 2017) are commonly framed as classification or regression tasks, and are not directly optimized towards profitable stock selection. Consider the toy example in Figure 2 that shows how methods having a higher classification accuracy may not always lead to higher overall profits. This research gap in NLP methods for stock prediction presents a new direction for stock selection, where both predictive performance and profits are jointly and directly optimized.

Contributions: We formulate stock prediction as a learning-to-rank problem (§**3.1**) and present `FAST`: **F**inancial News and Tweet based Time **A**ware Network for **S**tock **T**rading, which uses text for maximizing profit by jointly optimizing predictive power and the optimal ranking of stocks. `FAST` learns *time-aware* representations of financial news and tweets, and captures *relevant* market signals using hierarchical temporal attention for ranking stocks (§**3**). Through experiments (§**4**) on English and Chinese text corresponding to the NASDAQ, Shanghai, Shenzhen, and Hong Kong markets, we show that `FAST` outperforms state-of-the-art methods in terms of intraday returns by over 8% and risk-adjusted returns by over 10% (§**5.1**, §**5.2**). Further, through exploratory (§**5.3**, §**5.4**) and qualitative (§**6**) analyses, we demonstrate the practical applicability of `FAST` to daily stock trading.

2 Background

Conventional Methods: Stock prediction spans various methods, commonly framed as regression or classification tasks (Jiang, 2020). Conventional methods rely on numeric features like historical prices (Kohara et al., 1997; Lin et al., 2009), technical (Shynkevich et al., 2017), and macroeconomic indicators (Hoseinzade et al., 2019). These include discrete (Bollerslev, 1986), continuous (Andersen, 2007), and neural approaches (Zhang et al., 2017; Feng et al., 2019a). Despite their success, a limitation of these methods is that they are limited to numerical features and do not factor crucial stock influencing factors such as text (Lee et al., 2014).

Contemporary Methods: Newer models based on the EMH, leverage natural language features extracted from investor sentiments (Li and Shah, 2017), financial reports (Kogan et al., 2009; Rekabsaz et al., 2017), earnings calls (Qin and Yang, 2019), online news (Peng and Jiang, 2016; Chen et al., 2019a,b; Du and Tanaka-Ishii, 2020) and social media (Si et al., 2013; Tabari et al., 2018; Sawhney et al., 2020a) for stock price regression and movement classification tasks. These methods show how NLP can complement conventional price-based methods in capturing the effect of events like market surprises and mergers over stock returns. However, these methods do not directly optimize profit, and do not factor the fine-grain irregularities in release times of stock affecting text. For stock trading, the timing of release of information across these sources plays a critical role, as price changes rapidly factor all publicly available information (Norman, 2014). Firms may exploit investors' perception of market information (Forbes, 2009), for instance, by timing the release

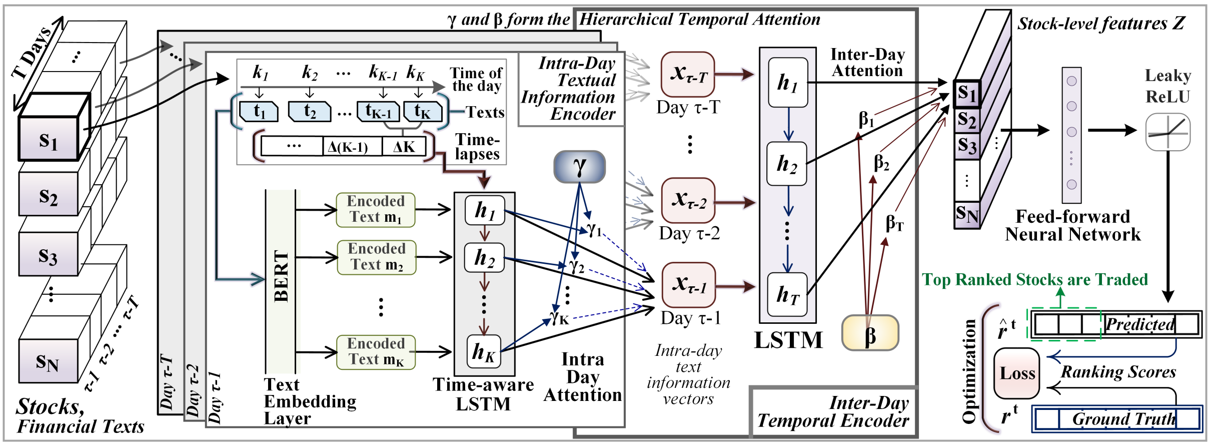

Figure 3: `FAST`: Time-aware modeling, hierarchical temporal attention, joint optimization for ranking.

of negative news between positive ones to minimize losses (Segal and Segal, 2016). These limitations hinder contemporary methods from modeling a time-aware progression of stock-affecting market signals to directly optimize profit generation.

Time-aware Methods: Recently, time-aware modeling of time series data has shown improvements over conventional sequential models like RNNs and LSTMs on various tasks such as patient subtyping (Baytas et al., 2017), suicide ideation and buildup detection using Twitter history (Sawhney et al., 2020b), disease progression (Gao et al., 2020), and much more. However, modeling the temporal dynamics inherent in social media and online news is complex as it involves noisy and diversely influential data across irregular time intervals. The intersection of modeling the temporal dynamics of natural language with finance presents an underexplored yet promising research avenue.

3 Proposed Approach: `FAST`

3.1 Problem Formulation: Stock Ranking

We adopt a learning to rank formulation for stock selection. Let $S = \{s_1, s_2, \dots, s_N\}$ represent a set of N stocks, where for every stock $s_i \in S$, on a trading day τ, there is an associated closing price p^τ and a one-day return ratio $r_i^\tau = \frac{p^\tau - p^{\tau-1}}{p^{\tau-1}}$. On any given trading day τ, there exists an optimal *ranking* $Y^\tau = \{y_1^\tau > y_2^\tau \cdots > y_N^\tau\}$ of the stocks, such that a total order exists between the ranks $y_i^\tau > y_j^\tau$ for any two stocks $s_i, s_j \in S$, provided $r_i^\tau > r_j^\tau$. Such an ordering of stocks S on a trading day τ represents a ranking list, where stocks achieving higher ranking scores Y are expected to generate a higher investment revenue (profit) on day τ. Formally, given stock-relevant textual data (financial news or tweets) for a lookback period of length T days (i.e., days $\in [\tau - T, \tau - 1]$), we aim to learn a ranking function that outputs a score $\hat{r}^\tau$ to rank each stock s on day τ in terms of their expected profit.

We now describe the components of `FAST` as shown in Figure 3, for *hierarchically* and *attentively* learning *time-aware* representations of news and tweets within (§**3.2**) and across (§**3.3**) the days in the lookback period. Lastly, we optimize `FAST` to rank stocks in terms of expected profitability (§**3.4**) for daily stock trading.

3.2 Intra-Day Textual Information Encoder

To model the news or tweets over a day, `FAST` first encodes the texts via an embedding layer.

Text Embedding Layer: Owing to the success of transfer learning and pre-training of language models in NLP, we use Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2019) to encode the texts. BERT has shown to capture more contextual text representations as opposed to methods like word2vec (Hu et al., 2017), GloVe (Xu and Cohen, 2018), ELMO (Mohammadi et al., 2019). We encode each text t to a higher dimensional representation $m = \text{BERT}(t) \in \mathbb{R}^d$ where $d = 768$, obtained by averaging the token level outputs from the final layer of BERT.

Learning Stock Representations for One Day: For each stock s on any given day i, a variable number of texts (news or tweets) $[t_1, t_2, \dots t_K]$ are posted at times $[k_1, k_2, \dots k_K]$ that may discuss news or express sentiments towards the stock. We encode each of the K texts posted in a day, using

BERT as $[m_1, m_2, \dots m_K]$. Often, analyzing a single text alone may not be informative enough to analyze a stock (Barber and Odean, 2007). Whereas, analyzing a *sequence* of texts released over the day provides a unified context to gain a more informed understanding of the performance of a stock (Hu et al., 2017).

RNNs, particularly LSTMs are a natural way to capture such *sequential context dependencies* in tweets and news over time (Akhtar et al., 2017). However, a standard LSTM assume inputs (texts) to be equally spaced sequences in time. In contrast, the time interval between news releases or tweets can vary widely, from a few seconds to many hours that can have a drastic impact on their influence on the market (Robertson et al., 2007; O'Hara, 2015). Consequently, news and opinions may change substantially over a day. Capturing the fine-grained granularities in the posting times of online text can lead to better and quicker reactions to market opportunities and increased profits.[2]

Since timing serves as a crucial factor to model the *progression* of market data (Tafti et al., 2016), we propose the use of a **time-aware LSTM** (t-LSTM) (Baytas et al., 2017), by modifying a standard LSTM. We feed the time between texts to the t-LSTM cell to model the **temporal irregularities** in news and tweets. The t-LSTM applies a decay to the short-term memory in the LSTM according to the time elapsed between the release of two successively posted texts. Formally, the t-LSTM adopts a decaying function of elapsed time, transforming the time differences into appropriate weights for each input as:

$$
\begin{aligned}
C^S_{k-1} &= tanh(W_d C_{k-1} + b_d) && \text{(Short-term memory)}\\
\tilde{C}^S_{k-1} &= C^S_{k-1} * g(\Delta k) && \text{(Discounted short-term memory)}\\
C^{LT}_{k-1} &= C_{k-1} - C^S_{k-1} && \text{(Long-term memory)}\\
C^{*}_{k-1} &= C^{LT}_{k-1} + \tilde{C}^S_{k-1} && \text{(Adjusted previous memory)}
\end{aligned}
$$

where C_{k-1} is the previous cell memory, $\{W_d, b_d\}$ are the network parameters, Δk is the elapsed time between two financial news or tweets $[t_k, t_{k-1}]$, and $g(\cdot)$ is a heuristic decaying function. We select $g(\Delta k) = 1/\Delta k$ empirically as suggested by Baytas et al. (2017). Intuitively, the greater the elapsed time between two news or tweets, the lesser impact they should have on each other due to the market's dynamic nature. The t-LSTM computes the current hidden state h_k for each input text t_k generated in a day, as:

$$
\begin{aligned}
\tilde{C} &= tanh(W_c m + U_c h_{k-1} + b_c) && \text{(Candidate memory)}\\
C_k &= f_k * C^{*}_{k-1} + i_k * \tilde{C} && \text{(Current memory)}\\
h_k &= o_k * tanh(C_k) && \text{(Current hidden state)}
\end{aligned}
$$

where $\{W_c, U_c, b_c\}$ are the network parameters of the candidate memory $\tilde{C}$, m is the embedding for text t_k and $\{i_k, f_k, o_k\}$ are input, forget and output gates. We encode the texts for each stock s on day i using the t-LSTM as:

$$h_j = \text{t-LSTM}(m_j, \Delta j, h_{j-1}); j \in [1, K] \tag{1}$$

where the hidden state h_j represents the current text j as well as the preceding texts while focusing on text j in a time-aware fashion. All news and tweets released in a day may not be equally informative, and have *diverse influence* over a stock's trend (Barber and Odean, 2007). We use an intra-day attention mechanism (Luong et al., 2015) to emphasize texts likely to have a more substantial influence on the price. As shown in Figure 3, the intra-day attention mechanism learns to adaptively aggregate the variable number of hidden states of the t-LSTM (due to a variable number of texts per day) into an *intra-day text information vector* x_i as:

$$x_i = \sum_j \gamma_j h_j, \gamma_j = \frac{\exp\left(h_j^{\mathrm{T}}(W\bar{h}_m)\right)}{\sum_{j=1}^{K} \exp\left(h_j^{\mathrm{T}}(W\bar{h}_m)\right)} \tag{2}$$

where $\bar{h}_m \in \mathbb{R}^{K \times d_m}$ denotes the concatenation of all the hidden states from the t-LSTM, d_m is the dimension of each hidden state, γ_j represents the learned attention weights, and W is a parameter.

3.3 Inter-Day Temporal Encoder

We now combine the representations learned from texts in each day across multiple days in a lookback period. We combine these representations in a *hierarchical* manner within and across days, using the sequence of intra-day text information vectors x. Since days are equally spaced in time, we first feed the vectors x to an LSTM layer as:

$$h_i = \text{LSTM}(x_i, h_{i-1}); \quad \tau - T \le i \le \tau - 1 \tag{3}$$

where, h_i is the hidden state representation for day i. However, as per the the adaptive market hypothesis (Lo, 2004), tweets and news published across different days have shown to have a varying impact on stock prices (Calvet and Fisher,

---

[2] Every millisecond lost results in \$100m per annum in lost opportunity. Details: `https://en.wikipedia.org/wiki/Low_latency_(capital_markets)`

2007), due to financial phenomena such as calendar anomalies (Jacobs and Levy, 1988), the week-day effect (Berument and Kiymaz, 2001), etc. To selectively weigh critical days, we employ an inter-day attention mechanism (Luong et al., 2015). The inter-day attention aggregates representations across all days into an *overall representation* z_τ using the learned attention weights β_i for day i as:

$$z_\tau = \sum_i \beta_i h_i, \beta_i = \frac{\exp\left(h_i^{\mathrm{T}}(W\bar{h}_z)\right)}{\sum_{i=1}^{T} \exp\left(h_i^{\mathrm{T}}(W\bar{h}_z)\right)} \tag{4}$$

where, W is a learned linear transform, $\bar{h}_z \in \mathbb{R}^{T \times d_z}$ represents the concatenated hidden states, d_z is the size of output space of LSTM. The inter-day and the intra-day attention together comprise a **hierarchical temporal attention**. FAST captures time-aware dependencies in large volumes of *chaotic* text to rank stocks, as described next.

3.4 Ranking and Network Optimization

To optimize FAST for stock ranking, we first concatenate the temporal representations z_τ obtained for each stock s to form stock-level features Z. We then feed Z to a feed-forward neural network followed by a Leaky-ReLU activation (Maas et al., 2013) which outputs the predicted return ratio $\hat{r}^\tau$ for stock ranking. We optimize FAST through a joint point-wise regression and pairwise rank-aware loss L, to minimize the differences between the predicted and the actual return ratios, while maintaining the relative order of the top-ranked stocks as:

$$L = \|\hat{r}^\tau - r^\tau\|^2 + \phi \sum_{i=1}^{N}\sum_{j=1}^{N} \max\left(0, -\left(\hat{r}_i^\tau - \hat{r}_j^\tau\right)\left(r_i^\tau - r_j^\tau\right)\right) \tag{5}$$

where $\hat{r}^\tau$ and r^τ are the predicted and actual scores for ranking stocks on day τ and ϕ is a loss weighing parameter.

4 Experimental Setup

4.1 Datasets and Stock Markets

US S&P 500[3] (Xu and Cohen, 2018): Comprises 109,915 *English tweets* from social media platform Twitter spanning January 2014 to December 2015, related to 88 high-trade-volume-stocks from the *NASDAQ* Stock Exchange forming the *S&P 500* index. Xu and Cohen (2018) extract stock specific tweets using regex queries made of stock tickers (e.g., $AAPL for Apple, $ is a *cashtag* on Twitter).

China & Hong Kong[4] (Huang et al., 2018): Comprises 90,361 financial *news headlines* in *Chinese* spanning from January to December 2015, aggregated by *Wind*[5] related to 85 top-traded *China A-share* stocks in Shanghai, Shenzhen and the Hong Kong Stock Exchange. Huang et al. (2018) extract corporate news from major financial websites.

Pre-processing: We pre-process English tweets using NLTK (Twitter mode), for treatment of URLs, identifiers (@) and hashtags (#). We adopt the Bert-Tokenizer for tokenization. For the English tweets, we use the pre-trained BERT-base-cased.[6] For the Chinese news, we adopt the Chinese-BERT.[6] We collect historical prices for all stocks from Yahoo Finance.[7] We align trading days by dropping samples that lack tweets for a consecutive 5-day trading window, and further align the data across trading windows for stocks to ensure data is available for all trading days in the window for the same set of stocks. We split the US S&P 500 temporally based on date ranges from 01/01/2014 to 31/07/2015 for training, 01/08/2015 to 30/09/2015 for validation, and 01/10/2015 to 01/01/2016 for testing. We split the China & HK dataset temporally based on date ranges from 01/01/2015 to 31/08/2015 for training, 01/09/2015 to 30/09/2015 for validation, and 01/10/2015 to 01/01/2016 for testing all models.

4.2 FAST Training Setup

We conduct all experiments on a Tesla P100 GPU. We use grid search to find optimal hyperparameters based on the validation Sharpe Ratio (§**4.3**) for all models. We explore lookback window length $T \in \text{range}[2, 10]$ (best $T = 5$), loss weighing factor $\phi \in \text{range}[1, 10]$ (best $\phi = 4$), and the hidden state dimension for both t-LSTM and LSTM $d \in [32, 64, 128]$ (best $d = 64$) for both datasets. We use Xavier initialization (Glorot and Bengio, 2010) to initialize all weights. We use an exponential learning rate scheduler (Li and Arora, 2019) with a decay rate of 0.05 and an initial learning rate of $5e-4$. We train FAST end-to-end using the Adam optimizer (Kingma and Ba, 2014) for 500 epochs requiring 8 hours of compute time.

4.3 Evaluation Metrics and Trading Strategy

Returns: To assess the profit generation ability of all methods (§4.4), we compute the **Sharpe ratio (SR)**, a measure of the return of a portfolio compared to its risk (Sharpe, 1994), and the cumulative **investment return ratio (IRR)**. Following Feng et al. (2019b), we adopt a daily *buy-hold-sell* trading strategy, that is, when the market closes on trading day $\tau-1$, the trader uses the method to get a ranked list of the predicted return ratio for each stock. The trader then buys the top η stocks and then sells the bought stocks on the market close of the trading day τ. The IRR on any day τ is defined as, $\text{IRR}^{\tau}=\sum_{i\in\mathcal{S}^{\tau-1}}\frac{p_i^{\tau}-p_i^{\tau-1}}{p_i^{\tau-1}}$ where, $\mathcal{S}^{\tau-1}$ denotes the set of stocks in the portfolio on day $\tau-1$ and p_i^{τ}, $p_i^{\tau-1}$ are the closing price of the stock i on days τ and $\tau-1$ respectively. We calculate SR by computing the earned return R_a in excess of the risk-free return[8] R_f, defined as: $\text{SR}=\frac{E[R_a-R_f]}{std[R_a-R_f]}$.

Ranking: We also evaluate the stock ranking ability of `FAST` using two widely-used ranking metrics: **Mean Reciprocal Rank (MRR)** and **Normalized Discounted Cumulative Gain (NDCG@η)**. MRR is the reciprocal rank of the first relevant stock while, NDCG@η sums the true scores for the top η stocks, ranked in the order induced by the predicted scores, after applying a logarithmic discount. For both returns and NDCG, we report results for top $\eta=5$ stocks, and present performance variations with different values of top stocks η (§5.4).

4.4 Baselines

We compare `FAST` with baselines spanning different formulations: *regression*, *classification*, *reinforcement learning*, and *ranking*. We follow the same preprocessing protocols as proposed by the works and adopt their implementation, if available.

***Regression* (REG)** These methods regress return ratios from past data and trade the top stocks.

- **AZFinText:** Proper noun-based text representations fed to Support Vector Regression for forecasting return ratios (Schumaker and Chen, 2009).
- **W-LSTM:** LSTMs with stacked autoencoders that encode noise-free data obtained through wavelet transform of historic prices (Bao et al., 2017).

***Classification* (CLF)** The following methods classify movements as $[up, down, neutral]$ and trade the stocks where prices are expected to rise.

- **TSLDA:** Topic Sentiment Latent Dirichlet Allocation, a generative model jointly exploiting topics and sentiments in text (Nguyen and Shirai, 2015).
- **CH-RNN:** An RNN with cross-modal attention on price trends and texts across days (Wu et al., 2018).
- **StockEmb:** Stock embeddings acquired using prices, and dual vector (word-level, context-level) representation of texts (Du and Tanaka-Ishii, 2020).
- **SN - HFA:** StockNet - HedgeFundAnalyst, a variational autoencoder with attention on texts and prices (Xu and Cohen, 2018).
- **HAN:** A Hierarchical Attention Network using GRU encoders with temporal attention on texts and days in the lookback period (Hu et al., 2017).

***Reinforcement Learning* (RL)** The following approaches optimize quantitative trading through reinforcement learning.

- **iRDPG:** An imitative RDPG algorithm exploiting temporal stock price features, while optimizing the Sharpe Ratio as the reward (Liu et al., 2020).
- **S-Reward:** Inverse-RL method to model relations between sentiments and returns (Yang et al., 2018).

***Ranking* (RAN)** The following methods rank stocks to select most profitable trading candidates.

- **R-LSTM:** Utilizes 5, 10, 20, 30-day averages and closing prices to train an LSTM (Feng et al., 2019b).
- **RankNet:** A DNN that utilizes sentiment-based shock and trend scores to optimize a probabilistic ranking function (Song et al., 2017).

5 Results and Discussion

5.1 Profitability Comparison with Baselines

As the ultimate goal of stock prediction is profit, we compare the profitability of `FAST` against baseline methods in Table 2. `FAST` generates significantly ($p < 0.001$) higher cumulative and risk-adjusted returns than all methods. Overall, we observe that RL and ranking methods are more profitable as they are directly optimized towards profit generation through stock selection. This observation validates the premise of formulating stock prediction as a learning-to-rank problem, compared to conventionally adopted regression and classification tasks.

Further, we find methods that study stock affecting information from news and tweets, generate profits higher or comparable to methods that only use historical prices. These improvements revalidate the effectiveness of leveraging textual sources to capture stock affecting signals like market surprises, announcements (mergers, acquisitions) and public sentiment. We attribute the higher profitability of `FAST` to two major reasons. First, through its hierarchical temporal attention mechanism, `FAST` captures the diverse influence of different texts and days over stock movements. Second, as `FAST` is time-aware, it models the influence of fine-grain temporal irregularities in the release of financial news and tweets over stock movements.

The test periods of the US S&P 500 and the China & Hong Kong datasets span diverse market conditions. The China & Hong Kong test period covers the 2015-16 China Stock Market Turbulence (Liu et al., 2016), a bearish market scenario,[9] and that of US S&P 500 covers standard market conditions. We find that `FAST` is profitable and outperforms existing baselines over such diverse market scenarios. Next, we further probe the performance of `FAST` through a series of ablative experiments.

5.2 `FAST` Component Ablation

Table 1 shows how `FAST`'s stock ranking ability and profitability benefits from each of its components. On just feeding all data into a single LSTM, we observe poor performance. As we adopt the intra-day (LSTM) and the temporal (LSTM) encoders, we observe higher profits that suggest benefit in modeling the sequential context of texts hierarchi-

---

[9] Bearish markets are those that experience prolonged price declines, and experience high volatility and risk on investments.

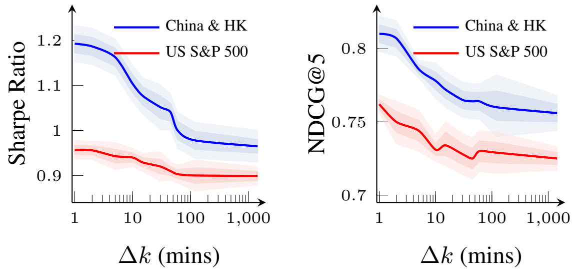

Figure 4: Profitability and ranking performance against granularities of time difference Δk adopted by t-LSTM

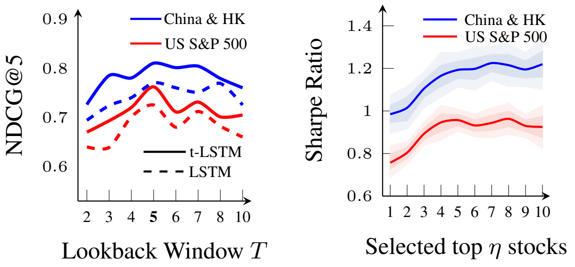

Figure 5: Sensitivity to parameters T and η

cally within and across days. Further, on adding intra-day attention, we note improvements in profit as `FAST` can better distinguish noise inducing text from relevant market signals, minimizing false evaluations and overreactions (De Long et al., 1990). The attention mechanism can likely diminish the impact of such noise (rumours, vague comments). Intuitively, complementing the intra-day with the inter-day attention lead to further improvements as `FAST` can better capture the *diverse influence* of texts, hierarchically within and across days.

Next, we note the biggest improvements on adding the t-LSTM instead of a standard LSTM as the intra-day encoder, suggesting that `FAST` benefits by factoring the fine-grain time irregularities in texts to model the flow of stock-affecting information (Kalev et al., 2004). Through this time-aware mechanism, `FAST` can potentially better react to online news and tweets, by discounting stale information more accurately by factoring in fine-grained elapsed time differences (seconds). We further quantify the impact of time-aware modeling on the improvements in ranking and profitability, next.

5.3 Advantages of Time-Aware Modeling

The influence of older information over the market decreases rapidly as newer data is released (Russell, 2010). As we coarsen the granularity of the elapsed time difference between two texts fed to the t-LSTM, from minutes, to hours, to a day, we observe drops in `FAST`'s performance as shown in Figure 4. At the coarsest granularity of a day, the t-LSTM essentially degenerates to an LSTM, and attains the lowest performance. The drops show that factoring time at finer granularities benefits `FAST` in modeling the temporal dynamics of market response to stock affecting signals. Our findings line with financial research that shows market reactions to news complete within minutes (Smales, 2013), and the impact of news and tweets achieves an equilibrium over time (Shen et al., 2018).

5.4 Parameter Analysis: Probing Sensitivity

Lookback window length T: Here, we study how `FAST`'s stock ranking performance (NDCG@5) varies with the length of lookback $T \in [2, 10]$ days in Figure 5. Lower ranking performance indicates the inability of shorter lookbacks to capture stock affecting market information, likely as public information requires time to absorb into price movements (Luss and D'Aspremont, 2015). As we increase T, we find that larger lookbacks allow the inclusion of stale information from older days having relatively lower influence on prices (Bernhaedt and Miao, 2004), thus deteriorating the ranking performance. We observe the best stock ranking performance for mid-sized (approx. 5-day) lookback periods.

Selected top stocks η: We analyze `FAST`'s profitability (SR) variation with the number of top stocks η in Figure 5. We find that `FAST` performs well across varying η, showing suitability to strategies having different risk taking appetites.

6 `FAST` Qualitative Analysis

We now conduct an extended analysis as shown in Figure 6 to elucidate on `FAST`'s explainable predictions and practical applicability to real-world quantitative trading. Here, we study the China & Hong Kong market during 5^{th} - 9^{th} December 2015. We visualize token-level and hierarchical temporal attention to analyze how `FAST` ranks stocks on 10^{th} December 2015, outperforming the state-of-the-art baseline methods: RankNet and SN-HFA.

Analyzing Hierarchical Attention: Within days, the intra-day attention filters less informative news and emphasizes more influential ones. For instance, we observe that the second news about BOE Technology on 7^{th} categorizes the stock as "overweight," a rating through which equity

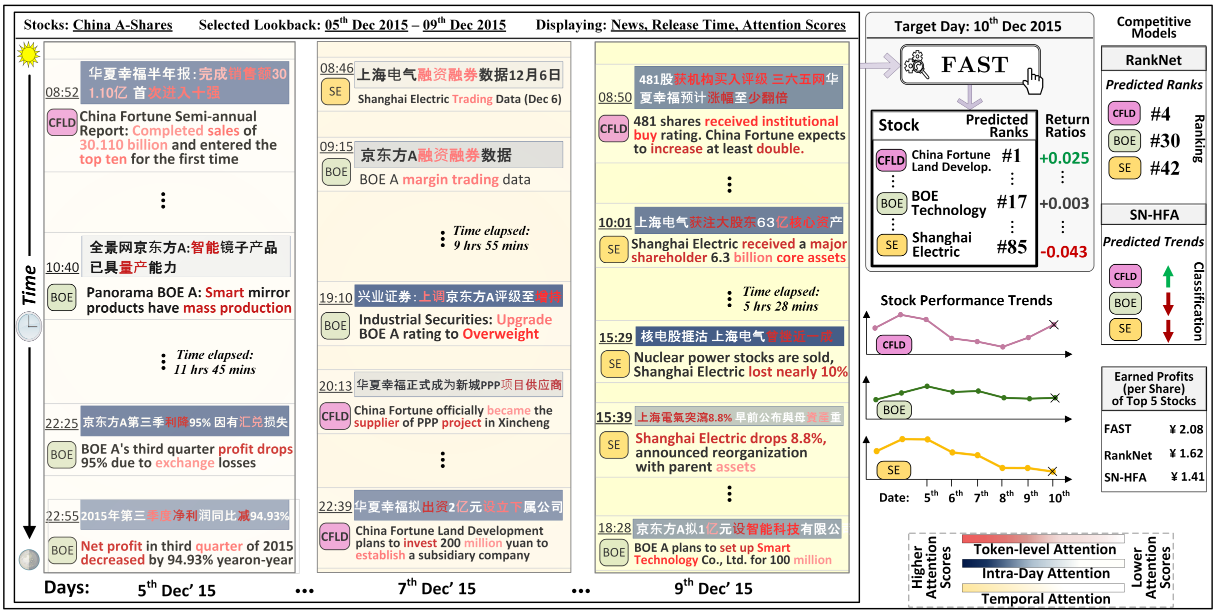

Figure 6: Financial news in Chinese (shown with corresponding English translations) during 5^{th}-9^{th} December 2015 for stocks in the China & Hong Kong dataset (test split), with visualization of FAST's attention mechanisms (left); Stock trading performance for 10^{th} December 2015 across FAST and competitive baseline methods (right).

analysts forecast better future performance (Kumar, 2009). Such news would likely induce positive public sentiments and drive more investment to the stock, as opposed to the less informative news about "margin trading data." The intra-day attention accurately captures the *diverse influence* of such news headlines. Further, we observe that news released on 9^{th} comprises relatively more crucial information than other days, and the inter-day attention accurately emphasizes its importance. These observations reiterate the diverse influence of different news and days over future stock returns, accurately captured by the hierarchical temporal attention mechanism.

Probing Time-aware Modeling: The news released for Shanghai Electric (SE) on the morning of 9^{th} reports a positive event, likely indicating future profits. Later during that afternoon, after a few hours, two other news report negative impacts over SE due to a loss in nuclear power stocks, indicating a downtrend for the upcoming days. `FAST` disregards older news to emphasize on the newer ones to forecast the upcoming loss and allots a lower rank to SE. In contrast, ranking methods such as RankNet assign a higher rank to SE, potentially due to their inability to model the time-aware dependencies. Further, classification methods like SN-HFA do not correctly predict the stock return trends, as they do not capture the fine-grain temporal irregularities in texts, and are not optimized towards profit. Consequently, `FAST` relatively outperforms SN-HFA by a margin of 47.5%, and RankNet by 28.4% in profits on 10^{th} December 2015.

7 Conclusion

We propose `FAST`, a neural approach to rank profitable stocks using stock-relevant textual data across online financial news and tweets. To model the market information, `FAST` hierarchically learns temporally relevant signals from texts and shows the positive effects of factoring the fine-grain temporal irregularities in textual data. Through quantitative and qualitative analyses on English tweets and Chinese financial news spanning four stock markets, we highlight the real-world applicability of `FAST`. In trading simulations on the S&P 500 and China A-shares indexes, `FAST` outperforms state-of-the-art methods across four different formulations by over 8% in terms of profit and Sharpe Ratio.

Abstract

Most well-established data collection methods currently adopted in NLP depend on the assumption of speaker literacy. Consequently, the collected corpora largely fail to represent swathes of the global population, which tend to be some of the most vulnerable and marginalised people in society, and often live in rural developing areas. Such underrepresented groups are thus not only ignored when making modeling and system design decisions, but also prevented from benefiting from development outcomes achieved through data-driven NLP. This paper aims to address the under-representation of illiterate communities in NLP corpora: we identify potential biases and ethical issues that might arise when collecting data from rural communities with high illiteracy rates in Low-Income Countries, and propose a set of practical mitigation strategies to help future work.

1 Introduction

The exponentially increasing popularity of supervised Machine Learning (ML) in the past decade has made the availability of data crucial to the development of the Natural Language Processing (NLP) field. As a result, much NLP research has focused on developing rigorous processes for collecting large corpora suitable for training ML systems. We observe, however, that many best practices for quality data collection make two implicit assumptions: that speakers have internet access and that they are literate (i.e. able to read and often write text effortlessly[1]). Such assumptions might be reasonable in the context of most High-Income Countries (HICs) (UNESCO, 2018). However, in Low-Income Countries (LICs), and especially in sub-Saharan Africa (SSA), such assumptions may not hold, particularly in rural developing areas where the bulk of the population lives (Roser and Ortiz-Ospina (2016), Figure 1). As a consequence, common data collection techniques – designed for use in HICs – fail to capture data from a vast portion of the population when applied to LICs. Such techniques include, for example, crowdsourcing (Packham, 2016), scraping social media (Le et al., 2016) or other websites (Roy et al., 2020), collecting articles from local newspapers (Marivate et al., 2020), or interviewing experts from international organizations (Friedman et al., 2017). While these techniques are important to easily build large corpora, they implicitly rely on the above-mentioned assumptions (i.e. internet access and literacy), and might result in demographic misrepresentation (Hovy and Spruit, 2016). In this paper, we make a first step towards addressing *how to build representative corpora in LICs from illiterate speakers*. We believe that this is a currently unaddressed topic within NLP research. It aligns with previous work investigating sources of bias resulting from the under-representation of specific demographic groups in NLP corpora (such as women (Hovy, 2015), youth (Hovy and Søgaard, 2015), or ethnic minorities (Groenwold et al., 2020)). In this paper, we make the following contributions: (i) we introduce the challenges of collecting data from illiterate speakers in §2; (ii) we define various possible sources of biases and ethical issues which can contribute to low data quality we define various possible sources of biases and ethical issues which can contribute to low data quality we define various possible sources of biases and ethical issues which can contribute to low data quality §3; finally, (iii) drawing on years of experience in data collection in LICs, we outline practical countermeasures to address these issues in §4.

---

[1] For example, input from speakers is often taken in writing, in response to a written stimulus which must be read.

(a) Adult literacy (% ages 15+, UNESCO (2018))

(b) Urban population (% total, UN-DESA (2018))

(c) Internet usage (% of total, ITU (2019))

Figure 1: Literacy, urban population, and internet usage in African countries. Note that countries with more rural populations tend to have less literacy and less internet users. These countries are likely to be under-represented in corpora generated using common data collection methods that assume literacy and internet access (Grey: no data).

2 Listening to the Illiterate: What Makes it Challenging?

In recent years, developing corpora that encompasses as many human languages as possible has been recognised as important in the NLP community. In this context, widely translated texts (such as the Bible (Mueller et al., 2020) or the Human Rights declaration (King, 2015)) are often used as a source of data. However, these texts tend to be quite short and domain-specific. Moreover, while the Internet constitutes a powerful data collection tool which is more representative of real language use than the previously-mentioned texts, it excludes illiterate communities, as well as speakers which lack reliable internet access (as is often the case in rural developing settings, Figure 1).

Given the obstacles to using these common language data collection methods in LIC contexts, the NLP community can learn from methodologies adopted in other fields. Researchers from fields such as sustainable development (SD, Gleitsmann et al. (2007)), African studies (Adams, 2014), and ethnology (Skinner et al., 2013), tend to rely heavily on qualitative data from oral interviews, transcribed verbatim. Collecting such data in rural developing areas is considerably more difficult than in developed or urban contexts. In addition to high illiteracy levels, researchers face challenges such as seasonal roads and low population densities. To our knowledge, there are very few NLP works which explicitly focus on building corpora from rural and illiterate communities: of those works that exist, some present clear priming effect issues (Abraham et al., 2020), while others focus on application (Conforti et al., 2020). A detailed description of best practices for data collection remains a notable research gap.

3 Definitions and Challenges

Guided by research in medicine (Pannucci and Wilkins, 2010), sociology (Berk, 1983), and psychology (Gilovich et al., 2002), NLP has experienced increasing interest in ethics and bias mitigation to minimise unintentional demographic misrepresentation and harm (Hovy and Spruit, 2016). While there are many stages where bias may enter the NLP pipeline (Shah et al., 2019), we focus on those pertinent to *data collection* from rural illiterate communities in LICs, leaving the study of biases in model development for future work[2].

3.1 Data Collection Biases

Biases in data collection are inevitable (Marshall, 1996) but can be minimised when known to the researcher (Trembley, 1957). We identify various biases that can emerge when collecting language data in rural developing contexts, which fall under three broad categories: sampling, observer, and response bias. Sampling determines who is studied, the interviewer (or observer) determines what information is sought and how it is interpreted, and the interviewee (or respondent) determines which information is revealed (Woodhouse, 1998). These categories span the entire data collection process and can affect the quality and quantity of language data obtained.

---

[2] Note, this paper does not focus on a particular NLP application, as once the data has been collected from illiterate communities it can be annotated for virtually any specific task.

3.2 Sampling or selection bias

Sampling bias occurs when observations are drawn from an unrepresentative subset of the population being studied (Marshall, 1996) and applied more widely. In our context, this might arise when selecting communities from which to collect language data, or specific individuals within each community. When sampling communities, bias can be introduced if convenience is prioritized. Communities which are easier to access may not produce language data representative of a larger area or group. This can be illustrated through Uganda's refugee response, which consists of 13 settlements (including the 2nd largest in the world) hosted in 12 districts (UNHCR, 2020). Data collection may be easier in one of the older, established settlements; however, such data cannot be generalised over the entire refugee response due to different cultural backgrounds, length of stay of refugees in different areas, and the varied stages along the humanitarian chain – emergency, recovery or development – found therein (Winter, 1983; OECD, 2019). Prioritizing convenience in this case may result in corpora which over-represents the cultural and economic contexts of more established, longer-term refugees. When sampling interviewees, bias can be introduced when certain sub-sets of a community have more data collected than others (Bryman, 2012). This is seen when data is collected only from men in a community due to cultural norms (Nadal, 2017), or only from wealthier people in cell-phone-based surveys (Labrique et al., 2017).

3.2.1 Observer bias

Observer bias occurs when there are systematic errors in how data is recorded, which may stem from observer viewpoints and predispositions (Gonsamo and D'Odorico, 2014). We identify three key observer biases relevant to our context.

Firstly, **confirmation bias**, which refers to the tendency to look for information which confirms one's preconceptions or hypotheses (Nickerson, 1998). Researchers collecting data in LICs may expect interviewees to express needs or hardships based on their preconceptions. As Kumar (1987) points out, "often they hear what they want to hear and ignore what they do not want to hear". A team conducting a needs assessment for a rural electrification project, for instance, may expect a need for electricity, and thus consciously or subconsciously seek data which confirms this, interpret potentially unrelated data as electricity-motivated (Hirmer and Guthrie, 2017), or omit data which contradicts their hypothesis (Peters, 2020). Using such data to train NLP models may introduce unintentional bias towards the original expectations of the researchers instead of accurately representing the community.

Secondly, the interviewer's understanding and interpretation of the speaker's utterances might be influenced by their class, culture and language. Note that, particularly in countries without strong language standardisation policies, consistent semantic shifts can happen even between varieties spoken in neighboring regions (Gordon, 2019), which may result in systematic **misunderstanding** (Sayer, 2013). For example, in the neighboring Ugandan tribes of Toro and Bunyoro, the same word *omunyoro* means respectively *husband* and *a member of the tribe*. Language data collected in such contexts, if not properly handled, may contain inaccuracies which lead to NLP models that misrepresent these tribes. Rich information communicated through gesture, expression, and tone (i.e. nonverbal data, Oliver et al. (2005)) may also be systematically lost during verbatim transcription, causing inadvertent inconsistencies in the corpora.

Thirdly, **interviewer bias**, which refers to the subjectivity unconsciously introduced into data gathering by the worldview of the interviewer (Frey, 2018). For instance, a deeply religious interviewer may unintentionally frame questions through religious language (e.g. *it is God's will*, *thank God*, etc.), or may perceive certain emotions (e.g. thankfulness) as inherently religious, and record language data including this perception. The researcher's attitude and behaviour may also influence responses (Silverman, 2013); for instance, when interviewers take longer to deliver questions, interviewees tend to provide longer responses (Matarazzo et al., 1963). Unlike in internet-based language data collection, where all speakers are exposed to uniform, text-based interfaces, collecting data from illiterate communities necessitates the presence of an interviewer, who cannot always be the same person due to scalability constraints, introducing this inevitable variability and subsequent data bias.

3.2.2 Response bias

Response bias occurs when speakers provide inaccurate or false responses to questions. This is particularly important when working in rural settings, where the majority of data collection is currently related to SD projects. The majority of existing data is biased by the projects for which it has been collected, and any newly collected data for NLP uses is also likely to be used in decision making for SD. This inherent link of data collection to material development outcomes inevitably affects what is communicated. There are five key response biases relevant to our context.

Firstly, **recall bias**, where speakers recall only certain events or omit details (Coughlin, 1990). This is often as a result of external influences, such as the presence of a data collector who is new to the community. Recall can also be affected by the distortion or amplification of traumatic memories (Strange and Takarangi, 2015); if data is collected around a topic a speaker may find traumatic, recall bias may be unintentionally introduced.

Secondly, **social desirability bias**, which refers to the tendency of interviewees to provide socially desirable/acceptable responses rather than honest responses, particularly in certain interview contexts (Bergen and Labonté, 2020). In tight-knit rural communities, it may be difficult to deviate from traditional social norms, leading to biased data. As an illustrative example, researchers in Nepal found that interviewer gender affected the detail in responses to some sensitive questions (e.g. sex and contraception): participants provided less detail to male interviewers (Axinn, 1991). Social desirability bias can produce corpora which misrepresent community social dynamics or under-represent sensitive topics.

Thirdly, **recency effect or serial-position**, which is the tendency of a person to recall the first and last items in a series best, and the middle items worst (Troyer, 2011). This can greatly impact the content of language data. For instance, in the context of data collection to guide development work, it is important to understand current needs and values (Hirmer and Guthrie, 2016); however, if only the most recent needs are discussed, long-term needs may be overlooked. To illustrate, while a community which has just experienced a poor agricultural season may tend to express the importance of improving agricultural output, other needs which are less top-of-mind (i.e. healthcare, education) may be equally important despite being expressed less frequently. If data containing *recency bias* is used to develop NLP models, particularly for sustainable development applications (such as for Automatic UPV Classification, Conforti et al. (2020)), these may amplify current needs and under-represent long-term needs.

Fourthly, **acquiescence bias**, also known as “yea” saying (Laajaj and Macours, 2017), which can occur in rural developing contexts when interviewees perceive that certain (possibly false) responses will please a data collector and bring benefits to their community. For example, if data collection is being undertaken by a group with a stated desire to build a school may be more likely to hear about how much education is valued.

Finally, **priming effect**, or the ability of a presented stimulus to influence one’s response to a subsequent stimulus (Lavrakas, 2008). Priming is problematic in data collection to inform SD projects; it can be difficult to collect data on the relative importance of simultaneous (or conflicting) needs if the community is primed to focus on one (Veltkamp et al., 2011). An example is shown in Figure 2a; respondents may be drawn to speak more about the most dominant prompts presented in the chart. This is typical of a broader failure in SD to uncover beneficiary priorities without introducing project bias (Watkins et al., 2012). Needs assessments, like the one referenced above linked to a rural electrification project, tend to focus explicitly on project-related needs instead of more broadly identifying what may be most important to communities (Masangwi, 2015; USAID, 2006). As speakers will usually know why data is being collected in such cases, they may be biased towards stating the project aim as a need, thereby skewing the corpora to over-represent this aim.

3.3 Ethical Considerations

Certain ethical codes of conduct must be followed when collecting data from illiterate speakers in rural communities in LICs (Musoke et al., 2020). Unethical data collection may harm communities, treat them without dignity, disrupt their lives, damage intra-community or external relationships, and disregard community norms (Thorley and Henrion, 2019). This is particularly critical in rural developing regions, as these areas are home to some of the world’s poorest and most vulnerable to exploitation (Christiaensen and Subbarao, 2005; de Ceni-val M., 2008). Unethical data collection can replicate extractive colonial relationships whereby data is extracted from communities with no mutual benefit or ownership (Dunbar and Scrimgeour, 2006). It can lead to a lack of trust between data collector and interviewees and unwillingness to participate in future research (Clark, 2008). These phenomena can bias data or reduce data availability. Ethical data collection practices in rural developing regions with high illiteracy include: obtaining consent (McAdam, 2004), accounting for cultural differences (Silverman, 2013), ensuring anonymity and confidentiality (Bryman, 2012), respecting existing community or leadership structures (Harding et al., 2012), and making the community the owner of the data. While the latter is not often currently practiced, it is an important consideration for community empowerment, with indigenous data sovereignty efforts (Rainie et al., 2019) already setting precedent.

4 Countermeasures

Drawing on existing literature and years of field experience collecting spoken data in LICs, below we outline a number of practical data collection strategies to minimise previously-outlined challenges (§3), enabling the collection of high-quality, minimally-biased data from illiterate speakers in LICs suitable for use in NLP models. While these measures have primarily been applied in SSA, we have also successfully tested them in projects focusing on refugees in the Middle East and rural communities in South Asia.

4.1 Preparation

Here, we outline practical preparation steps for careful planning, which can minimise error and reduce fieldwork duration (Tukey, 1980).

Local Context. A thorough understanding of local context is key to successful data collection (Hentschel, 1999; Bukenya et al., 2012; Launiala and Kulmala, 2006). Local context is broadly defined as facts, concepts, beliefs, values, and perceptions used by local people to interpret the world around them, and is shaped by their surroundings (i.e. their worldview, Vasconcellos and Vasconcellos Sobrinho (2014)). It is important to consider local context when preparing to collect data in rural developing areas, as common data collection methods may be inappropriate due to contextual linguistic differences and deep-rooted social and cultural norms (Walker and Hamilton, 2011; Mafuta et al., 2016; Nikulina et al., 2019; Wang et al.). Selecting a contextually-appropriate data collection method is critical in mitigating *social desirability bias* in the collected data, among other challenges. Researchers should review socio-economic surveys and/or consult local stakeholders who can offer valuable insights on practices and social norms. These stakeholders can also highlight current or historical matters of concern to the area, which may be unfamiliar to researchers, and reveal local, traditional, and indigenous knowledge which may impact the data being collected (Wu, 2014) and result in *recency effect*. It is good practice to identify local conflicts and segmentation within a community, especially in a rural context, where the population is vulnerable and systematically unheard (Dudwick et al., 2006; Mallick et al., 2011).

Case sampling. In qualitative research, sample cases are often strategically selected based on the research question (i.e. *systematic* or *purposive* sampling, Bryman (2012)), and characteristics or circumstances relevant to the topic of study (Yach, 1992). If data collected in such research is used beyond its original scope, *sampling bias* may result. So, while data collected in previous research should be re-used to expand NLP corpora where possible, it is important to be cognizant of the purposive sampling underlying existing data. A comprehensive dataset characterisation (Bender and Friedman, 2018; Gebru et al., 2018) can help researchers understand whether an existing dataset is appropriate to use in new or different research, such as in training new NLP models, and can highlight the potential ethical concerns of data re-use.

Participant sampling. Interviewees should be selected to represent the diverse interests of a community or sampling group (e.g. occupation, age, gender, religion, ethnicity or male/female household heads (Bryman, 2012)) to reduce *sampling bias* (Kitzinger, 1994). To ensure representativity in collected data, sampling should be random, i.e. every subject has equal probability to be included (Etikan et al., 2016). There may be certain societal subsets that are concealed from view (e.g. as a result of embarrassment from disabilities or physical differences) based on cultural norms in less inclusive societies (Vesper, 2019); particular care should be exercised to ensure such subsets are represented.

Group composition. Participant sampling best practices vary by data collection method, with particular care being necessary in group settings. In traditional societies where strong power dynamics exist, attention should be paid to group composition and interaction to prevent some voices from

	Bias & Definition	Key countermeasures
Sampling	**Community**: An unrepresentative sample set is generalised over the entire case being studied.	• Select representative communities & only apply data within same scope (i.e. consult data statements)
	Participant: Certain sub-sets of a community have more data collected from them than others.	• Select representative participants, only apply data within same scope & avoid tempting rewards
Observer	**Confirmation**: Looking for information that confirms one's preconceptions or hypotheses about a topic/research/sector.	• Employ interviewers that are impartial to the topic/research/sector investigated.
	Misunderstanding: Data is incorrectly transcribed or categorized as a result of class, cultural, or linguistic differences.	• Employ local people & minimise # of people involved for both data collection & transcription.
	Interviewer: Unconscious subjectivity introduced into data gathering by interviewers' worldview.	• Undertake training to minimise influence exerted from questions, technology, & attitudes.
Response	**Recall**: Tendency of speakers to recall only certain events or omit details	• Collect support data (e.g. from socio-economic data or local stakeholders) to compare with interviews.
	Social-desirability: Tendency of participants to provide socially desirable/acceptable responses rather than to respond honestly.	• Select interviewers & design interview processes to account for known norms which might skew responses
	Recency effect: Tendency to recall first or last items in a series best, & middle items worst.	• Minimise external influence on participants throughout data gathering (e.g. technologies, people, perceptions).
	Acquiescence: Respondents perceive certain, perhaps false, answers may please data collectors, bringing community benefits.	• Gather non-sectoral holistic insights (e.g. from socio-economic data or local stakeholders)
	Priming effect: Ability of a presented stimulus to influence one's response to a subsequent stimulus	• Use appropriate visual prompts (graphically similar), language and technology

Table 1: Sources of potential bias in data collection when operating in rural and illiterate settings in developing countries, and key countermeasures that can help mitigating them.

being silenced or over-represented (Stewart et al., 2007). For example, in Uganda, female interviewees may be less likely to voice opinions in the presence of male interviewees (FIDH, 2012; Axinn, 1991), introducing a form of *social desirability bias* in resulting corpora. To minimise this risk of data bias, relations and power dynamics must be considered during data collection planning (Hirmer, 2018). It may be necessary to exclude, for instance, close relatives, governmental officials, and village leaders from group discussions where data is being collected, and instead engage such stakeholders in separate activities to ensure that their voices are included in the corpora without biasing the data collected from others.

Interviewer selection. The interviewer has a significant opportunity to introduce *observer and response biases* in collected data (Salazar, 1990). Interviewers familiar with local language, including community-specific dialects, should be selected wherever possible. Moreover, to reduce *misunderstanding* and *recall biases* in collected data, it is useful to have the same person who conducts the interviews also transcribe them. This minimizes the layers of linguistic interpretation affecting the final dataset and can increase accuracy through familiarity with the interview content. If the interviewer is unavailable, the transcriber must be properly trained and briefed on the interviews, and made aware of the level of detail needed during transcription (Parcell and Rafferty, 2017).

Study design. In rural LIC communities, qualitative data like natural language is usually collected by observation, interview, and/or focus group discussion (or a combination, known as mixed methods) which are transcribed verbatim (Moser and Korstjens, 2018). Prompts are often used to spark discussion. Whether visual prompts (Hirmer, 2018) or verbalised question prompts are used during data collection, these should be designed to: (i) accommodate illiteracy, (ii) account for disabilities (e.g. visually impairment; both could cause *sampling bias*), and (iii) minimise bias towards a topic or sector (e.g. minimising *acquisition bias* and *confirmation bias*). For instance, visual prompts should be graphically similar and contain only visuals familiar to the respondents. This is analogous to the uniform interface with which speakers interact during text-based online data collection, where the platform used is graphically the same to all users inputting data. Using varied graphical styles or unfamiliar images may result in *priming* (Figure 2a). To minimise *recall bias* or *recency effect* in collected data, socio-economic data can be integrated in data analysis to better understand if the assertions made in collected data reference recent events, for example. These should be non-sector specific, to gain holistic insights and to minimise *acquisition bias* and *confirmation bias*.

4.2 Engagement

Here, we outline practical steps for successful community engagement to achieve ethical and high-quality data collection.

Defining community. Defining a community in an open and participatory manner is critical to meaningful engagement (Dyer et al., 2014). By understanding the community the way they understand themselves, misunderstandings and tensions that affect data quality can be minimized. The definition of the community (MacQueen et al., 2001) coupled with the requirements and use-cases for the collected data determines the data collection methodology and style which will be most appropriate (e.g. interview-based community consultation vs. collaborative co-design for mutual learning).

Follow formal structures. Researchers entering a community where they have no background to collect data should endeavour to know the community prior to commencing any work (Diallo et al., 2005). This could entail visiting the community and mapping its hierarchies of authority and decision-making pathways, which can guide the research team on how to interact respectfully with the community (Tindana et al., 2011). This process should also illuminate whether knowledgeable community members should facilitate entry by performing introductions and assisting the external data collection team. Following formal community structures is vital, especially in developing communities, where traditional rules and social conventions are strongly held yet often not articulated explicitly or documented. Approaching community leaders in the traditional way can help to build a positive long-term relationship, removing suspicion about the nature and motivation of the researchers' activities, explaining their presence in the community, and most importantly building trust as they are granted permission to engage the community by its leadership (Tindana et al., 2007).

Verbalising consent. Data ethics is paramount for research involving human participants (Accenture, 2016; Tindana et al., 2007), including any collection of personal and identifiable data, such as natural language. Genuine (i.e. voluntary and informed) consent must be obtained from interviewees to prevent use of data which is illegal, coercive, or for a purpose other than that which has been agreed (McAdam, 2004). The Nuffield Council on Bioethics (2002) caution that in LICs, misunderstandings may occur due to cultural differences, lower social-economic status, and illiteracy (McMillan et al., 2004) which can call into question the legitimacy of consent obtained. Researchers must understand that methods such as long information forms and consent forms which must be signed may be inappropriate for the cultural context of LICs and can be more likely to confuse than to inform (Tekola et al., 2009). The authors advise that consent forms should be verbal instead of written, with wording familiar to the interviewees and appropriate to their level of comprehension (Tekola et al., 2009). For example, to speak of data storage on a password protected computer while obtaining consent in a rural community without access to electricity or information technology is unfitting. Innovative ways to record consent can be employed in such contexts (e.g. video taping or recording), as signing an official document may be "viewed with suspicion or even outright hostility" (Upjohn and Wells, 2016), or seen as "committing ... to something other than answering questions". Researchers new to qualitative data collection should seek advice from experienced researchers and approval from their ethics committee before implementing consent processes.

Approaching participants. Despite having gained permission from community authorities and obtained consent to collect data, researchers must be cautious when approaching participants (Irabor and Omonzejele, 2009; Diallo et al., 2005) to ensure they do not violate cultural norms. For example, in some cultures a senior family member must be present for another household member to be interviewed, or a female must be accompanied by a male counterpart during data collection. Insensitivity to such norms may compromise the data collection process; so, they should be carefully noted when researching local context (§4.1) and interviews should be designed to accommodate them where possible. Furthermore, researchers should investigate the motivations of the participants to identify when inducements become inappropriate and may lead to either harm or data bias (McAdam, 2004).

Minimise external influence. Researchers must be aware of how external influences can affect data collection (Ramakrishnan et al., 2012). We find three main levels of external influence: (i) technologies unfamiliar to a rural developing country context may induce *social desirability bias* or *priming* (e.g. if a researcher arrives to a community in an expensive vehicle or uses a tablet for data collection); (ii) intergroup context, which according to Abrams (2010) refers to when "people in different social groups view members of other groups" and may feel prejudiced or threatened by these differences. This can occur, for instance, when a newcomer arrives and speaks loudly relative to the indigenous community, which may be perceived as overpowering; (iii) there is the risk of a researcher over-incentivizing the data collection process, using leading questions and judgemental framing (*interviewer bias* or *confirmation bias*). To overcome these influences, researchers must be cognizant of their influence and minimise it by hiring local mediators where possible alongside employing appropriate technology, mannerisms, and language.

4.3 Undertaking Interviews

Here, we detail practical steps to minimise challenges during the actual data collection.

Interview settings. People have personal values and drivers that may change in specific settings. For example, in the Ugandan Buganda and Busoga tribes, it is culturally appropriate for the male head if present to speak on behalf of his wife and children. This could lead to corpora where input from the husband is over-represented compared to the rest of the family. To account for this, it is important to collect data in multiple interview settings (e.g. individual, group male/female/mixed; Figures 2b, 2c). Additionally, the inputs of individuals in group settings should be considered independently to ensure all participants have an equal say, regardless of their position within the group (Barry et al., 2008; Gallagher et al., 1993). This helps to avoid *social desirability bias* in the data and is particularly important in various developing contexts where stereotypical gender roles are prominent (Hirmer, 2018). During interviews, verbal information can be supplemented through the observation of tone, cadence, gestures, and facial expressions (Narayanasamy, 2009; Hess et al., 2009), which could enrich the collected data with an additional layer of annotation.

Working with multiple interviewers. Arguably, one of the biggest challenges in data collection is ensuring consistency when working with multiple interviewers. Some may report word-for-word what is being said, while others may summarise or misreport, resulting in systematic *misunderstanding*. Despite these risks, employing multiple interviewers is often unavoidable when collecting data in rural areas of developing countries, where languages often exhibit a high number of regional, non-mutually intelligible varieties. This is particularly prominent across SSA. For example, 41 languages are spoken in Uganda (Nakayiza, 2016); English, the official language, is fluently spoken by only ∼5% of the population, despite being widely used among researchers and NGOs (Katushemererwe and Nerbonne, 2015). To minimise data inconsistency, researchers should: (i) undertake interviewer training workshops to communicate data requirements and practice data collection processes through mock field interviews; (ii) pilot the data collection process and seek feedback to spot early deviation from data requirements; (iii) regularly spot-check interview notes; (iv) support written notes with audio recordings[3]; and (v) offer quality based incentives to data collectors.

Participant remuneration. While it is common to offer interviewees some form of remuneration for their time, the decision surrounding payment is ethically-charged and widely contested (Hammett and Sporton, 2012). Rewards may tempt people to participate in data collection against their judgement. They can introduce *sampling bias* or create power dynamics resulting in *acquiescence bias* (Largent and Lynch, 2017). Barbour (2013) offers three practical solutions: (i) not advertise payment; (ii) omit the amount being offered; or (iii) offer non-financial incentives (e.g. products that are desirable but difficult to get in an area). The decision whether or not to remunerate should not be based upon the researcher's own ethical beliefs and resources, but instead by considering the specific context[4], interviewee expectations, precedents set by previous researchers, and local norms (Hammett and Sporton, 2012). Representatives from local organisations (such as NGOs or governmental authorities) may be able to offer advice.

---

[2] While participants' photographing permission was granted, photos were pixelised to protect identity.

[3] Relying only on audio data recording may be risky: equipment can fail or run out of battery (which is not easily remedied in rural off-grid regions) and seasonal factors (as noise from rain on corrugated iron sheets, commonly used for roofing in SSA) can make recordings inaudible (Hirmer, 2018)).

[4] In rural Uganda, for example, politicians commonly engage in *vote buying* by distributing gifts (Blattman et al., 2019) such as soap or alcohol. It is therefore considered an unruly form of remuneration and can only be avoided when known.

(a) (b) (c)

Figure 2: Collecting oral data in rural Uganda. 2a *Priming effect* (note the word "Energy" in the poster's title and the visual prompts differences between items). On the contrary, 2b and 2c show minimal priming; note also that different demographics are separately interviewed (women group, single men) to avoid *social desirability bias*.

4.4 Post-interviewing

Here, we discuss practical strategies to mitigate ethical issues surrounding the management and stewardship of collected data.

Anonymisation. To protect the participants' identity and data privacy, locations, proper names, and culturally explicit aspects (such as tribe names) of collected data should be made anonymous (Sweeney, 2000; Kirilova and Karcher, 2017). This is particularly important in countries with security issues and low levels of democracy.

Safeguarding data. A primary responsibility of the researcher is to safeguard participants' data (Kirilova and Karcher, 2017). In addition to anonymizing data, mechanisms for data management include in-place handling and storage of data (UKRI, 2020a). Whatever data management plan is adopted, it must be clearly articulated to participants before the start of the interview (i.e. as part of the consent process (Silverman, 2013)), as was discussed in §4.2 (*Verbalising consent*).

Withdrawing consent. Participants should have the ability to withdraw from research within a specified time frame. This is known as *withdraw consent* and is commonly done by phone or email (UKRI, 2020b). As people in rural illiterate communities have limited means and technology access, a local phone number and contact details of a responsible person in the area should be provided to facilitate withdraw consent.

Communication and research fatigue. While researchers frequently extract knowledge and data from communities, only rarely are findings fed back to communities in a way that can be useful to them. Whatever the research outcomes, researchers should share the results with participating communities in an appropriate manner. In illiterate communities, for instance, murals (Jimenez, 2020), artwork, speeches, or song could be used to communicate findings. Not communicating findings may result in research fatigue as people in *over-studied* communities are no longer willing to participate in data collection. This is common "where repeated engagements do not lead to any experience of change [...]" Clark (2008). Patel et al. (2020) offers practical guidance to minimise research fatigue by: (i) increasing transparency of research purpose at the beginning of the research, and (ii) engaging with gatekeeper or oversight bodies to minimise number of engagements per participant. Failure to restrict the number of times that people are asked to participate in studies risks poor future participation (Patel et al., 2020) which can also lead to *sampling bias*.

5 Conclusion

In this paper, we provided a first step towards defining best practices in data collection in rural and illiterate communities in Low-Income Countries to create globally representative corpora. We proposed a comprehensive classification of sources of bias and unethical practices that might arise in the data collection process, and discussed practical steps to minimise their negative effects. We hope that this work will motivate NLP practitioners to include input from rural illiterate communities in their research, and facilitate smooth and respectful interaction with communities during data collection. Importantly, despite the challenges that working in such contexts might bring, the effort to build substantial and high-quality corpora which represent this subset of the population can result in considerable SD outcomes.

Acknowledgments

We thank the anonymous reviewers for their constructive feedback. We are also grateful to Claire McAlpine, as well as Malcolm McCulloch and other members of the Energy and Power Group (University of Oxford) for providing valuable feedback on early versions of this paper. This research was carried out as part of the Oxford Martin Programme on Integrating Renewable Energy. Finally, we are grateful to the Rural Senses team for sharing experiences on data collection.

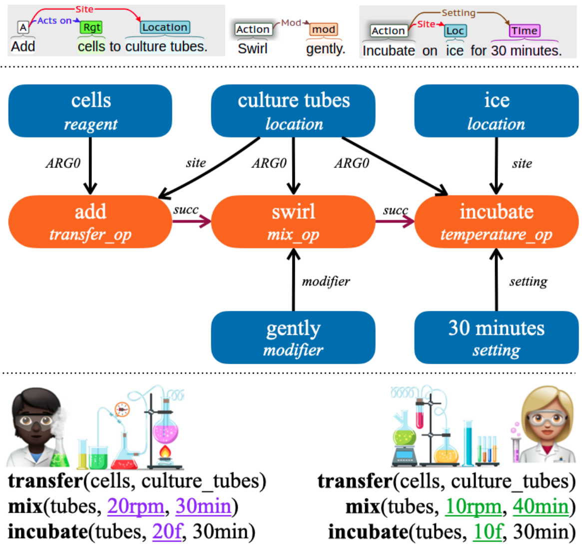
Abstract

We develop Process Execution Graphs (PEG), a document-level representation of real-world wet lab biochemistry protocols, addressing challenges such as cross-sentence relations, long-range coreference, grounding, and implicit arguments. We manually annotate PEGs in a corpus of complex lab protocols with a novel interactive textual simulator that keeps track of entity traits and semantic constraints during annotation. We use this data to develop graph-prediction models, finding them to be good at entity identification and local relation extraction, while our corpus facilitates further exploration of challenging long-range relations.[1]

1 Introduction

There is a drive in recent years towards automating wet lab environments, where menial benchwork procedures such as pipetting, centrifuging, or incubation are software-controlled, and either executed by fully automatic lab equipment (Lee and Miles, 2018), or with a human-in-the-loop (Keller et al., 2019). These environments allow reliable and precise experiment reproducbility while relieving researchers from tedious and laborious work which is prone to human error (Bates et al., 2017; Prabhu and Urban, 2017). To achieve this, several programmatic formalisms are developed to describe an experiment as an executable program. For example, Autoprotocol (Lee and Miles, 2018) defines a `mix` predicate taking three arguments: *mode*, *speed*, and *duration*.



transfer(cells, culture_tubes)
mix(tubes, 20rpm, 30min)
incubate(tubes, 20f, 30min)

transfer(cells, culture_tubes)
mix(tubes, 10rpm, 40min)
incubate(tubes, 10f, 30min)

Figure 1: We develop a scaffold (center) between sentence-level lab procedure representations (top) and low-level, lab-specific instructions (bottom). The Process Execution Graph (PEG) captures document-level relations between procedures (orange rounded nodes) and their arguments (blue rectangular nodes).

A promising direction to leverage automatic wet-lab environments is a conversion from natural language protocols, written in expressive free-form language, to low-level instructions, ensuring a non-ambiguous, repeatable description of experiments.

In this work, we focus on a crucial first step towards such conversion – the extraction and representation of the relations conveyed by the protocol in a formal graph structure, termed Process Execution Graphs (PEG), exemplified in Figure 1. PEGs capture both concrete, exact quantities ("*30 minutes*"), as well as vague instructions ("swirl *gently*"). A researcher can then port the PEG (either manually or automatically) to their specific lab equipment, e.g., specifying what constitutes a gentle swirl setting and adding missing arguments, such as the temperature of the

---

```
> op_type chill to temp_type
Set operation type!

> op_run chill
Failed: missing "ARG0" input for chill!

> take vial
You pick up the vial.

> ARG
       ARG0_assign vial to chill
       ARG1_assign vial to chill
       ARG2_assign vial to chill
```

Figure 2: Example interaction with our simulator, showing predicate grounding ("chill" is a `temp_type` operation) input assignment ("vial" is an argument of "chill"), validation (warning for a missing argument) and auto-complete driven by state-tracking, where only legal instructions in a given state are presented.

incubation in Figure 1.

Formally, PEGs are directed, acyclic labeled graphs, capturing how objects in the lab (e.g., *cells*, *tubes*) are manipulated by lab operations (e.g., `mixing`, `incubating`), and in what order. Importantly, PEGs capture relations which may span across multiple sentences and implicit arguments. For example, the PEG in Figure 1 explicitly captures the relation between *culture tubes*, mentioned in the first sentence, and `swirl` and `incubate` which appear in later sentences.

To annotate long and complex lab protocols, we develop a text-based game annotation interface simulating objects and actions in a lab environment (see example in Figure 2). Our annotators are given wet-lab protocols written in natural language taken from biochemistry publications, and are asked to repeat their steps by issuing textual commands to the simulator. The commands are deterministically converted to our PEG representation. This interface takes much of the burden off annotators by keeping track of object traits and commonsense constraints. For example, when the annotator issues a `transfer` command for a container, the simulator moves all its contents as well. We find that in-house annotators were able to effectively use this interface on complex protocols, achieving good agreement.

Finally, we use this data to explore several models, building upon recent advances in graph prediction algorithms (Luan et al., 2019; Wadden et al., 2019). We thoroughly analyze model performance and find that our data introduces interesting new challenges, such as complex coreference resolution and long-range, cross-sentence relation identification.

In conclusion, we make the following contributions:

- We formalize a PEG representation for free-form, natural language lab protocols, providing a semantic scaffold between free-form scientific literature and low-level instruments instruction.
- We develop a novel annotation interface for procedural text annotation using text-based games, and show that it is intuitive enough for wet-lab protocol annotation by non-experts.
- We release X-WLP, a challenging corpus of 279 PEGs representing document-level lab protocols. This size is on par with similar corpora of procedural text (Dalvi et al., 2018; Mysore et al., 2019; Vaucher et al., 2020).
- We develop two graph parsers: a pipeline model which chains predictions for graph sub-components, and a joint-model of mention and relation detectors.

2 Background and Motivation

Several formalisms for programmatic lab controller interfaces were developed in recent years (Yachie and Natsume, 2017; Lee and Miles, 2018). For instance, Autoprotocol defines 35 lab commands, including `spin`, `incubate`, and `mix`.[2] While these define wet-lab experiments in a precise and unambiguous manner, they do not readily replace their natural language description in scientific publications, much like a model implementation in python does not replace its high-level description in ML papers. Similarly to ML model descriptions, lab protocols are often not specified enough to support direct conversion to low-level programs. For example, the protocol in Figure 1 does not specify the swirling (mixing) speed or its duration.

Our process execution graph (PEG) captures the predicate-argument structure of the protocol, allowing it to be more lenient than a programming language (for example, capturing that *gently* modifies `swirl`). Better suited to represent underspecified natural language, PEGs can serve as a convenient scaffold to support downstream tasks such as text-to-code assistants (Mehr et al., 2020). For example, by asking researchers to fill in missing required arguments for `swirl`.

To annotate PEGs, we leverage the sentence-level annotations of Kulkarni et al. (2018) (WLP henceforth). WLP, exemplified at the top of

---

[2] https://autoprotocol.org/specification

Figure 1, collected sentence-level structures using the BRAT annotation tool (Stenetorp et al., 2012). For example, capturing that *cells*, *culture tubes* are arguments for `add`. However, WLP does not capture cross-sentence implicit relations such that *culture tubes* are an argument for `incubate`. These are abundant in lab protocols, require tracking entities across many sentences, and are not easy to annotate using BRAT (see discussion in §4). We vastly extend upon WLP annotations, aiming to capture the full set of expressed protocol relations, using a novel text-based games annotation interface which lends itself to procedural text annotation.

3 Task Definition: Process Execution Graphs

Intuitively, we extend the WLP annotations (Kulkarni et al., 2018) from the sentence level to entire documents, aiming to capture *all* of the relations in the protocol. Formally, our representation is a directed, labeled, acyclic graph structure, dubbed a Process Execution Graph (PEG), exemplified in Figures 1 and 3, and formally defined below.

Nodes PEG nodes are triggered by explicit text spans in the protocol, e.g., “swirl", or “ice”. Nodes consist of two types: (1) *predicates*, marked in orange: denoting lab operations, such as `add` or `incubate`; and (2) *arguments*, marked in blue: representing physical lab objects (e.g., *culture tubes*, *cells*), exact quantities (*30 minutes*), or abstract instructions (e.g., *gently*).

Operation type	Frequent example spans	Count	Pct.
Transfer	add, transfer, place	1301	33.2
Temperature Treatment	incubate, store, thaw	503	12.8
General	Initiate, run, do not vortex	469	11.9
Mix	mix, vortex, inverting	346	8.8
Spin	spin, centrifuge, pellet	282	7.2
Create	prepare, make, set up	178	4.5
Destroy	discard, decant, pour off	170	4.3
Remove	remove, elute, extract	168	4.3
Measure	count, weigh, measure	149	3.8
Wash	wash, rinse, clean	146	3.7
Time	wait, sit, leave	114	2.9
Seal	cover, seal, cap	68	1.7
Convert	change, transform, changes	21	0.5

Table 1: Details of PEG predicate types, along with example frequent trigger spans and relative frequency in X-WLP.

Argument type	Frequent example spans	Count	Pct.
Reagent	supernatant, dna, sample	3362	32.6
Measurement	1.5 mL, 595nm, 1pmol	1924	18.6
Setting	overnight, room temperature	1622	15.7
Location	tube, ice, plates	1373	13.3
Modifier	gently, carefully, clean	1070	10.3
Device	forceps, pipette tip	590	5.7
Method	dilutions, pipetting	271	2.6
Seal	lid, cap, aluminum foil	97	0.9

Table 2: Details of PEG argument types, along with example frequent trigger spans and relative frequency in X-WLP.

Node grounding The PEG formulation above is motivated as a scaffold towards fully-executable lab programs employed in automatic lab environments. To achieve this, we introduce an ontology for each of the node types, based on the Autoprotocol specification (Lee and Miles, 2018), as indicated below each text span in Figures 1 and 3. For example, `swirl` corresponds to an Autoprotocol `mix` operation, a *culture tube* is of type *location*, and *30 minutes* is a *setting*. See Tables 1, 2 for details of predicate and argument types respectively, their frequencies in our data and example spans.

Edges Following PropBank notation (Kingsbury and Palmer, 2003), PEGs consist of three types of edges derived from the Autoprotocol ontology, and denoted by their labels: (1) core-roles (e.g., “ARG0”, “ARG1”): indicating predicate-specific roles, aligning with Autoprotocol’s ontology. For example, *ARG0* of `mix` assigns the element to be mixed; (2) non-core roles (e.g., “setting”, “site”, or “co-ref”): indicate predicate-agnostic relations. For example, the *site* argument always marks the location in which a predicate is taking place; and (3) temporal edges, labeled with a special “succ” label: define a temporal transitive ordering between predicates. In Figure 1, `add` occurs before `swirl`, which occurs before `incubate`. See Table 3 for predicate-specific core-role semantics, and Table 6 for non-cores roles types and frequencies of all roles in X-WLP. See Appendix A.3 for the rules defining what relations can hold between various entity types.

Relation to Autoprotocol As shown at the bottom of Figure 1, a PEG is readily convertible to Autoprotocol or similar laboratory interfaces once it is fully instantiated, thanks to edge labels and node grounding to an ontology. For example, a

Operation	Role Semantics	Required
Spin	ARG0 centrifuged to produce solid phase ARG1 and/or liquid phase ARG2	ARG0
Convert	ARG0 converted to ARG1	ARG0, ARG1
Seal	ARG0 sealed with ARG1	ARG0
Create	ARG* are created	ARG0
General	-	ARG0
Destroy	ARG* discarded	ARG0
Measure	ARG* to be measured	ARG0
Mix	ARG* are mixed	ARG0
Remove	ARG0 removed from ARG1	ARG0
Temperature Treatment	ARG* to be heated/cooled	ARG0
Time	Wait after operation on ARG0	ARG0
Transfer	ARG* are sources, transferred to "site"	ARG0, site
Wash	ARG0 washed with ARG1	ARG0

Table 3: Details of core role semantics for all operation types. The "Required" column specifies which roles must be filled for a given operation. ARG* is short for {ARG0, ARG1, ARG2}.

researcher can specify what *gently* means in terms of mixing speed for their particular lab instruments.

Reentrancies and cross-sentence relations While the PEG does not form directed cycles,[3] it does form non-directed cycles (or *reentrancies*) – where there exists nodes u, v such that there are two different paths from u to v. This occurs when an object participates in two or more temporally-dependent operations. For example, see *culture tubes*, which participates in all operations in Figure 1. In addition, edges (u, v) may be triggered either by *within-sentence relations*, when both u and v are triggered by spans in the same sentence, or by *cross-sentence relations*, when u and v are triggered by spans in different sentences. In the following section we will show that both reentrancies and cross-sentence relations, which are not captured by previous annotations, are abundant in our annotations.

4 Data Collection: The X-WLP Corpus

In this section, we describe in detail the creation of our annotated corpus: X-WLP. The protocols in X-WLP are a subset (44.8%) of those annotated in the WLP corpus. These were chosen because they are covered well by Autoprotocol's ontology (for details on ontology coverage, see §A.1).

In total, we collected 3,708 sentences (54.1K tokens) in 279 wet lab protocols annotated with our graph representation. As can be seen in Table 4, X-WLP annotates long examples, often spanning dozens of sentences, and its size is comparable (e.g., in terms of annotated words) to the ProPara corpus (Dalvi et al., 2018) and other related procedural datasets.

	X-WLP (ours)	MSPTC	CSP	ProPara
# words	54k	56k	45k	29k
# words / sent.	14.6	26	25.8	9
# sentences	3,708	2,113	1,764	3,300
# sentences / docs.	13.29	9	N/A	6.8
# docs.	279	230	N/A	488

Table 4: Statistics of our annotated corpus (X-WLP). X-WLP annotates complex documents, constituting more than 13 sentences on average. X-WLP overall size is on par with other recent procedural corpora, including ProPara (Dalvi et al., 2018), material science (MSPTC; Mysore et al. (2019)) and chemical synthesis procedures (CSP; Vaucher et al. (2020)). CSP is comprised of annotated sentences (document level information is not provided).

4.1 WLP as a Starting Point

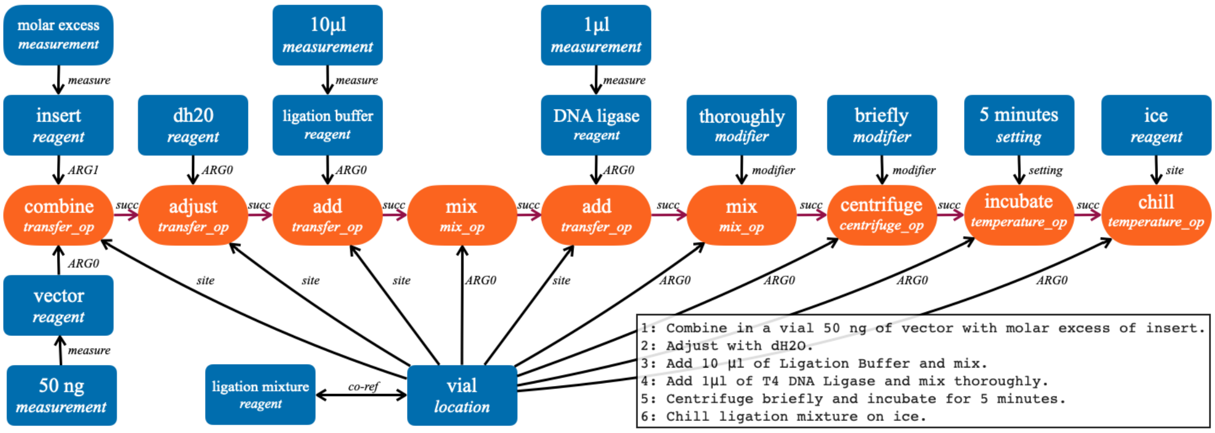
Despite WLP's focus on sentence-level relations (see top of Figure 1), it is a valuable starting point for a document-level representation. We pre-populate our PEG representations with WLP's gold object mentions (e.g., *cells*, *30 minutes*), operation mentions (`swirl` and `incubate`), and within-sentence relations (e.g., between *gently* and `swirl`). We ask annotators to enrich them with type grounding for operations and arguments, as well as cross-sentence relations, as defined in §3. From these annotations we obtain process-level representations as presented in Figures 1 and 3.

4.2 Process-Level Annotation Interface: Text-Based Simulator

Annotating cross-sentence relations and grounding without a dedicated user interface is an arduous and error-prone prospect. Consider as an example the *ligation mixture* mention in Figure 3. This mention is a metonym for *vial* (5 sentences earlier), after mixing in the *ligase*. This kind of metonymic co-reference is known to be difficult for annotation (Jurafsky and Martin, 2009), and indeed, such complicated annotation has been a factor in the omission of cross-sentence information in similar domains (Mysore et al., 2019). A simulator can provide a natural way to account for it by

---

[3] This happens because the temporal relations define a partial ordering imposed by the linearity of the execution.



1: Combine in a vial 50 ng of vector with molar excess of insert.
2: Adjust with dH2O.
3: Add 10 µl of Ligation Buffer and mix.
4: Add 1µl of T4 DNA Ligase and mix thoroughly.
5: Centrifuge briefly and incubate for 5 minutes.
6: Chill ligation mixture on ice.

Figure 3: A full process gold PEG annotation from X-WLP for a real-world wet lab protocol whose text is presented in the lower right corner (protocol 512), exemplifying several common properties: (1) complex, technical language, in relatively short sentences; (2) a chain of temporally-dependent, cross-sentence operations; (3) a common object that is being acted upon through side effects throughout the process (*vial*); and (4) *vial* is mostly omitted in the text after being introduced in the first sentence, despite participating in all following sentences. In the last sentence it appears with a metonymic expression (*ligation mixture*).

representing the relevant temporal and contextual information: after sentence 4, *vial* contains the *ligation buffer* mixed with other entities.

To overcome these challenges and achieve high-quality annotations for this complex task, we develop a simulator annotation interface, building upon the TextWorld framework (Côté et al., 2018). This approach uses text-based games as the underlying simulator environment, which we adapt to the biochemistry domain. The human annotator interacts with the text-based interface to simulate the raw wet lab protocol (Figure 2): setting the types of operations (the first interaction sets the span “chill" as a `temperature` operation) and assigning their inputs (the last line assigns `vial` as an input to `chill`), while the simulator tracks entity states and ensures the correct number and type of arguments, based on the Autoprotocol ontology. For example, the second interaction in Figure 2 indicates a missing argument for the `chill` operation (the argument to be chilled). Finally, tracking temporal dependency (“succ” edges) is also managed entirely by the simulator by tracking the order in which the annotator issues the different operations.

Further assistance is provided to annotators in the form of an auto-complete tool (last interaction in Figure 2), visualization of current PEG and a simple heuristic “linter” (Johnson, 1977) which flags errors such as ignored entities by producing a score based on the number of connected components in the output PEG.

See the project web page for the complete annotation guidelines, visualizations of annotated protocols, and demonstration videos of the annotation process.

4.3 Data Analysis

Four in-house CS undergraduate students with interest in NLP used our simulator to annotate the protocols of X-WLP, where 44 of the protocols were annotated by two different annotators to estimate agreement.

Inter-annotator agreement. We turn to the literature on abstract meaning representation (AMR; Banarescu et al., 2013) for established graph agreement metrics, which we adapt to our setting. Similarly to our PEG representation, the AMR formalism has predicate and argument nodes (lab operations and entities in our notation) and directed labeled edges which can form undirected cycles through reentrancies (nodes with multiple incoming edges).[4] In Table 5 we report a graph Smatch score (Cai and Knight, 2013) widely used to quantify AMR’s graph structure agreement, as well as finer grained graph agreement metrics, adapted from Damonte et al. (2017). Smatch values are comparable to those obtained for AMR, where reported gold agreement

---

[4] Unfortunately, we cannot follow this analogy to train AMR models on our graphs, since, to the best of our knowledge, they are currently limited to single sentences, notwithstanding a promising recent initial exploration into multi-sentence AMR annotation (O’Gorman et al., 2018).

Agreement Metric	**F1**
Smatch	84.99
Argument identification	89.72
Predicate identification	86.68
Core roles	80.52
Re-entrancies	73.12

Table 5: X-WLP inter-annotator agreement metrics. Smatch (Cai and Knight, 2013) quantifies overall graph structure. Following metrics provide a finer-grained break down (Damonte et al., 2017).

Relation	# Intra.	# Inter.	Total	# Re-entrancy
Core				
• ARG0	2962	952	3914	1645
• ARG1	560	127	687	3
• ARG2	84	123	207	77
Total (core)	3606	1202	4808	1725
Non-Core				
• site	1306	325	1631	360
• setting	3499	2	3501	-
• usage	1114	24	1138	-
• co-ref	129	1575	1704	-
• located-at	199	72	271	-
• measure	2936	18	2954	-
• modifier	1861	2	1863	-
• part-of	72	65	137	-
Total (non-core)	11116	2083	13199	360
Temporal	1218	788	2006	-
Grand Total	15940 (80%)	4073 (20%)	20013	2085

Table 6: Breakdown of PEG relation types by frequency in X-WLP, showing counts of inter/intra-sentence relations. Re-entrancies are possible only for core and "site" arguments, and may be either inter or intra-sentence.

varies between 0.69 – 0.89 (Cai and Knight, 2013), while our task deals with longer, paragraph length representations. Reentrancies are the hardest for annotators to agree on, probably since they involve longer-range, typically cross-sentence relations. On the other hand, local decisions such as argument and predicate identification achieve higher agreement, and also benefit greatly from the annotations of WLP.

Information gain from process-level annotation. Analysis of the relations in X-WLP, presented in Table 6, reveals that a significant proportion of arguments in PEGs are re-entrancies (32.4%) or cross-sentence (50.3%).[5] Figure 3 shows a representative example, with the *vial* participating in multiple re-entrancies and long-range relations, triggered by each sentence in the protocol. These relations are crucial to correctly model the protocols at the process level, and are inherently missed by sentence-level formalisms, showing the value of our annotations.

Dataset	Avg. #args/op	#Ops. w/o core arg.	#Ops.	Pct.
WLP	1.87	3297	17485	18.9
X-WLP	3.01	0	3915	0.0

Table 7: Comparison of average arguments per operation and percentage of semantically under-specified operations (missing core arguments) in WLP and X-WLP.

To shed light on the additional process-level information captured by our approach relative to WLP, in Table 7 we compare the average number of arguments per operation node as well as the amount of operation nodes with no core arguments. For example, see the `swirl` instruction at the top of Figure 1: in WLP, this predicate has no core role argument and is thus semantically under-defined. X-WLP correctly captures the core role of *culture tubes*. By definition, our use of input validation by the simulator prevents semantic under-specification, which is likely a significant factor in the higher counts for cross-sentence relations and overall average arguments in X-WLP.

Annotation cost. The time to annotate an average document of 13.29 sentences was approximately 53 minutes (roughly 4 minutes per sentence), not including annotator training. Our annotator pay was 13 USD / hour. The overall annotation budget for X-WLP was roughly 3,200 USD.

5 Models

We present two approaches for PEG prediction. First, in §5.1 we design models for separate graph sub-component prediction, which are chained to form a pipeline PEG prediction model. Second, in §5.2 we present a model which directly predicts the entire PEG using a span-graph prediction approach.

5.1 Pipeline Model (PIPELINE)

A full PEG representation as defined in §3 can be obtained by chaining the following models which predict its sub-components. In all of these, we use SciBERT (Beltagy et al., 2019) which was trained on scientific texts similar to our domain.

---

[5] For these calculations we consider only argument relations that can in principle occur as re-entrancies: "ARG*" and "site", see relation ontology in Appendix A.3 for details. Cross-sentence calculation includes co-reference closure information.

Mention identification. Given a scientific protocol written in natural language, we begin by identifying all experiment-involved text spans mentioning lab operations (predicates) or entities and their traits (arguments), which are the building blocks for PEGs. We model this problem of mention identification as a sequence tagging problem. Specifically, we transfer span-level mention labels, which are annotated in the WLP corpus into token-level labels using the BIO tagging scheme, then fine-tune the SciBERT model for token classification.

Predicate grounding. Next, we ground predicate nodes into the operation ontology types discussed in §3. See Table 1 in the Appendix for the complete list. Predicted mentions are marked using special start and end tokens (`[E-start]` and `[E-end]`), then fed as input to SciBERT. The contextual embedding of `[E-start]` is input to a linear softmax layer to predict the fine-grained operation type.

Operation argument role labeling. Once the operation type is identified, we predict its semantic arguments and their roles. Given an operation and an argument mention, four special tokens are used to specify the positions of their spans (Baldini Soares et al., 2019). Type information is also encoded into the tokens, for example, when the types of the operator and its argument are `mix-op` and `reagent` respectively, four special tokens `[E1-mix-op-start]`, `[E1-mix-op-end]`, `[E2-rg-start]` and `[E2-rg-end]` are used to denote the spans of the mention pair. After feeding the input into SciBERT, the contextualized embeddings of `[E1-op-mix-start]` and `[E2-rg-start]` are concatenated as input to a linear layer that is used to predict the entity's argument role. Arguments of an operation can be selected from anywhere in the protocol, leading to many cross-sentence operation-argument link candidates. To accommodate cross-sentence argument roles, we use the entire document as input to SciBERT for each mention pair. However, SciBERT is limited to processing sequences of at most 512 tokens. To address this limitation, longer documents are truncated in a way that preserves surrounding context, when encoding mention pairs.[6] Only 8 of the 279 protocols in our dataset contain more than 512 tokens.

Temporal ordering. Finally, we model order of operations using the `succ` relation (see Figure 3). These are predicted using a similar approach as argument role labeling, where special tokens are used to encode operation spans.

5.2 Jointly-Trained Model (MULTI-TASK)

To explore the benefits of jointly modeling mentions and relations, we experiment with a graph-based multi-task framework based on DYGIE++ model (Wadden et al., 2019). Candidate mention spans are encoded using SciBERT, and a graph is constructed based on predicted X-WLP relations and argument roles. A message-passing neural network is then used to predict mention spans while propagating information about related spans in the graph (Dai et al., 2016; Gilmer et al., 2017; Jin et al., 2018).

This approach requires computing hidden state representations for all $O(n^4)$ pairs of spans in an input text, which for long sequences, will exhaust GPU memory. While Wadden et al. (2019) considered primarily within-sentence relations, our model must consider relations across the entire protocol, which makes this a problem of practical concern. To address this, we encode a sliding window of w adjacent sentences when the full protocol does not fit into memory, allowing smaller windows for the start and end of the protocol, and concatenate sentences within each window as inputs to the model. As a result, each sentence is involved in w windows leading to repeated, possibly contradicting predictions for both mentions and relations. To handle this, we output predictions agreed upon by at least k windows, where k is a hyperparameter tuned on a development set.

6 Experiments

In §5, we presented a pipelined approach to PEG prediction based on SciBERT and a message-passing neural network that jointly learns span and relation representations. Next, we describe the details of our experiments and present empirical results demonstrating that X-WLP supports training models that can predict PEGs from natural language instructions.

---

[6] Given an input document, which has more than 512 words, with n words between two mentions, we truncate the context to keep at most $(512 - n)/2$ words for each side.

Data Split	System	F_1
original	Kulkarni et al. (2018)	78.0
	Wadden et al. (2019)	**79.7**
	Pipeline	78.3
X-WLP-eval	Pipeline	74.7

Table 8: Mention identification test set F_1 scores for models on the WLP dataset. Top: WLP dataset with the original train/dev/test split. Bottom: excluding X-WLP protocols from the WLP training data, and using them for evaluation.

Data. X-WLP is our main dataset including 279 fully annotated protocols. Statistics of X-WLP are presented in Table 4. Additionally, we have 344 protocols from the original WLP dataset. We use this auxiliary data only for training mention taggers in the pipeline model, and use X-WLP for all other tasks. For argument role labeling and temporal ordering, negative instances are generated by enumerating all possible mention pairs whose types appear at least once in the gold data. We use 5-fold cross validation; 2 folds (112 protocols) are used for development, and the other 3 folds (167 protocols) are used to report final results.

Model setup. The Pipeline framework employs a separate model for each task, by default using the propagated predictions from previous tasks as input. In addition, we evaluate the model for each task with gold input denoted as Pipeline `(gold)`. Finally, the Multi-task framework learns all tasks together and we decompose its performance into the component subtasks.

Implementation details. We use the uncased version of SciBERT[7] for all our models due to the importance of in-domain pre-training. The models under the Pipeline system are implemented using Huggingface Transformers (Wolf et al., 2020), and we use AdamW with the learning rate 2×10^{-5} for SciBERT finetuing. For the Multi-task framework, we set the widow size w to 5, the maximum value that enables the model to fit in GPU memory. For all other hyperparameters, we follow the settings of the WLP experiments in (Wadden et al., 2019).

6.1 Results

The results of the two models on the different subtasks are presented in Tables 8- 11. We identify three main observations based on these results.

System	P	R	F_1
Multi-task	76.0	69.0	72.3
Pipeline	71.8	76.3	74.0
• w/ gold mentions	79.0	80.2	79.6

Table 9: Predicate grounding test set results.

Task	Multi-task	Pipeline	# gold
Core			
• All roles	**57.9**	53.7	2839
• All roles (gold mentions)	-	76.5	2839
• ARG0	**61.0**	57.1	2313
• ARG1	**36.1**	32.9	412
• ARG2	**69.7**	61.4	114
Non-Core			
• All roles	**55.7**	48.8	4826
• All roles (gold mentions)	-	78.1	4826
• site	**58.7**	55.4	962
• setting	**77.4**	74.7	974
• usage	**35.6**	33.0	296
• co-ref	**39.8**	36.7	1014
• measure	**63.3**	56.6	804
• modifier	**51.0**	41.8	519
• located-at	9.7	**13.3**	179
• part-of	0.5	**10.8**	78
Temporal Ordering	**61.8**	57.3	2176
Temp. Ord. (gold mentions)	-	76.3	2176

Table 10: Operation argument role labeling (core and non-core roles, decomposed by relation) and temporal ordering test set F_1 performance.

Split	Multi-task	Pipeline	# gold
Intra-sentence	**63.4**	58.2	2160
Inter-sentence	**32.5**	39.1	679

Table 11: Operation argument role labeling (core roles) test set F_1, decomposed based on whether the operation and the argument are triggered within the same sentence (intra-sentence) versus different sentences (inter-sentence).

First, Pipeline outperforms Multi-task on the operation classification task in Table 9, as it uses all protocols from WLP as additional training data to improve mention tagging.

Second, Multi-task performs better than the Pipeline approach on most relation classification tasks in Table 10, but is worse than Pipeline when Pipeline uses gold mentions, demonstrating that jointly modeling mentions and relations helps in mitigating error propagation.

Third, *cross-sentence* relations are challenging for both models, as shown in Table 11. This explains the low performance of `co-ref`, which is comprised of 92.4% cross-sentence relations.

In addition, there are a couple of interesting points to note. In Table 8, the performance of Pipeline on the X-WLP subset is lower than its performance on the WLP test set, likely because

---

[7] `https://github.com/allenai/scibert`

there are fewer protocols in the training set. For the relation-decomposed performance in Table 10, we can see that some of the relations like "ARG2" can be correctly predicted by MULTI-TASK using only a few gold labels while some more widely used relations are harder to learn, such as "ARG0" and "site"; indeed, "ARG2" is only used in the `spin` operation (see Table 3), while the other roles participate in more diverse contexts.

7 Related Work

Natural Language Processing (NLP) for scientific procedural text is a rapidly growing field. To-date, most approaches have focused on text-mining applications (Isayev, 2019) and typically annotate only shallow, sentence-level semantic structures (e.g., Fig. 1, top). Examples include WLP (Kulkarni et al., 2018) and materials science procedures (Mysore et al., 2019; Kuniyoshi et al., 2020). Recent interest in automation of lab procedures has also led to sentence-level annotation of procedural texts with action sequences designed to facilitate execution (Vaucher et al., 2020).

However, as noted in recent concurrent work (Mehr et al., 2020), neither sentence-level semantic structures nor action sequences are sufficient for the goal of converting text to a machine-executable synthesis procedure; for this purpose, a more structured, process-level semantic representation is required. In particular, executable representations require a structured declaration of the locations and states of the different materials throughout a process, details not represented by sentence-level annotations. Our simulator can naturally represent such information by maintaining a stateful model of the process. Simulation fidelity can be controlled by implementing the execution semantics of operations to the level of detail required.

Mehr et al. (2020) have similarly proposed a process-level executable representation, but use an NLP pipeline consisting primarily of rules and simple pattern matching, relying on a human-in-the-loop for corrections; linking our approach with their framework is a promising future direction.

Structurally, PEGs are similar to abstract meaning representation (AMR; Banarescu et al. 2013), allowing us to use agreement and performance metrics developed for AMR. In contrast with the sentence-level AMR, a major challenge in this work is annotating and predicting procedure-level representations.[8]

Another line of research focuses on procedural text understanding for more general domains: simple scientific processes (Dalvi et al., 2018), open domain procedural texts (Tandon et al., 2020), and cooking recipes (Kiddon et al., 2015; Bosselut et al., 2018). These works represent process-level information and entity state changes, but typically feature shorter processes, simpler language and an open ontology, compared with our domain-specific terminology and grounded ontology.

Our framework also provides a link to text-based game approaches to procedural text understanding. Tamari et al. (2019) modelled scientific procedures with text-based games but used only synthetic data. Our simulator enables leveraging recent advances on text-based games agents (e.g., (Adhikari et al., 2020)) towards *natural* language understanding.

8 Conclusion

We developed a novel meaning representation and simulation-based annotation interface, enabling the collection of process-level annotations of experimental procedures, as well as two parsers (pipeline and joint modelling) trained on this data. Our dataset and experiments present several directions for future work, including the modelling of challenging long range dependencies, application of text-based games for procedural text understanding, and extending simulation-based annotation to new domains.

Acknowledgments

We would like to thank Peter Clark, Noah Smith, Yoav Goldberg, Dafna Shahaf, and Reut Tsarfaty for many fruitful discussions and helpful comments, as well as the X-WLP annotators: Pranay Methuku, Rider Osentoski, Noah Zhang and Michael Zhan. This work was partially supported by an Allen Institute for AI Research Gift to Gabriel Stanovsky. A Annotation Schema

In the following subsections, we provide further details of the annotation schema used. Section §A.1 describes how the ontology was constructed based on Autoprotocol, and §A.2 provides details on ontology coverage for the X-WLP protocols which were chosen for annotation. Section §A.3 details the rules defining valid PEG edges, or what relations can hold between various entity types. The annotation guidelines given to annotators are available on the project web page.

A.1 Ontology Construction

Operation nodes correspond to "action" entities in WLP. In X-WLP, to facilitate conversion to executable instructions, we further add a fine-grain operation type; for each operation, annotators were required to select the closest operation type, or a `general` type if none applied.

To define our operation type ontology, we consulted the Autoprotocol (Miles and Lee, 2018) open source standard used for executable biology lab protocols. Autoprotocol defines 35 different operation types,[9] from which we grouped relevant types into higher level clusters; X-WLP operation types are broadly aligned with Autoprotocol operation types, but are more general in scope, to not limit applicability to any one platform. For example, we use a more general `measure` operation type rather than the specific types of measurement operations in Autoprotocol (`spectrophotometry`, `measure-volume`, etc.).

Table 12 maps between X-WLP operation types and their equivalents in Autoprotocol, if one exists. The X-WLP operation types do not perfectly overlap with Autoprotocol as the former is written for humans, while the latter is designed for the more constrained domain of robot execution. Accordingly, some operations not currently supported in Autoprotocol were added, like `wash`. See Table 1 for example mention spans for each X-WLP operation type.

The set of supported operations was chosen to maximize coverage over the types of operations found in the sentence-level annotations of WLP (see §A.2 below for details).

A.2 Ontology Coverage

To identify candidate protocols for annotation which were well covered by the ontology, we created a mapping between ontology instruction types and the 100 most frequent text-spans of WLP action entities (constituting 74% of all action spans in WLP). WLP action text spans that didn't correspond to any ontology instruction were mapped to a `general` label; action text spans that could be mapped to the ontology we call ontology-covered actions. For annotation in X-WLP, we then selected WLP protocols estimated to have a high percentage of ontology-covered actions (based on the mapping above). This simple method was found to be effective in practice, as measured by the actual ontology coverage of X-WLP annotations, summarized in Fig. 4.

For each annotated protocol, we calculated the percentage of known (not `general`) operations. Fig. 4 plots, for each coverage percentile (y-axis), the percentage (x-axis) of X-WLP protocols with at least y percent known operations. From the plot we can see for example that half of the protocols in X-WLP have >90% ontology coverage, and 90% of the protocols have >70% ontology coverage.

X-WLP Operation	Autoprotocol Instructions
Spin	Spin
Convert	N/A
Seal	Seal, Cover
Create	Oligosynthesize, Provision
General	N/A
Destroy	N/A
Measure	Absorbance, Fluorescence, Luminescence, IlluminaSeq, SangerSeq, MeasureConcentration, MeasureMass, MeasureVolume, CountCells, Spectrophotometry, FlowCytometry, FlowAnalyze, ImagePlate
Mix	Agitate
Remove	Unseal, Uncover
Temperature Treatment	Thermocycle, Incubate, FlashFreeze
Transfer	AcousticTransfer, MagneticTransfer, Dispense, Provision, LiquidHandle, Autopick
Wash	N/A
Time	N/A

Table 12: Mapping between X-WLP operation types and corresponding Autoprotocol instructions (if any exist). Autoprotocol operations tend to be more specific as they are intended for machine execution. X-WLP protocols are written for humans, so operation types are defined at a higher level of abstraction.

---

[9] Based on `https://github.com/autoprotocol/autoprotocol-python/blob/master/autoprotocol/instruction.py` as of January 2021.

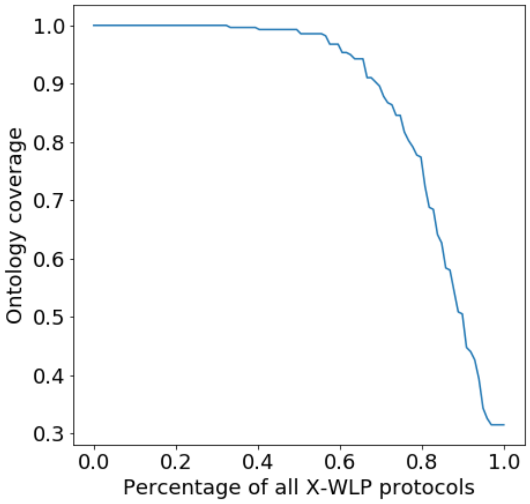

Figure 4: Plot displaying for each coverage percentile (y-axis), the percentage (x-axis) of X-WLP protocols with at least y percent known (ontology-covered) operations.

A.3 Syntax governing PEG edges

Formally, edges are represented by triplets of the form (s, r, t) where s and t are argument nodes and r is a core or non-core role. Dependent on a particular role r, certain restrictions may apply to the fine-grained type of s and t, as described below.

A.3.1 Core Roles

Core roles, displayed in Table 3, represent operation specific roles, for example "ARG1" for the `seal` operation is a *seal* entity representing the seal of the "ARG0" argument. For core roles, the following restrictions hold:

- Source nodes s are restricted to any of the *object* types $s \in \{reagent, device, seal, location\}$ representing physical objects. The only exception to this rule is that "ARG1" for the `seal` operation must be a *seal* entity.
- Target node t is a predicate of one of the types in Table 1.
- r is a core argument relation, $r \in \{\text{ARG0}, \text{ARG1}, \text{ARG2}\}$ or ARG* for short.
- Certain roles may be required for a valid predicate t, for example the `transfer` operation requires at minimum both source and target arguments to be specified by the ARG0 and "site" roles, respectively.

Role	Source Types	Target Types
co-ref	Object	Object
measure	Measurement	Object
setting	Setting	Object
modifier	Modifier	Object, Operation, Measurement
usage	Method, Object	Operation
located-at	Object	Object
part-of	Object	Object

Table 13: Details of non-core roles and restrictions on source and target node types. Object is short for the set of entity types representing physical objects: $\{reagent, device, seal, location\}$.

A.3.2 Non-core Roles

Non-core roles (e.g., "setting", "site", or "co-ref") indicate predicate-agnostic labels. For example, the *site* argument always marks the location in which a predicate is taking place. Non-core roles are displayed in Table 13, and role-specific restrictions on s and t are listed under "Source Types" and "Target Types", respectively.

Machine Translationese: Effects of Algorithmic Bias on Linguistic Complexity in Machine Translation

Abstract

Recent studies in the field of Machine Translation (MT) and Natural Language Processing (NLP) have shown that existing models amplify biases observed in the training data. The amplification of biases in language technology has mainly been examined with respect to specific phenomena, such as gender bias. In this work, we go beyond the study of gender in MT and investigate how bias amplification might affect language in a broader sense. We hypothesize that the 'algorithmic bias', i.e. an exacerbation of frequently observed patterns in combination with a loss of less frequent ones, not only exacerbates societal biases present in current datasets but could also lead to an artificially impoverished language: 'machine translationese'. We assess the linguistic richness (on a lexical and morphological level) of translations created by different data-driven MT paradigms – phrase-based statistical (PB-SMT) and neural MT (NMT). Our experiments show that there is a loss of lexical and morphological richness in the translations produced by all investigated MT paradigms for two language pairs (EN↔FR and EN↔ES).

1 Introduction

The idea of translation entailing a transformation is widely recognised in the field of Translation Studies (TS) (Ippolito, 2014). Translations are specific communicative acts occurring in a particular context governed by their own laws. Some of the features that characterize translated texts are defined as simplification, explicitation, normalization and leveling out (Baker, 1999). The fingerprints left by the translation process and the language this results into, have been referred to as 'translationese' (Gellerstam, 1986). Empirical evidence of the existence of translationese can be found in studies showing that machine learning techniques can be employed to automatically distinguish between human translated and original text by looking at lexical and grammatical information (Baroni and Bernardini, 2006; Koppel and Ordan, 2011). Translationese differs from original texts due to a combination of factors including intentional (e.g. explicitation and normalization) and unintentional ones (e.g. unconscious effects of the source language input on the target language produced). Unlike other work on (human) translationese (or even related work on 'Post-editese'), we delve into the effects of machine translation (MT) algorithms on language, i.e. 'machine translationese'.

So far, generating accurate and fluent translations has been the main objective of MT systems. As such, maintaining the richness and diversity in the outputs has understandably not been a priority (Vanmassenhove, 2020).[1] However, as MT systems have reached a quality that is (arguably) close to that of human translations (Läubli et al., 2018; Toral et al., 2018) and as such are being used widely on a daily basis, we believe it is time to look into the potential effects of (MT) algorithms on language itself.[2]

The main motivations behind this work are: (i) if algorithmic bias is indeed a by-product of our algorithms, a statistically biased MT system might prefer frequently occurring words (or sub-words) over others. Since MT systems do not necessarily distinguish between different synonymous translations (lexical richness) and morphological variants (grammatical richness), algorithmic bias could lead to the loss of morphological variety (and thus interfere with the ability of our systems to generate

---

[1] One might argue that for some tasks and domains, diversity can be harmful (specific in-domain translations would prefer consistency over e.g. lexical diversity).

[2] Google Translate alone translates more than 100 billions words per day and is used by at least 500 million people according to estimates (`https://www.blog.google/products/translate/ten-years-of-google-translate/`).

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2203–2213
April 19 - 23, 2021.

at all times a grammatically correct option); (ii) the sociolinguistic perspective of machine translationese since it has been established that language contact (e.g. via translationese) can entail language changes (Kranich, 2014). If machine translationese (and other types of 'NLPese') is a simplified version of the training data, what does that imply from a sociolinguistic perspective and how could this affect language on a longer term?

The main objective of the presented research is to establish whether there is indeed a quantitatively measurable difference between the linguistic richness of an MT system's training data and its output in terms of morphological and lexical diversity. To do so, we conduct an in-depth analysis that goes beyond frequently used standard lexical diversity metrics such as TTR, Yule's I and MTLD. We assess the lexical and morphological diversity through an adapted version of the Lexical Frequency Profile used to assess language acquisition, a measure of morphological diversity based on Shannon and Simpson Diversity and an novel automatic evaluation of synonym frequency. We focus on the most prominent data-driven MT paradigms: Neural MT (NMT), both LSTM (Bahdanau et al., 2015; Sutskever et al., 2014) and Transformer (Vaswani et al., 2017), and Phrase-Based Statistical MT (PB-SMT). Up to our knowledge this is the first research on lexical and morphological diversity of machine translation output, i.e. machine translationese.

The contributions of this work can be summarised as: (i) a detailed analysis of lexical and morphological diversity of machine translationese and the loss thereof to quantify the effects of algorithmic bias; (ii) the adaptation of a metric used in language acquisition for assessing lexical sophistication in MT[3]; (iii) the use of Shannon entropy and Simpson diversity to measure morphological richness, and (iv) a novel, automatic evaluation of synonym frequency.

2 Related Work

Several studies have exposed the societal biases present in datasets (racial bias (Merullo et al., 2019), political bias (Fan et al., 2019), gender bias (Vanmassenhove and Hardmeier, 2018). Existing NLP technology are likely to pick up biases present in the training data and various explorations of e.g. gender bias in NLP systems have indeed revealed the existence of harmful biases in the output they generate (Bolukbasi et al., 2016; Caliskan-Islam et al., 2016; Garg et al., 2018; Vanmassenhove et al., 2018; Stanovsky et al., 2019; Sun et al., 2019; Habash et al., 2019). Research related to bias has often focused on gender or race. Especially in a field such as MT, the implicit gender in a language such as English and its consecutive translations into morphologically richer languages with gender agreement, makes it relatively easy to expose and study biases related to gender in a contrastive linguistic setting. In the context of this paper, we would like to note that (statistical) bias is not limited to gender or race but can be defined as any systematic inaccuracy in one direction leading to an under (or over) estimation of observations.

A handful of recent work has mentioned the possibility of algorithmic bias on top of the already existing societal biases in the training data (Bolukbasi et al., 2016; Caliskan-Islam et al., 2016; Garg et al., 2018). For instance, Zhao et al. (2017) observe a phenomenon they refer to as 'bias amplification'. They note that in their training data an activity such as 'cooking' is associated 33% times more with women compared to men. After training a model on that dataset, the existing disparity is amplified to 68% times more associations with women.

In the field of MT, Vanmassenhove et al. (2019) address the effects of statistical bias on language generation in an MT setting. They assess lexical diversity using standard metrics –TTR, MTLD and Yule's K– and conclude that the translations produced by various MT systems (PB-SMT and NMT) are consistently less diverse than the original training data. Their approach was conducted on NMT systems that were trained without byte-pair-encoding (BPE) (Sennrich et al., 2016) which limits the creativity of the translation systems.

Toral (2019) measures the lexical diversity of 18 state-of-the-art systems on 6 language pairs, reaching similar conclusions. They do so focusing specifically on post-editese. The experiments indicate that post-editese is simpler and more normalised than human translationese. The post-editese also shows a higher degree of interference from the source compared to the human translations. Daems et al. (2017), like Toral (2019), centers around the automatic detection of post-editese and does not look into properties of unedited machine translationese. In Aranberri (Aranberri, 2020) different freely available MT systems (neural and rule-

---

[3] In fact, our implementation of the LFP metric can be employed for any NLP tasks.

based) are compared in terms of automatic metrics (BLEU, TER) and translationese features (TTR, length ratio input/output, perplexity, etc.) to investigate how such features correlate with translation quality. Bizzoni et al. (2020) presents a comparison using similar translationese features of three MT architectures and the human translations of spoken and written language.

In the field of PB-SMT, Klebanov and Flor (2013) show that PB-SMT suffers considerably more than human translations (HT) from lexical loss, resulting in loss of lexical tightness and text cohesion. Aharoni et al. (2014) proof that automatic and human translated sentences can be automatically identified corroborating that human translations systematically differ from the translations produced by PB-SMT systems.

Aside from Vanmassenhove et al. (2019), the above discussed related work uses metrics of lexical diversity to compare human translations to (post-edited) machine translations. In this work, we compare how and whether the output of an MT system differs (in terms of lexical and morphological diversity) from the data it was originally trained on. This way, we aim to investigate the effect of the algorithm (and algorithmic bias) on language itself.

3 Machine Translation Systems

MT paradigms have changed quickly over the last decades. Since this is the first attempt to quantify both the lexical and grammatical diversity of machine translationese, we experimented with the current state-of-the-art data-driven paradigms, LSTM and Transformer, as well as with PB-SMT. We used data from the Europarl corpus (Koehn, 2005) for two language pairs, English–French and English–Spanish in both direction (EN→FR, FR→EN, EN→ES and ES→EN). We are interested in both directions in order to verify whether there is a difference in terms of (the potential loss of) diversity when comparing translations from a morphologically poorer language (English) into morphologically richer ones (French and Spanish) and vice versa. Our data is summarised in Table 2.[4]

Lang. pair	Train	Test	Dev
EN-FR/FR-EN	1,467,489	499,487	7,723
EN-ES/ES-EN	1,472,203	459,633	5,734

Table 1: Number of parallel sentences for the training, testing and development sets.

The specifics of the MT systems we trained are:

PB-SMT For the PB-SMT systems we used Moses (Koehn et al., 2007) with default settings and a 5-gram language model with pruning of bigrams. We also tuned each system using MERT (Och and Ney, 2003) until convergence or for a maximum of 25 iterations. During translation we mask unknown words with the UNK token to avoid bleeding through (source) words which would artificially increase the linguistic diversity.

NMT For the RNN and Transformer systems we used OpenNMT-py.[5] The systems were trained for maximum of 150K steps, saving an intermediate model every 5000 steps or until reaching convergence according to an early stopping criteria of no improvements of the perplexity (scored on the development set) for 5 intermediate models. The options we used for the neural systems are:

- RNN: size: 512, RNN type: bidirectional LSTM, number of layers of the encoder and of the decoder: 4, attention type: MLP, dropout: 0.2, batch size: 128, learning optimizer: Adam (Kingma and Ba, 2014) and learning rate: 0.0001.
- Transformer: number of layers: 6, size: 512, transformer_ff: 2048, number of heads: 8, dropout: 0.1, batch size: 4096, batch type: tokens, learning optimizer Adam with $\text{beta}_2 = 0.998$, learning rate: 2.

All NMT systems have the learning rate decay enabled and their training is distributed over 4 nVidia 1080Ti GPUs. The selected settings for the RNN systems are optimal according to Britz et al. (2017); for the Transformer we use the settings suggested by the OpenNMT community[6] as the optimal ones that lead to quality on par with the original Transformer work (Vaswani et al., 2017).

For training, testing and validation of the systems we used the same data. To build the vocabularies for the NMT systems we used sub-word units, allowing NMT to be more creative; using sub-word units also mitigates to a certain extent the out of vo-

---

[4] We ought to address the fact that the Europarl data consists of both human-uttered and translated text which have different properties in terms of diversity. In this work we analyse the impoverishment of data when it passes through the "filter" of the MT system, i.e. the effect of algorithm. As the origin of the data, human-uttered or translated, has no impact on the inherent workings of the MT system we do not take this into account in our analysis.

[5] `https://opennmt.net/OpenNMT-py/`

[6] `http://opennmt.net/OpenNMT-py/FAQ.html`

cabulary problem. To compute the sub-word units we used BPE with 50,000 merging operations for all our data sets. In Table 2 we present the vocabulary sizes of the data used to train our PB-SMT and NMT systems.

Lang. pair	no BPE		with BPE	
	EN	FR/ES	EN	FR/ES
EN-FR/FR-EN	113,132	131,104	47,628	48,459
EN-ES/ES-EN	113,692	168,195	47,639	49,283

Table 2: Vocabulary sizes. For completeness we also present the vocabulary size without BPE, i.e. the number of unique words in the corpora.

The quality of our MT systems is evaluated on the test set using standard evaluation metrics – BLEU (Papineni et al., 2002) (as implemented in SacreBLEU (Post, 2018)) and TER (Snover et al., 2006) (as implemented in Multeval (Clark et al., 2011)). Our evaluation scores are presented in Table 3.

English as source

System	EN→FR		EN→ES	
	BLEU↑	TER↓	BLEU↑	TER↓
PB-SMT	35.7	50.7	38.6	45.9
LSTM	34.2	50.9	38.2	45.3
TRANS	**37.2**	**48.7**	**40.9**	**43.4**

English as target

System	FR→EN		ES→EN	
PB-SMT	36.2	47.1	39.3	44.0
LSTM	34.6	48.2	38.1	44.7
TRANS	**37.0**	**46.4**	**41.3**	**41.4**

Table 3: Quality evaluation scores for our MT systems. TRANS denotes Transformer systems.

We computed pairwise statistical significance using bootstrap resampling (Koehn, 2004) and a 95% confidence interval. The results shown in Table 3 are all statistically significant based on 1000 iterations and samples of 100 sentences. All metrics show the same performance trends for all language pairs: Transformer (TRANS) outperforms all other systems, followed by PB-SMT, and LSTM.

For all PB-SMT we replaced marked unknown words with only one token "UNK". While this does not effect the computation of BLEU and TER, it allows us not to artificially boost the lexical and grammatical scores for these MT engines (see Section 4) and assess their realistic dimensions.

4 Experiments and Results

Assessing linguistic complexity is a multifaceted task spanning over various domains (lexis, morphology, syntax, etc.). The lexical and grammatical diversity are two of its major components (Bachman, 2004; Bulté et al., 2008; Bulté, 2013). As such, we conduct an analysis using (i) lexical diversity and sophistication metrics (Section 4.2) and (ii) grammatical diversity metrics (Section 4.3). For lexical diversity, we use the following metrics: an adapted version of the Lexical Frequency Profile (LFP), three standard metrics commonly used to assess diversity –TTR, Yule's I and MTLD–, and three new metrics based on synonym frequency in translations. Up to our knowledge, this research is the first to employ LFP to analyze synthetic data. For grammatical diversity, we focus specifically on morphological inflectional diversity. We adopt the Shannon entropy and Simpson's diversity index to compute the entropy of the inflectional paradigms of lemmas, measuring the abundance and the evenness of wordforms per lemma.

Next, we will discuss the evaluation data and the aforementioned metrics designed in order to compare the diversity of the training data with the machine translationese. Our evaluation scripts are available at `https://github.com/dimitarsh1/BiasMT`; due to its large size, the data is not hosted in the github repository but is available upon request.

4.1 Evaluation data

To observe the effects of the MT algorithm on linguistic diversity, we used the MT engines (Section 3) to translate the source side of the training set, i.e. completely observed data. Data that has fully been observed during training is most suitable for our objectives as we are interested in the effects of the algorithm on language itself. It is also the most favourable translation (and evaluation) scenario for the MT systems since all data has been observed.

4.2 Lexical Diversity

Lexical Frequency Profile To look at the lexical sophistication and diversity in the text produced by the MT systems, we adapted the Lexical Frequency Profile (LFP) method (Laufer, 1994; Laufer and Nation, 1995). LFP is a measure that stems from research in second language (L2) acquisition and student writing methods. It is designed to study the lexical diversity or sophistication in texts produced by L2 learners. It is based on the observation that texts including a higher proportion of less frequent words are more sophisticated than those containing higher proportions of more frequent words (Kyle, 2019).

The LFP method measures diversity and sophistication by looking at frequency bands. In its original version, the LFP analysis would distinguish between 4 bands: (i) percentage of words in a text belonging to the 1000 most frequent words in that language, (ii) percentage of words in a text belonging to the next 1000 most frequent words, (iii) a list of academic words that did not occur in the first 2000 words and (iv) the remaining words. The lists used to determine the word bands are predefined word lists such as Nation's word lists (Nation, 1984). One shortcoming of the approach is that a mismatch between reference corpus and the target text can lead to misleading outcomes. However, since we are looking into the (side-)effects of the training algorithm, instead of using preset word lists in order to compute the LFP, we use the original training data to generate the word frequency lists. This allows for a better comparison between the original data and the machine translationese while bypassing the potential mismatch issue.

Several studies (Crossley et al., 2013; Laufer, 1994; Laufer and Nation, 1995) have employed the LFP method to assess L2 acquisition in learners. From these studies, it resulted that the less proficient a user of an L2, the more words belonged to the first band and the least words belong to the list of academic words or the remaining words (band 3 and 4 respectively of the original formulation).

The lexical profile mentioned above is a detailed profile, showing 4 types of words used by the learner. Because of interpretability issues, the 'Beyond 2000' is also frequently used to assess the profile of the users. It distinguishes between the first two bands (comprising of the first 2000 words) and the rest. This condensed profile has been found equally reliable and valid as the original LFP having the advantage that it reduces the profile to one single score facilitating a comparison between learners (or in our case MT systems).

Since we are interested in the difference between the original training data and the output of the MT systems, we compute the frequency bands on the original training data instead of based on pre-set word lists used in L2 research. As such, we leave out the third band consisting of a list of academic words. Presenting and computing the LFP this way, will give us immediately the 'Beyond 2000' metric score as well (as we distinguish between three bands only, the last one being anything beyond the first 2000 words).

	FR			ES		
	B1	B2	B3	B1	B2	B3
ORIG	**79.80**	6.59	13.61	**77.80**	6.83	15.36
PB-SMT	81.78	6.48	11.74	79.77	6.86	13.36
LSTM	82.95	6.18	10.88	80.34	6.84	12.81
TRANS	82.01	6.24	11.75	82.35	6.99	10.67

	EN$_{FR}$			EN$_{ES}$		
	B1	B2	B3	B1	B2	B3
ORIG	**80.83**	7.10	12.07	**80.81**	7.11	12.08

LSTM	83.23	6.93	9.81	83.29	6.93	9.78
TRANS	82.25	7.05	10.70	82.35	6.99	10.67

Table 4: Lexical Frequency Profile (French, Spanish, English (EN$_{FR}$ and EN$_{ES}$) with 3 bands (B1: 0-1000, B2: 1001-2000, B3: 2001-end) for the original data and the output of the MT systems.

The LFP for French, Spanish and English, from the EN→FR, EN→ES, FR→EN (denoted as EN$_{FR}$) and ES→EN (denoted as EN$_{ES}$) data is presented in Table 4. It shows that the original data is consistently more diverse than the output of the MT systems as (i) the percentage of text occupied by the 1000 most frequent words (B1) is lower than in the corresponding B1 scores for all MT systems which implies that the 1000 most frequent words take up a smaller percentage of the text in the original training data compared to in the output of the different MT systems; and (ii) the so-called 'Beyond 2000' measure, which in our LFP is equal to the third band (B3), showing us the percentage of text occupied by the words that do not belong to the first two bands, is consistently higher for the original data compared to the MT systems (meaning that the less frequent words occupy a bigger proportion of the original data than they do in its machine translationese variants). Note that it has been established that LFPs are large-grained so small gains in vocabulary are likely to be obscured (Kyle, 2019). The results indicate a consistent and clear difference between the original data and the different types of machine translationese for all language pairs.

Aside from the different LFP scores between the training data and the translations, we also see a difference between the languages themselves. French and Spanish have more variety (higher B1 and lower B3 (Beyond 2000) values) compared to EN$_{ES}$ and EN$_{FR}$. Since the LFPs are computed on tokens, this reflects the richer morphology in French and Spanish compared to English.

TTR, Yule's I and MTLD For completeness, we also present three more commonly used measures of lexical diversity: type/token ratio (TTR) (Templin, 1975), Yule's K (in practice, we use the reverse Yule's I) (Yule, 1944), and the measure of textual lexical diversity (MTLD) (McCarthy, 2005).

TTR presents the ratio of the total number of *different* words (types) to the *total* number of words (tokens). Higher TTR indicates a higher degree of lexical diversity. Yule's characteristic constant (Yule's K) (Yule, 1944) measures constancy of text as the repetitiveness of vocabulary. Yule's K and its inverse Yule's I are considered to be more resilient to fluctuations related to text length than TTR (Oakes and Ji, 2013). The third lexical diversity metric is MTLD. MTLD is evaluated sequentially as the mean length of sequential word strings in a text that maintains a given TTR value (McCarthy, 2005).[7] We present the scores for TTR, Yule's I and MTLD for our data and MT engines in Table 5.

	FR			ES		
	TTR	Yule's I	MTLD	TTR	Yule's I	MTLD
ORIG	**3.02**	**9.28**	**119.40**	**4.08**	**12.31**	**96.23**
PB-SMT	1.79	3.00	112.00	2.37	4.02	92.01
LSTM	1.56	2.14	104.89	2.03	2.95	86.57
TRANS	2.07	3.82	115.66	2.89	6.23	95.72

	EN$_{FR}$			EN$_{ES}$		
	TTR	Yule's I	MTLD	TTR	Yule's I	MTLD
ORIG	**2.89**	**6.64**	**108.70**	**2.88**	**6.61**	**108.46**
PB-SMT	1.74	2.07	94.65	1.82	2.25	93.18
LSTM	1.50	1.53	86.93	1.44	1.42	87.91
TRANS	2.04	3.10	101.95	2.09	3.26	99.62

Table 5: TTR, Yule's I and MTLD scores. For all metrics, higher scores indicate higher lexical richness. For ease of readability and comparison we multiplied TTR scores by 1,000 and Yule's I scores by 10,000.

The scores in Table 5 show that, overall, and according to all three metrics, the original training data has a higher lexical diversity than the machine translationese.

The data for the morphologically richer languages (FR, ES) as well as its machine translationese variants (PB-SMT, LSTM and TRANS) have higher lexical richness than the morphologically poor(er) language (EN).

Synonym Frequency Analysis The objective of synonym frequency analysis is to understand, for words with multiple possible translations, with what frequency the various translations for a given word appear in the translated text. It is called *synonym* frequency in reference to the fact that when translating from one language to another, it is common for a word in the source language to have a corresponding word in the target language to which the source word is typically translated, and that primary translated word can have many *synonyms* that constitute acceptable alternative translation options. Note that we perform this analysis only in one direction: from English into the morphologically richer languages French and Spanish.

	FR			ES		
	PTF↓	CDU↓	SynTTR↑	PTF↓	CDU↓	SynTTR↑
ORIG	**9.666**	**2.725**	**15.10**	**9.131**	**4.539**	**21.13**
PB-SMT	9.715	2.957	11.87	9.236	4.637	17.4
LSTM	9.748	3.154	10.96	9.32	4.782	15.34
TRANS	9.717	3.077	12.25	9.285	4.687	17.15

Table 6: Synonym frequency metrics for our MT systems: primary translation frequency (PTF), cosine distance from uniform (CDU) and TTR modified to only consider words with multiple translation options (SynTTR). The SynTTR scores were multiplied by 100,00 for easier viewing. Higher SynTTR scores indicate greater diversity, while lower PTF and CDU scores indicate greater diversity.

To examine synonym frequency, we first lemmatize the text using SpaCy.[8] Next, we map all nouns, verbs, and adjectives in the source to their possible translation options retrieved from bilingual dictionaries.[9] We then count the number of appearances of these different translation options for the ORIG as well as the MT data. For example, for the English word "look" with translation options in Spanish {"mirar", "esperar", "buscar", "parecer", "dar", "vistazo", "aspecto", "ojeada", "mirada"}, the number of appearances in the TRANS data are as follows: {("mirar": 4002), ("esperar": 3302), ("buscar": 2814), ("parecer": 1144), ("dar": 977), ("vistazo": 182), ("aspecto": 46), ("ojeada": 0), ("mirada": 0)}. From this mapping of translation option to number of appearances we take a vector consisting only of the numbers of appearances for each translation option, and refer to this as a translated word distribution. That is, for the aforementioned example, the distribution vector is: {4002, 3302, 2014, 1144, 997, 182, 46, 0, 0}. We use these counts and distributions as described below.

Our first synonym frequency metric deals di-

---

[7] In our experiments we used 0.72 as a TTR threshold.

[8] https://spacy.io/

[9] English-Spanish: https://github.com/mananoreboton/en-es-en-Dic, English-French: https://freedict.org/downloads

rectly with the primary translation frequency (PTF), where the "primary translation" is the translation for a given source word that appears in the target text most often. We argue that selecting secondary translation options for each source word less frequently, and selecting the primary option more frequently, indicates a decrease of lexical diversity. We measure the PTF by taking the average *primary translation prevalence* over all source words for each MT system.

As a second metric we used the cosine distance between a uniform translated word distribution, where each translation option would be equally prevalent, and the actual translation distributions (we denote this metric as CDU). While the ideal distribution of translations for a given word is almost certainly non-uniform (and therefore not perfectly diverse), this metric still gives valuable information about the tendencies of different systems to favor certain translation options over others.

The third metric is a modified TTR which we refer to as Synonym TTR (or SynTTR). Unlike with regular type/token ratio, rather than considering all tokens that appear in the text, we consider as types only translation options from the source-target mappings described above and as tokens we consider only appearances of valid types. This metric exposes where translation systems completely drop viable translation options from their vocabulary.

Table 6 shows the results for these 3 metrics. Interestingly, the MT systems can be ranked in the same order according to all these metrics: PB-SMT > TRANS > LSTM, where > denotes the comparison of lexical diversity (higher to lower). However, across the 3 metrics, for both language pairs, the reference translations (ORIG) appear to be the most lexically diverse in terms of synonym frequency, with the lowest PTF and CDU and highest SynTTR. This reinforces the idea that MT algorithms have a negative impact on the diversity of language.

4.3 Grammatical Diversity

Grammatical diversity manifests itself on the sentence (syntactic complexity) and word level (morphological complexity). With our experiments, we focus on the morphological complexity by averaging the inflectional diversity of all lemmas. To do so, we adopted two measures, originating from Information Theory: Shannon entropy (Shannon, 1948) and Simpson's Diversity Index (Simpson, 1949). The former emphasizes on the richness aspect of diversity while the latter on the evenness aspect of diversity. We used the Spacy-udpipe lemmatizer to retrieve all lemmas.[10]

Shannon Entropy Shannon entropy (H) measures the level of uncertainty associated with a random variable (X). It has been applied in use-cases from economy, ecology, biology, complex systems, language and many others (Page, 2007, 2011). In the study of language Shannon entropy has previously been used for estimating the entropy of language models (Behr et al., 2003). We use it to measure the entropy of wordforms given a lemma. In particular, the entropy of inflectional paradigm of a specific lemma could be computed by taking the base frequency of that lemma (frequency of all wordforms associated with that lemma) and the probabilities of all the wordforms within the inflectional paradigm of that particular lemma. Using such a formulation of entropy allows us to measure the morphological variety (or the loss thereof) for the machine translationese produced by each system – higher values of H indicate higher diversity and vice-versa. We use Equation 1 to compute the entropy of the inflectional paradigm of a lemma.

$$H(\ell) = -\sum_{wf \in \ell} p(wf|\ell) \log p(wf|\ell)) \qquad (1)$$

$H(\ell)$ denotes the entropy of the lemma ℓ and, for the wordform wf, $p(wf|\ell)$ is computed as the fraction of the counts of the wordform, $count(wf)$, to the count of all wordforms for the lemma ℓ, i.e. $p(wf|\ell) = \frac{count(wf)}{\sum_{wf^* \in \ell} count(wf^*)}$. We use $\in$ to indicate wordforms of a given lemma.

Simpson's Diversity Index Like Shannon Entropy, Simpson's Diversity Index (D) is a measure used to determine variation in categorical data. Values close to 1 indicate higher homogeneity, thus lower diversity and values close to 0 indicate higher variability, thus higher diversity.

Following the same reasoning as with Shannon entropy, we compute Simpson's diversity index for each lemma and the corresponding wordforms according to the formula in Equation 2.

$$D(\ell) = \frac{1}{\sum_{wf \in \ell} p(wf|\ell)^2} \qquad (2)$$

---

[10] `https://github.com/TakeLab/spacy-udpipe`

We average the Shannon entropy and Simpson's diversity index for all lemmas to get an indicative score for each translation system or the original text. We denote these with ***H*** and ***D***, accordingly. To the best of our knowledge, our work is the first to use Shannon entropy and Simpson's diversity index for the study of inflectional richness on a text level. The closest to our application of these two diversity metrics for measuring inflectional richness is the work by del Prado Martín et al. (2004). Their work on morphological processing uses Shannon entropy to compute the amount of information carried by a morphological paradigm.

An illustration of the Shannon entropy and Simpson's diversity index of a lemma is given in Table 7. We list the number of occurrences for every wordform (male singular, male plural, female singular and female plural) appearing in our datasets for the French lemma 'président' (EN: president). We then compute H and D by applying Equation 1 and Equation 2 accordingly. While both Shannon H and Simpson's D scores usually range between 0–1, for ease of readability we multiply the scores presented in Table 7 and Table 8 by 100 to present them in the range of $[0 - 100]$.

	lemma: président				H↑	D↓
	président	présidents	présidente	présidentes		
ORIG	93774	2029	1490	8	**18.11**	**92.95**
PB-SMT	99367	2019	496	1	12.81	95.16
LSTM	95272	2039	291	N/A	12.17	95.3
TRANS	92946	1952	617	N/A	13.86	94.74

Table 7: An illustration of the Shannon entropy and the Simpson's diversity index computed for the occurrences of the different wordforms of the French lemma for 'president' (président).

For lemmas with a single wordform Shannon entropy and Simpson's diversity index will be $H = 0.0$ and $D = 1.0$, respectively. While this makes sense when measuring the diversity of one morphological paradigm, they actually impact the average scores ***H*** and ***D*** without contributing to the understanding of diversity in a comparative study such as ours. In particular, lemmas with single wordforms may be either an evidence of low diversity, e.g. a translation system will always generate only one form or of high diversity, e.g. rare words that are single wordform for a particular lemma (such as synonyms of more common words) can indicate the ability of a system to generate more diverse language (in terms of synonymy). That is why we computed ***H*** and ***D*** on lemmas with two or more wordforms. For completeness, we also present the number of single wordform lemmas. The Shannon entropy and Simpson's diversity index for French, Spanish and English for all datasets are presented in Table 8. The scores are shown in the range $[0 - 100]$ as noted above.

	FR			ES		
	H↑	***D***↓	Single	***H***↑	***D***↓	Single
ORIG	**75.20**	**56.42**	79k	**78.42**	**54.96**	92k
PB-SMT	69.00	59.64	51k	71.79	58.56	54k
LSTM	69.28	59.48	53k	72.84	58.29	55k
TRANS	73.13	57.70	58k	77.23	56.26	64k

	EN_{FR}			EN_{ES}		
	H↑	***D***↓	Single	***H***↑	***D***↓	Single
ORIG	**59.04**	**63.43**	78k	**59.05**	**63.42**	78k
PB-SMT	55.57	65.80	51k	56.31	65.29	61k
LSTM	53.15	67.02	50k	53.85	66.64	48k
TRANS	55.85	65.43	58k	56.22	65.19	68k

Table 8: Shannon entropy (***H***) for French, Spanish, English (EN_{FR} and EN_{ES}) and Simpson's diversity index (***D***) for original training data and the output of the PB-SMT, LSTM and TRANS systems. Scores are multiplied by 100 for ease of readability.

The ***H*** and ***D*** scores in Table 8 are an evidence of the negative impact of MT on the morphological diversity – the scores for the ORIG indicate a consistent higher diversity. Comparing the MT systems, it results that TRANS retains morphological diversity better than the others. LSTM performs better than PB-SMT for translations into the morphologically richer languages (FR and ES) but PB-SMT seems much better than LSTM for translations into English. While the loss of lexical diversity could, in some cases be a desirable side-effect of MT systems (in terms of simplification or consistency), the uncontrolled loss of morphological richness is problematic as it can prevent systems from picking the grammatically correct option.

5 Conclusions

In this work, we explore the effects of MT algorithms on the richness and complexity of language. We establish that there is indeed a quantitatively measurable difference between the linguistic richness of MT systems' training data and their output – a product of algorithmic bias. These findings are in line with previous results described in Vanmassenhove et al. (2019). Assessing diversity or richness in language is a multifacted task spanning over various domains. As such, we approach this task from multiple angles focusing on lexical diversity and sophistication, morphological variety and a more translation specific metric focusing on synonymy. To do so, we analyse the results of 9 different metrics including established, newly proposed and adapted ones. The metrics suit we developed is unprecedented in the study of MT quality and we believe it could drive future research on MT evaluation.

Based on a wide range of experiments with 3 different MT architectures, we draw the following main conclusions: (i) all 9 metrics indicate that the original training data has more lexical and morphological diversity compared to translations produced by the MT systems. This is the case for all language pairs and directions; (ii) Comparing the MT systems among themselves, there is a strong indication (for most metrics) that Transformer models outperform the others in terms of lexical and morphological richness. We also ought to note that, on average, the ranking of the systems in terms of diversity metrics correlates with the quality of the translations (in terms of BLEU and TER). This is something that would need to be further explored in future work; (iii) The data for the morphologically richer languages (ES, FR) has higher lexical and (evidently) morphological diversity than the English data both in the original data and in the translations generated by all systems. However, for PB-SMT, LSTM and TRANS the difference in scores is much smaller than the ORIG, indicating that the MT systems have a stronger negative impact (in terms of diversity and richness) on the morphologically richer languages.

Abstract

Multilingual pretrained language models have demonstrated remarkable zero-shot cross-lingual transfer capabilities. Such transfer emerges by fine-tuning on a task of interest in one language and evaluating on a distinct language, not seen during the fine-tuning. Despite promising results, we still lack a proper understanding of the source of this transfer. Using a novel layer ablation technique and analyses of the model's internal representations, we show that multilingual BERT, a popular multilingual language model, can be viewed as the stacking of two sub-networks: a multilingual encoder followed by a task-specific language-agnostic predictor. While the encoder is crucial for cross-lingual transfer and remains mostly unchanged during fine-tuning, the task predictor has little importance on the transfer and can be reinitialized during fine-tuning. We present extensive experiments with three distinct tasks, seventeen typologically diverse languages and multiple domains to support our hypothesis.

1 Introduction

Zero-shot Cross-Lingual transfer aims at building models for a *target* language by reusing knowledge acquired from a *source* language. Historically, it has been tackled with a two-step *standard cross-lingual pipeline* (Ruder et al., 2019): (1) Building a shared multilingual representation of text, typically by aligning textual representations across languages. This step can be done using feature extraction (Aone and McKee, 1993; Schultz and Waibel, 2001) as with the delexicalized approach (Zeman and Resnik, 2008; Søgaard, 2011) or using word embedding techniques (Mikolov et al., 2013; Smith et al., 2017) by projecting monolingual embeddings onto a shared multilingual embedding space, this step requiring explicit supervision signal in the target language in the form of features or parallel data. (2) Training a task-specific model using supervision on a source language on top of the shared representation.

Recently, the rise of multilingual language models entailed a paradigm shift in this field. Multilingual pretrained language models (Devlin et al., 2019; Conneau and Lample, 2019) have been shown to perform efficient zero-shot cross-lingual transfer for many tasks and languages (Pires et al., 2019; Wu and Dredze, 2019). Such transfer relies on three-steps: (i) pretraining a mask-language model (e.g. Devlin et al. (2019)) on the concatenation of monolingual corpora across multiple languages, (ii) fine-tuning the model on a specific task in the source language, and (iii) using the fine-tuned model on a target language. The success of this approach is remarkable, and in contrast to the standard cross-lingual pipeline, the model sees neither aligned data nor task-specific annotated data in the target language at any training stage.

The source of such a successful transfer is still largely unexplained. Pires et al. (2019) hypothesize that these models learn shared multilingual representations during pretraining. Focusing on syntax, Chi et al. (2020) recently showed that the multilingual version of BERT (mBERT) (Devlin et al., 2019), encodes linguistic properties in shared multilingual sub-spaces. Recently, Gonen et al. (2020) suggest that mBERT learns a language encoding component and an abstract cross-lingual component. In this work, we are interested in understanding the mechanism that leads mBERT to perform zero-shot cross-lingual transfer. More specifically, we ask **what parts of the model and what mechanisms support cross-lingual transfer?**

By combining behavioral and structural analyses (Belinkov et al., 2020), we show that mBERT operates as the stacking of two modules: (1) A multilingual encoder, located in the lower part of the model, critical for cross-lingual transfer, is in charge of

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2214–2231
April 19 - 23, 2021.

aligning multilingual representations; and (2) a task-specific, language-agnostic predictor which has little importance for cross-lingual transfer and is dedicated to performing the downstream task. This mechanism that emerges out-of-the-box, without any explicit supervision, suggests that mBERT behaves like the standard cross-lingual pipeline. Our contributions advance the understanding of multilingual language models and as such have the potential to support the development of better pretraining processes.

2 Analysis Techniques

We study mBERT with a novel behavioral test that disentangles the task fine-tuning influence from the pretraining step (§2.1), and a structural analysis on the intermediate representations (§2.2). Combining the results from these analyses allows us to locate the cross-lingual transfer and gain insights into the mechanisms that enable it.

2.1 Locating Transfer with RANDOM-INIT

In order to disentangle the impact of the pretraining step from the fine-tuning, we propose a new behavioral technique: RANDOM-INIT. First, we randomly initialize a set of parameters (e.g. all the parameters of a given layer) instead of using the parameters learned during the pretraining step. Then, we fine-tune the modified pretrained model and measure the downstream performance.[1]

By replacing a given set of pretrained parameters and fine-tuning the model, *all other factors being equal*, RANDOM-INIT enables us to quantify the contribution of a given set of pretrained parameters on downstream performance and therefore to locate which pretrained parameters contribute to the cross-lingual transfer.

If the cross-language performance is significantly lower than same-language performance, we conclude that these layers are more important to cross-language performance than they are for same-language performance. If the cross-language score does not change, it indicates that cross-language transfer does not rely on these layers.

This technique is reminiscent of the recent *Amnesic Probing* method (Elazar et al., 2020), that removes from the representation a specific feature, e.g. Part-of-Speech, and then measures the outcome on the downstream task. In contrast, RANDOM-INIT allows to study a specific architecture component, instead of specific features.

2.2 Hidden State Similarities across Languages

To strengthen the behavioral evidence brought by RANDOM-INIT, and provide finer analyses that focus on individual layers, we study how the textual representations differ between parallel sentences in different languages. We hypothesize that an efficient fine-tuned model should be able to represent similar sentences in the source and target languages similarly, even-though it was fine-tuned only on the source language.

To measure the similarities of the representation across languages, we use the Central Kernel Alignment metric (CKA), introduced by Kornblith et al. (2019). We follow Conneau et al. (2020) who use the CKA as a similarity metric to compare the representations of monolingual and bilingual pretrained models across languages. In our work, we use the CKA to study the representation difference between source and target languages in pretrained and fine-tuned multilingual models. For every layer, we average all contextualized tokens in a sentence to get a single vector.[2] Then we compute the similarity between target and source representations and compare it across layers in the pretrained and fine-tuned models. We call this metric the *cross-lingual similarity*.

3 Experimental Setup

Tasks, Datasets and Evaluation We consider three tasks covering both syntactic and semantic aspects of language: Part-Of-Speech Tagging (POS), dependency parsing, and Named-Entity Recognition (NER). For POS tagging and parsing we use the Universal Dependency (Nivre et al., 2018) treebanks, and for NER, we use the WikiANN dataset (Pan et al., 2017). We evaluate our systems with the standard metrics per task; word-level accuracy for POS tagging, F1 for NER and labeled attachment score (LAS) for parsing. All the reported scores are computed on the test set of each dataset.

We experiment with English, Russian and Arabic as source languages, and fourteen typologically diverse target languages, including Chinese, Czech, German and Hindi. The complete list can be found in the Appendix A.1.2.

---

[1] Note that we perform the same optimization procedure for the model with and w/o RANDOM-INIT (optimal learning rate and batch size are chosen with grid-search).

Table 1: Relative Zero shot Cross-Lingual performance of mBERT with Random-init (§2.1) on pairs of consecutive layers compared to mBERT without any random-initialization (Ref). In Src-Trg, Src indicates the source language on which we fine-tune mBERT, and Trg the target language on which we evaluate it. Src-X is the average across all 17 target language with X $\neq$ Src. Detailed results per target language are reported in tables 6, 7 and 8 in the Appendix. Coloring is computed based on how mBERT with Random-init performs compared to the Ref model. $\geq$ Ref $<$ Ref $\leq$ -2 points $\leq$ -5 points

The results of a model that is fine-tuned and evaluated on the *same* language are referred to as *same-language* and those evaluated on *distinct* languages are referred to as *cross-language*.

Multilingual Model We focus on mBERT (Devlin et al., 2019), a 12-layer model trained on the concatenation of 104 monolingual Wikipedia corpora, including our languages of study.

Fine-Tuning We fine-tune the model for each task following the standard methodology of Devlin et al. (2019). The exact details for reproducing our results can be found in the Appendix. All reported scores are averaged on 5 runs with different seeds.

4 Results

4.1 Disentangling the Pretraining Effect

For each experiment, we measure the impact of randomly-initializing specific layers as the difference between the model performance without any random-initialization (Ref) and with random-initialization (Random-init). Results for two consecutive layers are shown in Table 1. The rest of the results, which exhibit similar trends, can be found in the Appendix (Table 5).

For all tasks, we observe sharp drops in the cross-language performance at the lower layers of the model but only moderate drops in the same-language performance. For instance, the parsing experiment with English as the source language, results in a performance drop on English of only 0.96 points (En-En), when randomly-initializing layers 1 and 2. However, it leads to an average drop of 15.77 points on other languages (En-X).

Furthermore, we show that applying Random-init to the upper layers does not harm same-language and cross-language performances (e.g. when training on parsing for English, the performance slightly decreases by 0.09 points in the same-language while it increases by 1.00 in the cross-language case). This suggests that the upper layers are *task-specific* and *language-agnostic*, since re-initializing them have minimal change on performance. We conclude that mBERT's upper layers do not contribute to cross-language transfer.

Does the Target Domain Matter? In order to test whether this behavior is specific to the cross-language setting and is not general to out-of-distribution (OOD) transfer, we repeat the same Random-init experiment by evaluating on same-language setting while varying the evaluated domain.[3] If the drop is similar to cross-language performance, it means that lower layers are important for out-of-distribution transfer in general. Otherwise, it would confirm that these layers play a specific role for cross-language transfer.

We report the results in Table 2. For all analyzed domains (Web, News, Literature, etc.) applying Random-init to the two first layers of the models leads to very moderate drops (e.g. -0.91 when the target domain is English Literature for parsing), while it leads to large drops when the evaluation is done on a distinct language (e.g. -5.82 when evaluated on French). The trends are similar for all the domains and tasks we tested on. We conclude that the pretrained parameters at the lower layers are consistently more critical for cross-language transfer than for same-language transfer, and cannot be explained by the possibly different domain of the evaluated datasets.

---

[3] Although other factors might play a part in out-of-distribution, we suspect that domains plays a crucial part in transfer. Moreover, it was shown that BERT encodes out-of-the-box domain information (Aharoni and Goldberg, 2020)

Table 2: Relative Zero shot Cross-Lingual performance of mBERT with RANDOM-INIT (§2.1) on pairs of consecutive layers compared to mBERT without any random-initialization (REF). We present experiments with English as the source language and evaluate across various target domains in English in comparison with the cross-lingual setting when we evaluate on French. EN-LIT. refers to the Literature Domain. UGC refers to User-Generated Content. FR-TRAN. refers to sentences translated from the English *In-Domain* test set, hence reducing the domain-gap to its minimum.

≥ REF < REF ≤ -2 points ≤ -5 points

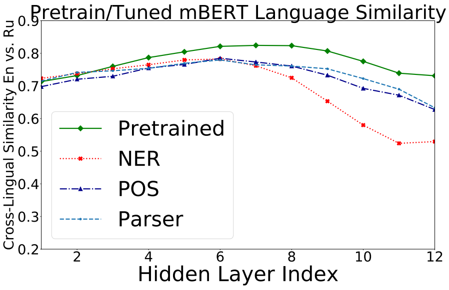

Figure 1: Cross-Lingual similarity (CKA) between representations of pretrained and fine-tuned models on POS, NER and Parsing between English and Russian.

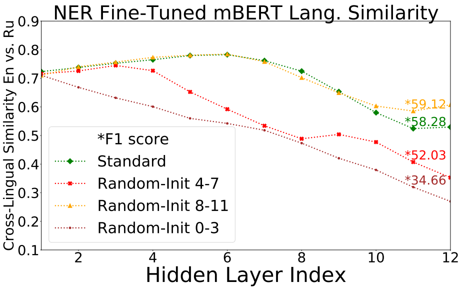

Figure 2: Cross-Lingual similarity (CKA) of the representations of a fine-tuned model on NER with and w/o RANDOM-INIT between English (source) and Russian (target). The higher the score the greater the similarity.

4.2 Cross-Lingual Similarity in mBERT

The results from the previous sections suggest that the lower layers of the model are responsible for the cross lingual transfer, whereas the upper layers are language-agnostic. In this section, we assess the transfer by directly analyzing the intermediate representations and measuring the similarities of the hidden state representations between source and target languages. We compute the CKA metric (cf. §2.2) between the source and the target representations for pretrained and fine-tuned models using parallel sentences from the PUD dataset (Zeman et al., 2017). In Figure 1, we present the similarities between Russian and English with mBERT pretrained and fine-tuned on the three tasks.[4]

The cross-lingual similarity between the representations constantly increases up to layer 5 for all the three tasks (reaching 78.1%, 78.1% and 78.2% for parsing, POS tagging and NER respectively). From these layers forward, the similarity decreases. We observe the same trends across all languages (cf. Figure 5). This demonstrates that the fine-tuned model creates similar representations regardless of the language and task, and hints on an alignment that occurs in the lower part of the model. Interestingly, the same trend is also observed in the pretrained model, suggesting that the fine-tuning step preserves the multilingual alignment.

These results do not match the findings of Singh et al. (2019), who found no language alignment across layers, although they inspected Natural Language Inference, a more "high-level task" (Dagan et al., 2005; Bowman et al., 2015). We leave the inspection of this mismatch to future work.

4.3 Better Alignment Leads to Better Cross-Lingual Transfer

In the previous section we showed that fine-tuned models align the representations between parallel sentences, across languages. Moreover, we demonstrated that the lower part of the model is critical for cross-language transfer but hardly impacts the same-language performance. In this section, we show that the alignment measured plays a critical role in cross-lingual transfer.

As seen in Figure 2 in the case of English to Russian (and in Figures 6-8 in the Appendix for other languages), when we randomly-initialize the lower part of the model, there is no alignment: the

---

[4] We report the comparisons for 5 other languages in Figure 5 in the Appendix.

similarity between the source and target languages decreases. We observe the same trend for all other languages and tasks and report it in the Appendix in Figures 6-8. This result matches the drop in cross-lingual performance that occurs when we apply RANDOM-INIT to the lower part of the model while impacting moderately same-language performance.

For a more systematic view of the link between the cross-lingual similarities and the cross-language transfer, we measure the Spearman correlation between the *cross-lang gap* (i.e the difference between the same-language perfromance and the cross-language performance) (Hu et al., 2020) and the cross-lingual similarity averaged over all the layers. We measure it with the cross-lingual similarity computed on the pretrained and fine-tuned models (without random-initialization) on all the languages. We find that the cross-lingual similarity correlates significantly with the *cross-lang gap* for all three tasks, both on the fine-tuned and pretrained models. The spearman correlation for the fine-tuned models are 0.76, 0.75 and 0.47 for parsing, POS and NER, respectively.[5] In summary, our results show that the cross-lingual alignment is highly correlated with the cross-lingual transfer.

5 Discussion

Understanding the behavior of pretrained language models is currently a fundamental challenge in NLP. A popular approach consists of probing the intermediate representations with external classifiers (Alain and Bengio, 2017; Adi et al., 2017; Conneau et al., 2018) to measure if a specific layer captures a given property. Using this technique, Tenney et al. (2019) showed that BERT encodes linguistic properties in the same order as the "classical NLP pipeline". However, probing techniques only indirectly explain the behavior of a model and do not explain the relationship between the information captured in the representations and its effect on the task (Elazar et al., 2020). Moreover, recent works have questioned the usage of probing as an interpretation tool (Hewitt and Liang, 2019; Ravichander et al., 2020). This motivates our approach to combine a structural analysis based on representation similarity with behavioral analysis. In this regard, our findings extend recent work from Merchant et al. (2020) in the multilingual setting, who show that fine-tuning impacts mainly the upper layers of the model and preserves the linguistic features learned during pretraining. In our case, we show that the lower layers are in charge of aligning representations across languages and that this cross-lingual alignment learned during pretraining is preserved after fine-tuning.

6 Conclusion

The remarkable performance of multilingual languages models in zero-shot cross-lingual transfer is still not well understood. In this work, we combine a *structural* analysis of the similarities between hidden representation across languages with a novel *behavioral* analysis that randomly-initialize the models' parameters to understand it. By combining those experiments on 17 languages and 3 tasks, we show that mBERT is constructed from: (1) a multilingual encoder in the lower layers, which aligns hidden representations across languages and is critical for cross-language transfer, and (2) a task-specific, language-agnostic predictor that has little effect to cross-language transfer, in the upper layers. Additionally, we demonstrate that hidden cross-lingual similarity strongly correlates with downstream cross-lingual performance suggesting that this alignment is at the root of these cross-lingual transfer abilities. This shows that mBERT reproduces the standard cross-lingual pipeline described by Ruder et al. (2019) without any explicit supervision signal for it. Practically speaking, our findings provide a concrete tool to measure cross-lingual representation similarity that could be used to design better multilingual pretraining processes.

Acknowledgments

We want to thank Hila Gonen, Shauli Ravfogel and Ganesh Jawahar for their insightful reviews and comments. We also thank the anonymous reviewers for their valuable suggestions. This work was partly funded by two French National funded projects granted to Inria and other partners by the Agence Nationale de la Recherche, namely projects PARSITI (ANR-16-CE33-0021) and SoSweet (ANR-15-CE38-0011), as well as by the third author's chair in the PRAIRIE institute funded by the French national agency ANR as part of the "Investissements d'avenir" programme under the reference ANR-19-P3IA-0001. Yanai Elazar is grateful to be partially supported by the PBC fellowship for outstanding Phd candidates in Data Science.

A Appendices

A.1 Reproducibility

A.1.1 Optimization

We fine-tune our models using the standard Adam optimizer (Kingma and Ba, 2015). We warmup the learning rate on the first 10% steps and use linear decay in the rest of the training. Using the validation set of the source language, we find the best combination of hyper-parameters with a grid search on batch size among {16, 32} and learning rate initialization among {1e-5, 2.5e-5, 5e-5} We select the model with the highest validation performance out of 15 epochs for parsing and out of 6 epochs for POS tagging and NER.

Hyperparameters In Table 3, we report the best hyper-parameters set for each task, the bound of each hyperparameter, the estimated number of grid search trial for each task as well as the estimated run time.

A.1.2 Data

Data Sources We base our experiments on data originated from two sources. The Universal Dependency project (McDonald et al., 2013) downloadable here `https://lindat.mff.cuni.cz/repository/xmlui/handle/11234/1-2988` and the WikiNER dataset (Pan et al., 2017). We also make use of the CoNLL-2003 shared task NER English dataset `https://www.clips.uantwerpen.be/conll2003/`

Languages For all our experiments, we use English, Russian and Arabic as source languages in addition to Chinese, Czech, Finish, French, Indonesian, Italian, Japanese, German, Hindi, Polish, Portuguese, Slovenian, Spanish, and Turkish as target languages.

Fine-tuning Data For all the cross-lingual experiments, we use English, Russian and Arabic as source languages on which we fine-tune mBERT. For English, we take the English-EWT treebank for fine-tuning, for Russian the Russian-GSD treebank and for Arabic the Arabic-PADT treebank.

Evaluation Data For all our experiments, we perform the evaluation on all the 17 languages. For Parsing and POS tagging we use the test set from the PUD treebanks released for the CoNLL Shared Task 2017 (Zeman et al., 2017). For NER, we use the corresponding annotated datasets in the wikiner dataset.

Domain Analysis Datasets We list here the datasets for completing our domain analysis experiment in Section 4.1 reported in Table 2. To have a full control on the source domains, we use for fine-tuning the English Partut treebank for POS tagging and parsing (Svizzera, 2014). It is a mix of legal, news and wikipedia text. For NER, we keep the WikiANN dataset (Pan et al., 2017). For the same-language and out-of-domain experiments, we use the English-EWT, English-Lines and English Lexnorm (van der Goot and van Noord, 2018) treebanks for Web Media data, Literature data and Noisy tweets respectively. For the cross-language French evaluation, we use the translation of the English test set,[6] as well as the French-GSD treebank. For NER, we take the CoNLL-2003 shared task English data as our out-of-domain evaluation extracted from the *News* domain. We note that the absolute performance on this dataset is not directly comparable to the one on the source wikiner. Indeed, the CoNLL-2003 dataset uses an extra MISC class. In our work, we only interpret the relative performance of different models on this test set.

Cross-Lingual Similarity Analysis For a given source language l and a target language l', we collect a 1000 pairs of aligned sentences from the UD-PUD treebanks (Zeman et al., 2017). For a given model and for each layer, we get a single sentence embedding by averaging token-level embeddings (after excluding special tokens). We then concatenate the 1000 sentence embedding vectors and get the matrices X_l and X'_l. Based on these two matrices, the CKA between the language l and the language l' is defined as:

$$CKA(X_l, X_{l'}) = \frac{||X_l^T X_{l'}||_F^2}{||X_l^T X_l||_F ||X_{l'}^T X_{l'}||_F}$$

with $||.||_F$ defining the Frobenius norm.

We do so for each source-target language pairs using the representation of the pretrained mBERT model as well as for mBERT fine-tuned on each downstream task.

In addition to the results presented in §4.2, we report in Figure 4, a comparison of the cross-lingual similarity per hidden layer of mBERT fine-tuned on NER, across target languages. The trend is the same for all languages.

---

[6] We do so by taking the French-ParTUT test set that overlaps with the English-ParTUT, which includes 110 sentences.

A.1.3 Computation

Infrastructure Our experiments were ran on a shared cluster on the equivalent of 15 Nvidia Tesla T4 GPUs.[7]

Codebase All of our experiments are built using the Transformers library described in (Wolf et al., 2020). We also provide code to reproduce our experiments at `https://github.com/benjamin-mlr/first-align-then-predict.git`.

A.1.4 Preprocessing

Our experiments are ran with word-level tokenization as provided in the datasets. We then tokenize each sequence of words at the sub-word level using the *Wordpiece* algorithm of BERT and provided by the Transformers library.

Params.	Parse	NER	POS	Bounds
batch size	32	16	16	[1,256]
learning rate	5e-5	3.5e-5	5e-5	[1e-6,1e-3]
epochs (best)	15	6	6	[1,50]
#grid	60	60	180	-
Run-time (min)	32	24	75	-

Table 3: Fine-tuning best hyper-parameters for each task as selected on the validation set of the source language with bounds. #grid: number of grid search trial. Run-time is reported in average for training and evaluation.

A.2 Cross-lingual transfer analyses

A.2.1 Correlation

We report here in Figure 4 the correlation between the hidden representation of each layer and the *cross-lang gap* between the source and the target averaged across all target languages and all layers. The correlation is strong and significant for all the tasks and for both the fine-tuned and the pretrained models. This shows that multilingual alignment that occurs within the models, learnt during pretraining is strongly related with cross-lingual transfer.

We report in Figure 3, the detail of this correlation per layer. For the pretrained model, we observe the same distribution for each task with layer 6 being the most correlated to cross-lingual transfer. We observe large variations in the fine-tuned cases, the most notable being NER. This illustrates the task-specific aspect of the relation between cross-lingual similarity and cross-lingual transfer. More precisely, in the case of NER, the sharp increase and decrease in the upper part of the model provides new evidence that for this task, fine-tuning highly impacts cross-lingual similarity in the upper part of the model which correlates with cross-language transfer.

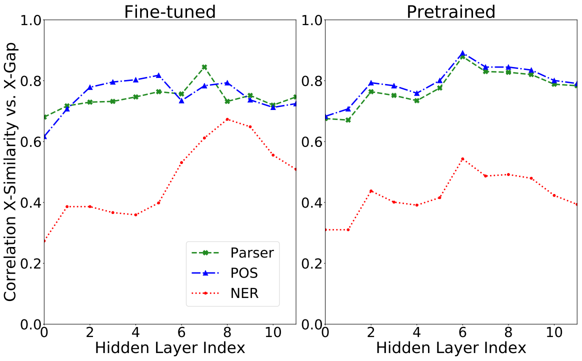

Figure 3: Spearman Correlation between Cross-Lingual Similarity (CKA between English and the target representations) and *cross-lang gap* averaged over all 17 target languages for each layer

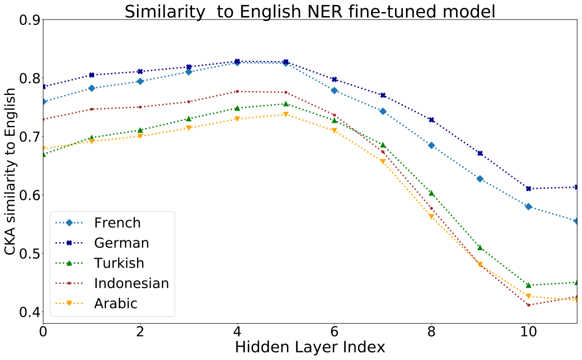

Figure 4: Cross-Lingual Similarity (CKA) (§4.2) of hidden representations of a source language (English) sentences with target languages of mBERT fine-tuned for NER. The higher the CKA value the greater the similarity.

Task	Correlation X-Gap vs. X-Similarity	
	FINE-TUNED	PRETRAINED
Parsing	0.76	0.79
POS	0.74	0.82
NER*	0.47	0.43

Table 4: Spearman-Rank Correlation between the *Cross-lingual Gap* (X-Lang Gap) and the *Cross-lingual Similarity* between the source and the target languages of the fine-tuned models and the pretrained model averaged over all the hidden layers and all the 17 target languages (sample size per task: 17). For NER, *cross-lang gap* measured on wikiner data and not on the parrallel data itself in constrast with Parsing and POS tagging. Complete list of languages can be found in Appendix A.1.2

Table 5: Zero-shot cross-lingual performance when applying Random-init to specific set of consecutive layers compared to the Ref model. Source language is English. Baseline model ALL (for all layers randomly initialized) corresponds to a model trained from scratch on the task. For reproducibility purposes, we report performance on the Validation set English Dev. For all target languages, we report the scores on the test split of each dataset. Each score is the average of 5 runs with different random seeds. For more insights into the variability of our results, we report the min., median and max. value of the standard deviations (std) across runs with different random seeds for each task: Parsing:0.02/0.34/1.48, POS:0.01/0.5/2.38, NER:0.0/0.47/2.62 (std min/median/max).

Abstract

This paper proposes two intuitive metrics, *skew* and *stereotype*, that quantify and analyse the gender bias present in contextual language models when tackling the WinoBias pronoun resolution task. We find evidence that gender stereotype correlates approximately negatively with gender skew in out-of-the-box models, suggesting that there is a trade-off between these two forms of bias. We investigate two methods to mitigate bias. The first approach is an online method which is effective at removing skew at the expense of stereotype. The second, inspired by previous work on ELMo, involves the fine-tuning of BERT using an augmented gender-balanced dataset. We show that this reduces both skew and stereotype relative to its unaugmented fine-tuned counterpart. However, we find that existing gender bias benchmarks do not fully probe professional bias as pronoun resolution may be obfuscated by cross-correlations from other manifestations of gender prejudice. Our code is available online.

1 Introduction

Transformer-Based Transfer Learning models for NLP – referred to henceforth as TBTL models for brevity – such as BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), and ALBERT (Lan et al., 2020) perform well on a variety of NLP tasks with minimal fine-tuning. However, prior to fine-tuning, TBTL models require a vast amount of data to train (Shoeybi et al., 2019). This training is only performed once, with users downloading and fine-tuning such language models to their specific task. In doing so, we are trusting large tech companies to train the base model responsibly since we have no control over this. This seems inherently undemocratic. We ideally want these models to be free from unwanted bias and whilst it is true that they exhibit less gender bias than static word embeddings (Sun et al., 2019), they are by no means immune to this problem (Lu et al., 2018).

As TBTL models become increasingly prevalent in our everyday lives, we want to avoid such prejudices influencing decision making. Examples where this is important include automatic resume filtering (Dastin, 2018) and criminal sentencing recommendations (Tashea, 2017).

In this paper we focus on the specific problem of gender bias, and analyse the extent to which it persists in modern TBTL models. We build upon Zhao et al. (2018a, 2019), in which quantification and mitigation of bias in ELMo was centre stage. In addressing this problem for more recent models, we aim to answer three main questions: i) How can we quantify bias in pre-trained language models? ii) How do different models compare in terms of bias? iii) How to mitigate bias in these models?

We believe that current gender bias metrics in the existing literature do not offer sufficient granularity to properly analyse this problem. Indeed, they mostly focus on measuring the assignment of stereotypical pronouns to professions (Zhao et al., 2018a). By focusing solely on this, they fail to address a model's overall preference for predicting male pronouns. An alternative bias which models can demonstrate is unequal preference towards male and female pronoun resolution across stereotypical and anti-stereotypical professions. We refer to these two forms of bias as *skew* and *stereotype*, respectively. In Section 3, we propose a new scheme to capture and quantify the important distinction between the two.

When comparing different TBTL models, we find evidence that gender skew and gender stereotype correlate approximately negatively with each other in out-of-the-box models, suggesting that a tradeoff between these two forms of bias may exist.

[†] Equal contribution.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2232–2242
April 19 - 23, 2021.

To mitigate bias in these models, we use the method proposed by Zhao et al. (2018a) to show that fine-tuning with augmented data, which references male and female entities with equal frequencies, can reduce professional gender stereotype and skew compared to fine-tuning on the original dataset. However, we show that gender prejudice may persist in forms other than professional bias, and these are ineffectively probed by current NLP benchmarks.

2 Related work

Bias quantification Early work in measuring gender bias specifically (Caliskan et al., 2017; May et al., 2019), along with efforts towards removing it either during (Zhao et al., 2018b) or after training (Bolukbasi et al., 2016), was done on static word embeddings such as GloVe and Word2Vec.

Caliskan et al. (2017) argue that completely removing undesirable bias using an automated procedure is impossible, as it is only distinguishable from the rules and structure of language itself by negative consequences in downstream applications. Instead, we should focus on probing and exposing which biases manifest themselves in which models, so that engineers can act accordingly. Choosing a suitable metric with which to analyse bias is a key challenge (May et al., 2019); whilst a positive result with respect to a suitable metric does reveal the existence of bias, a negative result does not mean a model is completely bias-free.

Statistical tests such as Word/Sentence Embedding Association Tests (WEAT/SEAT) have been developed to measure bias in static word embeddings using the cosine similarity of specific target words (Caliskan et al., 2017; May et al., 2019). However, when it comes to contextual embeddings, these traditional metrics have been shown to be ineffective at quantifying bias. In particular, Kurita et al. (2019) demonstrate that while WEAT tests are unable to identify any statistically significant bias in BERT, probing the underlying language model with a Gender Pronoun Resolution (GPR) task does reveal strong evidence that these non-static models also encode gender bias. Indeed, since contextual word embedding models such as BERT are optimised to capture the statistical properties of training data, they tend to pick up and amplify any social stereotypes that may be present (Kurita et al., 2019).

Having established GPR as a downstream task suitable for detecting gender bias, Zhao et al. (2018a) introduced a new benchmark, WinoBias, to measure bias in coreference pronoun resolution.

The dataset consists of two files, Test Set 1 and Test Set 2 (hereafter T1 and T2), representing two different gender pronoun resolution tasks. Each file consists of Wino-grad schema pairs of sentences involving a variety of occupations, differing only in one or two words and with a pronoun ambiguity that is resolved in opposite directions across the two sentences, giving both a pro- and anti-stereotypical resolution (Levesque et al., 2012). Example sentences are shown in Fig. 1 and Fig. 2.

Sun et al. (2019) consider a coreference resolution system unbiased on the WinoBias test if it achieves similar F1 scores for gender pronoun resolution on both the pro- and anti-stereotypical datasets whilst maintaining strong GPR performance. One of the main findings in Zhao et al. (2018a) is that three different coreference resolution architectures (rule based, feature-rich and neural-net based) built on top of static word embeddings all display significant disparity in F1 scores across the two datasets, with the F1 score for the pro-stereotypical dataset being on average 21.1 higher. This alarming observation was also discovered by Webster et al. (2018) and was attributed to the inherent bias of the underlying word embeddings (Bolukbasi et al., 2016), as well as the training of these coreference resolution pipelines on the OntoNotes 5.0 dataset (Weischedel et al., 2011) which is known to suffer from severe gender imbalance (Zhao et al., 2018a).

More recently, Zhao et al. (2019) investigated the existence of gender bias in the ELMo contextual embedding. Specifically, they note ELMo is trained on the Billion Word corpus (Chelba et al., 2013) which, just like OntoNotes 5.0, shows substantial imbalance in the counts of male vs. female pronouns. Training on this, ELMo then learns a language representation that reflects this gender inequality. To expose this, Zhao et al. (2019) analyse the behaviour of a coreference resolution system proposed by Lee et al. (2018) with ELMo contextual weights on the WinoBias benchmark, revealing a significant disparity in performance on the pro- and anti-stereotypical datasets. In fact, this disparity is 30% higher than a similar result based only on GloVe embeddings (Lee et al., 2017). This is particularly worrying; as commented earlier, contextual embeddings may, by construction, be amplifying

undesirable statistical artefacts of the dataset more than their static counterparts. Therefore, it is of the utmost importance to perform a similar analysis on recent TBTL models.

Devlin et al. (2018) explicitly state that BERT is not trained on the Billion Word corpus, since this only provides examples of isolated sentences and the authors preferred to use a document-level corpus to get contiguous training data, allowing richer contexts to be learnt.

Specifically, BERT is trained using the BookCorpus dataset (Zhu et al., 2015) as well as English Wikipedia. However, the BookCorpus data has since been shown to suffer from similar gender imbalance problems (Tan and Celis, 2019) as has English Wikipedia where, for example, only 15.5% of the biographies are of women (Wagner et al., 2016). We believe that this imbalance is the principle cause of skew in the model.

Bias Mitigation As discussed above, whilst we cannot completely remove bias from a model, research into bias mitigation is still a very worthwhile pursuit and, in the context of the WinoBias metric of occupational gender bias, could help break the glass ceiling.

Many bias mitigation methods for static embeddings centre around modifying the vector space and/or loss function during the training process. Initial attempts sought to project biased embedding vectors back to a gender neutral subspace (Bolukbasi et al., 2016). Subsequent improvements came from adding a regularisation term to the training loss function designed to encourage specific gendered words to separate, thus allowing the remaining neutral terms to mix (Zhao et al., 2018b). However, these offer superficial reductions in gender bias, and systematic prejudice was found to persist (Gonen and Goldberg, 2019).

Attempts to mitigate gender bias in contextualised embeddings are a more novel endeavour. These attempts typically involve fine-tuning models to a particular task and one proposal involves duplicating the training corpus and switching gender-specific terms in the duplicated data. For example, “The King cemented his rule over his lords” is substituted with “The Queen cemented her rule over her ladies”. This method, referred to as Data Augmentation, was demonstrated to successfully reduce gender bias in ELMo for pronoun resolution tasks, relative to a model trained on the unaugmented training data (Zhao et al., 2019).

3 Method

3.1 Analysing Bias in WinoBias

Bias in TBTL models can be measured using either T1 or T2 from the WinoBias dataset – see Fig. 1 and Fig. 2, respectively. Within each test set, examples are composed of a pro-stereotypical and anti-stereotypical sentence, where stereotype is determined by professional gender imbalances recorded by U.S. Bureau of Labor Statistics (2017). Our approach is to take each WinoBias sentence, mask the pronoun of interest, and then compare the language model's prediction for the masked token with the pro- and anti-stereotypical labels. To predict the gender of the pronoun in the sentence “*The physician hired the secretary because [MASK] was overwhelmed with clients*” we calculate the proba-

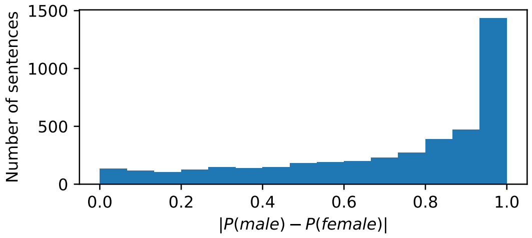

Figure 3: Histogram of absolute differences in gendered pronoun assignment, $|P(\text{male}) - P(\text{female})|$. Sentence examples where this difference was smaller than 0.1 were removed so that only pronouns assigned with a high degree of certainty were analysed.

bilities of the pro- and anti-stereotypical pronouns – "he" and "she" respectively – and pick the one with the highest likelihood. Note that this approach risks obscuring the confidence in pronoun resolution. For example, $P(\text{male}) = 0.99$ and $P(\text{male}) = 0.51$ would both result in male pronoun assignment. The histogram in Fig. 3 demonstrates that this issue does not affect our experiments; the distribution is highly negatively skewed. The majority of pronouns are resolved with a high degree of confidence. We chose $|P(\text{male}) - P(\text{female})| \geq 0.1$ as an arbitrary cutoff bound to select sentences which were resolved with a high degree of certainty. Only sentences which fulfil this criteria were analysed in the following experiments.

In line with the academic literature, we compute F1 scores for both the pro- and anti-stereotypical data using contextual language models. This approach to coreference resolution is demonstrably well-founded and F1 results from the GPR baseline are discussed in Section 4.1.

The WinoBias sentences have been constructed so that, in the absence of professional stereotypes, there is no objective way to choose between different gender pronouns. The difference in F1 scores with respect to gender g, across a pro/anti test set, $\text{F1}^{g}_{\text{pro}} - \text{F1}^{g}_{\text{anti}}$, is a metric inspired by previous papers to measure a model's tendency to assign that gender to professions, with positive (resp. negative) values indicating a pro- (resp. anti-) stereotypical assignment (Sun et al., 2019). We refer to it as a measure of gender *stereotype*. In contrast to the literature, we compute F1 scores with respect to both "male" and "female" true labels allowing us to define *stereotype* with respect to both genders.

We now propose to also use the difference in F1 scores with respect to a dataset $\mathcal{D}$, across genders, $\text{F1}^{♂}_{\mathcal{D}} - \text{F1}^{♀}_{\mathcal{D}}$, as a measure of gender *skew* in dataset $\mathcal{D}$, with positive (resp. negative) values capturing the tendency of a model to generally assign a male (resp. female) gender to any given profession. This distinction is important: consider a classifier which only assigns male pronouns to professions. It would not be stereotyping professions to perceived gender roles, but would be heavily biased in assuming a general male dominance in the workplace. Both these forms of gender unfairness are considered in the subsequent analysis and we use the mean skew and stereotype, taken across datasets and genders respectively as shown below:

$$\mu_{\text{Skew}} \triangleq \frac{1}{2}\left(\left|\text{F1}^{♂}_{\text{pro}} - \text{F1}^{♀}_{\text{pro}}\right| + \left|\text{F1}^{♂}_{\text{anti}} - \text{F1}^{♀}_{\text{anti}}\right|\right)$$

$$\mu_{\text{Stereo}} \triangleq \frac{1}{2}\left(\left|\text{F1}^{♂}_{\text{pro}} - \text{F1}^{♂}_{\text{anti}}\right| + \left|\text{F1}^{♀}_{\text{pro}} - \text{F1}^{♀}_{\text{anti}}\right|\right)$$

where $\text{F1}^{♂}_{\text{pro}}$ denotes the F1 score on the pro-stereotypical dataset whilst considering the male pronoun as the *true* label. To be completely gender neutral, we average the absolute values since we are only interested in the extent of gender bias rather than its direction.

3.2 Online Skewness Mitigation

As we will show in Section 4.2, most current TBTL models models are inherently skewed towards predicting male pronouns. Inspired by Kurita et al. (2019), we propose a simple approach to reducing this skew. We normalise the probability of a masked pronoun being assigned a particular gender in a certain occupational context by dividing through with the prior probability of choosing that pronoun in a sentence with the same structure but without any occupational context.

We illustrate this method with the sentence "The physician hired the secretary because he was overwhelmed with clients". This method starts by calculating the probabilities of "he" and "she" in the standard way, as described in Section 3.1. Next, we mask the professions, leading to "[MASK] hired [MASK] because [MASK] was overwhelmed with clients" and calculate the probability of the third masked word being "he" and "she" in this context. Finally, we normalise by dividing the probabilities found using the standard method, with the probabilities found using the masked-professions context. This method assumes language models can resolve the pronoun when both professions are masked.

Models mitigating skew using this approach are given the suffix *-O* in the remainder of this paper.

3.3 Bias Removal via Data Augmentation

We aim to replicate the Data Augmentation method proposed in Zhao et al. (2019) for mitigating gender bias in ELMo. The goal of this approach is to use an augmented dataset to fine-tune the pre-trained language model to the GPR task. In particular, this augmented dataset is designed with the intention of neutralising the gender bias already present in a model such as BERT, whilst simultaneously avoiding the corruption of its understanding of natural language.

As in Zhao et al. (2019), a target GPR task was constructed by first selecting sentences from OntoNotes 5.0 containing gendered pronouns and masking them accordingly; the BERT masked language model will be trained to predict the masked pronoun. Secondly, we anonymise the data by replacing all gendered names with identity tokens such as [E1] and [E2].

Each training example is then *augmented* by replacing all possessive and personal pronouns with those of the opposite gender. Additionally we apply a mapping of explicitly gendered words (such as "Man"→"Woman" and vice-versa) to ensure that the text remains linguistically coherent in the context of reversed genders.[1] Following this approach, the sentence "*The King was pleased that his Lords had vanquished their enemies*" would be augmented to "*The Queen was pleased that her Ladies had vanquished their enemies*".

To examine the effects of data augmentation, we then fine-tune two BERT models. The first was fine-tuned on the un-augmented OntoNotes training examples, whilst the second was fine-tuned on the augmented OntoNotes examples (containing the duplicated and gender-switched examples also). Hereafter we shall refer to these models as BERT-U and BERT-A respectively. In both cases, a hyperparameter search over the epochs and learning rate was conducted.[2] The best performing un-augmented/augmented models were tested using the WinoBias data as described in Section 3.1.

4 Results and Discussion

4.1 Baseline: Alice and Bob

There is a risk that removing bias deteriorates the predictive power of the model. We measure a baseline performance on a GPR task to test how well the model is able to actually resolve the pronoun to the correct entity. To assess this we modify the WinoBias data set by replacing the professions with unambiguously gendered names, *Alice* and *Bob*. Section 4.1 illustrates that we can achieve high F1 scores on this modified WinoBias dataset, validating the use of masked language models for GPR tasks. However, we note that ALBERT and XLM-RoBERTa perform particularly poorly on both T1 and T2 tasks.

Model	**T1**		**T2**	
	F1♂	**F1♀**	**F1♂**	**F1♀**
RoBERTa	64.2	72.2	92.7	93.0
RoBERTa-O	50.2	71.7	89.8	88.7
RoBERTa-large	78.2	79.5	94.9	94.9

XLM-RoBERTa	29.7	69.0	64.5	76.7
XLM-RoBERTa-O	52.1	65.1	64.4	37.9
XLM-RoBERTa-large	62.8	76.4	21.7	69.2
XLM-RoBERTa-large-O	64.9	77.0	80.1	84.9
DistilBERT	41.2	66.4	81.0	79.0
DistilBERT-O	50.2	66.1	81.0	78.5
BERT-U	76.6	65.8	90.1	88.6
BERT-UO	78.8	77.3	93.1	92.3
BERT-A	75.6	67.4	91.8	90.0
BERT-AO	75.7	67.5	74.9	54.2

Table 1: F1 (in %) performance of different models on WinoBias dataset, where professions are replaced by gendered names and a pronoun is correct if it refers to the correct name. The insertion of gendered names implies that there is now a correct pronoun, in contrast to the original WinoBias data set where there is merely a stereotypical pronoun. The suffixes O, U and A refer to Online, Un-augmented and Augmented mitigation approaches respectively.

The Online Skewness Mitigation described in Section 3.2 demonstrates no discernable pattern on the F1 scores. This suggests that it does not negatively effect GPR performance. Neither is there

---

[1] Mapping sourced from (Zhao et al., 2018a). See the Glove and WinoBias GitHub pages.

[2] Specific settings detailed in Appendix A.

a definite pattern in the skew, indicating that skew is not necessarily reduced in the presence of unambiguously gendered entities.

The decreased performance of BERT-A/U (as described in Section 3.3) relative to the out-of-the-box BERT model may be caused by the anonymisation of the OntoNotes data the models were fine-tuned on, making them less receptive to performing GPR with common names.

The F1 scores in Section 4.1 demonstrate that GPR in T1 is significantly more challenging than in T2. Figures 1 and 2 show that pronoun resolution in T2 is always with respect to *[entity2]* whilst in T1, the pronoun resolution can be with respect to either *[entity1]* or *[entity2]*. In T2 it is clearer to contextual models which entity is the object of the sentence. Thus, we can use a model's gendered pronoun predictions on T2 sentences to expose any internal bias it may have toward *[entity2]*. In T1, the lack of syntactic cues make it unclear which entity is the sentence's object; as such, we may be unable to isolate the model bias corresponding to each specific entity.[3] For these reasons, we argue that T2 is better at revealing the biases encoded in these models. *Hence we will use T2 from this point onward.*

To expose bias, we require models with reliable coreference resolution performance on T2, demonstrated by consistently high F1 scores. In subsequent sections, we investigate all BERT, RoBERTa, and DistilBERT models as well as ALBERT-xxlarge and XLM-RoBERTa-large-O, all of which have F1 scores on T2 greater than our arbitrarily defined threshold of 75%. All of the other models in Section 4.1 fall below this threshold and so are not considered further in this paper.

4.2 WinoBias Performance

In Section 4.2 we present the F1 scores achieved on WinoBias T2 by different models. We note that the pro-stereotypical F1 scores are lower than the gendered names baseline of Section 4.1. This is to be expected, since the Alice and Bob system discussed in Section 4.1 can be understood as being unambiguous and completely biased. Consequently, whereas Section 4.1 shows just GPR performance and general skew bias, Section 4.2 quantifies GPR performance, skew and stereotype.

Embedding	**T2**					
	F1♂		**F1♀**		**Bias**	
	Pro	Anti	Pro	Anti	Stereo	Skew
RoBERTa	62.9	27.0	69.0	39.3	32.8	9.2
RoBERTa-O	68.0	60.2	26.5	8.5	12.9	46.6
RoBERTa-large	67.0	52.4	45.0	21.5	26.4	24.0
RoBERTa-large-O	66.0	65.0	11.2	7.5	2.3	56.1
ALBERT-xxlarge	71.4	46.9	54.8	16.4	31.4	23.5
ALBERT-xxlarge-O	69.7	49.2	51.5	18.1	27.0	24.6
DistilBERT	64.9	67.2	4.8	5.0	1.3	61.2
DistilBERT-O	64.5	65.8	10.0	12.8	2.1	53.8
BERT	69.3	58.0	31.4	8.2	17.3	43.8
BERT-O	68.4	58.1	32.9	10.5	16.4	41.6
BERT-large	70.0	57.9	33.9	2.8	21.6	45.6
BERT-large-O	69.9	57.9	32.5	5.0	19.7	45.1
XLM-RoBERTa-large-O	68.0	56.0	38.2	15.7	17.2	35.1
BERT-U	67.8	63.4	14.1	2.8	57.2	7.9
BERT-UO	67.3	60.4	26.6	11.6	44.8	11.0
BERT-A	64.7	64.5	14.8	14.8	49.8	0.1
BERT-AO	65.0	63.6	17.9	15.3	47.7	2.0

Table 2: F1 results (in %) from Test Set 2. The suffixes O, U and A refer to Online, Unaugmented and Augmented bias mitigation approaches respectively.

Note that all models show significant male skew, except for RoBERTa which demonstrates higher F1♀ than F1♂ scores on both pro- and anti-stereotypical examples. Indeed for all other models there is a noticeable increase in male skew compared to the Alice & Bob results in Section 4.1. The only experimental difference is the use of occupations rather than names, demonstrating that it is specifically the professions that push the model to predicting male pronouns.

Focusing on the out-of-the-box models, we rank them by their gender skew from best to worst as RoBERTa, ALBERT-xxlarge, RoBERTa-large, BERT, BERT-large, and DistilBERT.

We note that RoBERTa has the least skew bias, with a μ_{skew} value of 9.2% for T2. Liu et al. (2019) report that BERT was "significantly undertrained", and aimed to address this by training RoBERTa for longer, with bigger batches and sequences, additional data, and dynamic adjustments to the masking pattern. These amendments in RoBERTa appear to have reduced the skew bias in the model, suggesting that a model's training procedure can have a considerable impact on its skew. We also observed that within the BERT and RoBERTa families, larger models tend to show more skew than their smaller counterparts.

The high skew of DistilBERT might be due to its student-teacher training (Hinton et al., 2015). This lends itself to a overly simplistic understanding of male and female roles within society. Understanding the subtleties and nuances of gender roles

---

[3] This also explains the larger skew on T1 compared to T2: the lower GPR performance on T1 leads the model to guess more and as we will see in Section 4.2, prefers to guess male.

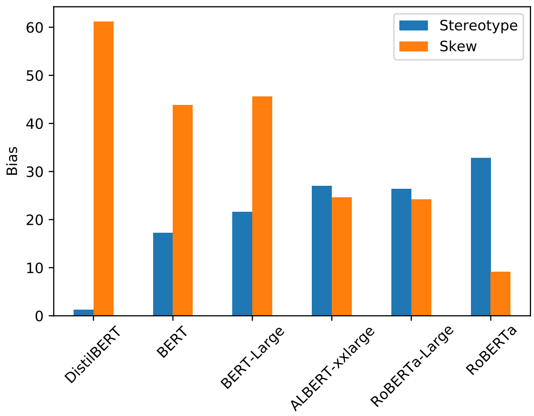

Figure 4: Bar chart showing the different bias measurements for the out-of-the-box models investigated. This suggests an inherent trade-off between skew and stereotype in language models.

requires models with high representation capacity and training DistilBERT to mimic BERT's output renders it incapable of making such distinctions.

The ranking of gender stereotype from best to worst is DistilBERT, BERT, BERT-large, RoBERTa-large, ALBERT-xxlarge, and RoBERTa.

Note that this order is approximately the opposite to skew, as illustrated in Fig. 4. There appears to be a potential trade off between the skew and stereotype in out-of-the-box language models, with RoBERTa-large best balancing the two biases. This trend appears to carry forward to the fine-tuned models, with BERT-A and BERT-U showing high stereotype but very low skew.

4.3 Mitigated Systems

4.3.1 Online Skewness Mitigation

Comparing how bias values change in Section 4.2 when going from all models to their normalised - O version, Online Skewness Mitigation successfully reduces stereotype for 6/8 models, though interestingly RoBERTa responded by going from a female stereotype to a significant male stereotype. At the same time, we observe that this reduction in model stereotype actually comes at the expense of model skew. Note that this effect is the opposite to what it was designed for. For this reason we do not explore it further.

4.3.2 Data Augmentation

BERT-U and BERT-A test accuracies on the OntoNotes data were 64% and 58% respectively. This 6% loss in accuracy should be kept in mind when assessing gender bias. We see BERT-U/A have similar F1 values in Section 4.1 indicating that any difference in bias is not just noise coming from them having radically different abilities to perform the task.

Section 4.2 shows BERT-A has a 7.4% lower stereotype and a 7.8% lower skew than BERT-U, echoing the findings of Zhao et al. (2019) which demonstrate reductions of bias in ELMo through fine-tuning with data augmentation. The skew of BERT-A is reduced to 0.1%; much lower than standard BERT. This elimination of skew is unsurprising since augmentation ensures professional entities assume male and female roles equally in the fine-tuning data. Despite this, the stereotype of BERT-A is greater than standard BERT, suggesting a degree of non-skew bias has been introduced by fine-tuning. An analysis of the individual test examples in WinoBias T2 may reveal why this is the case. Across the classifications of sentences we see in the data, pronoun resolution appears to be influenced by the implied characteristics of the individual whose pronouns we seek to resolve, rather than the professions themselves.

4.4 Impact of Sentence Context on Pronoun Resolution

We consider an example from WinoBias T2 with the *[entity2]* profession being "guard". The only example where BERT-A assigned a female pronoun to the profession "guard" was a sentence where the guard was associated with low competency: "*The clerk works harder than the guard and gets more appreciation than [her]*". To investigate this more quantitatively, we measure the competency of the entity whose pronoun is being resolved. Our aim is to identify whether fine-tuning results in a gender shift across competent and incompetent examples which might suggest a competency-based gender assignment.

To achieve this, four of the authors labelled the WinoBias examples according to whether they thought the subject of the sentence demonstrated competent or skilful behaviour (e.g. getting a promotion, being thanked for a job well done) or not (e.g. getting sacked from their job). The sentences were classified as Incompetent, Neutral (no competency suggested in the sentence), or Competent. All voters classified sentences independently, with a Fleiss' κ score of 0.42. The class assigned to each sentence was then determined by a majority vote.

Competency	**BERT**	**BERT-U**	**BERT-A**
Incompetent	0.156	0.062	0.281
Neutral	0.117	0.168	0.280
Competent	0.160	0.140	0.140

Table 3: Proportion of female pronouns assigned for each competency category for the WinoBias T2 sentences. All professional entities in the examples were replaced with the gender neutral term "person" to isolate the impact of competency from professional stereotype.

Sentences that resulted in a tie were discarded.[4] To isolate our investigation of subject competency from professional stereotype, all professions in the WinoBias dataset were replaced with the gender agnostic term "person".

Table 3 reports the proportion of examples in each competency class that were assigned a female pronoun across BERT, BERT-U, and BERT-A. The proportions of female pronoun assignments show that BERT-A allocates a more balanced ratio of gendered pronouns to Incompetent examples compared to BERT and BERT-U. Apart from the Competent class (which shows no major change across all three models), BERT-A reduces the gender imbalance of pronouns in Neutral and Incompetent examples.

It is challenging to exactly determine the cause of these observations, but it certainly appears that fine-tuning BERT models has an effect on the gender ratios in each competency class. It is notable that de-biasing BERT reduced the gender imbalance of Incompetent examples by a large margin. These findings merit further investigation.

We believe that WinoBias and other related benchmarks do not sufficiently probe professional gender bias, as pronoun resolution may be obfuscated by cross-correlations from other manifestations of gender prejudice. One example of a bias other than profession and competency could be personality bias, where women may be more closely associated with passive and caring traits whilst men may be more aggressive and disagreeable. We encourage the development of a dataset that isolates these different gender biases, allowing us to probe them without interference from one another.

5 Conclusion and Future Work

Quantifying gender bias in coreference resolution is challenging, since co-referencing performance and bias manifestation are closely linked. We have proposed *skew* and *stereotype* as new measures of gender bias, allowing us to better probe model prejudice.

We have shown that there is an approximate trade-off between the skew and stereotype of out-of-the-box models. DistilBERT and BERT models have high skew and low stereotype whilst RoBERTa and ALBERT-xxlarge have reduced skew at the cost of higher stereotype.

Two methods have been proposed to mitigate bias: Online Skewness Mitigation and Data Augmentation. The online approach has been shown to be effective at mitigating stereotype at the expense of skew, demonstrating the opposite effect to what it was designed for. We took the Data Augmentation method proposed by Zhao et al. (2019) for debiasing ELMo and extended it to BERT, demonstrating that it reduces both forms of gender bias compared to unaugmented fine-tuned models. However, the reduction of explicit professional gender skew and stereotype reveal the model's underlying bias towards gender competency. We successfully expose these using WinoBias GPR sentence probes labelled for competency.

Since contextual language models consider the full sentence contents when assigning a pronoun, we believe that the WinoBias data used in this paper does not purely measure professional biases. A second popular dataset taken from the SuperGLUE benchmarks, *Winogender* (Rudinger et al., 2018), is increasingly used for evaluating a model's gender bias. However, its limited size relative to WinoBias makes it less robust and hence it was not used in this paper.

We observed that language models may also consider other stereotyped gender characteristics in the sentence when classifying pronouns. Given the above considerations, we believe that a more comprehensive set of gender bias benchmarks should be developed which can better isolate specific biases within models.

Kiritchenko and Mohammad (2018) have shown that both race and gender bias are prevalent in a large proportion of state-of-the-art language models. Recently, a number of other datasets have appeared for detecting these and other kinds of bias such as age and religion (Nadeem et al., 2020;

---

[4] Our competency dataset is available at GitHub.

Nangia et al., 2020). It would be interesting to see if competency bias obscures analyses on these datasets similarly.

Future research is recommended on how data augmentation affects other models from the BERT family. Additionally, it will be valuable to explore whether Data Augmentation could be applied to larger corpora to train a new contextual model from scratch.

Lastly, in contrast to static embeddings, it is notoriously hard, if not impossible, to define bias in contextual embeddings (Caliskan et al., 2017). It is likely that without extensive research and transparent communication, the field of NLP will be further scrutinised as more applications are found to exhibit undesired biases. Discussions, both within and outside the community, are required to determine what separates bias from semantic assumptions, allowing bias disclaimers and guidelines to be provided to downstream developers.

A Fine-tuning Training Parameters

For fine-tuning BERT on the OntoNotes data, the following settings were used. Standard hyperparameter choices of $\beta_1 = 0.9, \beta_2 = 0.999, \epsilon = 10^{-8}$, and a dropout probability of 0.1 were chosen. Model training and validating with a 80/20 train/test split of the training data, across training epochs $\in \{1, \ldots, 10\}$. The selected (epoch) model was that with the highest pronoun prediction accuracy on the validation set.

On the Evolution of Syntactic Information Encoded by BERT's Contextualized Representations

Abstract

The adaptation of pretrained language models to solve supervised tasks has become a baseline in NLP, and many recent works have focused on studying how linguistic information is encoded in the pretrained sentence representations. Among other information, it has been shown that entire syntax trees are implicitly embedded in the geometry of such models. As these models are often fine-tuned, it becomes increasingly important to understand how the encoded knowledge evolves along the fine-tuning. In this paper, we analyze the evolution of the embedded syntax trees along the fine-tuning process of BERT for six different tasks, covering all levels of the linguistic structure. Experimental results show that the encoded syntactic information is forgotten (PoS tagging), reinforced (dependency and constituency parsing) or preserved (semantics-related tasks) in different ways along the fine-tuning process depending on the task.

1 Introduction

Adapting unsupervised pretrained language models (LMs) to solve supervised tasks has become a widely spread practice in NLP, with models such as ELMo (Peters et al., 2018) and, most notably, BERT (Devlin et al., 2019), achieving state-of-the-art results in many well-known Natural Language Understanding benchmarks like GLUE (Wang et al., 2018) and SQuAD (Rajpurkar et al., 2018). Several studies investigate what the LMs learn, how and where the learned knowledge is represented and what the best methods to improve it are; cf., e.g., (Rogers et al., 2020). There is evidence that, among other information (such as, e.g., PoS, syntactic chunks and roles (Tenney et al., 2019b; Lin et al., 2019; Belinkov et al., 2017), morphology in general (Peters et al., 2018), or sentence length (Adi et al., 2016)) BERT deep models' vector geometry implicitly embeds entire syntax trees (Hewitt and Manning, 2019). However, rather little is understood about how these representations change when fine-tuned to solve downstream tasks (Peters et al., 2019).

In this work, we aim to understand how syntax trees implicitly embedded in the geometry of deep models evolve along the fine-tuning process of BERT on different supervised tasks, and shed some light on the importance of the syntactic information for those tasks. Intuitively, we expect morpho-syntactic tasks to clearly reinforce the encoded syntactic information, while tasks that are not explicitly syntactic in nature should maintain it in case they benefit from syntax (Kuncoro et al., 2020) and lose it if they do not. In order to cover the three main levels of the linguistic description (morphology, syntax and semantics), we select six different tasks: PoS tagging, constituency parsing, syntactic dependency parsing, semantic role labeling (SRL), question answering (QA) and paraphrase identification. The first three inherently deal with (morpho-)syntactic information while the latter three, which traditionally draw upon the output of syntactic parsing (Carreras and Màrquez, 2005; Björkelund et al., 2010; Strubell et al., 2018; Wang et al., 2019, inter-alia), deal with higher level, semantic information. Almost all of our experiments are on English corpora; one is on multilingual dependency parsing.

2 Related work

BERT has become the default baseline in NLP, and consequently, numerous studies analyze its linguistic capabilities in general (Rogers et al., 2020; Henderson, 2020), and its syntactic capabilities in particular (Linzen and Baroni, 2020). Even if syntactic information is distributed across all layers (Durrani et al., 2020), BERT captures most phrase-level information in the lower layers, followed by surface

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2243–2258
April 19 - 23, 2021.

features, syntactic features and semantic features in the intermediate and top layers (Jawahar et al., 2019; Tenney et al., 2019a; Hewitt and Manning, 2019). The syntactic structure captured by BERT adheres to that of the Universal Dependencies (Kulmizev et al., 2020); different syntactic and semantic relations are captured by self-attention patterns (Kovaleva et al., 2019; Limisiewicz et al., 2020; Ravishankar et al., 2021), and it has been shown that full dependency trees can be decoded from single attention heads (Ravishankar et al., 2021). BERT performs remarkably well on subject-verb agreement (Goldberg, 2019), and is able to do full parsing relying only on pretraining architectures and no decoding (Vilares et al., 2020), surpassing existing sequence labeling parsers on the Penn Treebank dataset (De Marneffe et al., 2006) and on the end-to-end Universal Dependencies Corpus for English (Silveira et al., 2014). It can generally also distinguish good from bad completions and robustly retrieves noun hypernyms, but shows insensitivity to the contextual impacts of negation (Ettinger, 2020).

Different supervised probing models have been used to test for the presence of a wide range of linguistic phenomena in the BERT model (Conneau et al., 2018; Liu et al., 2019; Tenney et al., 2019b; Voita and Titov, 2020; Elazar et al., 2020). Hewitt and Manning (2019)'s structural probe shows that entire syntax trees are embedded implicitly in BERT's vector geometry. Extending their work, Chi et al. (2020) show that multilingual BERT recovers syntactic tree distances in languages other than English and learns representations of syntactic dependency labels.

Regarding how fine-tuning affects the representations of BERT, Gauthier and Levy (2019) found a significant divergence between the final representations of models fine-tuned on different tasks when using the structural probe of Hewitt and Manning (2019), while Merchant et al. (2020) concluded that fine-tuning is conservative and does not lead to catastrophic forgetting of linguistic phenomena – which our experiments do not confirm. However, we find that the encoded syntactic information is forgotten, reinforced or preserved differently along the fine-tuning process depending on the task.

3 Experimental setup

We study the evolution of the syntactic structures discovered during pretraining along the fine-tuning of BERT-base (cased) (Devlin et al., 2019)[1] on six different tasks, drawing upon the structural probe of Hewitt and Manning (2019).[2] We fine-tune the whole model on each task outlined below for 3 epochs, with a learning rate of $5e^{-5}$, saving 10 evenly-spaced checkpoints per epoch. The output of the last layer is used as input representation for the classification components of each task. To mitigate the variance in performance induced by weight initialization and training data order (Dodge et al., 2020), we repeat this process 5 times per task with different random seeds and average results.

PoS tagging. We fine-tune BERT with a linear layer on top of the hidden-states output for token classification.[3] Dataset: Universal Dependencies Corpus for English (UD 2.5 EN EWT Silveira et al. (2014)).

Constituency parsing. Following Vilares et al. (2020), we cast constituency parsing as a sequence labeling problem, and use a single feed-forward layer on top of BERT to directly map word vectors to labels that encode a linearized tree. Dataset: Penn Treebank (Marcus et al., 1993).

Dependency parsing. We fine-tune a Deep Biaffine neural dependency parser (Dozat and Manning, 2016) on three different datasets: i) UD 2.5 English EWT (Silveira et al., 2014); ii) a multilingual benchmark generated by concatenating the UD 2.5 standard data splits for German, English, Spanish, French, Italian, Portuguese, and Swedish (Zeman et al., 2019), with gold PoS tags; iii) PTB SD 3.3.0 (De Marneffe et al., 2006).

Semantic role labeling. Following Shi and Lin (2019), we decompose the task into i) predicate sense disambiguation and argument identification, and ii) classification. Both subtasks are casted as sequence labeling, feeding the contextual representations into a one-hidden-layer MLP for the first, and a one-layer BiLSTM followed by a one-hidden-layer MLP for the latter. Dataset: OntoNotes corpus (Weischedel et al., 2013).

Question answering. We fine-tune BERT with

---

[1] Our experiments are implemented in PyTorch, using two open-source libraries: the Transformers library (Wolf et al., 2019) and AllenNLP (Gardner et al., 2017). Implementation details, pretrained weights and full hyperparameter values can be found in the libraries documentation.

[2] We use the same experimental setup used by the authors. Source: `https://github.com/john-hewitt/structural-probes`

[3] Source: `https://github.com/Tarpelite/UniNLP/blob/master/examples/run_pos.py`

a linear layer on top of the hidden-states output to compute span start logits and span end logits.[4] Dataset: Stanford Question Answering Dataset (SQuAD (Rajpurkar et al., 2018)).

Paraphrase identification. We fine-tune BERT with a linear layer on top of the pooled sentence representation.[5] Dataset: Microsoft Research Paraphrase Corpus (MRPC) (Dolan and Brockett, 2005).

4 Evolution of syntax trees

Hewitt and Manning (2019)'s structural probe evaluates how well syntax trees are embedded in a linear transformation of the network representation space, performing two different evaluations: i) Tree distance evaluation, in which squared L2 distance encodes the distance between words in the parse tree, and ii) Tree depth evaluation, in which squared L2 norm encodes the depth of the parse tree.

Using their probe, Hewitt and Manning show that the 7th layer of BERT-base is the layer that encodes more syntactic information. Therefore, to analyze the evolution of the encoded syntax trees, we train the probes on the 7th layer of the different checkpoint models generated along the fine-tuning process of each task.[6]

4.1 Tree distance evaluation

The probe evaluates how well the predicted distances between all pairs of words in a model reconstruct gold parse trees by computing the Undirected Unlabeled Attachment Score (*UUAS*). It also computes the Spearman correlation between true and predicted distances for each word in each sentence, averaging across all sentences with lengths between 5 and 50 (henceforth referred to as *DSpr.*).

Morpho-syntactic tasks As shown in Figures 1 and 2, both metrics follow a similar behaviour (shades represent the variability across the 5 model runs). PoS tagging shows an important loss of performance all along the fine-tuning process, especially noticeable for UUAS (Figure 1), suggesting that distance-related syntactic information is of less relevance to PoS tagging than could be intuitively assumed. As many words have a clear preference towards a specific PoS, especially in English, and most of the ambiguous cases can be resolved using information in the close vicinity (e.g., a simple 3-gram sequence tagger is able to achieve a very high accuracy (Manning, 2011)), syntactic structure information may not be necessary and, therefore, the model does not preserve it. This observation is aligned with Pimentel et al. (2020), who found that PoS-tagging is not an ideal task for contemplating the syntax contained in contextual word embeddings. The loss is less pronounced on depth-related metrics, maybe because the root of the sentence usually corresponds to the verb, which may also help in identifying the PoS of surrounding words.

Constituency parsing and dependency parsing share a very similar tendency, with a big improvement in the first fine-tuning steps preserved along the rest of the process. As both tasks heavily rely on syntactic information, this improvement intuitively makes sense. Dependency parsing fine-tuned on the Penn Treebank (PTB) shows even higher results since the probing is trained on the same dataset. In-

[6] Cf. also Supplementary Material.

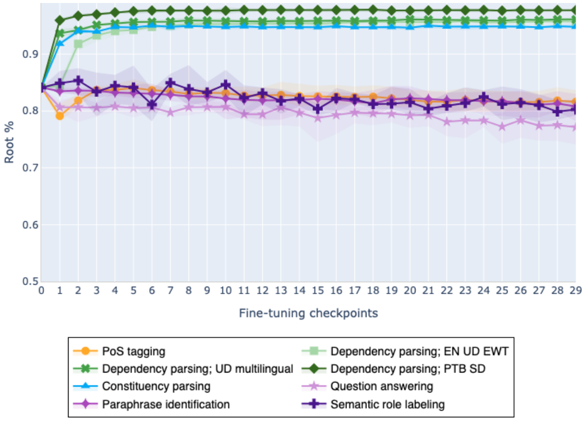

Figure 3: Tree depth evaluation. *Root %* evolution.

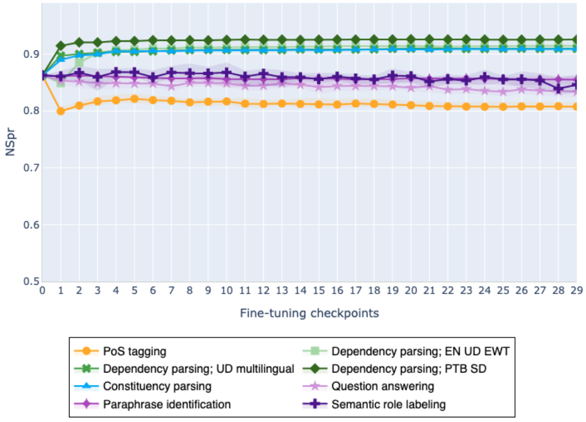

Figure 4: Tree depth evaluation. *Nspr* evolution.

terestingly, the probe performs similarly even if the parsing task is modeled as a sequence labeling problem (as in constituency parsing), suggesting that the structure of syntax trees emerges in such models even when no tree is explicitly involved in the task. The initial drop observed for PoS tagging and monolingual dependency parsing with UD, trained on UD EN EWT, may be related to the size of the dataset, since UD EN EWT is significantly smaller than the other datasets and therefore the models see less examples per checkpoint.

Semantics-related tasks As shown in Figures 1 and 2, both metrics follow different behaviours (again, shades represent the variability across the 5 model runs). Paraphrase identification shows a small but constant UUAS loss along the fine-tuning, while QA shows a slightly steeper loss trend. Initially, SRL loses around 12 points, suggesting that it discards some syntactic information right at the beginning, and follows a similar downward trend afterwards. Those three tasks show a stable performance along the fine-tuning for the DSpr metric, which implies that even if there is a loss in UUAS information it does not impact the distance ordering.

4.2 Tree depth evaluation

The probe evaluates models with respect to their ability to recreate the order of words specified by their depth in the parse tree, assessing their ability to identify the root of the sentence as the least deep word (*Root %*) and computing the Spearman correlation between the predicted and the true depth ordering, averaging across all sentences with lengths between 5 and 50 (henceforth referred to as *NSpr*).

Morpho-syntactic tasks Again, both metrics follow a similar behaviour, as shown in Figures 3 and 4. PoS tagging shows a sustained loss of performance, though softer than the loss observed for the distance metrics. This loss is slightly less pronounced for *Root %* than for *Nspr*, suggesting that while depth-related syntactic information may be of less relevance to PoS tagging than it is to the other morpho-syntactic tasks, identifying the root of the sentence may be important, as the root of the sentence is likely to become one of the ambiguous tags and therefore identifying it may help to select the correct label. Constituency parsing and dependency parsing share a similar tendency, with a big improvement in the first steps preserved along the rest of the fine-tuning process, reinforcing the intuition previously introduced in Section 4.1 about the structure of syntax trees emerging in models even when no tree is explicitly involved in the task. Again, an initial drop can be observed for PoS tagging and monolingual dependency parsing with UD, most probably related to the smaller size of the UD EN EWT dataset used in both tasks.

Semantics-related tasks Both metrics follow a similar behaviour, as shown in Figures 3 and 4, with all tasks following a soft but sustained loss of performance until the end of the fine-tuning process, specially noticeable for *Root %*.

5 Conclusions

We show that fine-tuning is not always a conservative process. Rather, the syntactic information initially encoded in the models is forgotten (PoS tagging), reinforced (parsing) or preserved (semantics-related tasks) in different (sometimes unexpected) ways along the fine-tuning, depending on the task. Thus, we expected that morpho-syntactic tasks clearly reinforce syntactic information. However, PoS tagging forgets it, which, on the other side, can also be justified linguistically (cf. Section 4.1). In contrast, tasks closer to semantics mostly preserve the syntactic knowledge initially encoded. This interesting observation reinforces recent findings that models benefit from explicitly injecting syntactic information for such tasks (Singh Sachan et al., 2020).

Overall, we observed that morpho-syntactic tasks experiment substantial changes in the initial phases, while semantic-related tasks maintain a more stable trend, highlighting the importance of syntactic information in tasks that are not explicitly syntactic in nature (Kuncoro et al., 2020). These observations lead to some interesting insights, but also to further questions; for instance: Can we find a specific set of probes covering different linguistic phenomena to be used as a pretraining stopping criteria? Would this lead to an improvement in the encoding of the linguistic information on pretrained models?

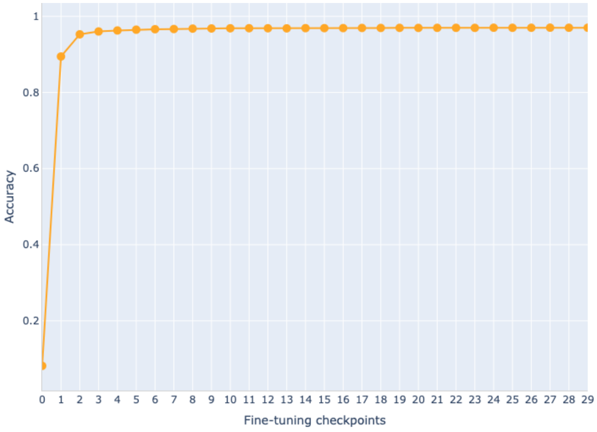
A Target tasks performance evolution

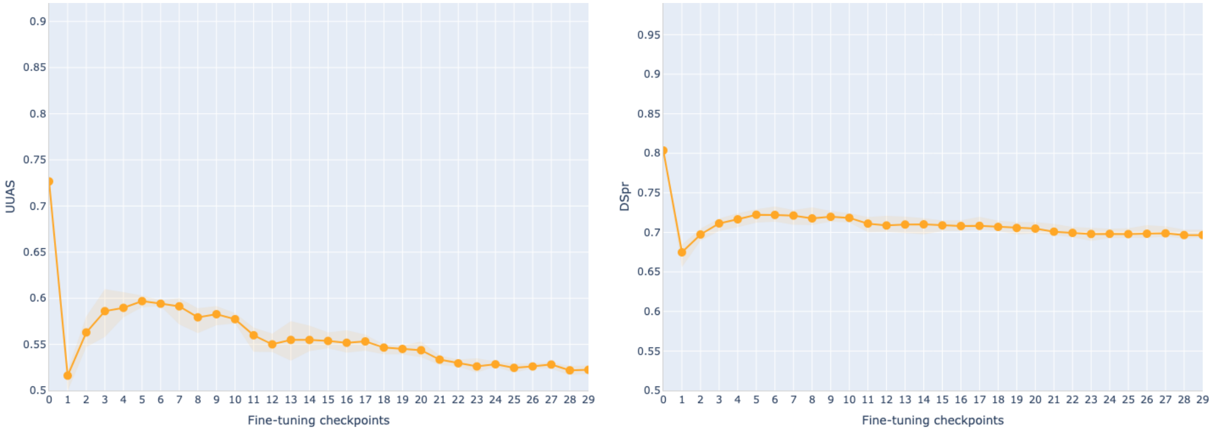
To complement the results shown in the main paper, we include here the performance curves of the target tasks for which the models are fine-tuned, along with the performance curves of the structural probes metrics, facilitating the comparison of the evolution of the encoded syntax trees information and the target tasks performances.

Along with the performance curves of the four structural probes metrics (*UUAS*, *Nspr*, *Root %* and *Dspr*), the following figures include the performance curves of the target tasks and a brief discussion of the results, to help interpretation. Figure 5 shows the accuracy evolution of PoS tagging. Figures 6, 7 and 8 show the Labeled Attachment Score (LAS) of Dependency parsing with PTB SD, EN UD EWT and UD multilingual, respectively. Figure 9 shows the accuracy evolution of Constituency parsing. Figure 10 shows the F1 score evolution of Question Answering. Figure 11 shows the F1 score and accuracy evolution of Paraphrase identification. Finally, Figure 12 shows the F1 score evolution of Semantic Role Labeling.

PoS tagging reaches a 0.95 accuracy in only two checkpoints, ending up with a 0.97 on the last checkpoint (Figure 5a). It shows a loss of accuracy for the four probing metrics all along the fine-tuning process, especially noticeable for *UUAS* (Figure 5b) and *Root %* (Figure 5d), suggesting that syntactic information is of less relevance to PoS tagging than could be intuitively assumed. The loss is less pronounced on depth-related metrics, maybe due to the fact that the root of the sentence usually corresponds to the verb, which may also help in identifying the PoS of surrounding words.

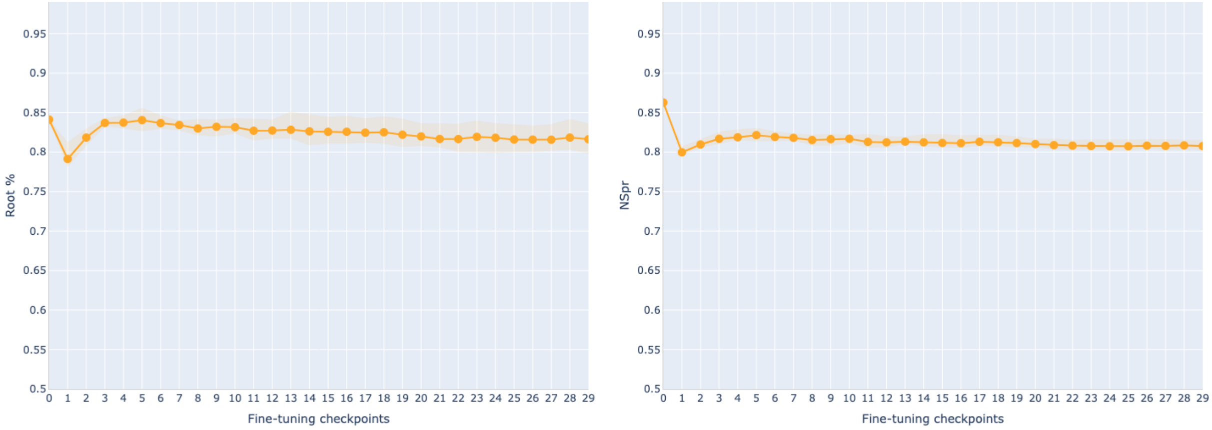


(a) Fine-tuning. Accuracy



(b) Structural probes tree distance evaluation. *UUAS*

(c) Structural probes tree distance evaluation. *Dspr*

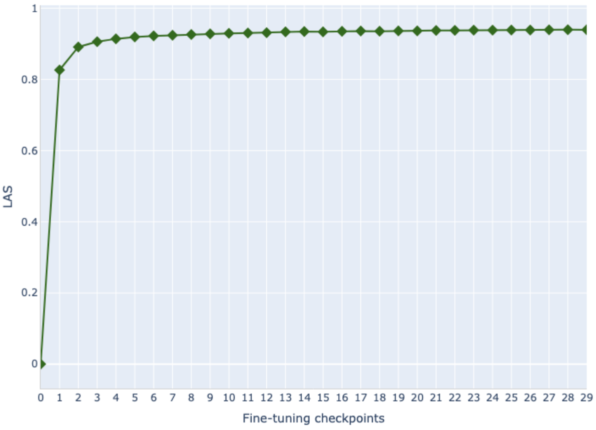


(d) Structural probes tree depth evaluation. *Root %*

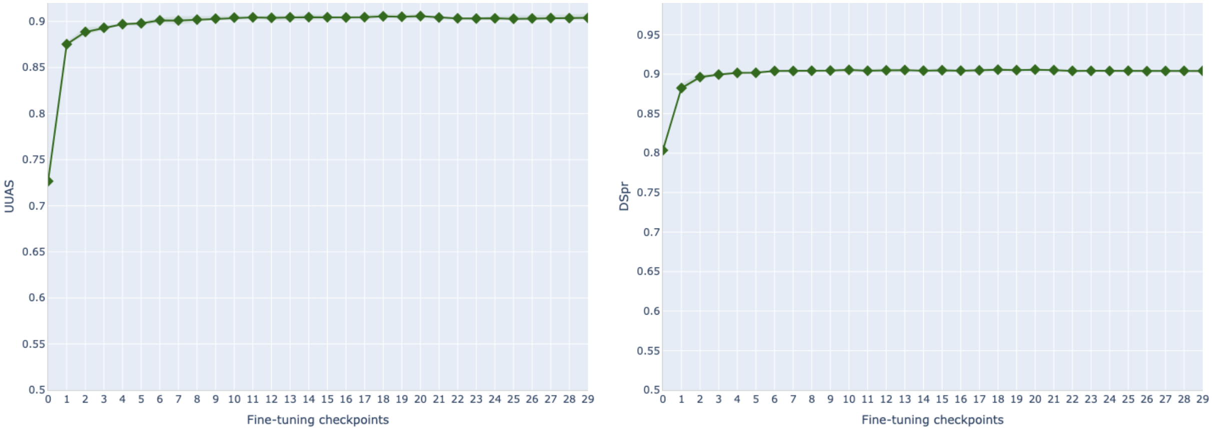
(e) Structural probes tree depth evaluation. *Nspr*.

Figure 5: POS Tagging. Fine-tuning & probing metrics evolution.

Dependency parsing with PTB SD shows a steep learning curve (Figure 6a), reaching a performance of 0.90 LAS on the third checkpoint, up to a final 0.94. All four probing metrics show an important improvement in the first fine-tuning step (Figures 6b, 6c, 6d and 6e), which is preserved along the rest of the process. As the task heavily relies on syntactic information, this improvement intuitively makes sense. Compared to the result of the other dependency parsing experiments, this one show bigger improvements because the probing is trained on the same dataset.

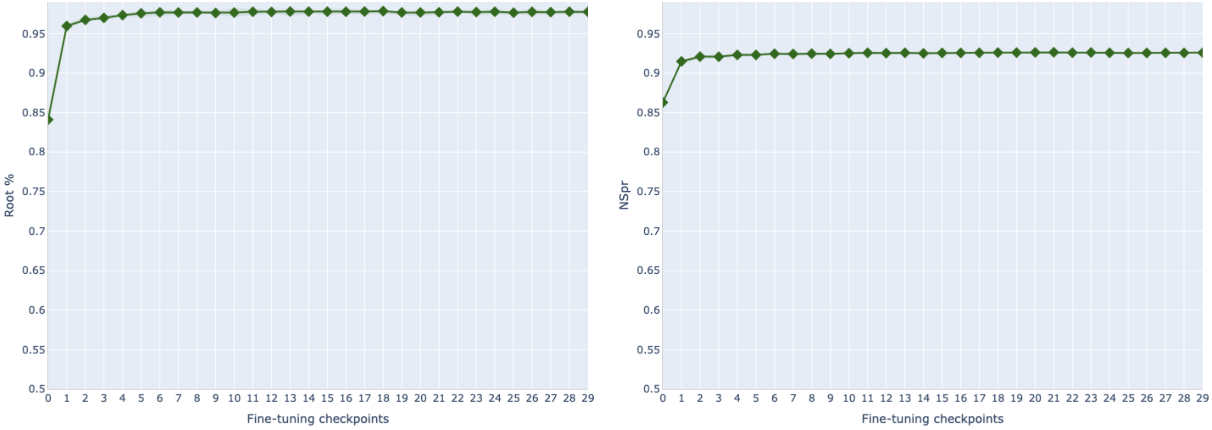


(a) Fine-tuning. LAS



(b) Structural probes tree distance evaluation. *UUAS*

(c) Structural probes tree distance evaluation. *Dspr*.

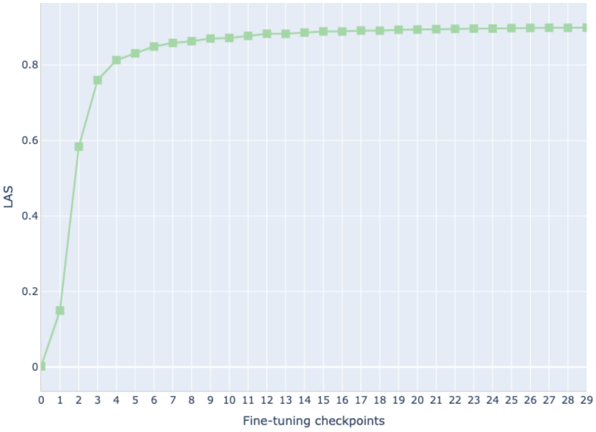


(d) Structural probes tree depth evaluation. *Root %*

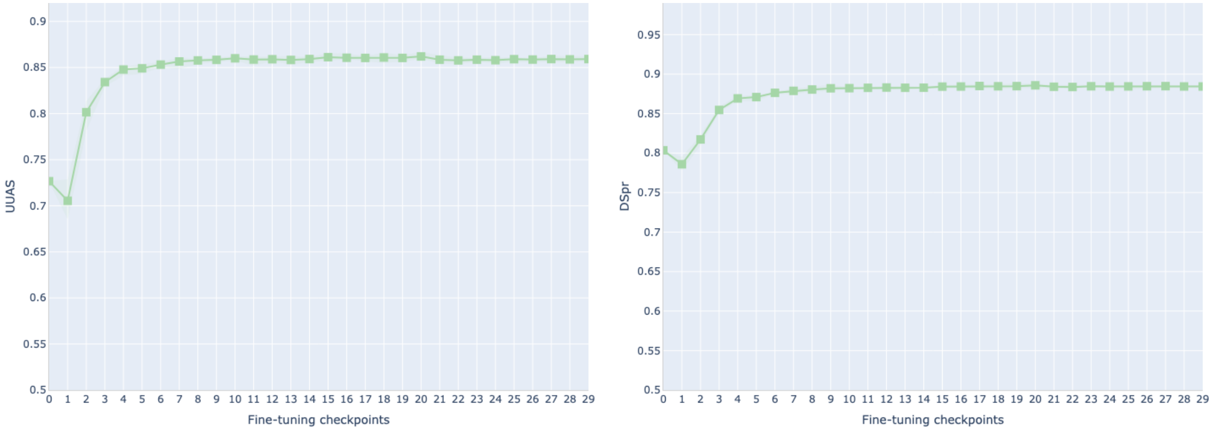
(e) Structural probes tree depth evaluation. *Nspr*

Figure 6: Dependency Parsing PTB SD. Fine-tuning & probing metrics evolution.

Dependency parsing with EN UD EWT shows a shallower learning curve than other experiments (Figure 7a), as the dataset is significantly smaller than the multilingual and PTB and therefore the models see less examples per checkpoint, ending up with a high performance of 0.9. After an initial drop (probably due to the dataset size, as mentioned before), the probing metrics show a big improvement in the first fine-tuning steps, preserved along the rest of the process (Figures 7b, 7c, 7d and 7e). As the task heavily relies on syntactic information, this improvement intuitively makes sense.

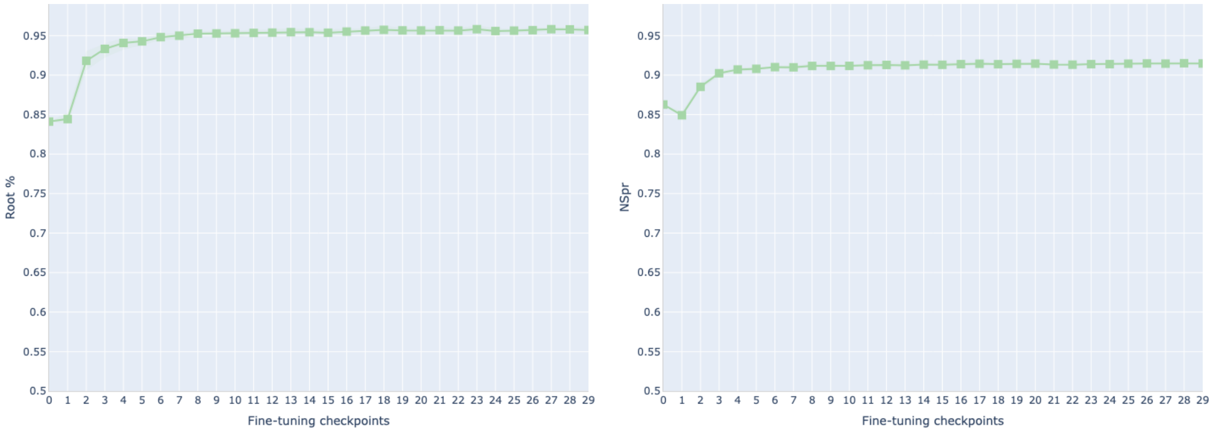


(a) Fine-tuning. LAS



(b) Structural probes tree distance evaluation. *UUAS*

(c) Structural probes tree distance evaluation. *Dspr*.

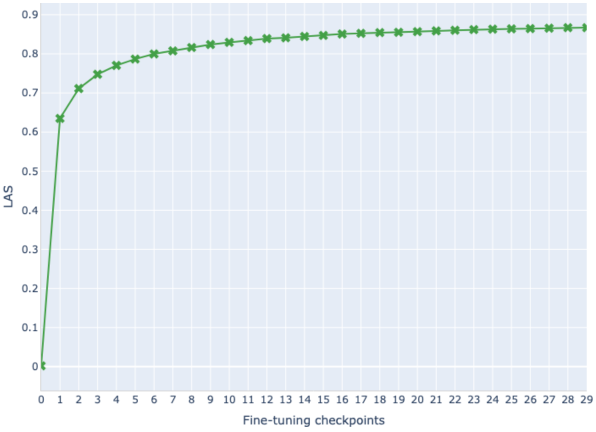


(d) Structural probes tree depth evaluation. *Root %*

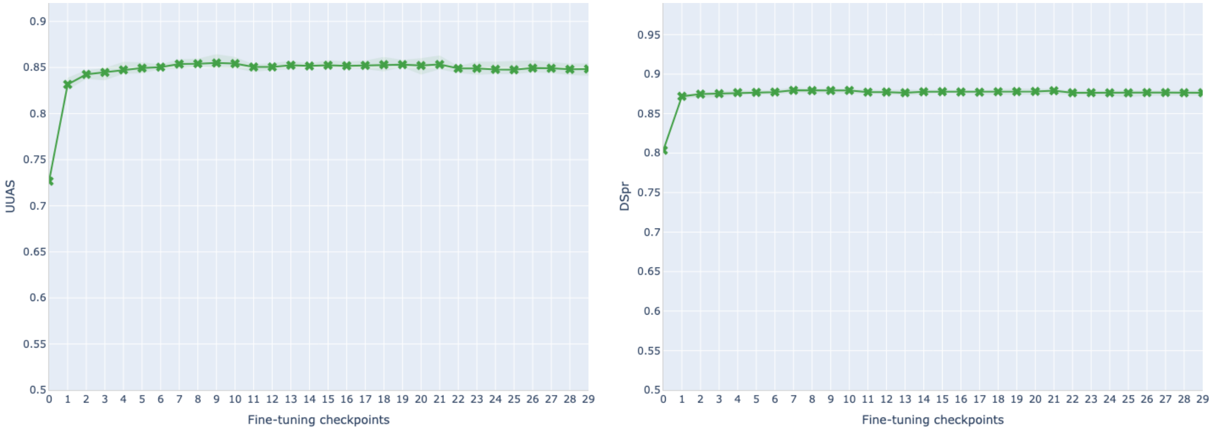
(e) Structural probes tree depth evaluation. *Nspr*

Figure 7: Dependency Parsing EN UD EWT. Fine-tuning & probing metrics evolution.

Multilingual dependency parsing shows a steeper learning curve than dependency parsing with EN UD EWT, as it is trained with a larger dataset (Figure 8a), reaching a performance of 0.87 in LAS. All four probing metrics show a big improvement in the first fine-tuning step, preserved along the rest of the process (Figures 8b, 8c, 8d and 8e). As the task heavily relies on syntactic information, this improvement intuitively makes sense.

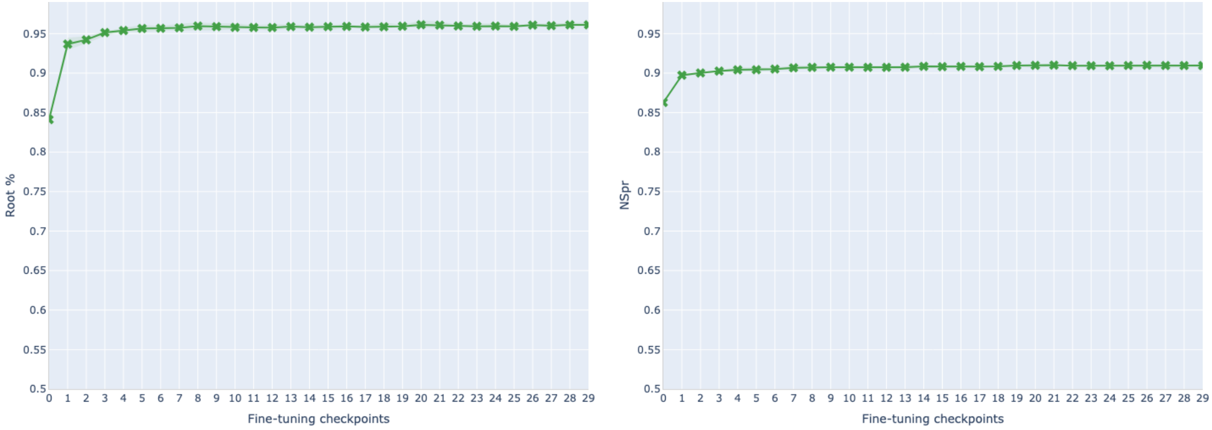


(a) Fine-tuning. LAS



(b) Structural probes tree distance evaluation. *UUAS*

(c) Structural probes tree distance evaluation. *Dspr*.

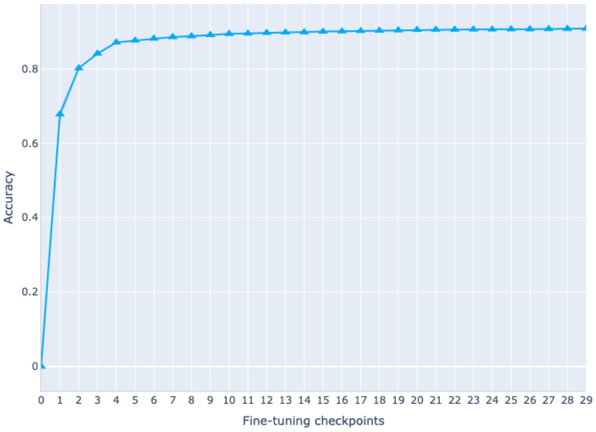


(d) Structural probes tree depth evaluation. *Root %*

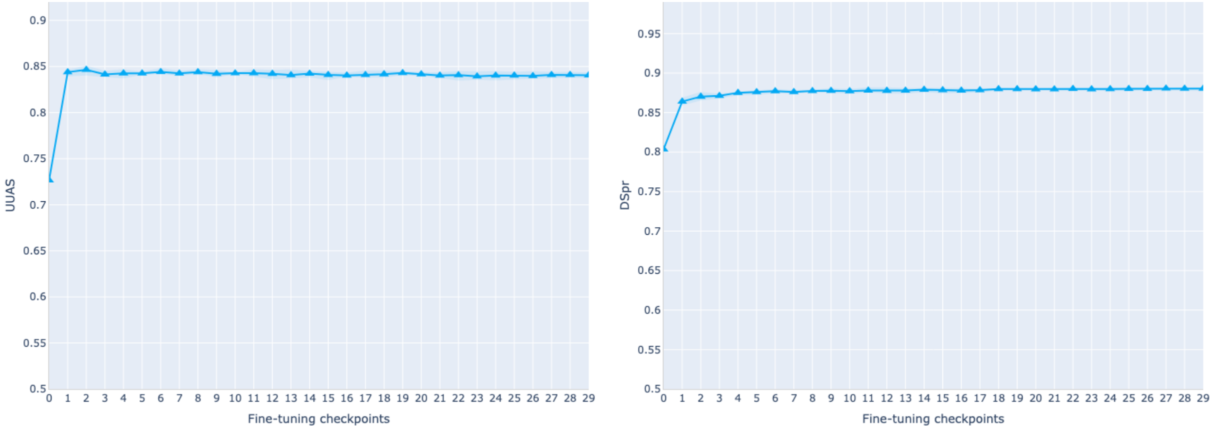
(e) Structural probes tree depth evaluation. *Nspr*

Figure 8: Dependency Parsing UD Multilingual. Fine-tuning & probing metrics evolution.

Constituency parsing fine-tuning follows a steep curve, quickly reaching an Accuracy of 0.87 that is further improved to 0.9 in the last checkpoint (Figure 9a). All four probing metrics show a big improvement in the first fine-tuning steps, preserved along the rest of the process (Figures 9b, 9c, 9d and 9e). As the task heavily relies on syntactic information, this improvement intuitively makes sense. Interestingly, even though the task is modeled as a sequence labeling problem, the probe performs similarly to the dependency parsing tasks, suggesting that the structure of syntax trees emerges in such models even when no tree is explicitly involved in the task.

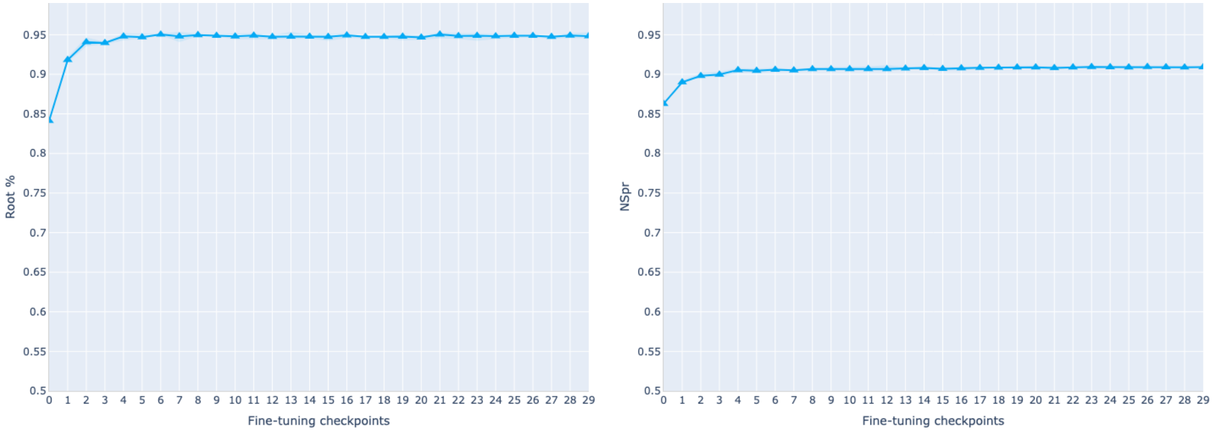


(a) Fine-tuning. Accuracy



(b) Structural probes tree distance evaluation. *UUAS*

(c) Structural probes tree distance evaluation. *Dspr*.

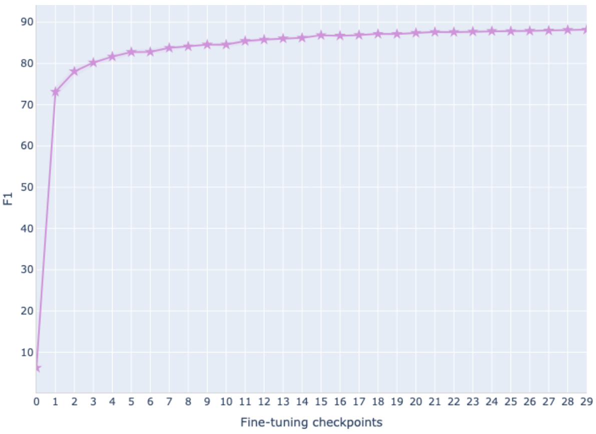


(d) Structural probes tree depth evaluation. *Root %*

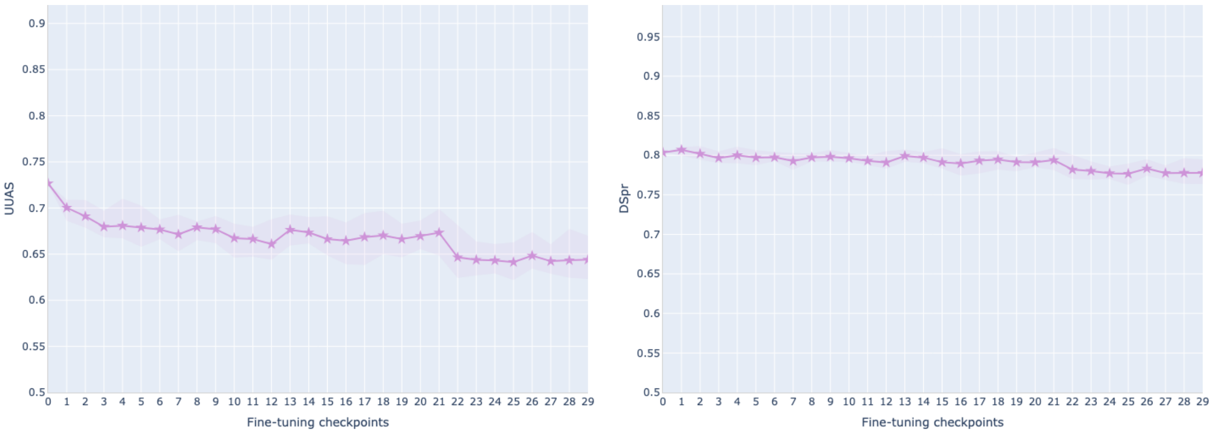
(e) Structural probes tree depth evaluation. *Nspr*

Figure 9: Constituent Parsing. Fine-tuning & probing metrics evolution.

Question answering fine-tuning quickly reaches an F1 score of 0.73 on the first step, which is further improved to 0.88 in the last checkpoint (Figure 10a). All four probing metrics show a clear loss trend (Figures 10b, 10c, 10d and 10e). The loss is specially noticeable for *UUAS* and *Root %*, and more stable for the Spearman correlations, suggesting that even if there is a loss of information it does not impact the distance and depth orderings.

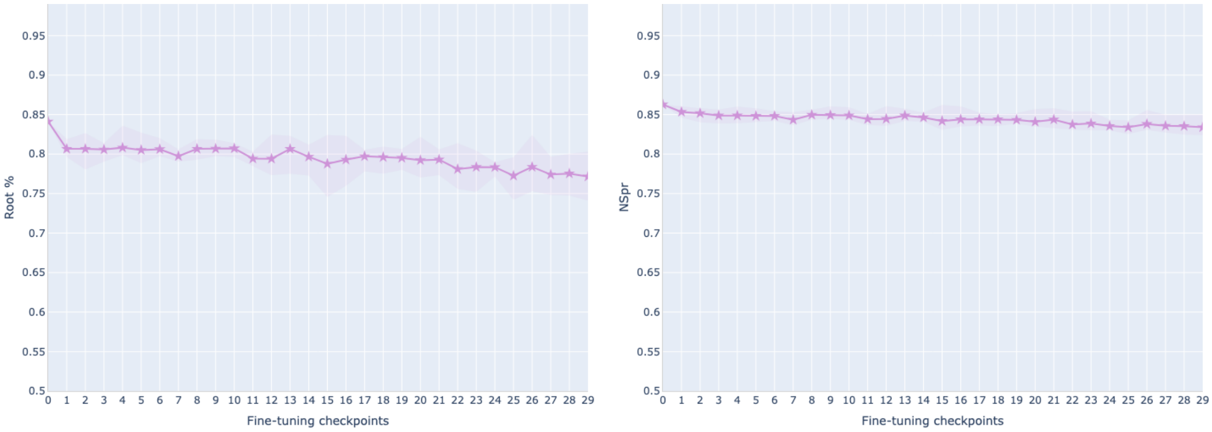


(a) Fine-tuning. F1



(b) Structural probes tree distance evaluation. *UUAS*

(c) Structural probes tree distance evaluation. *Dspr*.

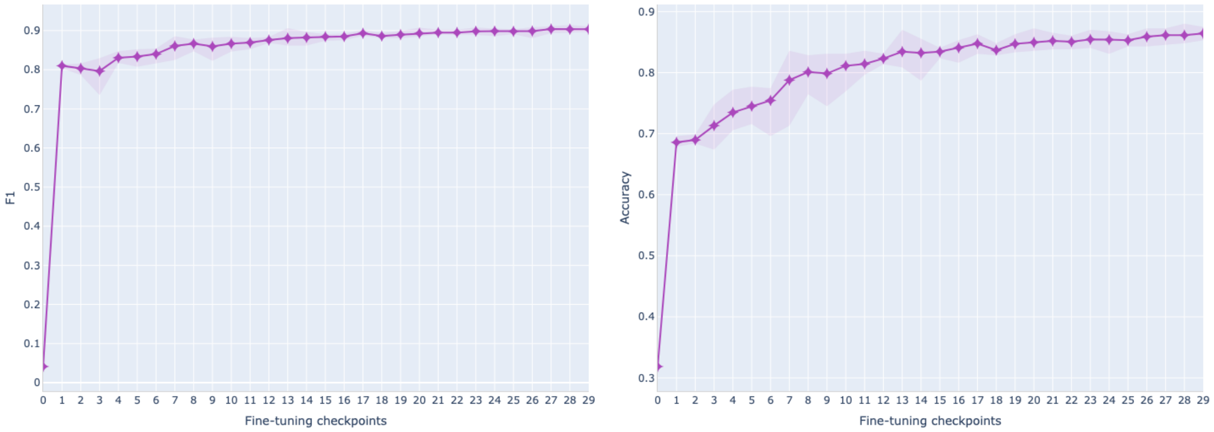


(d) Structural probes tree depth evaluation. *Root %*

(e) Structural probes tree depth evaluation. *Nspr*

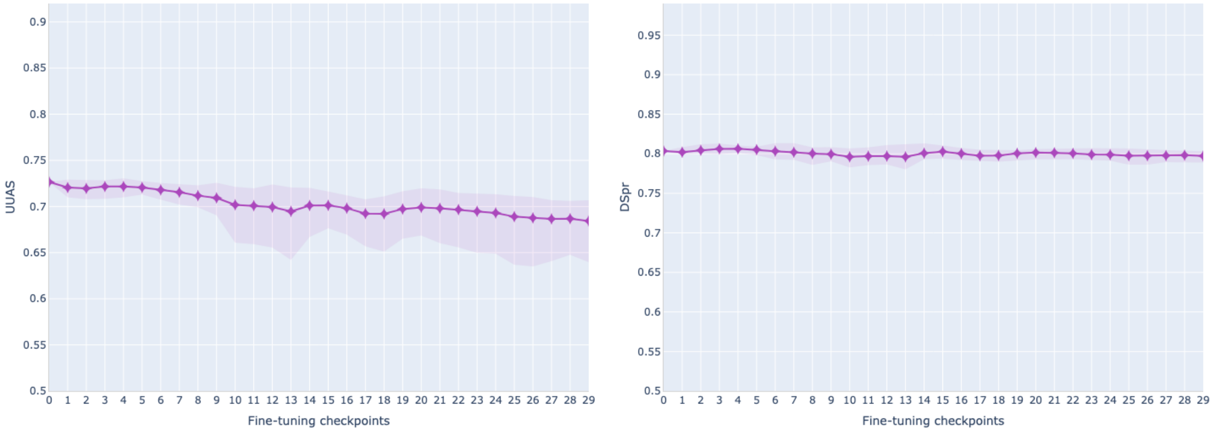
Figure 10: Question Answering. Fine-tuning & probing metrics evolution.

Paraphrase identification fine-tuning starts with an F1 score of 0.81 on the first step that is further improved to 0.90 in the last checkpoint (Figure 11a). Regarding accuracy, after reaching 0.69 on the first checkpoint it follows a shallower curve to a final 0.86 (Figure 11b). All four probing metrics follow a loss trend (Figures 11c, 11d, 11e and 11f). The loss is specially noticeable for *UUAS* and *Root %*, and more stable for the Spearman correlations, suggesting that even if there is a loss of information it does not impact the distance and depth orderings.



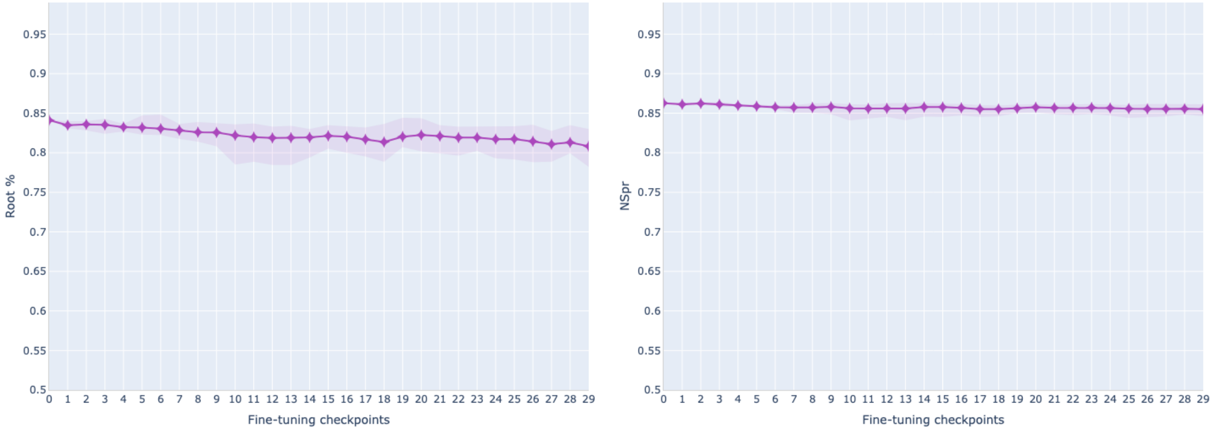
(a) Fine-tuning. F1

(b) Accuracy



(c) Structural probes tree distance evaluation. *UUAS*

(d) Structural probes tree distance evaluation. *Dspr*.

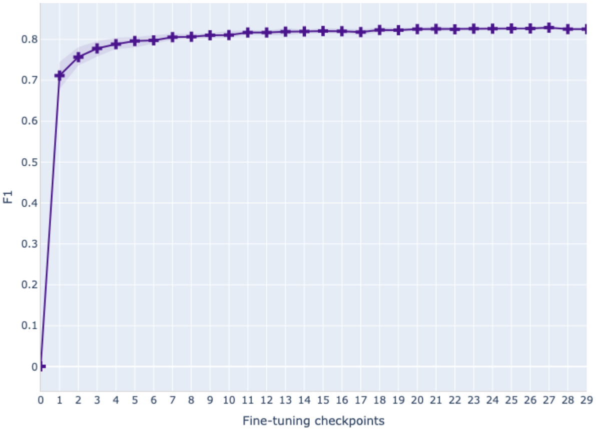


(e) Structural probes tree depth evaluation. *Root %*

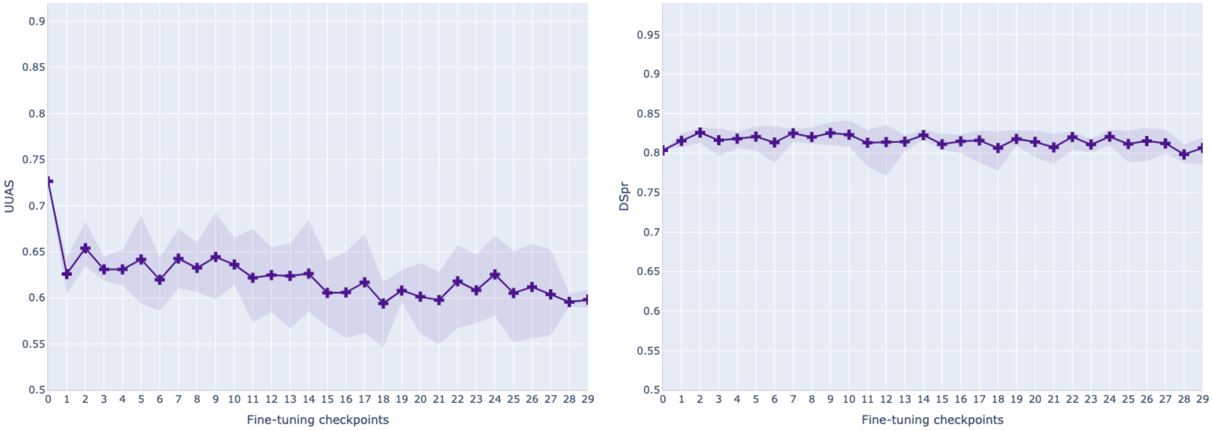
(f) Structural probes tree depth evaluation. *Nspr*

Figure 11: Paraphrase identification. Fine-tuning & probing metrics evolution.

Semantic Role Labeling fine-tuning follows a steep curve for F1, quickly reaching an F1 score of 0.71 on the first step that is further improved to 0.82 in the last checkpoint (Figure 12a). All four probing metrics follow a loss trend (Figures 12b, 12c, 12d and 12e). The loss is specially noticeable for *UUAS*, which initially loses around 12 *UUAS* points, and more stable for the Spearman correlations, suggesting that even if there is a loss of information it does not impact the distance and depth orderings.



(a) Fine-tuning. F1



(b) Structural probes tree distance evaluation. *UUAS*

Identify, Align, and Integrate: Matching Knowledge Graphs to Commonsense Reasoning Tasks

Lisa Bauer

Abstract

Integrating external knowledge into commonsense reasoning tasks has shown progress in resolving some, but not all, knowledge gaps in these tasks. For knowledge integration to yield peak performance, it is critical to select a knowledge graph (KG) that is well-aligned with the given task's objective. We present an approach to assess how well a candidate KG can correctly identify and accurately fill in gaps of reasoning for a task, which we call KG-to-task match. We show this KG-to-task match in 3 phases: knowledge-task identification, knowledge-task alignment, and knowledge-task integration. We also analyze our transformer-based KG-to-task models via commonsense probes to measure how much knowledge is captured in these models before and after KG integration. Empirically, we investigate KG matches for the SocialIQA (SIQA) (Sap et al., 2019b), Physical IQA (PIQA) (Bisk et al., 2020), and MCScript2.0 (Ostermann et al., 2019) datasets with 3 diverse KGs: ATOMIC (Sap et al., 2019a), ConceptNet (Speer et al., 2017), and an automatically constructed instructional KG based on WikiHow (Koupaee and Wang, 2018). With our methods we are able to demonstrate that ATOMIC, an event-inference focused KG, is the best match for SIQA and MCScript2.0, and that the taxonomic ConceptNet and WikiHow-based KGs are the best matches for PIQA across all 3 analysis phases. We verify our methods and findings with human evaluation.[1]

1 Introduction

Recently, several datasets (Sap et al., 2019b; Huang et al., 2019; Bhagavatula et al., 2020; Talmor et al., 2019b) have been released to tackle the challenge of commonsense reasoning. While deep pretrained language-models (LMs) (Devlin et al., 2019; Radford et al., 2019; Liu et al., 2019; Yang et al., 2019) have been at the top of most leaderboards, they still have shortcomings when it comes to commonsense reasoning (Sap et al., 2019b; Rajani et al., 2019; Mitra et al., 2019). Thus, incorporating knowledge graph (KG) information into these models is an active area of research (Lin et al., 2019a; Sun et al., 2019; Mitra et al., 2019; Bosselut et al., 2019). However, when selecting a KG match for a task, it is often difficult to quantitatively assess what kind of knowledge is missing from these models and how much of the missing knowledge required for the task is available in a candidate KG. It is also critical to examine how easily transformer-based models can learn commonsense knowledge, to determine the benefits of integrating a KG.

We investigate how well a KG matches with a task objective, referred to as *KG-to-task match*. We use a 3-step process that examines knowledge *identification, alignment,* and *integration*. We utilize a modular pipeline approach to allow for interpretable results and easy replacement of new and different modules. Our approach reveals features such as: how often a KG identifies a knowledge gap in a question-answer pair (identification), whether a KG identifies the correct knowledge gap (alignment), and whether the inserted knowledge correctly fills the knowledge gap required for the task (integration). These steps are depicted in Fig. 1. We also compare the effects of knowledge content, structure, and shape.

The results of this analysis are impacted by the model we use, and thus we also develop *probes* to examine how much commonsense knowledge LMs already know and how easy it is for them to learn. We evaluate our KG-to-task models in a QA probe setup to examine how much commonsense is learned with and without the matched KG. Our probes are automatically built from ATOMIC, en-

---

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2259–2272
April 19 - 23, 2021.

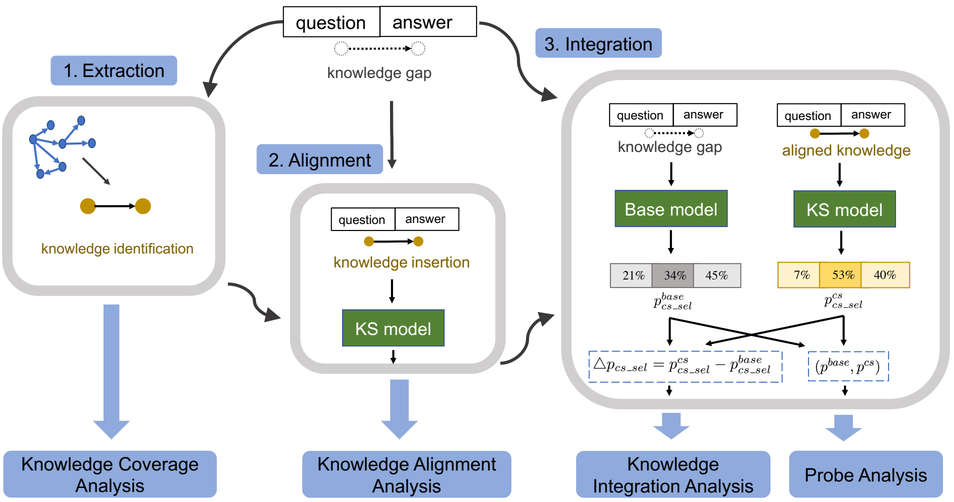

Figure 1: We illustrate our 3 phases of analysis: Knowledge-Task Extraction Analysis, Knowledge-Task Alignment Analysis, and Knowledge-Task Integration Analysis with Probing Analysis.

abling us to leverage existing knowledge sources as a probing base without relying on expensive collection methods. We also include an MLM probe setup to obtain zero-shot and fine-tuned results on probes for social relations, agent-patient assignment, and world knowledge.

We present detailed empirical results on three diverse datasets: SocialIQA (SIQA) task (Sap et al., 2019b), which requires social knowledge; Physical IQA (PIQA) (Bisk et al., 2020) which requires physical knowledge; and MCScript2.0 (Ostermann et al., 2019), which requires commonsense script knowledge, not restricted to a particular domain. Since both SIQA and PIQA require a particular domain of commonsense knowledge, these tasks allow us to draw strong conclusions about KG integration, as knowledge must be well aligned with the tasks to yield performance gains. Analyzing MCScript2.0, on the other hand, allows us to understand how this analysis applies to a task where the best match is not obvious. We compare KG-to-task match with three diverse KGs: ATOMIC (Sap et al., 2019a), ConceptNet (Speer et al., 2017), and automatically extracted subgraphs from WikiHow. Each KG is tailored for a different commonsense domain: ATOMIC focuses on social commonsense, ConceptNet on taxonomic commonsense, and WikiHow on instruction-based commonsense. This allows us to see how different tasks require different types of commonsense knowledge.

To investigate KG-to-task match, we follow three phases: identify, align, and integrate. In our first phase, we examine knowledge gap identification by analyzing our extraction quantities. In our second phase, we examine alignment by utilizing a 'knowledge-surrounded' (KS) model, in which we replace task candidate answers with knowledge-surrounded answers. We found that ATOMIC is the best match for SIQA across both identification and alignment: 11% more ATOMIC data is extracted for question-answer knowledge gaps than ConceptNet data, with a 4.8% performance increase over BERT using our ATOMIC KS model. We use our third phase, integration, to investigate the classification change distributions from BERT to the KS model, finding that our model is more confident about correct classification changes, supporting the ATOMIC-SIQA match. Additionally, both ConceptNet and WikiHow graphs outperformed ATOMIC on PIQA: 8% more ConceptNet data is extracted than ATOMIC and a 17.4% performance increase is achieved with our ConceptNet KS model, whereas we get a 15.5% increase with our WikiHow KS model. Finally, we find that ATOMIC is the best match for MCScript2.0, with a 2.7% increase with our ATOMIC KS model.

We also perform human evaluation and show important connections between the analysis phases. We see that if our KS model shows improvement for high quality settings, our extraction step is a valid knowledge-gap identification metric between 74% and 89% of the time, depending on the dataset. We also show that our best alignment strategy for ATOMIC-SIQA fills knowledge gaps 66% of the time, outperforming the best alignment strategy for ConceptNet-SIQA, which supports our KS model performance results. We find similar trends for PIQA alignment and also find that the amount of information available at inference time may affect alignment results for MCScript2.0. Human evaluation shows that 93% of ATOMIC-SIQA KS model prediction changes (with respect to the baseline) select the answer with the highest knowledge quality, verifying our integration phase as a quality metric.

Our commonsense QA probes before and after KG integration show that our KS model only considerably outperforms the BERT baseline on certain relational probes, indicating the type of knowledge gaps ATOMIC is better at resolving, e.g., relational knowledge such as feelings, reactions, etc.

Overall, our methods not only illustrate the type of knowledge that current transformer-based models are missing to approach human-level commonsense reasoning but also how we can identify, align, and integrate knowledge between a KG and a task to find the best match to fill in these missing gaps of reasoning.

2 Related Work

Language Model Probes: Recent work in probe construction has examined neural model knowledge (Richardson and Sabharwal, 2019; Zhou et al., 2020b; Rogers et al., 2020; Lin et al., 2020). Talmor et al. (2019a) constructed eight tasks that evaluated LMs for operations such as comparison, conjunction, and composition. Zhou et al. (2020a) created logically equivalent probes to evaluate robustness on commonsense tasks to syntax. Kwon et al. (2019) proposed tests based on ConceptNet to measure what types of commonsense MLMs understand. Our work instead focuses on probing models for causal, social commonsense in both the MLM and QA setup before and after KG integration and fine-tuning, and automatically constructs probes from existing knowledge sources.

Commonsense Reasoning: Recent commonsense reasoning datasets (Bhagavatula et al., 2020; Zellers et al., 2018; Zhou et al., 2019; Sap et al., 2019b; Bisk et al., 2020; Lin et al., 2019b; Zellers et al., 2019; Ostermann et al., 2019) have motivated research in several domains of commonsense: abductive, grounded, temporal, social, and physical. Commonsense reasoning can be learned either by KGs pre-training (Bosselut et al., 2019; Bosselut and Choi, 2019; Ye et al., 2019) or by integrating explicit knowledge (Chen et al., 2017; Mitra et al., 2018; Bauer et al., 2018; Lin et al., 2019a; Zhang et al., 2019; Xiong et al., 2019). We show how finding nuanced knowledge for successful commonsense reasoning can be quantitatively examined.

Commonsense Knowledge Analysis: Zhang et al. (2020) presented a categorization of essential knowledge for the Winograd Schema Challenge (Levesque et al., 2012) via human annotation to identify what knowledge was required for better commonsense reasoning. Ma et al. (2019) investigated how KG integration methods affected model performance on different tasks and found that the degree of domain overlap between the KG and the task plays a crucial role in performance. We further investigate this by measuring KG-to-task match across 3 automatic phases, considering different extraction methods, and probing models for knowledge before and after KG integration.

3 Tasks & Knowledge Graphs

3.1 Tasks

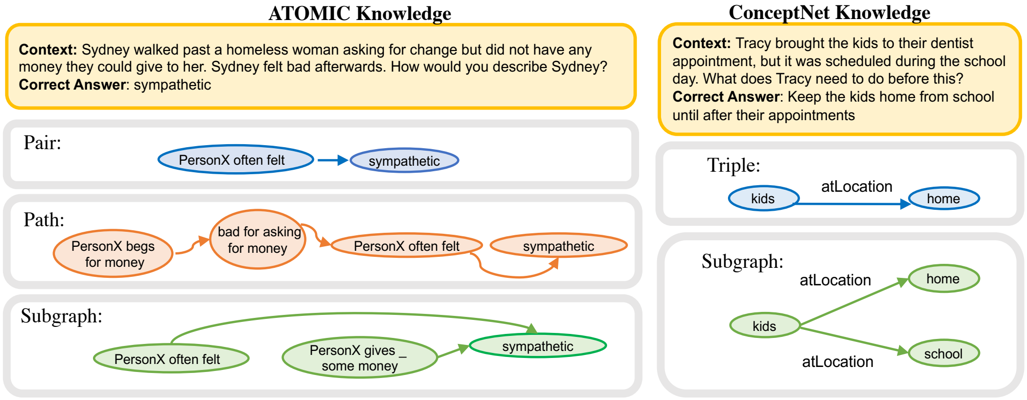
SIQA: The SocialIQA (SIQA) (Sap et al., 2019b) task focuses on social commonsense. Given a context and question, a model selects from 3 answers. SIQA contexts are based on ATOMIC (Sap et al., 2019a) events and SIQA question types are guided by ATOMIC inference dimensions. Thus, we expect ATOMIC to match SIQA requirements. For simplicity, we refer to the concatenation of context and question as the question throughout the paper.

PIQA: The PhysicalIQA (PIQA) (Bisk et al., 2020) task objective focuses on physical commonsense reasoning. Given a goal, a model selects from 2 candidate solutions. PIQA is derived from the instruction domain, and thus we expect instructional physical commonsense to benefit PIQA. For simplicity, we refer to the goal as the question.

MCScript2.0: MCScript2.0 (Ostermann et al., 2019) focuses on script events and participants, requiring commonsense knowledge, in particular script knowledge, to answer questions correctly. We specifically choose this dataset such that it does not have a strong preference for any of the KGs we investigate, to illustrate what our analysis may look like for an unpredictable result. For simplicity, we refer to the concatenation of context and question as the question throughout the paper.

3.2 Knowledge Sources

We show results across three knowledge graphs to illustrate differences in KG-to-task identification, alignment, and integration, and to show how BERT



Context: Sydney walked past a homeless woman asking for change but did not have any money they could give to her. Sydney felt bad afterwards. How would you describe Sydney?
Correct Answer: sympathetic

Context: Tracy brought the kids to their dentist appointment, but it was scheduled during the school day. What does Tracy need to do before this?
Correct Answer: Keep the kids home from school until after their appointments

Figure 2: Examples of different knowledge shapes per KG given SIQA context and ground truth answer.

KG	Shape	Cond.	Filter	Sets	Pres.
AT	triple	QC	HQ	CS-1	KS+
CN	path	A	HR	CS-2	KS-
WH	subgraph	-	-	CS-3	-

Table 1: Variations for each knowledge setting. AT=ATOMIC, CN=ConceptNet, WH=WikiHow, QC=question-conditioned, A=unconditioned, HR=high recall, HQ=high quality, KS+/-=knowledge presence at inference time.

responds differently to various types of knowledge.
ATOMIC: ATOMIC (Sap et al., 2019a) is an inferential knowledge atlas that focuses on if-then reasoning. This knowledge is structured as event-inference pairs, where each pair reflects one of 9 possible inference dimensions for different if-then reasoning relations (cause vs. effect, etc). Knowledge is in the form of short, abstracted, free-text. See the left of Fig 2 for examples.
ConceptNet: ConceptNet (Speer et al., 2017) is a taxonomic knowledge graph that connects natural language concepts with relation edges. While there are relation edges similar to ATOMIC inference dimensions, the structure of the knowledge is in the form of structured triples and generally tends to focus on relations between words or phrases. See the right of Fig 2 for examples.
WikiHow: We automatically extract subgraphs from WikiHow (Koupaee and Wang, 2018) to build our own instruction-based, domain-specific KG. Details are found in the appendix.

4 Phase 1: Identify

4.1 Setup

We identify knowledge using the following extraction methods for each KG. Our setup with all possible options is illustrated in Table 1. We will use Fig 2 as a running example throughout this section.

4.1.1 Knowledge Conditioning

Unconditioned (A) Answer-Knowledge:
ATOMIC: For each candidate answer, we extract a pool of top scoring knowledge using tf-idf between the answer and all ATOMIC event-inference pairs.
ConceptNet & WikiHow: For each candidate answer, we extract knowledge that links concepts in the answer to any concept in the KG, where concepts are tokens in the answer and nodes in the KG.
Example: Consider the SIQA context and ground-truth answer on the right side of Fig 2. Here, the A conditioning setup for ConceptNet would extract the triple [keep, Antonym, get_rid].
Question-Conditioned (QC) Answer-Knowl.:
ATOMIC: We select a question-conditioned knowledge pool via the top scoring tf-idf match between the question & candidate answer and all ATOMIC event-inference pairs. We then select a pool of top scoring knowledge for each candidate answer using tf-idf between the candidate answer and the question-conditioned knowledge pool.
ConceptNet & WikiHow: For each candidate answer, we extract knowledge that links concepts in the question directly to concepts in the answer.
Example: All knowledge illustrated in Fig 2 is extracted using QC conditioning.

4.1.2 Knowledge Shape

Knowledge Pairs/Triples:
ATOMIC: We take the highest scoring knowledge pair determined by the conditioning step.
ConceptNet & WikiHow: We select a triple at random from the conditioning step.
Knowledge Paths:
ATOMIC: In the QC setup, for each data point, we extract a question-knowledge pool via top scoring

tf-idf match between the question and all ATOMIC event-inference pairs. If there exists a concept link between the question-knowledge pool and the answer-knowledge pool from the conditioning step, we link this knowledge as a path. In the A setup, we make the modification that our answer-knowledge pool can link to any pair in ATOMIC.

WikiHow: In the QC setup, we find a path from a word in the question, to another word in the question, to a word in the answer. In the A setup, we find a path from a word in the answer to any word it connects to in the KG, as a path through the KG.

Knowledge Subgraphs:

ATOMIC: We take a maximum of the 3 highest scoring knowledge triples determined by the conditioning step to create 1-hop subgraphs.

ConceptNet & WikiHow: From the conditioning knowledge pool, we add the subgraph with the highest number of edges, as we assume these to be the most informative. We only consider 1-hop edges and take the top 5.

Example: All three shape variations are illustrated in Fig 2, using QC conditioning.

4.1.3 Knowledge Filtering

High Quality/Low Recall (HQ): We constrain each answer candidate to keep its highest scoring unique knowledge such that no answer candidate shares knowledge, intending to ensure the relevance of the knowledge to that candidate alone.

Low Quality/High Recall (HR): Candidate keeps its highest scoring knowledge regardless of knowledge sharing among candidates.

4.1.4 Data Subsets & Baseline Training

We split data into subsets depending on how many candidate answers extracted knowledge (CS-X) to evaluate knowledge impact on task performance fairly. For our main results, we use the split in which each answer has access to knowledge (CS-2 for PIQA and MCScript2.0, CS-3 for SIQA). Table 2 illustrates the percent of original data for each split. We compare KS model subset results against a BERT baseline trained and evaluated on the same subset simply without the added knowledge.

4.2 Analysis

We examine how often a KG identifies a potential knowledge gap between a question and an answer. This is illustrated on the far left in Fig. 1. Table 2 shows the percent of knowledge extracted for each QC-HQ subset. We use the QC-HQ setting to show how often our KG specifically identifies question-answer knowledge gaps. We use each KG's best aligned shape in this comparison (Section 5.2.2). For SIQA, we extract more ATOMIC data than for ConceptNet and for PIQA, we extract more ConceptNet data than for ATOMIC. This illustrates that ATOMIC identifies more knowledge gaps for SIQA, and ConceptNet identifies more knowledge gaps for PIQA. For MCScript2.0, we see that the same total knowledge is extracted from both KGs, however more ATOMIC knowledge is extracted in the CS-2 setup, indicating better coverage.

Variation	ATOMIC	ConceptNet
SIQA:		
QC-HQ CS-1	**51**%	39%
QC-HQ CS-2	**24**%	22%
QC-HQ CS-3	2%	**6**%
QC-HQ CS	**77**%	66%
PIQA:		
QC-HQ CS-1	16%	**24**%
QC-HQ CS-2	8%	8%
QC-HQ CS	24%	**32**%
MCScript2.0:		
QC-HQ CS-1	2%	**36**%
QC-HQ CS-2	**88**%	54%
QC-HQ CS	90%	90%

Table 2: %Knowledge extracted for each subset wrt. original data size. Results shown for the best aligned KG shape in the QC-HQ setting: SIQA=CN triples, ATOMIC paths; PIQA=CN subgraphs, ATOMIC pairs; MCScript2.0=CN subgraphs, ATOMIC pairs.

5 Phase 2: Align

5.1 Setup

Baseline Model: We fine-tune BERT-base (Devlin et al., 2019) as our baseline on SIQA following Sap et al. (2019b), BERT-base on MCScript2.0, and BERT-large (Devlin et al., 2019) as our baseline on PIQA following Koupaee and Wang (2018). See original papers for hyperparameter settings.

Knowledge-Surrounded (KS) Model: We enhance task candidate answers with knowledge-surrounded answers, in which answer-specific knowledge is appended to each candidate answer. This knowledge is intended to explicitly add missing knowledge gaps to the answer. This model is used in the *alignment* and *integration* steps in Fig. 1. We encode input as follows. For a question q_i, we modify each candidate answer, c_{ij}, by appending its respective knowledge k_{ij}. The sequence of tokens $\{$[CLS] q_i [SEP] $c_{ij}k_{ij}$ [SEP]$\}$ is then

Variation	Base.	KS+	KS-
SIQA AT. QC-HQ	38.1	**42.9**	40.5
SIQA AT. QC-HR	**60.3**	59.0	56.4

Table 3: Accuracy for extraction variations on: SIQA CS-3 for ATOMIC paths & ConceptNet triples; PIQA CS-2 for ATOMIC pairs & ConceptNet subgraphs & WikiHow paths; and MCScript2.0 CS-2 for ATOMIC pairs & ConceptNet subgraphs.

passed as input to BERT. Thus, each candidate answer is surrounded by knowledge that allows BERT to potentially fill reasoning gaps between the question and answer. The extraction variations for k_{ij} are described in Section 4.1.

5.2 Analysis

We investigate how well the extracted knowledge and the task are aligned by allowing the knowledge to fill in the question-answer knowledge gap and determining whether this improves performance. This is illustrated in the center of Fig. 1.

5.2.1 Extraction Variation Analysis

Table 3 illustrates performance for each KG across each of the different extractions, using the subset in which each candidate answer has access to knowledge. We compare question-conditioned, unconditioned, high recall, and high quality settings for the best aligned knowledge shape (ConceptNet triples, ATOMIC paths for SIQA; ConceptNet subgraphs, ATOMIC pairs, WikiHow paths for PIQA; ConceptNet subgraphs, ATOMIC pairs for MCScript2.0) across the three KGs. For each setting, we show results both for when knowledge is present during inference time (KS+) and when it is not (KS-). We see that SIQA performed best when it received QC-HQ knowledge from ATOMIC, reflecting the strong, one-to-one alignment between SIQA and ATOMIC. PIQA, however, performs well across most extractions for ConceptNet, indicating that PIQA is generally well aligned with ConceptNet and only performs poorly when the extraction process becomes too noisy. Additionally, PIQA performs well with WikiHow for the unconditioned, high quality setting, indicating that the WikiHow KG is not well aligned across question-answer pairs, but does identify useful knowledge gaps within the answer that may improve performance on the task. Finally, we see that MCScript2.0 performed best when it received QC-HQ knowledge from ATOMIC, and similarly to SIQA, improves when seeing this knowledge at inference time.

5.2.2 Knowledge Shape Analysis

We discuss knowledge shape effects on alignment.

ATOMIC: For SIQA, ATOMIC paths have the best alignment, due to the high quality achieved when constraining knowledge for the SIQA question to link to knowledge for the answer. ATOMIC pairs and subgraphs seem to be learned more implicitly and do not yield large overall improvements when added explicitly during inference time. It seems that SIQA requires longer, more informative knowledge at inference time, which pairs and subgraphs do not offer. For example, consider the SIQA context and answer on the right of Fig 2. For this data point, we extract the following ATOMIC path: [PersonX has to go to the dentist, need to make an appointment, PersonX picks _ up from school, to drive kids home], and the following ATOMIC pair: [PersonX picks _ up from school, to drive kids home]. We can see that the path clearly contains more context and detail for the knowledge required to make the correct prediction. For PIQA, we saw the largest improvements for ATOMIC pairs and subgraphs, where pairs ultimately perform best, indicating that PIQA might find concise and direct information from ATOMIC more useful. For MCScript2.0, ATOMIC pairs aligned best exclusively.

ConceptNet: For SIQA, ConceptNet triples and subgraphs show similar alignment results and we do not see major improvements. It seems that the content of ConceptNet is not aligned well to SIQA, regardless of shape. For PIQA, we see improvements for both triples and subgraphs, and get our best improvements with subgraphs, indicating that the extra knowledge encoded in a subgraph shape via ConceptNet is helpful for the PIQA task. Similarly to SIQA, MCScript2.0 performed best with ConceptNet subgraphs, but these do not yield major improvements. Interestingly, results on MCScript2.0 only show slight improvement for ConceptNet when knowledge is present at inference time, and shows no improvement otherwise.

WikiHow: WikiHow paths performed best, indicating that paths were the best way to extract information, as WikiHow pairs and subgraphs might have contained redundant information given limitations with the WikiHow KG extraction process.

5.2.3 Knowledge Graph Analysis

Given our alignment results, it is clear to see that ATOMIC is the best match for SIQA, that ConceptNet is the best match for PIQA, and that ATOMIC is the best match for MCScript2.0 (most likely due to its need for script knowledge, which often requires social knowledge). The encoding of each KG plays an important role in this match. We see that the ConceptNet to PIQA match is more robust to extraction methods, which may be a side effect of ConceptNet's encoding, where directly linking nodes is less noisy than using tf-idf measures for the ATOMIC encoding, in which we only see positive results when we have very selective filters in our extraction techniques. The concise, short nature of ConceptNet's knowledge also lends itself to more implicit knowledge learning for certain types of tasks, whereas the more descriptive nature of ATOMIC can be read during inference time (see Fig 2 for examples). This illustrates the possibility that ConceptNet may boost performance as a regularizer for certain tasks.

6 Phase 3: Integrate

6.1 Setup

We analyze two aspects of integration, depicted on the far right in Fig. 1. First, we construct commonsense probes to demonstrate how much knowledge we gain from our KGs via our transformer-based KS model with respect to a BERT baseline. Second, we examine distributional changes in our models before and after commonsense integration and verify our results with human evaluation. With our probes, we can compare how well models distinguish between several types of ATOMIC-style knowledge, outlined below.

Type	Baseline	KS model
Relation Probes		
xWant vs xEffect	**53.66**	46.59
xWant vs xReact	51.66	**77.39**
xWant vs xIntent	**52.05**	45.77
xWant vs xNeed	47.99	**50.32**
xWant vs xAttr	**71.74**	65.19
xEffect vs xReact	43.32	**63.36**
xEffect vs xIntent	**54.29**	44.85
xEffect vs xNeed	49.22	**52.48**
xEffect vs xAttr	**61.52**	59.44
xReact vs xIntent	52.34	**73.32**
xReact vs xNeed	49.21	**74.76**
xReact vs xAttr	48.48	**57.71**
xIntent vs xNeed	**44.18**	42.24
xIntent vs xAttr	**78.96**	64.64
xNeed vs xAttr	**68.97**	68.49
oWant vs oEffect	**51.74**	41.83
oWant vs oReact	43.90	**72.04**
oEffect vs oReact	49.12	**59.02**
Agent-Patient Probes		
xWant vs oWant	**70.12**	70.09
xEffect vs oEffect	**74.34**	73.51
xReact vs oReact	**74.34**	69.51
Concept Probes		
inference	74.96	**77.40**
event	**67.74**	65.07

Table 4: QA probe results on ATOMIC-SIQA QC-HQ KS model vs BERT baseline.

Relational Probes: We predict the ATOMIC relation between an event and inference pair, constraining our candidate answer set to two specified inference dimensions. For example, `xWant` vs `xNeed` might refer to a probe that will predict an answer from the candidate set: [Person `wants` recognition, Person `needs` recognition] given some event, essentially pitting the two relations against each other to evaluate the difficulty of distinguishing.

Agent-Patient Probes: We predict the agent of the inference where the candidate set is the agent and patient of the event (using ATOMIC abstractions).

Concept Probes: We predict concepts and constrain our candidate answer set to the most salient concept in the sequence and its respective antonym. A full description of probe construction and examples for each knowledge type can be found in the appendix. We evaluate QA probes via standard accuracy after fine-tuning.

6.2 Analysis: Commonsense Probes

Table 4 compares the performance between the best performing ATOMIC-SIQA KS model and respective SIQA BERT baseline. We see notable performance differences for our relation probes, showing that the KS model does well at identifying the `React` relation and that the baseline tends

Correct	Incorrect
19.5%	12.4%

Table 5: Distribution changes for selected class from baseline to KS model.

to identify the `Attribute` relation well. While the KS model improves on several QA relational probes, the performance was comparable for agent-patient and world knowledge probes, indicating the knowledge gaps ATOMIC is better at resolving, i.e., relational (feelings, reactions, etc.) versus antonym/synonym information about concepts.

6.3 Analysis: Distribution Change

We conduct an integration analysis on our best ATOMIC-SIQA setting (QC-HQ). We examine 40 multiple choice questions and analyze KS model prediction changes with respect to the baseline. We observe that 93% of prediction changes were made because the new prediction's knowledge had the best reasoning flow to resolve a knowledge gap.

Fig. 1 defines our distribution change analysis as $\Delta p_{cs\_sel} = p^{cs}_{cs\_sel} - p^{base}_{cs\_sel}$. Here, $p^{cs}_{cs\_sel}$ indicates the KS Model's probability of selecting the KS Model's selected answer and $p^{base}_{cs\_sel}$ indicates the baseline's probability of selecting the KS Model's selected answer. Thus, Δp_{cs_sel} indicates the change in the probability of selection for the KS Model's selected answer before (Base Model) and after (KS Model) knowledge integration.

Table 5 shows the distribution change from the baseline to the KS model for the selected answer. When a switch became positive, the average probability increase of the selected ground truth candidate answer was 19.5%, whereas when a switch became negative the increase was 12.4%. Thus, the distribution change shows more confidence about ground truth selection with added knowledge, indicating that the quality of a ground truth's knowledge is higher than that of a negative candidate.

6.4 Analysis: Human Evaluation

We performed human evaluation on 100 SIQA, 100 PIQA, and 100 MCScript2.0 question-answer pairs to determine the validity of our process for both knowledge gap identification and alignment.[2] To show the validity of our QC-HQ extraction method as a measure for knowledge gap identification, we find that this extraction method is a valid potential SIQA knowledge gap identification 89% of the time for ATOMIC and 91% for ConceptNet. Valid, in this case, means that the correct concepts (that identify a relevant knowledge gap) were used to create a link. These results are found in Table 6. We also show that for our best ATOMIC extraction (QC-HQ), we extract the correct knowledge for the gap 66% of the time, demonstrating the connection between KS model improvement and alignment. Correct, in this case, means that the content of the link itself is relevant to resolve the commonsense gap. These results are found in Table 7. In contrast, we see that our best ConceptNet extraction (A-HQ) finds the correct knowledge for the gap 18% of the time. This is probably why we do not see much improvement when we give our ConceptNet KS model knowledge during inference time and why it seems to improve mostly via regularization.

	ATOMIC	CN
SIQA	89%	**91%**
PIQA	48%	**82%**
MC	**75%**	74%

Table 6: Human evaluation for valid knowledge gap.

	ATOMIC	CN
SIQA	**66%**	18%
PIQA	16%	**22%**
MC	31%	**43%**

Table 7: Human evaluation for correct knowledge gap.

On PIQA, we find that this extraction method is a valid potential knowledge gap identification 48% of the time for ATOMIC and 82% for ConceptNet. We conclude that if we do not see alignment improvement on the QC-HQ setting (as is true of ATOMIC-PIQA), then extraction does not indicate the best knowledge gap coverage. Additionally, we find that for our best ATOMIC extraction method (A-HQ), we extract the correct knowledge for the gap 16% of the time and that for our best ConceptNet extraction method (A-HQ), we extract the correct knowledge for the gap 22% of the time.

For MCScript2.0, we found the best empirical performance with QC-HQ settings for both ATOMIC and ConceptNet. With these settings, we found that a valid potential knowledge gap identification occurs 75% of the time for ATOMIC and 74% for ConceptNet. Additionally, we find that with ATOMIC, we extract the correct knowledge for the gap for 31% of examples, and with ConceptNet for 43%. The higher correct extractions for

Concept Probes		
inference	79.15	**80.68**
event	**68.91**	68.51

Table 8: MLM probe zero-shot results.

ConceptNet are most likely due to the best performing extraction settings being QC-HQ. ATOMIC QC-HQ settings visibly outperform the baseline empirically, whereas ConceptNet QC-HQ settings perform only slightly better. This may be due to the fact that MCScript2.0 has a much larger context than any of our other datasets, and thus a model may already be able to implicitly infer the explicit taxonomic knowledge offered by ConceptNet.

7 MLM Commonsense Probes

We evaluate the transformer-based models used in our setup to assess how much knowledge LMs already know and how easy it is for them to learn.

7.1 Setup

We examine our MLM probes in two settings: zero-shot and fine-tuned. For the zero-shot setting, we use a pre-trained LM without any fine-tuning. This is to examine how much knowledge a pre-trained transformer model already holds. For the fine-tuned setting, we train on each probe's respective train set and evaluate using the same metrics as in Talmor et al. (2019a). This is to examine how fast a model learns given its encoding before fine-tuning. Results, set up, metrics, and analysis for fine-tuned settings are found in the appendix.

7.2 Results

Table 8 compares the performance of BERT and RoBERTa for zero-shot results. Majority label results are found in the appendix.

Zero-shot Results: RoBERTa and BERT perform comparably for most Relation probes. While performance is poor for most settings, both models perform very well at discerning between `Want` and `React` (`xWant` vs `xReact`, `oWant` vs `oReact`), and between `xReact` vs `xNeed`. Both models perform reasonably well at discerning `Attr` and `Intent` from other dimensions in certain settings (`xWant` vs `xAttr`, `xNeed` vs `xAttr`, `xEffect` vs `xIntent`, `xReact` vs `xIntent`). In general, the models seem to most consistently discern `React` from other dimensions. Finally, both models perform comparably and reasonably well on Concept probes, whereas the performance for Agent-Patient probes differs largely between the models and is often poor.

8 Conclusion

We proposed a method to analyze how well a candidate KG can correctly identify and accurately fill in gaps of reasoning for a given task. We presented a three step approach for analyzing this KG-to-task match via identification, alignment, and integration. We found that the ATOMIC KG aligns best with the SIQA task, and quantitatively analyze the quality of the extracted commonsense. We also found that the ConceptNet and WikiHow based KGs match best with the PIQA task. Finally, we see that the ATOMIC KG also aligns best with MCScript2.0, which was a novel discovery and is most likely a result of the task's script knowledge requirement. We demonstrate the knowledge contained and learned by our KS model via our commonsense probes, illustrating what knowledge transformer-based models already know and what they can learn. This analysis can be extended to any set of tasks and KGs to analyze match potential.

A Appendix

A.1 WikiHow Subgraph Extraction Procedure

We extract PIQA-conditioned WikiHow subgraphs for each PIQA datapoint. We do this in three steps:

1. Given a PIQA goal, extract relevant titles in Wikihow via tf-idf.
2. Dependency parse the PIQA goal, extracted

Type	Data Size
xWant vs xEffect	10012
xWant vs xReact	10693
xWant vs xIntent	9790
xWant vs xNeed	9829
xWant vs xAttr	11730
xEffect vs xReact	9519
xEffect vs xIntent	8616
xEffect vs xNeed	8655
xEffect vs xAttr	10556
xReact vs xIntent	9297
xReact vs xNeed	9336
xReact vs xAttr	11237
xIntent vs xNeed	8433
xIntent vs xAttr	10334
xNeed vs xAttr	10334
oWant vs oEffect	3873
oWant vs oReact	3873
oEffect vs oReact	3685
xWant vs oWant	7974
xEffect vs oEffect	5911
xReact vs oReact	7293
inference	8401
event	13228

Table 9: MLM & QA dev probe sizes.

Wikihow title, and each sentence in the title's corresponding paragraph.
3. Find overlapping concepts in the dependency parses for which to create concept nodes. Then, create a graph by combining all possible edges for a concept node (found in all dependency parses).

A.2 Probe Construction Details

A.2.1 QA

We use ATOMIC events and respective inferences and map them into the following QA formats.

Relational Probes. For relational probes, we state the event and follow it with "What happens next?". We then create candidates out of a corresponding inference, each with a different relation. For example,

PersonX puts out a fire. What happens next?

For the probe `xWant` vs `xNeed`, we select from the candidate answers: *[PersonX wants to receive recognition, PersonX needs to receive recognition]*, where our ground truth is *PersonX wants to receive recognition*.

Agent-Patient Probes. ATOMIC inference dimensions are either assigned to "PersonX" (most often the agent of the event, unless otherwise specified) or "others" (who are often influenced by the effects of PersonX's actions and may not be directly referred to in the event, see original ATOMIC paper for more details). For Agent-Patient probes, we state the event and follow it with "Who [relation] [inference]"? Using our previous example, we have the following:

PersonX puts out a fire. Who wants to receive recognition?

Where our candidate answers are: *[PersonX, others]*.

Concept Probes. For event concept prediction, we first state the inference and then ask "What happened?" We then create event candidates with a ground truth salient concept (determined in the same way as the MLM salient concepts described in the next section) and an antonym concept. For example:

PersonX wants to receive recognition. What happened?

Where our candidate answers would be: *[PersonX puts out a fire, PersonX puts out a water]*.

For inference concept prediction, we state the event and follow it with "What happens next?". We then create inference candidates with a ground truth salient concept and an antonym concept. For example:

PersonX puts out a fire. What happens next?

Where our candidate answers would be: *[PersonX wants to receive recognition, PersonX wants to give recognition]*.

A.2.2 MLM

Relational Probes. For inference dimensions relating to PersonX, we map the inference dimensions `xWant`, `xNeed`, `xIntent`, `xReact`, `xEffect`, `xAttr` onto the verbs *wants*, *needs*, *intends*, *feels*, *effect*, and *is*. For example, given the event:

PersonX puts out a fire.

We have the following inference in the `xWant` dimension: *to receive recognition*. We map this onto text for the following probe:

PersonX puts out a fire. PersonX [MASK] to receive recognition.

The correct prediction for [MASK] is *wants*. So for the probe `xWant` vs `xNeed`, our candidate answers for predicting the mask would be *[wants, needs]*.

Table 10: Majority label and fine-tuning results for MLM probes.

For inference dimensions relating to Others, we map the inference dimensions `oWant`, `oReact`, and `oEffect` to the same verbs as before: *wants*, *feels*, and *effect* respectively. We set up probes in the same way as above.

Agent-Patient Probes. We create probes to evaluate whether a model can determine whether an inference dimension is assigned to PersonX or others. For example, consider the following probe:

PersonX puts out a fire. [MASK] wants to receive recognition.

In this example, the correct prediction is *PersonX*. However, in the below probe, the correct prediction is *others*.

PersonX puts out a fire. [MASK] want to thank PersonX.

Both of these probes use the following answer candidates: *[PersonX, others]*. We also remove plurals to ensure that the model does not make predictions using hints from grammar.

Concept Probes. We investigate two kinds of concepts in our probe: event concepts and inference concepts. In event concept probe construction, we find the most salient concept in the event via POS tagging. We then replace this concept with [MASK] and set candidate answers as the ground truth answer and an antonym, as found via WordNet (Miller, 1995). For example, given the event and inference:

PersonX discovers the answer. PersonX feels accomplished.

We identify *discovers* as the most salient concept in the event, and use the lemma from WordNet: *discovery*. We then use this to find a viable antonym: *lose*. Finally, we have the probe:

PersonX [MASK] the answer. PersonX feels accomplished.

And the candidates: *[discovery, lose]*.

We lemmatize the answers to allow for fair prediction between the truth concept and the antonym (which often comes lemmatized from Wordnet).

Similarly, we construct inference concept probes by predicting salient concepts in the inference dimension instead of the event.

A.2.3 Training Setup

We create a training and a development set for each of our probes using the ATOMIC train and dev set.

We show the sizes of our probe dev sets in Table 9. The sizes are directly derived from ATOMIC dev sizes. We train each model using 1 GeForce GTX 1080 Ti GPU.

A.3 Commonsense MLM Probes: Fine-tuned

A.3.1 Setup

We evaluate our MLM probes in a fine-tuned setting. We train on each probe's respective training set and evaluate the max and WS as in Talmor et al. (2019a), which defines (1) max as the maximal accuracy on the learning curve and (2) WS as the weighted average of accuracies on the learning curve, where higher weights are assigned to earlier points on the curve. This is to examine how fast the model learns given its encoding before fine-tuning.

A.3.2 Results

Table 10 compares the performance of BERT and RoBERTa for fine-tuned results.

Fine-tuning Results: After fine-tuning on probe training sets, both models do not fully solve the following categories: `xWant` vs `xIntent`, `xWant` vs `xNeed`, `xReact` vs `xAttr`, and `xIntent` vs `xNeed`. This demonstrates that these commonsense knowledge categories are difficult to learn even with fine-tuning. Additionally, BERT does learn faster than RoBERTa for the following Subject Probes: `xWant` vs `xIntent`, `xNeed` vs `xIntent`, and `xReact` vs `xIntent`. Overall, this illustrates that BERT and RoBERTa do not capture much ATOMIC commonsense in a zero-shot setting, and that many of these relations are difficult to learn even with fine-tuning, including nuanced relations like `xWant` vs `xIntent` and `xWant` vs `xNeed`. Agent-Patient relations seem difficult to learn and do not achieve high final results. Similarly, BERT and RoBERTa perform poorly on Concept Probes in zero-shot setting, however seem to learn these quickly with high final results. Overall, it seems that both models perform comparably for most probes.

A.4 Reproducibility

We train each KS model using 2 GeForce GTX 1080 Ti GPUs. Hyperparameter settings are used from previously reported BERT results on each task (Sap et al., 2019b; Bisk et al., 2020; Da and Kasai, 2019).

Calculating the optimal step of arc-eager parsing for non-projective trees

Mark-Jan Nederhof
School of Computer Science
University of St Andrews, UK
`markjan.nederhof@googlemail.com`

Abstract

It is shown that the optimal next step of an arc-eager parser relative to a non-projective dependency structure can be calculated in cubic time, solving an open problem in parsing theory. Applications are in training of parsers by means of a 'dynamic oracle'.

1 Introduction

A deterministic transition-based dependency parser is often driven by a classifier that determines the next step, given features extracted from the current configuration (Nivre et al., 2004). The classifier may be trained on parser configurations and steps that exactly correspond to 'gold' trees from a treebank. However, better accuracy is generally obtained by also including configurations reached by letting the parser stray from the gold trees, to let the classifier learn how best to recover from any mistakes. This is associated with the term *dynamic oracle*. If the parser is projective while the gold trees are non-projective moreover, then it is unavoidable that configurations be considered that do not correspond to the gold trees.

Determining the desired output of the classifier requires calculation of the best next step given an arbitrary configuration and a gold tree. Typically, this is the step that allows the most accurate tree to be reached, in terms of the gold tree.[1]

For a gold tree that is projective, the optimal step can be determined in linear time for arc-eager parsing (Goldberg and Nivre, 2012, 2013) and for shift-reduce parsing (Nederhof, 2019). For a non-projective gold tree, the optimal step can be determined for several types of non-projective parsers (Gómez-Rodríguez et al., 2014; Gómez-Rodríguez and Fernández-González, 2015; de Lhoneux et al., 2017; Fernández-González and Gómez-Rodríguez, 2018), as well as for shift-reduce parsing (Nederhof, 2019). However, for arc-eager parsing, the problem has been unsolved until now. Aufrant et al. (2018) propose an *approximation* of the optimal step, based on the procedure for projective gold trees, and demonstrate the advantages of training a projective parser directly on non-projective trees.

The current paper introduces an *exact* calculation of the optimal step for arc-eager parsing and a non-projective gold tree, within the same framework as Nederhof (2019), which consists of a generic cubic-time tabular dependency parsing algorithm and a fixed context-free grammar that is applied on a string extracted from the current configuration, with edge weights determined by the gold tree.

For arc-eager parsing, the context-free grammar is considerably more complex than in the case of shift-reduce parsing. This is a consequence of theoretical properties of arc-eager parsing, which we first need to investigate in detail before we can define 'optimality' of the next step.

2 Dependency structures

Let $w = a_1 \cdots a_n$ be a sentence consisting of n tokens, which can be words or punctuation. Where we use indices between 1 and n, we also refer to these as tokens, relying on the assumption that given an index i we can retrieve the actual token a_i. An additional index 0 represents an imaginary token prepended to the sentence.

An *unlabeled dependency structure* T for w is an unlabeled tree with $\{0, 1, \ldots, n\}$ as the set of nodes, of which 0 is the root. We represent such a tree as a set of edges, each represented as a pair (a, b), where index a is the *parent* and index b is the *child*. The *descendants* of a node are the node itself and the descendants of its children. A dependency structure is *projective* if the set of de-

---

[1] There are alternative perspectives on how to determine the best next step; cf. Straka et al. (2015).

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2273–2283
April 19 - 23, 2021.

scendants of each node in the tree can be written as $\{i, i+1, \ldots, j-1, j\}$ for some i and j $(0 \leq i \leq j \leq n)$.

We assume each sentence $w = a_1 \cdots a_n$ has a distinguished *gold* tree T_g. The *score* of an arbitrary tree T for the same w is defined as $|T \cap T_g|$. The *accuracy* of T is its score divided by n.

A dependency parser is usually designed to find a tree that is as accurate as possible, given an input sentence. Such a parser can generally be extended in a natural way to find a *labeled* dependency structure, which is analogously defined as a *labeled* tree with root 0. An edge label in such a structure is called a *dependency relation*. This paper focuses on unlabeled dependency parsing.

3 Transition-based dependency parsing

Transition-based dependency parsing is commonly formalized in terms of a set of configurations and a finite set of transitions between configurations. For now, a *configuration* for input sentence $w = a_1 \cdots a_n$ is a 3-tuple (α, β, T), where α is the *stack*, β is the *remaining input*, and T is a subset of (the set of edges of) a dependency structure. We assume $\alpha\beta$ is a subsequence of $0\ 1\ \cdots\ n$, and β is more specifically a suffix of $1\ \cdots\ n$. A *transition* is a partial function, mapping one configuration to another. A *step* is one application of a transition. A *computation* is a sequence of steps, starting with the *initial* configuration $(0, 1\ \cdots\ n, \emptyset)$ and ending in a *final* configuration $(0, \varepsilon, T)$ where ε denotes the empty string; here T is the resulting tree.

A transition may have a *precondition*, i.e. a condition on the current configuration that must hold for the transition to be applicable. Unrestricted preconditions are less than convenient for our purposes, and therefore we opt for a more uniform framework, in which a stack element is a pair (a, A) consisting of a token a and a *label* A taken from a fixed set.[2] To avoid clutter, we write a^A in place of (a, A); this also emphasizes the relation to more traditional formulations of dependency parsing, which are obtained by omitting the superscripts.

A first illustration of this is traditional shift-reduce dependency parsing, defined by the transitions in Table 1, here without labels, or alternatively, one may consider there to be only one such label, which is left implicit.[3]

shift:
$(\alpha,\ b\beta,\ T) \vdash^{\text{SH}} (\alpha b,\ \beta,\ T)$
reduce_left:
$(\alpha a_1 a_2,\ \beta,\ T) \vdash^{\text{RL}} (\alpha a_1,\ \beta,\ T \cup \{(a_1, a_2)\})$
reduce_right:
$(\alpha a_1 a_2,\ \beta,\ T) \vdash^{\text{RR}} (\alpha a_2,\ \beta,\ T \cup \{(a_2, a_1)\})$,
if $|\alpha| > 0$

Table 1: Shift-reduce dependency parsing.

shift:
$(\alpha a^C,\ b\beta,\ T) \vdash^{\text{SH}} (\alpha a^C b^N,\ \beta,\ T)$
complete:
$(\alpha a^N,\ \beta,\ T) \vdash^{\text{CO}} (\alpha a^C,\ \beta,\ T)$
reduce_left:
$(\alpha a_1^C a_2^C,\ \beta,\ T) \vdash^{\text{RL}} (\alpha a_1^C,\ \beta,\ T \cup \{(a_1, a_2)\})$
reduce_right:
$(\alpha a_1^C a_2^N,\ \beta,\ T) \vdash^{\text{RR}} (\alpha a_2^N,\ \beta,\ T \cup \{(a_2, a_1)\})$,
if $|\alpha| > 0$

Table 2: Shift-reduce dependency parsing enforcing the left-before-right policy.

This form of parsing suffers from spurious ambiguity in that left and right children may be attached in different orders. E.g. if token b has left child a_1 and right child a_2, then after a **shift** of a_1 and b, there may be a **reduce_right** followed by a **shift** of a_2 followed by a **reduce_left**. Or there may be a **shift** of a_2 followed by a **reduce_left** followed by a **reduce_right**. This can be resolved by requiring that left children are attached before right children are. In our framework, this left-before-right policy can be enforced by introducing a label C, which is given to a token to signal that it is 'complete' with regard to its left children. Initially, shifted tokens carry label N (for 'no restriction'). The 0 token always has label C. This results in Table 2.

There is a simple one-to-one correspondence between a computation according to Table 2 and a computation according to Table 1 satisfying the left-before-right policy. The difference is merely an application of **complete** just before a token ceases to be a topmost stack element, either because it is reduced into the token to its left, or because another token is pushed on top. If a token

---

[2] There is a close connection to bilexical context-free grammars (Eisner and Satta, 1999), on the basis of which one may alternatively choose to refer to such a label as a 'delexicalized stack symbol', in a kind of lexicalized pushdown automaton.

[3] Shift-reduce dependency parsing has been known at least since Fraser (1989) and Nasr (1995). It is also referred to as 'arc-standard' parsing (Nivre, 2008).

shift:
$(\alpha,\ b\beta,\ T) \vdash^{\text{SH}} (\alpha b,\ \beta,\ T)$
left_arc:
$(\alpha a,\ b\beta,\ T) \vdash^{\text{LA}} (\alpha,\ b\beta,\ T \cup \{(b,a)\}),$
$\quad$ if $a \neq 0 \wedge \nexists a'[(a',a) \in T]$
right_arc:
$(\alpha a,\ b\beta,\ T) \vdash^{\text{RA}} (\alpha ab,\ \beta,\ T \cup \{(a,b)\}),$
$\quad$ if $\nexists a'[(a',b) \in T]$
reduce:
$(\alpha a,\ \beta,\ T) \vdash^{\text{RE}} (\alpha,\ \beta,\ T),$
$\quad$ if $\exists a'[(a',a) \in T]$

Table 3: Arc-eager parsing (Nivre, 2008, p. 525).

shift:
$(\alpha,\ b\beta,\ T) \vdash^{\text{SH}} (\alpha b^L,\ \beta,\ T)$
left_arc:
$(\alpha a^L,\ b\beta,\ T) \vdash^{\text{LA}} (\alpha,\ b\beta,\ T \cup \{(b,a)\})$
right_arc:
$(\alpha a^X,\ b\beta,\ T) \vdash^{\text{RA}} (\alpha a^X b^R,\ \beta,\ T \cup \{(a,b)\})$
reduce:
$(\alpha a_1^X a_2^R,\ \beta,\ T) \vdash^{\text{RE}} (\alpha a_1^X,\ \beta,\ T)$
reduce_correct:
$(\alpha a_1^X a_2^L,\ \beta,\ T) \vdash^{\text{RC}} (\alpha a_1^X,\ \beta,\ T \cup \{(a_1,a_2)\})$

Table 4: Reformulated arc-eager parsing, with $X \in \{R, L\}$, with an extra fifth transition needed to make it work in practice.

becomes non-topmost and reappears later on top of the stack, after applications of **reduce_left** that give it right children, then it will still have label C, which prevents it from taking further left children.

Table 3 is almost verbatim the formulation of arc-eager parsing by Nivre (2008), except that we renamed symbols, and we ignore dependency relations; the formulations by e.g. Nivre (2003, 2004) and Nivre et al. (2004) are largely equivalent. It is easy to see that the condition $\nexists a'[(a',b) \in T]$ for **right_arc** is redundant, as no tokens in the remaining input can obtain parents before they are shifted to the stack.

Taking shift-reduce parsing as starting point, **reduce_right** corresponds roughly to **left_arc**, while the role of **reduce_left** is only partly fulfilled by **right_arc**, which postulates that b is a right child of a, but without removing b as yet, allowing b to take right children, and only later is that b removed by **reduce**. Here shift-reduce parsing would postpone the decision whether that b is the left or the right child of its parent until all descendants of b have been shifted and reduced into it.

From the perspective of parsing of artificial languages (Sippu and Soisalon-Soininen, 1990), this is counter-intuitive. The conventional wisdom of deterministic parsing is that one should postpone commitment to occurrences of grammar rules (or here, dependency edges) for as long as possible, until enough information is available to resolve any local ambiguity, assuming left-to-right processing of the input string, and the ability to inspect only the top of the stack and the next k tokens of the remaining input, for a fixed, small number k.

Two arguments have been given why arc-eager parsing is nonetheless superior for processing natural language. The first is that this earlier commitment made by **right_arc**, in terms of the earlier creation of the dependency edge, offers additional information about the tree under construction, to better predict the next steps, using some type of classifier. The second argument in favor of arc-eager parsing is that the earlier creation of the dependency edge ensures that the partial tree under construction remains as connected as possible, which may help simultaneous syntactic and semantic processing. See Nivre (2004, 2008) and Damonte et al. (2017) for related discussions.

Next we rephrase arc-eager parsing to use labels to express preconditions, to prepare us for Section 4. Note that a token is transferred from the remaining input to the stack by either **shift** or **right_arc**. In the former case, it must eventually become a left child of its parent, and in the latter case, it becomes a right child. We use labels L and R for these cases.[4] In a configuration with set T as third element, existence of a stack element a^L implies $\nexists a'[(a',a) \in T]$ and a^R implies $\exists a'[(a',a) \in T]$. We thereby obtain the first four transitions in Table 4. Token 0 always has label R, and cannot be popped by **reduce** due to the a_1^X. The fifth transition will be discussed later.

Arc-eager parsing in either of the above two formulations cannot work in practice. The problem is illustrated in Table 5. In the last configuration, none of the steps is applicable. The situation arises when the remaining input becomes empty while there is a L label *anywhere* in the stack. Assuming the classifier used for predicting the next step cannot look unboundedly deep in the stack, this problem is unavoidable.

---

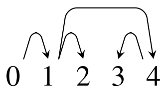
[4] L and R are akin to 0 and 1 from Kuhlmann et al. (2011).

$$\begin{array}{llll}
(0^R & , \; 1\,2\,3, & \emptyset &) \vdash^{\mathrm{SH}} \\
(0^R\,1^L & , \; 2\,3, & \emptyset &) \vdash^{\mathrm{RA}} \\
(0^R\,1^L\,2^R & , \; 3, & \{(1,2)\} &) \vdash^{\mathrm{RA}} \\
(0^R\,1^L\,2^R\,3^R, & , & \{(1,2),(2,3)\} &) \vdash^{\mathrm{RE}} \\
(0^R\,1^L\,2^R & , & \{(1,2),(2,3)\} &) \vdash^{\mathrm{RE}} \\
(0^R\,1^L & , & \{(1,2),(2,3)\} &)
\end{array}$$

Table 5: Arc-eager parsing is stuck in a configuration without applicable transitions.

shift:
$(\alpha,\ b\beta,\ T) \vdash^{\mathrm{SH}} (\alpha b^L,\ \beta,\ T)$
left_arc:
$(\alpha a^L,\ b\beta,\ T) \vdash^{\mathrm{LA}} (\alpha,\ b\beta,\ T \cup \{(b,a)\})$
right_arc:
$(\alpha a^X,\ b\beta,\ T) \vdash^{\mathrm{RA}} (\alpha a^X b^R,\ \beta,\ T)$
reduce:
$(\alpha a_1^X a_2^Y,\ \beta,\ T) \vdash^{\mathrm{RE}} (\alpha a_1^X,\ \beta,\ T \cup \{(a_1,a_2)\})$

Table 6: Corrected arc-eager parsing, with $X, Y \in \{R, L\}$.



$$\begin{array}{lllll}
& (0^R\,1^R\,2^R & , 3\,4, & \emptyset &) \vdash^{\mathrm{SH}} \\
& (0^R\,1^R\,2^R\,3^L, & \;\; 4, & \emptyset &) \vdash^{\mathrm{LA}} \\
& (0^R\,1^R\,2^R & , \;\; 4, & \{(4,3)\} &) \vdash^{\mathrm{RE}} \\
& (0^R\,1^R & , \;\; 4, & \{(1,2),(4,3)\} &) \vdash \ldots \\
\text{or} & & & & \\
& (0^R\,1^R\,2^R & , 3\,4, & \emptyset &) \vdash^{\mathrm{RE}} \\
& (0^R\,1^R & , 3\,4, & \{(1,2)\} &) \vdash^{\mathrm{SH}} \\
& (0^R\,1^R\,3^L & , \;\; 4, & \{(1,2)\} &) \vdash^{\mathrm{LA}} \\
& (0^R\,1^R & , \;\; 4, & \{(1,2),(4,3)\} &) \vdash \ldots
\end{array}$$

Table 7: Same structure obtained in two ways.

One possible fix is to add the **unshift** transition of Nivre and Fernández-González (2014); see also Honnibal and Johnson (2015). As this causes considerable complications to our framework, we will solve this in another way, reminiscent of Honnibal et al. (2013), which also helps to make a connection with shift-reduce parsing later. Our proposed fix is to allow a **reduce** even if the top of stack has label L, by means of the fifth transition of Table 4, **reduce_correct**. This transition is not needed during training if only computations are considered that most straightforwardly correspond to gold trees, with **left_arc** applied only on a token that is to become the left child of its parent. This may mean however that, in the case of labeled dependency parsing, the trained classifier has no basis to predict the dependency relation of the edge created by this transition when applied during testing. This can be solved by moving the creation of the edge from **right_arc** to **reduce**, and by then merging **reduce** and **reduce_correct**, as in Table 6.

This formulation at first sight appears to nullify the property that has been argued to give arc-eager an advantage over shift-reduce parsing, namely the early availability of edges connecting a parent and a right child. However, these edges are still identified by investigating which tokens in the stack have label R: their parent is the token immediately left to it in the stack. In other words, a classifier predicting the next step can be made to have access to the exact same feature values as before.

This formulation of arc-eager parsing, as do the original formulations (Goldberg and Nivre, 2012, p. 963), allow the same dependency structure to be obtained in two different ways; cf. Table 7. There are few studies that compare parsing accuracy between the two ways of resolving this, by preferring either **shift** before **reduce**, or **reduce** before **shift**, and some literature suggests the choice is arbitrary,[5] although the results from one study (Qi and Manning, 2017) suggest the shift-before-reduce policy could be slightly better.

One way to enforce the reduce-before-shift policy is to opt for a different division of labor between stack and the leftmost token of the remaining input, whereby we must shift a node from remaining input to stack before it obtains its first left child or before it is decided whether it is to be a left child or a right child. Table 8 presents this *normalized* arc-eager parsing. The **shift** is now simply the transfer of a token from remaining input to stack, without making a commitment whether it is to become a left or right child, which is indicated by the N label. Where before we had **shift** and **right_arc**, we now have **left_child** and **right_child**, which commit a token on top of the stack to be a left or right child of its parent, respectively. Where before we had **left_arc**, we now have **reduce_right**, and **reduce** is more appropriately renamed to **reduce_left**. There is a simple one-to-one correspondence between a computation according to Table 8 and a computation according to Table 6 satisfying the reduce-before-

---

shift:
$(\alpha a^X,\ b\beta,\ T) \vdash^{\text{SH}} (\alpha a^X b^N,\ \beta,\ T)$
left_child:
$(\alpha a^N,\ \beta,\ T) \vdash^{\text{L}} (\alpha a^L,\ \beta,\ T)$
right_child:
$(\alpha a^N,\ \beta,\ T) \vdash^{\text{R}} (\alpha a^R,\ \beta,\ T)$
reduce_left:
$(\alpha a_1^X a_2^Y,\ \beta,\ T) \vdash^{\text{RL}} (\alpha a_1^X,\ \beta,\ T \cup \{(a_1, a_2)\})$
reduce_right:
$(\alpha a_1^L a_2^N,\ \beta,\ T) \vdash^{\text{RR}} (\alpha a_2^N,\ \beta,\ T \cup \{(a_2, a_1)\})$

Table 8: Normalized arc-eager parsing, with $X, Y \in \{R, L\}$.

shift policy. Moreover, the same feature values can be used, albeit after renaming. Specifically, if the top of stack has label N, then e.g. a feature referring to the top of stack in the case of Table 6 should instead refer to the first element underneath the top of stack in the case of Table 8.[6]

One advantage of the normalized formulation is that it clearly reveals the relation to shift-reduce parsing. In particular, instead of **complete** in Table 2, we have the more specific **left_child** and **right_child**, of which the latter constitutes the early commitment of a token to be right child, as explained before.

4 Calculating the optimal step

Assume there are τ transitions, denoted by $\vdash^1, \ldots, \vdash^\tau$. Let $\vdash$ represent an application of any of these transitions, and let $\vdash^*$ denote the reflexive transitive closure of $\vdash$. For a given configuration (α, β, T) for input sentence w with gold tree T_g, there are up to τ steps $(\alpha, \beta, T) \vdash^i (\alpha_i, \beta_i, T_i)$, $i = 1, \ldots, \tau$. For each of these, the *score* is the maximal $\rho_i = |T'_i \cap T_g|$ with $(\alpha_i, \beta_i, T_i) \vdash^* (0^R, \epsilon, T'_i)$ for some T'_i; if $\vdash^i$ is not applicable on (α, β, T), or if no final configuration is reachable from (α_i, β_i, T_i), then we set $\rho_i = -\infty$. The task is now to compute that ρ_i for each i. This determines which transition to apply next, to eventually obtain the highest-scoring tree, irrespective of any 'incorrect' steps performed in the past, that is, steps that were inconsistent with the gold tree. Because $|T \cap T_g|$ is the same for all i, and because the value of $|T''_i \cap T_g| \leq 1$ with $(\alpha, \beta, \emptyset) \vdash^i (\alpha_i, \beta_i, T''_i)$ is easily determined by a single lookup, the remaining problem is to compute the maximal $\sigma_i = |T'''_i \cap T_g|$ with $(\alpha_i, \beta_i, \emptyset) \vdash^* (0^R, \epsilon, T'''_i)$.

As shown by Goldberg and Nivre (2012, 2013), the optimal step can be determined in linear time for (uncorrected) arc-eager parsing, provided the gold tree is projective. The procedure is defined in terms of *costs* of transitions, rather than in terms of scores. We revisit this in Section 5.

For normalized arc-eager parsing (Table 8) and projective gold trees, the problem appears to be no easier than for shift-reduce parsing, but can still be solved in linear time, by a straightforward refinement of the algorithm by Nederhof (2019), blocking a token from becoming a left child of its parent if its label is R.

Now assume the gold tree may be non-projective. For shift-reduce parsing, Nederhof (2019) presents a cubic-time algorithm for calculating σ_i, generalizing the procedure of Goldberg et al. (2014), which is applicable only on projective trees. The algorithm has a modular design, in terms of a generic tabular dependency parsing algorithm (Eisner and Satta, 1999), plus an explicitly 'split' bilexical context-free grammar (Eisner and Satta, 1999; Eisner, 2000; Johnson, 2007) that encodes computations of shift-reduce parsing. A given configuration is translated to an input string, and weights between pairs of input positions are set according to existence of edges between corresponding tokens in the gold tree. Exhaustive parsing of the string by the grammar, using an appropriate semiring, yields σ_i.

Here we show that the same framework is applicable on arc-eager parsing. The generic tabular dependency parsing algorithm remains the same, but a new grammar is needed to encode computations of arc-eager parsing. Following Nederhof (2019), nonterminals are either single symbols or pairs of symbols, and rules are of one of the forms: $A \rightarrow (B, C)$, $(B, C) \rightarrow a$, $(B', \_) \rightarrow A\ (B, \_)$ or $(\_, C') \rightarrow (\_, C)\ A$, where a is a terminal. The last two forms are shorthand for any rules obtained by consistent substitution of the two underscores; which symbols can be meaningfully substituted is clear from context, as exemplified below.

We start with the normalized form (Table 8), which requires the grammar in Table 9, with the indicated translation from the configuration to an input string. The intuition behind this grammar is similar to the one by Nederhof (2019), but more cases need to be distinguished due to the labels. Grammar symbols R and R_t correspond to tokens

---

[6] The division of labor between stack and remaining input is also what distinguishes Table 2 from the *hybrid model* of Kuhlmann et al. (2011).

1) $(R,R) \rightarrow \boldsymbol{r}$

2) $(R_t,R_t) \rightarrow \boldsymbol{r_t}$

3) $(\_,R_t) \rightarrow (\_,R)\ R_t$

4) $(\_,R_t) \rightarrow (\_,R)\ L_t$

5) $(\_,R_t) \rightarrow (\_,R)\ N$

6) $(\_,R_t) \rightarrow (\_,R_t)\ N$

7) $R \rightarrow (R,R)$

8) $R_t \rightarrow (R,R_t)$

9) $R_t \rightarrow (R_t,R_t)$

10) $(L,L) \rightarrow \boldsymbol{\ell}$

11) $(L_t,L_t) \rightarrow \boldsymbol{\ell_t}$

12) $(\_,L_t) \rightarrow (\_,L)\ R_t$

13) $(\_,L_t) \rightarrow (\_,L)\ L_t$

14) $(\_,L_t) \rightarrow (\_,L)\ N$

15) $(\_,L_t) \rightarrow (\_,L_t)\ N$

16) $L \rightarrow (L,L)$

17) $L_t \rightarrow (L,L_t)$

18) $L_t \rightarrow (L_t,L_t)$

19) $(N,N) \rightarrow \boldsymbol{n}$

20) $(\_,N) \rightarrow (\_,N)\ N$

21) $(N,\_) \rightarrow N\ (N,\_)$

22) $(N,\_) \rightarrow L\ (N,\_)$

23) $(N,\_) \rightarrow L_t\ (N,\_)$

24) $(N,\_) \rightarrow L_b\ (N,\_)$

25) $N \rightarrow (N,N)$

26) $(L_b,L_b) \rightarrow \boldsymbol{\ell_b}$

27) $(\_,L_b) \rightarrow (\_,L_b)\ N$

28) $L_b \rightarrow (L_b,L_b)$

Table 9: Grammar for normalized arc-eager dependency parsing of a string in $\{\boldsymbol{r},\boldsymbol{\ell}\}^{k-1}\{\boldsymbol{r_t},\boldsymbol{\ell_t},\boldsymbol{\ell_b},\boldsymbol{n}\}\boldsymbol{n}^m$, representing a stack of length k and a remaining input of length m. A label R in the top of stack is translated to $\boldsymbol{r_t}$, and other occurrences of R are translated to $\boldsymbol{r}$. A label L in the top of stack is translated to $\boldsymbol{\ell_t}$, unless the candidate transition is **left_child**, in which case it is translated to $\boldsymbol{\ell_b}$; other occurrences of L are translated to $\boldsymbol{\ell}$. A label N in the top of stack is translated to $\boldsymbol{n}$.

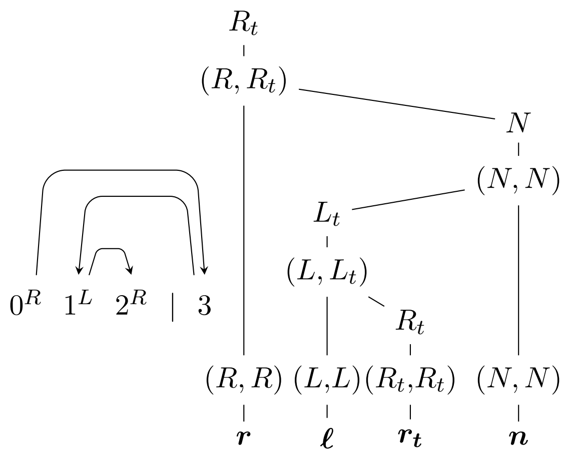

Figure 1: Dependency structure and configuration with stack of height 3 and remaining input of length 1, and corresponding derivation.

in the stack with label R, where R_t specifically means that the token is on top of the stack. Rules (3)–(4) distinguish the two cases $Y \in \{R, L\}$ of **reduce_left** with $X = R$. The rules are best read from right to left, as here for example "if the top of stack has label R or L, and if the token underneath has label R, then the latter keeps its label R and becomes the top of stack". Rules (5)–(6) allow for **reduce_left** with a right child that was in the remaining input, or that was the top of stack with label N. In (6), the underscore can be substituted by R or R_t. In (3)–(5), the only meaningful substitution is by R. Rules (10)–(18) are analogous to (1)–(9). Rules (20)–(21) allow any projective parse of the remaining input (as well as of the top of stack if that had label N), and (22)–(24) handle a token in the remaining input taking a left child in the stack, provided it has label L. In (20)–(24), the only meaningful substitution of the underscore is by N.

If a token has already been given label L, then it becoming a right child by (4) or (13) amounts to correcting a mistake made earlier, and may be necessary so the computation does not get stuck (cf. Table 5). If the next transition to be considered is **left_child** however, which puts L in the top of stack, then we do not wish the corresponding token to become a right child; **right_child** should be applied instead. Label L is then translated to $\boldsymbol{\ell_b}$ with $\boldsymbol{b}$ for 'blocking' (4) and (13).

Figure 1 exemplifies a derivation encoding a computation. A formal proof of correctness is by induction, showing that existence of a subderivation of the grammar implies existence of a corresponding subcomputation with the same score, and vice versa. Cf. the proof sketch by Nederhof (2019) for shift-reduce parsing.

Unnormalized arc-eager parsing (Table 6) requires a different approach, due to the different division of labor between stack and remaining input. We now need to count the number of right children of a token in the stack that were themselves in the stack, up to but not exceeding 1. E.g. rule (5) in Table 10 counts the first right child, but there is no further rule with right-hand side $(\_, R_1)\ R$ to allow a second right child from among the stack elements; other children from the remaining input are allowed, as e.g. by rule (10).

We now also need to observe the chosen policy. With the shift-before-reduce policy, if the candidate transition is **reduce**, then the first symbol of the remaining input becomes $\boldsymbol{n_p}$ ($\boldsymbol{p}$ for 'policy'). There is a notable absence of a rule with right-hand side $N_p\ (N, \_)$, which means that this token cannot become a left child without first taking a child from the stack as by (39) and (43), because if it were, the policy would be violated: the token should have been shifted, and reduced into its parent on the right, *preceding* the **reduce**. There is no restriction on the token becoming a right child, as e.g.

by (4).

A *strict* reduce-before-shift policy implies that a token in the stack should not be reduced into the token to its right if other tokens were previously shifted on top, unless it is to obtain more right children. This is because by the policy, the reduction should have happened earlier. Alternatively we may opt for a *non-strict* reduce-before-shift policy that allows us to correct mistakes made earlier. Either variant uses $\boldsymbol{r_p}$, $\boldsymbol{\ell_p}$, R_p and L_p to enforce the policy. E.g. there are no rules with R_p in the right-hand side, effectively blocking a derivation. Here rules (7)–(9) are needed to give an R-labeled stack element at least one right child, which by (14)–(15) allows the token to participate in a full derivation.

In order to compute the score for arc-eager parsing without our correction (starting in Table 4 with **reduce_correct**), one should omit the rules from Table 10 that correspond to L-labeled tokens becoming right children, i.e. (6), (9), (22), (25). Whether the **unshift** from Nivre and Fernández-González (2014) and Honnibal and Johnson (2015) can be handled in our framework requires further study.

5 Calculation for projective trees

If the gold tree is projective, then the problem becomes much easier. Here we assume the formulation of arc-eager parsing as in Table 6. The number σ_i, as defined in Section 4, for a configuration with stack $\alpha_i = a_1 \cdots a_k$ and remaining input $\beta_i = b_1 \cdots b_m$, can be calculated by counting in the first instance:

- the number of gold edges (a_{p-1}, a_p), where $1 < p \leq k$, plus
- the number of gold edges (a_p, b_q), plus
- the number of gold edges (b_p, a_q), such that a_q has label L, plus
- the number of gold edges (b_p, b_q),

but discounting a number of these, as follows. First, consider the case of the candidate transition being **shift**. If $m = 0$, the score becomes $-\infty$, as there is no available parent for the shifted token. If $m > 0$, we discount a possible gold edge (a_k, b_p) if the rightmost descendant of b_p is b_m, because no projective tree exists in which a_k is a left child while its descendants include the end of the input. We further discount a possible gold edge (a_{k-1}, a_k), because if a_k is to become a right child of a_{k-1}, then the correct step is **right_arc** in place of **shift**.

1) $(R, R) \rightarrow \boldsymbol{r}$
2) $(R_p, R_p) \rightarrow \boldsymbol{r_p}$
3) $(\_, R) \rightarrow (\_, R)\ N$
4) $(\_, R) \rightarrow (\_, R)\ N_p$
5) $(\_, R_1) \rightarrow (\_, R)\ R$
6) $(\_, R_1) \rightarrow (\_, R)\ L$
7) $(\_, R) \rightarrow (\_, R_p)\ N$
8) $(\_, R_1) \rightarrow (\_, R_p)\ R$
9) $(\_, R_1) \rightarrow (\_, R_p)\ L$
10) $(\_, R_1) \rightarrow (\_, R_1)\ N$
11) $(\_, R_1) \rightarrow (\_, R_1)\ N_p$
12) $R \rightarrow (R, R)$
13) $R \rightarrow (R, R_1)$
14) $R \rightarrow (R_p, R)$
15) $R \rightarrow (R_p, R_1)$
16) $R_p \rightarrow (R_p, R_p)$
17) $(L, L) \rightarrow \boldsymbol{\ell}$
18) $(L_p, L_p) \rightarrow \boldsymbol{\ell_p}$
19) $(\_, L) \rightarrow (\_, L)\ N$
20) $(\_, L) \rightarrow (\_, L)\ N_p$
21) $(\_, L_1) \rightarrow (\_, L)\ R$
22) $(\_, L_1) \rightarrow (\_, L)\ L$
23) $(\_, L) \rightarrow (\_, L_p)\ N$
24) $(\_, L_1) \rightarrow (\_, L_p)\ R$
25) $(\_, L_1) \rightarrow (\_, L_p)\ L$
26) $(\_, L_1) \rightarrow (\_, L_1)\ N$
27) $(\_, L_1) \rightarrow (\_, L_1)\ N_p$
28) $L \rightarrow (L, L)$
29) $L \rightarrow (L, L_1)$
30) $L \rightarrow (L_p, L)$
31) $L \rightarrow (L_p, L_1)$
32) $L_p \rightarrow (L_p, L_p)$

33) $(N, N) \rightarrow \boldsymbol{n}$
34) $(N_p, N_p) \rightarrow \boldsymbol{n_p}$
35) $(\_, N) \rightarrow (\_, N)\ N$
36) $(\_, N_p) \rightarrow (\_, N_p)\ N$
37) $(N, \_) \rightarrow N\ (N, \_)$
38) $(N, \_) \rightarrow L\ (N, \_)$
39) $(N, \_) \rightarrow L\ (N_p, \_)$
40) $(N, \_) \rightarrow L_p\ (N, \_)$
41) $(N, \_) \rightarrow L_b\ (N, \_)$
42) $N \rightarrow (N, N)$
43) $N \rightarrow (N, N_p)$
44) $N_p \rightarrow (N_p, N_p)$
45) $(L_b, L_b) \rightarrow \boldsymbol{\ell_b}$
46) $(\_, L_b) \rightarrow (\_, L_b)\ N$
47) $L_b \rightarrow (L_b, L_b)$

Table 10: Grammar for unnormalized arc-eager dependency parsing. With reduce-before-shift, the string is in $\boldsymbol{r}\{\boldsymbol{r}, \boldsymbol{r_p}, \boldsymbol{\ell}, \boldsymbol{\ell_p}\}^{k-2}\{\boldsymbol{r}, \boldsymbol{r_p}, \boldsymbol{\ell}, \boldsymbol{\ell_p}, \boldsymbol{\ell_b}\}\boldsymbol{n}^m$, for stack length k and remaining input length m. Now $\boldsymbol{\ell_b}$ is used if the candidate transition is **shift**, and a non-bottommost symbol to the left of that becomes $\boldsymbol{r_p}$ or $\boldsymbol{\ell_p}$. For a *strict* reduce-before-shift policy moreover, the second to the $k-2$-th symbols become $\boldsymbol{r_p}$ or $\boldsymbol{\ell_p}$, and furthermore the $k-1$-th becomes $\boldsymbol{r_p}$ or $\boldsymbol{\ell_p}$ if the candidate transition is **left_arc** or **reduce**, and furthermore the k-th becomes $\boldsymbol{r_p}$ or $\boldsymbol{\ell_p}$ if the candidate transition is **left_arc**; otherwise, these symbols are $\boldsymbol{r}$ or $\boldsymbol{\ell}$. With shift-before-reduce, the string does not contain $\boldsymbol{r_p}$ or $\boldsymbol{\ell_p}$, and the first $\boldsymbol{n}$ is replaced by $\boldsymbol{n_p}$ if the candidate transition is **reduce**.

Second, if the candidate transition is **reduce**, we discount up to one gold edge in case of the shift-before-reduce policy, as follows, and as illustrated by Figure 2. Let r be largest such that, for some $p > 1$, there is a gold edge (b_p, a_r) where a_r has label L, or there is a gold edge (a_r, b_p); if no such gold edge exists, let $r = 1$. If there is no s ($r < s \leq k$) such that a_s has label L and (a_{s-1}, a_s) is not a gold edge, then we discount any gold edge

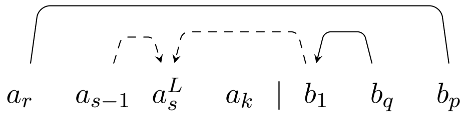

Figure 2: Discounting of (b_q, b_1) if s does not exist.

(b_q, b_1). The rationale is that if b_1 can be given a child from among the tokens in the stack (by a gold edge or otherwise, and without discounting another gold edge elsewhere), then this justifies postponing the **shift** until after the **reduce**. If it cannot be, then b_1 becoming a left child violates the shift-before-reduce policy.

Lastly, if the candidate transition is **shift**, we discount further gold edges in case of the non-strict reduce-before-right policy, which requires a_{k-1} to either become a child of some b_p or take some b_p as child, to justify it not having been reduced into a_{k-2} before the shift.[7] From among the cases to be distinguished, we choose the one that discounts the fewest edges. First, if the label of a_{k-1} is L, we can let it become a left child, but should then discount a possible gold edge (a_{k-2}, a_{k-1}). Second, if there is a gold edge (a_{k-1}, b_p), then no edges need be discounted. Otherwise, we need to find a child b_p of a_{k-1}, for which there are five options, illustrated in Figure 3: (A) The first option is applicable if a_k has descendants among the remaining input or has a parent b_q $(q > 1)$ among the remaining input. In the former case, choose b_p to be the rightmost among the descendants (but let $p = m - 1$ if the rightmost descendant is b_m), and in the latter case choose $p = 1$. In effect we assume non-gold edges (a_{k-1}, b_p) and (b_p, a_k), and consequently we discount any gold edge (b_q, b_p) and any gold edge to a_k. (B1) If a_k has a parent b_q in the remaining input, choose b_p to be b_q. In effect we assume non-gold edge (a_{k-1}, b_q), and consequently we discount any gold edge (a_r, b_q) with $r \leq k-2$ or any gold edge (b_r, b_q), as well as any gold edges (b_q, a_s) with $s \leq k-2$. (B2) If a_k does not have a parent in the remaining input, let b_q be the token immediately to the right of the rightmost descendant of a_k among the remaining input (but let $q = m$ if the rightmost descendant is b_m), and let $q = 1$ if a_k has no descendants among the remaining input. As in (B1), we in effect assume non-gold edge (a_{k-1}, b_q), and discount any gold edge (a_r, b_q) with $r \leq k-2$ or any gold edge (b_u, b_q), as well as any gold edges (b_q, a_s) with $s \leq k-2$.

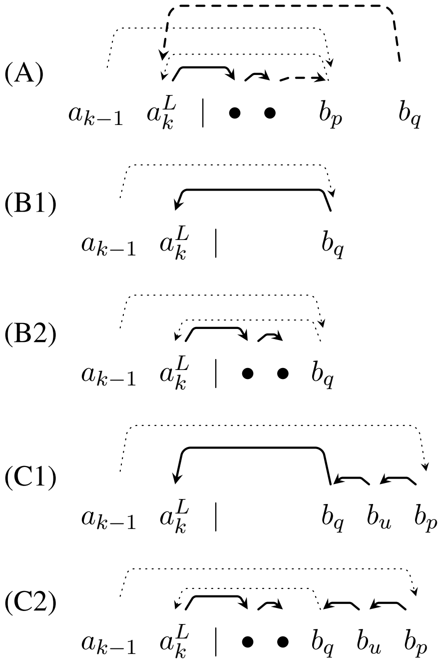

Figure 3: Non-strict reduce-before-shift policy. Bold edges are gold. Dashed edges are discounted. Dotted edges are non-gold.

(C1) and (C2) are similar to (B1) and (B2), but b_p is chosen to be the first ancestor of b_q that does not have a parent in the remaining input (but it may have in the stack). Much as before, we discount any gold edge (a_r, b_p) with $r \leq k-2$, as well as any gold edges (b_u, a_s) with $s \leq k-2$, where b_u is b_q or b_p or any other token on the path of gold edges from b_q to b_p. One can show that choices of b_p other than in (A), (B1), (B2), (C1), (C2) would entail discounting of at least as many edges.

Aufrant et al. (2018) propose approximating the calculation of the optimal step for a non-projective gold tree, by a procedure defined in terms of *costs* of transitions, analogous to the procedure by Goldberg and Nivre (2012, 2013), but without taking full account of edges that violate projectivity. Similarly, if the above procedure to calculate *scores* is applied on a non-projective tree, then an approximation is obtained. The advantage is the simplicity and the linear time complexity.

6 Empirical results

The advantage of ‘dynamic oracles’ for improving parsing accuracy has been demonstrated before. Our experiments have therefore concentrated on

---

[7] The *strict* reduce-before-right policy is more difficult to realize, and discussion is omitted for space reasons.

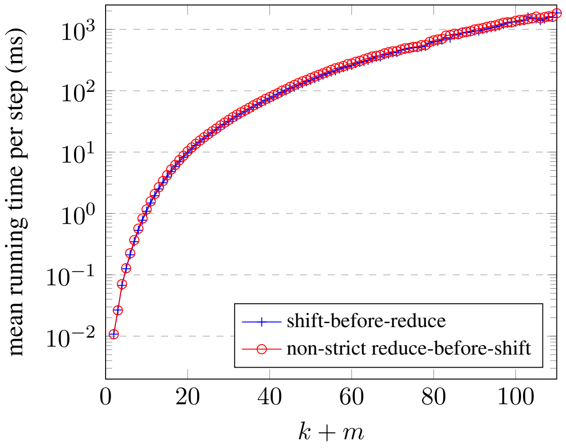

Figure 4: Mean running time per (exact) calculation of the optimal step (milliseconds) against the total length $k+m$ of configurations.

two obvious questions, viz. whether the cubic-time calculation is feasible in practice, and whether the higher time costs are rewarded with a more accurate output, relative to a linear-time approximation of the kind discussed in Section 5.

Considered here is unnormalized arc-eager parsing. The classifier, implemented in Java and DL4J, uses simple features (gold POS of the three rightmost elements of the stack and three leftmost elements of the remaining input, and leftmost and rightmost dependency relations in the topmost two stack elements).

The parser was first trained on configurations corresponding to projectivized gold trees from the German (GSD) corpus of Universal Dependencies v2.2. The trained parser was then applied on the unprojectivized trees, and the optimal step was calculated for each configuration thus visited.

6.1 Running time

Figure 4 presents running time, on a laptop with an Intel i7-7500U processor (4 cores, 2.70 GHz) with 8 GB of RAM. The larger context-free grammar of Table 10, relative to the one for shift-reduce parsing, leads to a higher constant factor in the time complexity. Nonetheless, the calculation is feasible even for long sentences.

6.2 Accuracy of the approximation

In 8.0% and 8.1% of the visited configurations, one or more of the values $\rho_1, \ldots, \rho_4$ for the four transitions differed between the exact calculation (Section 4) and the approximation (Section 5), for the shift-before-reduce and non-strict reduce-before-shift policies respectively. However, we are less interested in the absolute values of the scores than in which of them is highest. Note further that more than one may be equal to their maximum. By comparing the sets of transitions with the maximum calculated score, we found that the true set and the approximate set differed for only 0.4% and 0.5% of the total number of configurations, for the two policies respectively. The most frequent errors are listed in Table 11. Somewhat surprisingly, in the great majority of cases, the approximate set was contained in the true set; these cases sum to 89.0% and 87.8% of the total number of errors, respectively. The implication is that if a parser trained with a 'dynamic oracle' does arbitrary tie breaking between multiple optimal transitions, then there are few immediate prospects to improve parsing accuracy by incorporating the exact calculation. The situation may change if future research reveals better alternatives to arbitrary tie breaking.

exact SH-b.-RE	approximation	proportion

{RE}	{SH,RA,RE}	2.9%

Table 11: Proportions of the seven most frequent errors made by the approximation of the optimal transition(s).

7 Conclusions

Our exact calculation of the optimal step solves an open problem in parsing theory. Further research into the application of 'dynamic oracles' is needed to determine whether this can be exploited to improve parsing accuracy.

Abstract

Contextual word-representations became a standard in modern natural language processing systems. These models use subword tokenization to handle large vocabularies and unknown words. Word-level usage of such systems requires a way of pooling multiple subwords that correspond to a single word. In this paper we investigate how the choice of subword pooling affects the downstream performance on three tasks: morphological probing, POS tagging and NER, in 9 typologically diverse languages. We compare these in two massively multilingual models, mBERT and XLM-RoBERTa. For morphological tasks, the widely used 'choose the first subword' is the worst strategy and the best results are obtained by using attention over the subwords. For POS tagging both of these strategies perform poorly and the best choice is to use a small LSTM over the subwords. The same strategy works best for NER and we show that mBERT is better than XLM-RoBERTa in all 9 languages. We publicly release all code, data and the full result tables at `https://github.com/juditacs/subword-choice`.

1 Introduction

Training of contextual language models on large training corpora generally begins with segmenting the input into subwords (Schuster and Nakajima, 2012) to reduce the vocabulary size. Since most tasks consume full words, practitioners have the freedom to decide whether to use the first, the last, or some combination of all subwords. The original paper introducing BERT, Devlin et al. (2019), suggests using the first subword for named entity recognition (NER), and did not explore different poolings. Kondratyuk and Straka (2019) also use the first subword, for dependency parsing, and remark in a footnote that they tried the first, last, average, and max pooling but the choice made no difference. Kitaev et al. (2019) report similar findings for constituency parsing, but nevertheless opt for reporting results only using the last subword. Hewitt and Manning (2019) take the average of the subword vectors for syntactic and word sense disambiguation tasks. Wu et al. (2020) use attentive pooling with a trainable norm for news topic classification and sentiment analysis in English. Shen et al. (2018) use hierarchical pooling for sequence classification tasks in English and Chinese.

Here we show that for word-level tasks (morphological, POS and NER tagging), particularly for languages where the proportion of multi-subword tokens (i.e. those word tokens that are split into more than one subword) is high, more care needs to be taken as both pooling strategy, and that the choice of language matters. We demonstrate this clearly for European languages with rich morphology, and in Chinese, Japanese and Korean (CJK). Similar to subword pooling, the choice of the lowest layer, the topmost one, or some combination of the activations in different layers has to be made. Here our main focus is subword pooling, but we do discuss layer pooling to the extent it sheds light on our main topic. We observe that the gap between using the first and the last subword unit is larger in lower layers than in higher ones.

We describe our data and tasks in Section 2, and the subword pooling strategies investigated in Section 3. Our results are presented in Section 4, and in Section 5 we offer our conclusions.

Our main contributions are:

- we show that subword pooling matters, the differences between choices are often significant and not always predictable;
- XLM-RoBERTa (Conneau et al., 2019) is slightly better than mBERT in the majority of morphological and POS tagging tasks; while mBERT is better at NER in all languages;

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2284–2295
April 19 - 23, 2021.

- the common choice of using the first subword is generally worse than using the last one for morphology and POS but the best for NER;
- the difference between using the first and the last subword is larger in lower layers than in higher layers and it is more pronounced in languages with rich morphology than in English;
- the choice of subword pooling makes a large difference for morphological and POS tagging but it is less important for NER;
- we release the code, the data and the full result tables.

2 Tasks, languages, and architectures

We investigate pooling through three kinds of tasks. In *morphological* tasks we attempt to predict morphological features such as gender, tense, or case. In *POS* tasks we predict the lexical category associated with each word. In *NER* tasks we assign BIO tags (Ramshaw and Marcus, 1995) to named entities. We chose word-level, as opposed to syntactic, tasks because they can be tackled with fairly simple architectures and thus allow for a large number of experiments that highlight the differences between subword pooling strategies. Our experiments are limited only by the availability of standardized multilingual data.

We use Universal Dependencies (UD) (Nivre et al., 2018) for morphological and POS tasks, and WikiAnn (Pan et al., 2017) for NER. We pick the largest treebank in each language from UD and sample 2000 train, 200 dev and 200 test sentences for the morphological probes and up to 10,000 train, 2000 dev and 2000 test sentences – often limited by the size of the treebank – for POS. We chose languages with reasonably large treebanks in order to generate enough training data, making sure we have an example from each language family, as well as one from European subfamilies since their treebanks tend to be very large. We use 10,000 train, 2000 dev and 2000 test sentences for NER. Preprocessing steps are further explained in Appendix A. Our choice of languages are Arabic, Chinese, Czech, English, Finnish, French, German, Japanese, and Korean. UD's gold tokenization is kept and we run subword tokenization on individual tokens rather then the full sentences.

Morphological tasks UD assigns zero or more tag-value pairs to each token such as `VerbForm=Ger` for 'asking'. We define a probe as a triplet of $\langle$language, tag, POS$\rangle$, i.e. we train a classifier to predict the value of a single tag in a sentence in a particular language.[1] The task $\langle$English, VerbForm, VERB$\rangle$ would be trained to predict one of three labels for each English verb: finite, infinite or gerund. We pick 4 tasks that are applicable to at least 3 of the 6 languages where the task makes sense (there are no morphological tags for Chinese and Japanese, and Korean uses a different tagging scheme). Table 1 lists the probing tasks.

Part-of-speech tagging assigns a syntactic category to each token in the sentence. Usually treated as a crucial low level task to provide useful features for higher level linguistic analysis such as syntactic and semantic parsing. Universal POS tags (UPOS) are available in UD in all 9 languages.

Named entity recognition is a classic information extraction subtask that seeks to identify the span of named entities mentioned in the sentence and classify them into pre-defined categories such as person names, organizations, locations etc. NER was the only token level task explored in the original BERT paper Devlin et al. (2019).

Architectures BERT and other contextual models use subword tokenizers that generate one or more subwords for each token. In this study we compared mBERT and XLM-RoBERTa, two Transformer-based large scale language models with support for over 100 languages. We pick these two since they are architecturally similar (both have 12 layers and the same hidden size) making our comparison easier. mBERT was trained on Wikipedia while XLM-RoBERTa was trained on CommonCrawl (Wenzek et al., 2020). Both models have been extensively applied to English and multilingual tasks, but generally at the sentence or sentence pair level, where subword issues do not come to the fore. mBERT uses a common wordpiece vocabulary with 118k subword units. When a word is split into multiple subword units, each token that is not the first one is prefixed with `##`. XLM-RoBERTa's vocabulary was trained in a similar fashion but with 250k units and a special start symbol (Unicode lower eights block) instead of

---

[1] Consolidating these triplets across POS would be misleading in that the results show large variation across different POS values.

Language	**Tag**	**POS**	**# class**
Arabic	case	NOUN	3
Arabic	gender	ADJ	2
Czech	gender	ADJ	3
Czech	gender	NOUN	3
English	verbform	VERB	4
Finnish	case	NOUN	12
Finnish	verbform	VERB	3
French	gender	ADJ	2
French	gender	NOUN	2

German	case	NOUN	4
German	gender	ADJ	3
German	gender	NOUN	3
German	verbform	VERB	3

Table 1: List of morphological probing tasks. The last column is the number of classes in a particular task.

continuation symbols. Each word is prefixed with this start symbol before it is tokenized into one or more subword units. These start symbols are often then tokenized as single units, particularly before Chinese, Japanese and Korean characters, therefore artificially increasing the subword unit count. We indicate the proportion of words starting with a standalone start symbol along with other tokenization statistics in Table 2.

As Table 2 shows, the number of subword tokens is highly dependent on the language. English words are only split in 14.3% (resp. 16.9%) of the time by the two models, while in many other languages more than half of the words are tokenized into two or more subword units. We hypothesize that this is due to the combination of the characteristics of the English language and its overrepresentation in the training data and the subword vocabulary.

We also observe that the two models' tokenizers work in very different ways. Out of the 2800 morphological test examples, only 58 are tokenized the same way and 51 of these are not split into multiple subwords. Only 7 words that are in fact tokenized, are tokenized the same way. Although the full tokenization is rarely the same, the first and the last subwords are the same in 45.5% and in 44.7% of the cases.

	mBERT		**XLM-RoBERTa**		
	count	2+	count	2+	_start
Arabic	1.95	48.9	1.49	35.0	3.4
Chinese	1.58	53.5	2.13	88.5	86.6
Czech	2.04	53.0	1.7	45.2	1.6
English	1.25	14.3	1.25	16.9	0.8
Finnish	2.32	67.3	1.86	53.0	2.3
French	1.34	22.4	1.41	28.7	2.1
German	1.64	30.6	1.57	29.7	1.3
Japanese	1.6	43.0	2.25	94.6	92.9
Korean	2.44	75.7	2.16	67.3	9.0

Table 2: Subword tokenization statistics by language and model. First and third columns: average number of pieces that one word is split into. Second and fourth columns: proportion of multi-subword words. Last column: proportion of words that start with a standalone start token in XLM-RoBERTa.

3 Subword pooling

We test 9 types of pooling methods listed in Table 3 and grouped in three broad types. The first group uses the first and last subword representations in some combination. In F+L pooling the mixing weight is the only learned parameter. The second group are parameter-free elementwise pooling operations.

Method	**Explanation**	**Params**
FIRST	first subword unit	none
LAST	last subword unit	none
LAST2	concatenation of the last two subword units	none
F+L	$wu_{\text{first}} + (1-w)u_{\text{last}}$	w
SUM	elementwise sum	none
MAX	elementwise max	none
AVG	elementwise average	none
ATTN	Attention over the subwords, weights generated by an MLP	MLP
LSTM	biLSTM reads all vectors, final hidden state	LSTM

Table 3: Subword unit pooling methods. u_{first} and u_{last} refer to the first and the last units respectively.

The last two methods rely on small neural networks that learn to combine the subword representations. Our subword ATTN has one hidden layer of 50 neurons with ReLU activation and a final softmax layer that generates a probability distribution over the subword units of the token. Similarly to self-attention, these probabilities are used to compute the weighted sum of subword representations to produce the final token vector. The LSTM uses a biLSTM (Hochreiter and Schmidhuber, 1997) that summarizes the 768-dimensional vectors (the hidden size of both models) into a 50-dimensional hidden vector in each direction, which are then concatenated and passed onto the classifier. These two are considerably more complicated and slower to train than the other methods, but ATTN works well for morphological tasks, and LSTM for POS tagging in CJK languages. Shen et al. (2018) found hierarchical pooling beneficial, but they investigated sentence level tasks where the subword stream is much longer than in the word-level tasks we are considering (words are rarely split into more than 4 subwords) and hierarchical pooling has better traction.

Layer pooling effects Both mBERT and XLM-RoBERTa have an embedding layer followed by 12 hidden layers. The only contextual information available in the embedding layer is the position of the token in the sentence. Hidden activations are computed with the self-attention layers, therefore in theory have access to the full sentence. We ran our experiments for each layer separately as well as for the sum of all layers. For all tasks, as we move up the layers, results also move up or down in tandem. As exhaustive experiments considering different combinations of layers were computationally too expensive for our setup, and would significantly complicate presentation of our results, we pick a single setting for all experiments by computing the best *expected layer* for each task as

$$\mathbb{E}(L) = \frac{\sum_{l_i \in L} i A(l_i)}{\sum_{l_i \in L} A(l_i)}, \qquad (1)$$

where L is the set of all layers, l_i is the ith layer, and $A(l_i)$ is the development accuracy at layer i. As Figure 1 shows, the expected layers are almost always centered around the 6th layer. Therefore, with the exception of comparing FIRST and LAST, which we analyze in greater detail in 4.1, we chose the 6th layer to simplify the presentation.

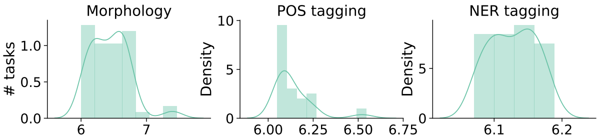

Figure 1: Distribution of the weighted average of layers across all tasks.

Probing setup Every experiment is trained separately, with no parameter sharing between the tasks and the experiments. We probe the morphology on fixed representations with a small MLP (multilayer perceptron) with a single hidden layer of 50 neurons and ReLU activation. We train the same model for POS tagging and NER on top of each token representation. We keep the number of parameters intentionally low, about 40k, to avoid overfitting on the probing data and to force the MLP to probe the representation instead of memorizing the data. We do note, however, that ATTN and LSTM increase the number of trained parameters to 77k and 330k respectively. We run each configuration 3 times with different random seeds. The standard deviation of results is always less than 0.06 for morphology and less than 0.005 for POS and NER. Further details are available in Appendix B.

Choosing the size of the LSTM LSTM is our subword pooling method with the most parameters. The number of parameters scales quadratically with the hidden dimension of the LSTM. We pick this dimension with binary parameter search on morphology tasks. Our early experiments showed that increasing the size over 1000 showed no significant improvement, and a binary search between 2 and 1024 led us to choose a biLSTM with 100 hidden units.

4 Results

Our analysis consisted of two steps. We first performed the FIRST and LAST tasks at each layer (see Figure 2). Based on the results of this, we picked a single layer, the 6th, to test all 9 subword pooling choices. The full list of results on the 6th layer is listed in Appendix C.

4.1 Layer pooling

We find that although LAST is almost always better than FIRST, the gap is smaller in higher layers. We quantify this with the ratio of the accuracy of LAST and FIRST at the same layer. Figure 2 illustrates this ratio for a few selected morphological tasks and POS and NER for all 9 languages. We split the morphological tasks into two groups, Finnish tasks and other tasks. ⟨Finnish, Case, NOUN⟩ shows the largest gap in the lower layers, LAST is 8 times better than FIRST. We observe smaller gaps in other tasks. POS shows a fairly uniform picture with the exception of Korean, where FIRST is worse in all layers and both models. Lower layers in mBERT show a larger gap in Czech and the same is true for Chinese and Japanese in XLM-RoBERTa. NER shows little difference between FIRST and LAST except for the first few layers, particularly in Chinese and Korean. To interpret these results, keep in mind that CJK tokenization is handled somewhat arbitrarily by XLM-RoBERTa, particularly in the first subword (c.f. Table 2).

4.2 Morphology

We present the results of 14 morphological probing tasks (see Table 1) and 9 subword pooling strategies (see Table 3) using the 6th layer of each model.

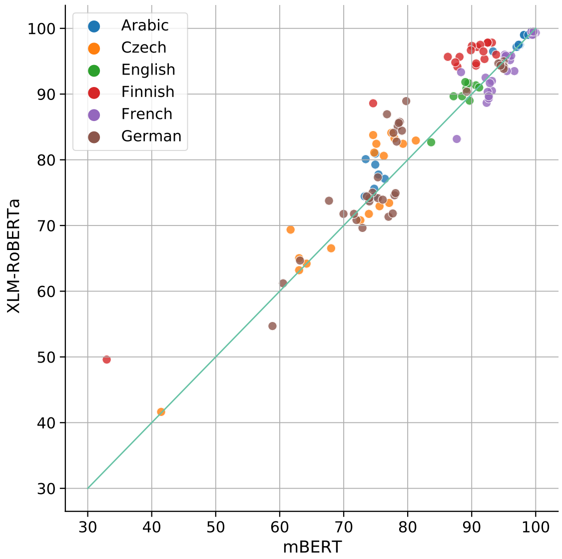

Figure 3: Accuracy of mBERT vs. XLM-RoBERTa on morphological tasks.

mBERT vs. XLM-RoBERTa Averaging over all tasks, XLM-RoBERTa achieves 85.7% macro accuracy while mBERT achieves 83.9%. On a per-language basis, XLM-RoBERTa is slightly better than mBERT except for French. Figure 3 shows our findings. The two models generally perform similarly with the exception of French and Finnish: mBERT is almost always better at French tasks, while XLM-RoBERTa is always better at Finnish tasks. Similar trends emerge when looking at the results by subword pooling method. XLM-RoBERTa is always better regardless of the pooling choice but the difference is only significant ($p < 0.05$) for MAX and SUM.[2] These findings suggest that XLM-RoBERTa retains more about the orthographic presentation of a token, and it uses tokenization that is closer to morpheme segmentation, hence performing better at inflectional morphology, which is most often derivable from the word form alone.

First or last subword? As Figure 4 shows, with the exception of the ⟨Arabic, Case, N⟩ task, LAST is always better than FIRST. We find the largest difference in favor of LAST in Finnish and Czech. Table 4 lists all tasks where the difference between FIRST and LAST is larger than 20% along with the only counterexample (where the difference is about 10% in the other direction). These findings are likely due to the fact that Finnish and Czech exhibit the richest inflectional morphology in our sample.

The exceptional behavior of Arabic case may relate to the fact that case often disappears in modern Arabic (Biadsy et al., 2009). When this occurs the first token, being closest to the previous word, may provide a more reliable indicator, especially if that word was a preposition. Given the complex distribution of Arabic case endings, our sample is too small to ascertain this, and the results, about 75% on a 3-way classification task, are clearly too far from the optimum to draw any major conclusion (note that on Finnish case, a 12-way classification task, we get above 94%[3]).

Other pooling choices While FIRST is clearly inferior in morphology, the picture is less clear for the other 8 pooling strategies. As Figure 5 illustrates, ATTN is better than all other choices for both models but its advantage is only significant over a few other choices. We observe larger – and more often significant – differences in the case of mBERT than in XLM-RoBERTa.

---

[2] We use paired t-tests on the accuracy of the models on the 14 tasks.

[3] Finnish has more than 12 cases but infrequent ones were excluded.

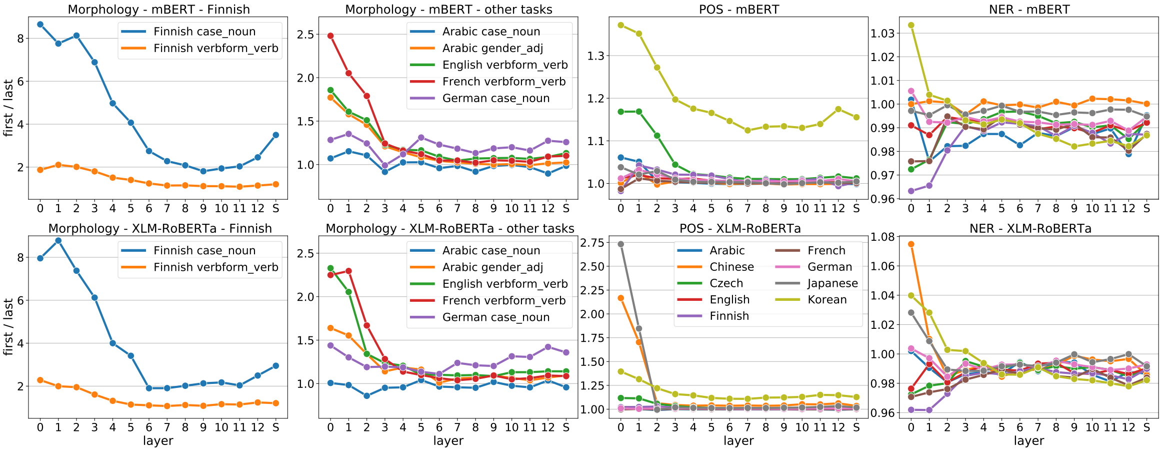

Figure 2: LAST-FIRST ratio of the test accuracy of some morphological tasks and of POS and NER in all languages across all layers. We plot Finnish morphological tasks separately since the effect is so pronounced that presenting them on the same plot would render the scaling uninformative for the other cases. S is the sum of all layers. Note that we do not have a strongly prefixing language due to the lack of available probing data.

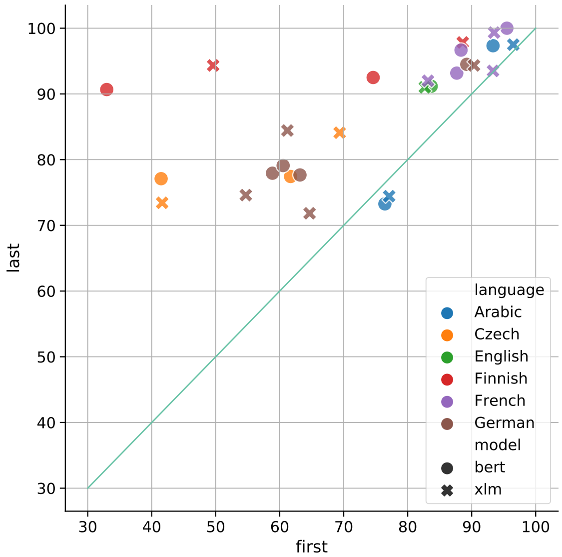

Figure 4: FIRST vs. LAST on morphological tasks.

task	model	first	last
⟨Finnish, Case, N⟩	mBERT	33.0	90.7
⟨Finnish, Case, N⟩	XLM-RoBERTa	49.6	94.4
⟨Czech, Gender, A⟩	mBERT	41.5	77.1
⟨Czech, Gender, A⟩	XLM-RoBERTa	41.6	73.5
⟨German, Gender, N⟩	XLM-RoBERTa	61.2	84.4
⟨Arabic, Case, N⟩	XLM-RoBERTa	77.1	74.5
⟨Arabic, Case, N⟩	mBERT	76.5	73.3

Table 4: Morphological tasks with the largest difference between FIRST and LAST. The two tasks where FIRST is better than LAST are also listed.

	XLM-RoBERTa	mBERT
first	7.1%	6.0%
last	81.5%	83.7%
middle	5.9%	6.3%
single	5.5%	4.0%

Table 5: Distribution of the location of the highest weighted subword. Single refers to tokens that are not split by the tokenizer.

Attention weights The MLP used in ATTN assigns a weight to each subword which are then normalized by softmax. We examine these weights for each token in the test data for morphology. Table 5 lists the proportion of tokens where ATTN assigns the highest weight to the first, last or a middle token, or the token is not split by the tokenizer. The last subword is weighted highest in more than 80% of the cases. The only task where the last subword is not the most frequent winner is ⟨Arabic, Case, N⟩, where the first is weighted highest in 60% of the tokens by both models. These findings are in line with the behavior of FIRST and LAST.

4.3 POS tagging

We train POS tagging models for 9 languages with 9 subword pooling strategies. We evaluate the models using tag accuracy.

mBERT vs. XLM-RoBERTa As with morphological probing tasks, XLM-RoBERTa is slightly better than mBERT (95.4 vs. 94.6 macro average). We also observe that the choice of subword makes less difference than it does in morphological probing. Figure 6 shows that experiments in one language tend to cluster together regardless of the

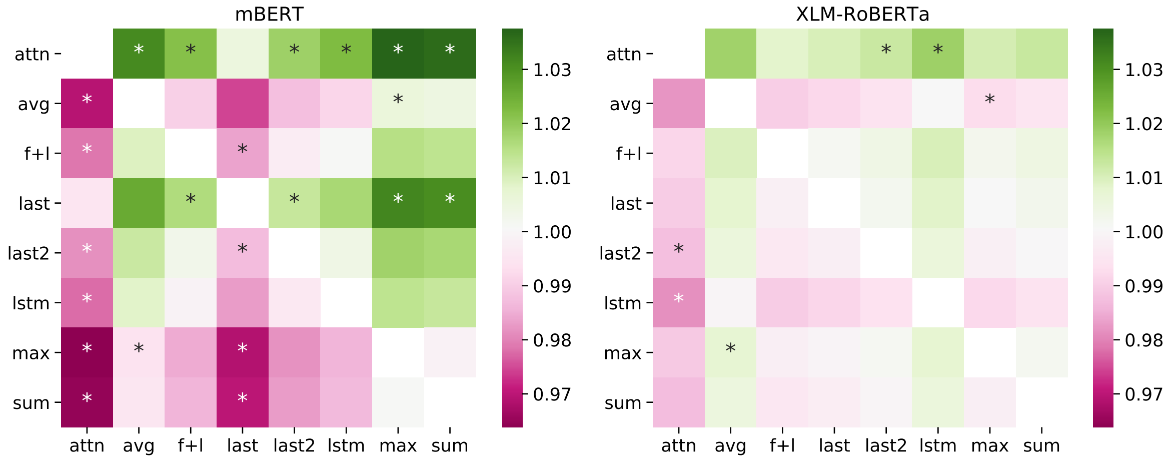

Figure 5: Pairwise ratio of test accuracy by subword choice on morphological tasks. Colors indicate row/column ratios. Green cells mean that the row subword choice yields better results than the column choice. $*$ marks pairs where the difference is statistically significant. ATTN is better than all other choices, therefore its row is green. FIRST is omitted for clarity as it is much worse than the other choices.

subword pooling choice except for a few outliers: FIRST for Chinese and Korean is much worse in both models. The same result can be observed in Japanese, to a lesser extent though. Language-wise we find that XLM-RoBERTa is much better at Finnish and somewhat worse in Chinese but the two models generally perform similarly.

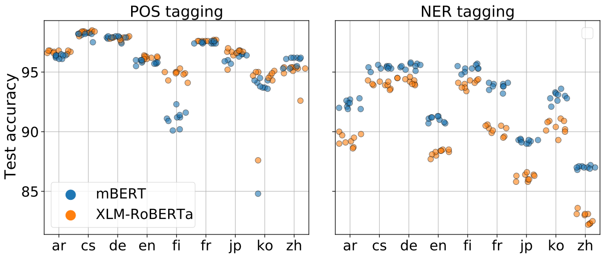

Figure 6: mBERT vs. XLM-RoBERTa for POS tagging and NER.

Choice of subword. As with morphology FIRST the is the worst choice, but the effect is not as marked for POS tasks. In Figure 6 we observe 3 outliers, XLM-RoBERTa, FIRST for Chinese and FIRST for Korean for both models. The only consistent trend is that XLM-RoBERTa is clearly better for Finnish regardless of the choice of subword pooling. The picture is less clear for other languages.

We split the analysis into CJK and non-CJK languages. Figure 7 and Figure 8 show a comparison for non-CJK languages and CJK languages respectively. The difference between choices is generally much smaller than for morphology. FIRST is the worst choice both for CJK and non-CJK languages. Interestingly one of the best choices for morphology, LAST, is the second worst choice for POS tagging, while one of the worst for morphology, LSTM, is one of the best for POS tagging. We hypothesize that this is due to overparametrization for morphology. POS tagging is a much more complex task that needs a larger number of trainable parameters (recall that LSTM parameters are shared across all tokens).

4.4 Named entity recognition

As Figure 6 shows, in NER the choice of subword pooling makes far less difference than in morphology. In terms of models, mBERT has a clear advantage over XLM-RoBERTa when it comes to NER. The difference between the two models is generally larger than the difference between two subword choices within the same language. The smallest difference between the two models appears to be in Czech, Finnish and German, which all have rich, partially agglutinative, morphology. This fits with our earlier findings that showed that XLM-RoBERTa might be better at handling rich morphology. Overall FIRST and the related F+L as well as LSTM come out as winners, the differences are rather small and often not statistically significant for CJK.

4.5 Discussion

Throughout our extensive experiments we observed that pooling strategies can have a significant impact on the conclusions drawn from probing experiments. When considering multiple typologically different languages, the strength of the conclusions

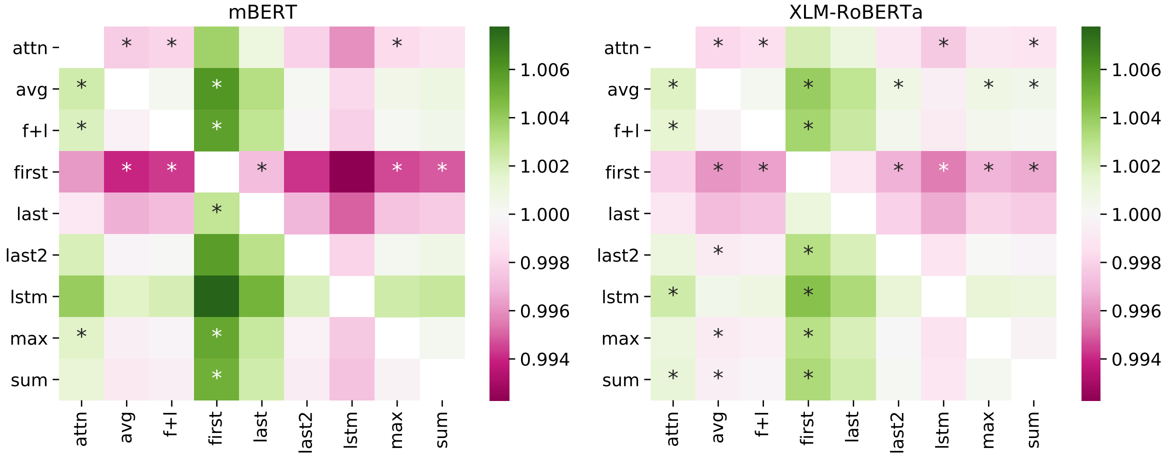

Figure 7: Subword choices for POS tagging in non-CJK languages. See Figure 5 for an explanation of the figure. FIRST is included.

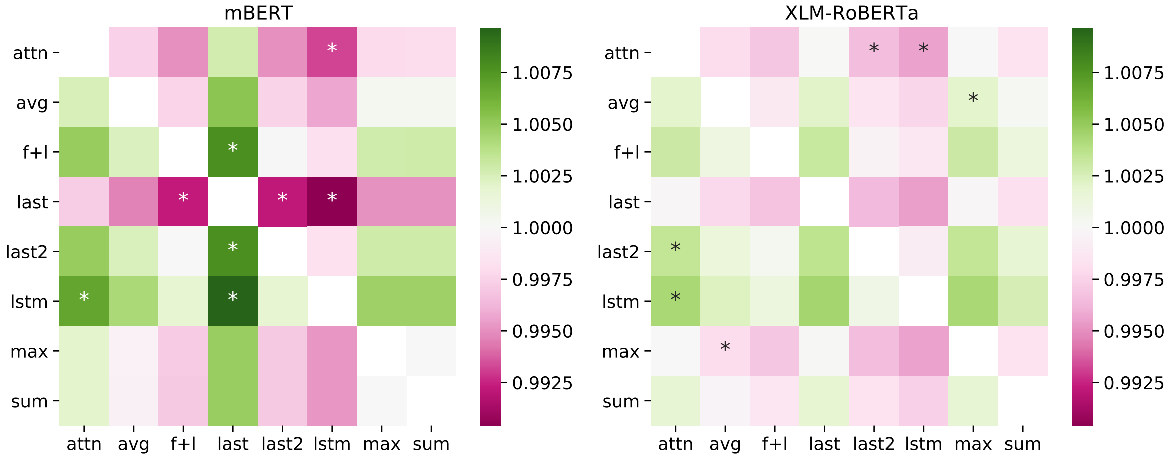

Figure 8: Subword choices for POS tagging in CJK languages. See Figure 5 for an explanation of the figure. FIRST is omitted for clarity as it is much worse than the other choices.

drawn from experiments can be weakened by considering a single pooling option. Our recommendation for NLP practitioners is to try at least three subword pooling strategies, particularly for tasks in languages other than English. FIRST and LAST usually gives a general picture – as a third control we recommend ATTN and LSTM. More complicated tasks such as POS or NER tagging may require LSTM with many parameters, while tasks that rely more on the orthographic representation such as morphology tend to benefit from ATTN.

One of the greatest attractions of the current generation of models is that they do away with labor-intensive feature engineering. Currently, subword pooling acts as the little finderscope mounted on the side of the main telescope to get it to point in the right region, but over the long haul we expect the systems to develop in a way that pooling also becomes part of the end to end process.

Our methodology is only limited by the availability of data. It would be interesting to extend these study with languages that use prefixes too such as Indonesian or Swahili.

5 Conclusion

The key takeaway from our work is that performance on lower level tasks depends on the way we pool over multiple subword units that belong in a single word token. This is more of an issue in languages other than English, where a significantly larger proportion of words are represented by multiple subword units.

Morphological and POS tasks are both probing word-level attributes, but the results show huge disparity: for the morphological tasks FIRST pooling is the worst strategy, and ATTN is the best, while for POS tagging ATTN is almost as bad as FIRST, the best being LSTM. The NER task is intermediary between word- and phrase-level, and subword pooling effects are less marked, but still statistically significant (see the full result tables in the Appendix).

Appendices

A Data preparation

A.1 Morphological probes

We extract 2000 train, 200 dev and 200 test sentences for each task. We keep UD's original splits, in other words, all of our train sentences come from

UD's train set. We sample the sentences in a way that avoids overlaps in target words between train, dev and test splits, in other words, if a word is the target in the train set, we do not allow the same target word in the dev or test set. A target word is the word that needs to be classified according to some morphological tag. We also limit class imbalance to 3:1 at max. This results in the removal of rare tags such as a few of the numerous Finnish noun cases. These restrictions and the size of the treebanks do not allow generating larger datasets.

A.2 POS dataset

We use the largest treebank in each language for POS. The only preprocessing we do is that we filter sentences longer than 40 tokens. Since this results in an uneven distribution in the training size, we limit the number of training sentences to 2000. We note that experiments using 10,000 sentences are underway but due to resource limitations, we were unable to include them in this version of the paper.

A.3 NER dataset

NER is sampled from WikiAnn. WikiAnn is a silver standard large scale NER corpus and the number of sentences is over than 100,000 in each language. We deduplicated the dataset and discarded sentences longer than 40 tokens or 200 character in the case of Chinese and Japanese. WikiAnn annotates Chinese and Japanese at the character level. We aligned this with mBERT's tokenizer and retokenized it. Due to memory constraints, we had to cut off the training data size at 10,000.

B Training details

Each classifier is trained separately from randomly initialized weights with the Adam optimizer (Kingma and Ba, 2014) with $(lr = 0.001, \beta_1 = 0.9, \beta_2 = 0.999)$ and early stopping on the development set. We report test accuracy scores averaged over 3 runs with different random seeds.

We ran about 14,000 experiments on GeForce RTX 2080 GPUs which took 7 GPU days. We cache mBERT's and XLM-RoBERTa's output when possible. We used PyTorch and our own framework for experiment management. We release the framework along with the final submission.

Abstract

We explore the task of quotability identification, in which, given a document, we aim to identify which of its passages are the most quotable, i.e. the most likely to be directly quoted by later derived documents. We approach quotability identification as a passage ranking problem and evaluate how well both feature-based and BERT-based (Devlin et al., 2019) models rank the passages in a given document by their predicted quotability. We explore this problem through evaluations on five datasets that span multiple languages (English, Latin) and genres of literature (e.g. poetry, plays, novels) and whose corresponding derived documents are of multiple types (news, journal articles). Our experiments confirm the relatively strong performance of BERT-based models on this task, with the best model, a RoBERTA sequential sentence tagger, achieving an average ρ of 0.35 and NDCG@1, 5, 50 of 0.26, 0.31 and 0.40, respectively, across all five datasets.

1 Introduction

Unlike in scientific writing, where authors use terse citations due to space constraints, direct quotation of source material is an essential part of writing in many fields. Journalists, humanities scholars, and students, for instance, often quote from a range of source documents, such as interviews, speeches, and books. Quotes can be used to substantiate a claim, lend authority to an argument, or offer a viewpoint to reflect on or argue against, among many others. Modeling the process of quotation selection is thus an important step in modeling how authors compose entire new documents.

In this paper, we explore the problem of quotability identification, identifying which passages in a source work (e.g. *Hamlet*) are likely to be quoted by later, derived works (e.g. humanities journal articles). Prior research has attempted to identify the specific factors that influence a passage or document's quotability. Most work, therefore, has focused on manual feature engineering and development of careful analysis frameworks to test which features have statistically significant relationships to quote counts (Tan et al., 2018; Danescu-Niculescu-Mizil et al., 2012). We, instead, reframe quotability identification as a practical passage ranking task and evaluate how well models can rank the passages in a given document by their predicted quotability. We benchmark and analyze the performances of multiple models, exploring both BERT-based passage ranking models and feature-based models equipped with "quotability" features identified in prior work.

We collect five large-scale datasets to study this problem. Each dataset consists of sets of source documents, derived documents, and alignments between them – the direct quotes. The proposed datasets are diverse, allowing us to model quotability dynamics across multiple source and derived document genres and languages.

Uses for our proposed passage ranking task include: 1) to help users discover quotable source content for use in an essay or article (Tan et al., 2016; MacLaughlin et al., 2021); 2) to select striking quotes from new books to help readers get a sense of them; 3) for use in extractive summaries, search result snippets, and other compressed versions of a text – since quotability implies the ability of a passage to have meaning outside its original source context, quotability scores could be incorporated with traditional measures of informativeness and non-redundancy to determine which passages should be excerpted.

The primary contributions of this paper include:

- We present five large-scale quotability identification datasets (§4) which span multiple

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2296–2314
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

source genres (novels, poems, plays, scripture, etc.) and languages (English, Latin).

- We compare the performance of multiple models (§6) on each of the five datasets: 1) feature-based models with bag-of-words and "quotability" features drawn from prior work (Bendersky and Smith, 2012) and 2) state-of-the-art BERT-based models for passage ranking and sequential sentence tagging. The best performing model, a RoBERTA-based sequential sentence tagger, achieves an average ρ of 0.35 and NDCG@1, 5, 50 of 0.26, 0.31 and 0.40, respectively, across all five datasets.
- We focus on a single source text, the King James Bible, to conduct a thorough analysis (§8.2). We analyze similarities and differences in both quoting patterns and modeling performance across two sets of aligned quoting labels – one from a large collection of 18th-20th century American Newspapers (11M pages), the other from the set of all journal articles in JSTOR (12M articles).

2 Related Work

There has been substantial previous research in identifying and analyzing what makes specific source content popular, i.e. how many times a given source is quoted, cited, retweeted, etc. The source documents analyzed in prior work span a wide range of domains, from political speeches and debates (Tan et al., 2018; Niculae et al., 2015) to books (Bendersky and Smith, 2012), movie scripts (Danescu-Niculescu-Mizil et al., 2012), scientific articles (Guerini et al., 2012; Yogatama et al., 2011), tweets (Hong et al., 2011; Tan et al., 2014), and news articles (Bandari et al., 2012). The aligned derived documents also span multiple domains, from social media (Booten and Hearst, 2016; Danescu-Niculescu-Mizil et al., 2012; Bendersky and Smith, 2012; Bandari et al., 2012; Hong et al., 2011; Tan et al., 2014) to news articles (Tan et al., 2018; Niculae et al., 2015), and scientific papers (Guerini et al., 2012; Yogatama et al., 2011).

Prior work has focused on both 1) predicting the popularity of an entire source document, e.g. a scientific article's citation count (Yogatama et al., 2011) and 2) similar to our work, identifying which specific passages in a given source work will receive the most attention (Tan et al., 2018; Danescu-Niculescu-Mizil et al., 2012; Bendersky and Smith, 2012). The most similar work to ours, Bendersky and Smith (2012), also explores applications of quotability identification models to literary works (Project Gutenberg). However, due to their lack of supervised data, they instead focus on the problem of identifying what sorts of passages are *likely to be* quoted, rather than modeling what sorts of phrases are *actually* quoted in derived works.

The contributions of prior work have been, primarily, feature engineering (e.g. number of personal pronouns, use of negative/positive words) and design of testing frameworks to determine which features have a statistically significant relationship to quotablity/popularity in a *single language* and in a *specific domain of interest* (e.g. English language movie quotes and their popularity on IMDB: Danescu-Niculescu-Mizil et al. (2012)). Unlike prior work, our main contributions are not feature engineering, but a re-framing of the task as a practical document-level ranking task and an analysis of several models through extensive experiments with multiple datasets spanning various source and derived document genres and languages.

3 Problem Formulation

We formulate quotability identification as passage ranking, identifying which passages in a source document are likely to be quoted in related derived works. We measure quotability directly by counting how many times a passage is quoted across a collection of derived texts. Concretely, given a source document and a set of derived texts, we –

1. Use fuzzy text alignment methods from text reuse detection, e.g. Smith et al. (2015), to identify alignments (quotes) between subsequences in the source and derived texts.
2. Split the source text into passages (e.g. prose: by sentence, poetry: by verse, plays: by line).
3. Map the starts and ends of the (source, derived) alignments, i.e. quotes, to specific source passages.
4. Label each source passage with the number of alignments that overlap it.
5. Learn to rank the passages by their quote count labels.
6. Measure how well a model can rank the passages in a source document w.r.t. each other.

4 Datasets

We have collected five datasets across two languages (English, Latin) and multiple genres (novels, poems, plays, scripture, etc.) to study this problem. Each dataset consists of source texts (e.g. Shakespeare's plays, books of the Bible) and a set of alignments to a corpus of derived documents (e.g. humanities journal articles, news articles). Each alignment is an instance where a derived work quotes a passage(s) in a specific source work, e.g. an author quotes from *Hamlet*, "To be, or not to be: that is the question," in a humanities journal article.

4.1 Source Document Datasets

We use four publicly available[1] source document datasets:

- **King James Bible (KJB)**: the standard English Bible from the mid-17th to the early 20th century, consisting of 66 books (Old and New Testaments, no Apocrypha), with an average of 471 verses per book (median 217).
- **Shakespeare (SHAK)**: Shakespeare's 38 plays, with an average of 3,284 lines per play (median 3,246).
- **American & British Literature (ABL)**: a collection of 70 American and British great works from the 17th-20th centuries, containing books (e.g. *Emma*), poetry (e.g. "Eve of St. Agnes"), essays (e.g. "On The Duty of Civil Disobedience"), speeches (e.g. "I Have a Dream"), and legal documents (e.g. US Constitution), with an average of 6,165 passages per work (median 5,457).
- **Latin Texts (LAT)**: a collection of 329 works of prose and poetry from the Perseus Digital Library (Crane, 2001), with an average of 1,832 sentences per document (median 853).

As seen in Table 1, there is substantial variation across the four datasets, both in terms of total numbers of documents and passages in each dataset and in median numbers of passages per document and tokens per passage. For example, LAT contains a relatively large number of documents and passages, but each document is relatively short (median 853 passages/doc). ABL, on the other hand, contains roughly 5x fewer documents, but each document contains roughly 6x more passages (median 5,457). Passages in KJB are the longest (median 27 tokens), but documents in KJB contain the smallest number of passages (median 217). See Appendix A for lists of the source documents in each dataset.

4.2 Derived Documents

We work with three collections of derived documents which discuss and quote from the above source documents (see Table 2 for more details):

- **Chronicling America (CA)**: A publicly available collection of roughly 11 million historic (1789-1963) newspaper pages from the Library of Congress's Chronicling America collection (Library of Congress, 2005).
- **JSTOR: Early Journal Content (EJC)**: A publicly available subset of the entire JSTOR collection, containing approximately 644k articles published prior to 1923 in the United States and prior to 1870 elsewhere.
- **JSTOR: All (JA)**: The entire JSTOR journal collection, consisting of over 12 million academic journal articles (not publicly available).

4.3 Source-Derived Alignments

We use three different sets of alignments between our source and derived document collections to generate labels for our datasets[2]:

- **KJB - CA**: alignments from America's Public Bible (Mullen, 2016). Using text reuse detection methods, Mullen (2016) identified quotations of the Bible or verbal allusions to specific biblical verses in newspapers from the Chronicling America collection. There are a total of 866,127 quotes from 383,387 unique pages across 1,706 different newspapers.
- **JSTOR Understanding Series**: alignments from the JSTOR Understanding Series (JSTOR Labs, 2019). The JSTOR Labs team created a database of all quotations within JSTOR, then, using text reuse detection methods, aligned those quotations to passages in a number of great works, including the King James Bible, Shakespeare, and American and British Literature datasets. JSTOR has provided us with the set of all alignments. There are a total of 65,093 quotes from 30,876 derived documents aligned to the Bible, 131,712 quotes from 24,060 derived documents aligned to Shakespeare's plays, and 130,582 quotes from

---

[1] KJB: Wikitext, ABL: Wikitext & Project Gutenberg, SHAK: Folger Shakespeare Library, LAT: Perseus

[2] The KJB-CA alignments (Mullen, 2016), the CA collection (Library of Congress, 2005) and the EJC are available for download. We also release processed, labeled versions of our KJB-CA and LAT-EJC datasets for download here. We are unable to release any JA data.

Source	Lang	Genre	Passage Type	# Docs	# Passages	Mdn # Passages / Doc	Mdn # Toks / Passage
KJB	en	Scripture	Verse	66	31,102	217	27
SHAK	en	Play	Line	38	124,809	3,246	9
ABL	en	Various	Verse, Sentence	70	431,580	5,457	19
LAT	la	Various	Sentence	329	602,676	853	13

Table 1: Summary statistics for the four source document datasets – King James Bible (KJB), Shakespeare's plays (SHAK), and collections of great works of literature from America and Britain (ABL) and the ancient Roman world (LAT).

Derived	Doc Type	# Documents
CA	newspaper pages	≈ 11,000,000
EJC	journal article	138,636
JA	journal article	≈ 12,000,000

Table 2: Summary statistics for the three derived document datasets – Chronicling America (CA), JSTOR: Early Journal Content (EJC) and JSTOR: All (JA).

28,986 derived documents aligned to the collection of American and British literature.

- **LAT - EJC**: We use the passim text alignment software (Smith et al., 2015) to detect quotes of the Latin texts in the JSTOR EJC using the Smith–Waterman alignment algorithm. This yielded a total of 124,679 aligned quotes from 26,619 derived journal articles.

As noted above, given a source document, a collection of derived documents, and set of alignments between the source and derived texts, we split the source into passages (sentences/lines/verses/etc) then count the number of times each passage is aligned to (in part or wholly) a distinct portion of a derived text. We then use these quote counts to label each passage in the source. See Appendix B for discussion of the implementation and accuracy of the different alignment-detection models.

As seen in Table 3, there is substantial variation across datasets with respect to the total number of aligned quotes and the proportion of source passages that are quoted. On one end of the spectrum, since there are many alignments between KJB and CA and KJB is a relatively small source (in terms of number of passages), 84% of source passages in the KJB-CA alignment dataset are quoted at least once, the median passage is quoted five times, and the median document contains a maximal passage quoted 480 times. On the other end of the spectrum, the ABL and LAT source datasets both contain a large number of passages, and there are relatively few alignments, leading to significantly sparser ABL-JA and LAT-EJC alignment datasets. Only 18% (ABL) and 25% (LAT) of passages are quoted at least once, and the median documents contain maximal passages quoted 43 (ABL) and 7 (LAT) times. In the middle are the KJB-JA and SHAK-JA datasets, where slightly over half of the passages are quoted at least once, the passages in the 75th percentile are quoted three times, and the median documents contain maximal passages quoted 30 (KJB-JA) and 53 (SHAK-JA) times.

5 Linguistic Attributes of Quotations

As a first step at modeling the quotability identification problem, we draw on quotability features from prior work (Bendersky and Smith, 2012; Danescu-Niculescu-Mizil et al., 2012; Tan et al., 2018) and attempt to identify which linguistic attributes influence passage quotability. We explore both lexical (e.g. passage begins with a stop word) and part of speech features (e.g. contains past tense verb).

For each dataset, we featurize each of the corresponding passages, then compare its highly-quoted (top 20%) and minimally-quoted (bottom 20%) passages. We use Welch's t-test with Bonferroni correction to test whether the scores for each feature are significantly different between the two groups.

Table 4 discusses each feature and the associated statistic and significance for each dataset. Most features' relationship with quotability varies across the five datasets. For instance, highly-quoted passages are *shorter* in KJB-CA, but *longer* in other datasets. We suspect this reflects a difference between a popular audience (CA) who might prefer short Bible verses with a succinct message vs. academia (JSTOR), where writers are focused on careful passage analysis and less space-constrained. We also observe differences between the two KJB datasets and the other datasets. In the KJB, the relationship between quotability and presence of dialogue words (says, etc.) is positive, but negative in the others. This difference may be because many important Bible verses report direct speech by Jesus or God, whereas the other datasets, e.g. ABL, contain many uninteresting dialogue passages that serve to move the story along (e.g. "'No,' said the boy").

Source	Derived	# Aligned Derived Quotes	# Aligned Derived Docs	# Quotes / Source Passage Q_1	Q_2	Q_3	Max	% Passages w/ ≥ 1 Quote	Mdn Max # Quotes / Doc
KJB	CA	866,127	383,387	1	5	19	4,949	84%	480
KJB	JA	65,093	30,876	0	1	3	303	58%	30
SHAK	JA	131,712	24,060	0	1	3	905	58%	53
ABL	JA	130,582	28,986	0	0	0	1,536	18%	43
LAT	EJC	124,679	26,619	0	0	0	62	25%	7

Table 3: Summary statistics for the five sets of source-derived alignments. Each set of alignments is between one source dataset (KJB, SHAK, ABL, LAT) and one derived document dataset (CA, JA, EJC). Each source passage is labeled by the total number of times it is quoted in the corresponding derived documents. # Quotes / Source Passage measures of how many quotes each source passage receives - we display the first, second and third quartiles and the max for passages across the entire source dataset. % Passages w/ $\geq$ 1 Quote measures what percentage of passages in the source dataset have at least 1 aligned quote. To calculate Mdn Max # Quotes / Doc, we find the most quoted passage in each document in the source dataset, then take the median over those quote counts.

Feature Set		KJB-CA	KJB-JA	SHAK-JA	ABL-JA	LAT-EJC
Length: Number of tokens in passage. (Bendersky and Smith, 2012)	# Words	↓↓↓↓	↑↑↑↑	↑↑↑↑	↑↑↑↑	↑↑↑↑
Capitalized: Proportion of words capitalized (Bendersky and Smith, 2012).	% Capital	↓↓↓↓	↓↓↓↓	↓↓↓↓	↓↓↓↓	↑↑↑↑
Stop Words: 1) Proportion of words in passage that are stop words, 2) Binary feature if passage begins with a stop word (Bendersky and Smith, 2012).	% Stop	–	↑↑↑↑	↑↑↑↑	↑↑↑↑	↓↓↓↓
	Begin-Stop	–	–	–	↑↑	↓↓↓↓
Generality: 1) Proportion of words in passage that are indefinite articles 2) Binary feature if passage contains an abstract noun (Bendersky and Smith, 2012; Danescu-Niculescu-Mizil et al., 2012; Tan et al., 2018).	% Indefinite	↑↑↑↑	↑↑↑↑	↑↑↑↑	↑↑↑↑	×
	Abstract	↑↑↑↑	↑↑↑↑	↑↑↑↑	↑↑↑↑	×
Universal Quantifiers: Binary feature if passage contains a universal quantifiers (20 quantifiers, e.g., all, whole, nobody). (Bendersky and Smith, 2012).	Universal	↑↑↑↑	↑↑↑↑	↑↑↑↑	↑↑↑↑	×
Pronouns: Proportion of words in passage that are first, second, or third person pronouns (Tan et al., 2018).	% 1st	↑↑↑↑	↑↑↑↑	–	↓↓↓↓	↑↑↑↑
	% 2nd	↑↑↑↑	↑↑↑↑	↓↓↓↓	↓↓↓↓	↑↑↑↑
	% 3rd	–	↓↓↓↓	↓↓↓↓	↓↓↓↓	×
Language Model: We compute the ratio between the log-likelihood of the passage under a LM trained on a collection of popular quotes and one trained on a background corpus (Bendersky and Smith, 2012, eq. 1). The more likely a passage is under the quotable LM relative to the background LM, the higher the ratio will be (Danescu-Niculescu-Mizil et al., 2012; Tan et al., 2018).	LLR	↑↑↑↑	↑↑↑↑	↑↑↑↑	↑↑↑↑	×
Dialogue Words: Binary feature if passage contains a dialogue word (e.g. says, dicit). (Bendersky and Smith, 2012)	Dialogue	↑↑↑↑	↑↑↑↑	↓	↓↓↓↓	↓↓↓↓
Emphasis: 1) Binary feature if passage contains a comparative adjective or adverb form, 2) Binary feature if passage contains a superlative adjective or adverb form (Bendersky and Smith, 2012; Tan et al., 2018).	Comparative	↑↑↑↑	↑↑↑↑	↑↑↑↑	↑↑↑↑	↑↑↑↑
	Superlative	↑	–	↑↑↑↑	↑↑↑↑	↑↑↑↑
Verb Tenses: Proportion of words in passage that are past or present tense verbs (Bendersky and Smith, 2012; Danescu-Niculescu-Mizil et al., 2012).	Past	–	↓↓↓↓	↑↑↑↑	↓↓↓↓	↑↑↑↑
	Present	↑↑↑↑	↑↑↑↑	↓↓↓↓	–	↓↓↓↓

Table 4: Results from examination of linguistic attributes of quotations. Upward arrows indicate that frequently quoted passages (top 20% of source passages by # of quotes) have larger scores in that feature, while downward arrows indicate that passages with very few or no quotes (bottom 20% of source passage by # of quotes) have larger scores in the feature (↑↑↑↑: $p < 0.0001$, ↑↑↑: $p < 0.001$, ↑↑: $p < 0.01$, ↑: $p < 0.05$). p refers to the p-value after the Bonferroni correction. × indicates that the feature set is not available for the corresponding dataset. A '–' symbol indicates that there is no significant relationship.

While there are no features whose relationship with quotability is negative across all datasets, there are a few that are consistently significantly positive: **1) general language:** highly-quoted passages contain more general language which can be more easily adapted to a new contexts, such as indefinite articles and abstract concepts (e.g. adventure, charity); **2) universal quanitifiers:** similar to maxims, proverbs and other short, pithy statements, quotable phrases often contain universal quantifiers (e.g. always, never); **3) comparative adjectives:** highly-quoted passages use more comparative adjectives to compare a noun to something else; **4) language model**: quotable phrases have higher likelihoods under our quotable language model than a background language model trained on the corresponding source corpus.

6 Models

Next, we examine the effectiveness of two classes of models on our passage ranking task: feature-based models with "quotability" features and neural models for sentence classification. We benchmark both pointwise regression models for count data and listwise and pairwise ranking models.

6.1 Feature-based

We evaluate three feature-based models: **poisson regression**, **SVM^{rank}** (Joachims, 2002) and **lambdaMART** (Burges, 2010). Poisson regression (PR) is a generalized linear model for count data, SVM^{rank} is a commonly used pairwise feature-based ranker, and lambdaMART (λMART) is a state-of-the-art feature-based listwise ranker. Each feature-based model uses the same set of features: **bag-of-word features**, **"quotability" features** (Bendersky and Smith, 2012; Danescu-Niculescu-Mizil et al., 2012; Tan et al., 2018, Including the features discussed in §5), and **positional features** (e.g. relative position in book). See Appendix E for a list of all features.

6.2 BERT-based

BERT-based models (Devlin et al., 2019) have recently achieved state-of-the-art performance on multiple sentence classification tasks, including single sentence classification, e.g. sentiment analysis, and classification of a sequence of sentences into their corresponding categories, e.g. extractive summarization (Liu and Lapata, 2019) and scientific abstract sentence classification (Cohan et al., 2019). We work with two BERT-based models, RoBERTA (Liu et al., 2019) and XLM-RoBERTA (XLM-R) (Conneau et al., 2019). We fine-tune RoBERTA on our English datasets and XLM-R on the Latin dataset. We benchmark both models as both single passage and sequential passage predictors:

- **RoBERTA**$_{single}$ **/ XLM-R**$_{single}$: we fine-tune RoBERTA and XLM-R on individual passages. Thus, each training example contains a single passage and its quote count label. We follow the standard fine-tuning setup, using the final hidden state of the [`CLS`] token as the aggregate representation for a passage and feeding it into an output layer for prediction.

- **RoBERTA**$_{seq}$ **/ XLM-R**$_{seq}$: in order to model a passage's context in the broader document, we also fine-tune RoBERTA and XLM-R as passage-level sequence taggers (Cohan et al., 2019). Due to the models' 512 WordPiece length limit, we break up each document into 512 WordPiece segments and feed those into the models independently. Thus, each training example contains some number n of consecutive passages from the same work (up to 512 WordPieces total) and n quote count labels, one for each passage. Following Cohan et al. (2019), we insert a [`SEP`] token between each of the n passages in each example. We use the final hidden state of each [`SEP`] token as the aggregate representation for each passage and feed it into a multi-layer feedforward network to make a prediction.

Since we are modeling quote counts for each passage, we train all $single$ and seq models with poisson negative log likelihood loss.

Finally, since our task is a ranking task, we also benchmark a BERT-based pairwise ranker, as pairwise neural rankers have shown strong performance on other ranking tasks, such as ad-hoc retrieval (Xiong et al., 2017; Dai et al., 2018):

- **RoBERTA**$_{pair}$ **/ XLM-R**$_{pair}$: Each training example consists of two passages sampled from the same work and a single label for the pair based on which passage is quoted more. Each passage is fed into RoBERTA or XLM-R separately and follows the standard fine-tuning setup as described for RoBERTA$_{single}$.

We train RoBERTA$_{pair}$ and XLM-R$_{pair}$ with hinge loss: $\mathcal{L}(s^+, s^-; \Theta) = max(0, 1 - f(s^+) + f(s^-))$, where passages s^+ and s^- are from the same document, s^+ is quoted more than s^-, and $f(s)$ is the output of running passage s through RoBERTA/XLM-R and the final output layer.

For all neural models, we also add special tokens to each passage to act as positional indicators so the model has a better sense of which part of the document it is reading (Alberti et al., 2019). These special tokens vary by dataset, but are generally added to the start or end of a passage and have forms such as [`Starts-Paragraph`], [`Ends-Act`], or [`Book@N`] where `N` is the decile in the book in which the passage occurs. See Appendix F for the full list of positional tokens used in each dataset.

7 Experimental Settings

We evaluate models using five-fold cross validation. We train and evaluate models on each dataset separately and report means over the five folds for each. We split datasets into folds at the document level (e.g. train: *Frankenstein*, etc., val: *Emma*, etc., test: *Paradise Lost*, etc.). Then, for a given validation or test set, we evaluate performance on each document separately, then average over documents.

For the feature-based models, we select hyperparameters by performing nested five-fold cross validation on each fold's training set, again splitting by document. Due to computational restrictions, for the neural models we select hyperparameters by using 20% of the documents in the fold's training set as a validation set. See Appendix H for a list of all hyperparameters.

7.1 Evaluation Metrics

Since our task is a passage ranking task, we evaluate models using two common ranking metrics: average NDCG@k (Croft et al., 2009) and spearman's ρ. NDCG@k is defined as $\frac{DCG_k}{IDCG_k}$, where $DCG_k = quoted_1 + \sum_{i=2}^{k} \frac{quoted_i}{log_2(i)}$ and $quoted_i$ is the number of times the passage ranked in the ith position by the model has been quoted across all corresponding derived documents, and $IDCG_k =$ the ideal DCG_k, the maximum DCG_k computed by ranking passages by their true quote counts. We evaluate NDCG@k at six ranks, $k \in [1, 3, 5, 10, 25, 50]$. We calculate both NDCG and ρ at the document level, i.e. ranking a passage in a document versus all other passages in that document, then average across documents.

8 Results & Analysis

Tables 5 and 6 display the results of all models across all five datasets[3]. On the whole, we find that modeling a passage's context in its broader document is important, with the BERT-based sequential sentence models RoBERTA$_{seq}$ and XLM-R$_{seq}$ performing the best. They achieve the highest average NDCG score across all ranks k on three datasets (KJB-CA, SHAK-JA, LAT-EJC) and the highest ρ on all five datasets. The sequential sentence models achieve their highest *relative* performance on SHAK-JA, outperforming the second-best models by roughly 40% relative on NDCG and 19% on ρ.

Similar to results on other passage ranking tasks (Nogueira and Cho, 2019; Qiao et al., 2019), we find that the single passage BERT-based models (RoBERTA$_{single}$, XLM-R$_{single}$) provide strong baselines, outperforming the feature-based models on nearly all datasets and achieving the second-best overall performance. Furthermore, on KJB-JA, RoBERTA$_{single}$ achieves the best NDCG performance, outperforming RoBERTA$_{seq}$ by an average of 0.02 across each k. Investigating the KJB-JA results further, we find that Roberta$_{single}$ outperforms Roberta$_{seq}$ on 34 of the 64 KJB books. Of these 34, five books (Numbers, Revelation, Zechariah, Leviticus, and Peter-1) account for over a third of the total increase in NDCG over Roberta$_{seq}$. In four of the five books, Roberta$_{single}$ successfully ranks the most quoted passage at the top, while Roberta$_{seq}$ ranks passages with single- or near-single-digit labels. Notably, Roberta$_{seq}$ fails, while Roberta$_{single}$ succeeds, in properly ranking the Great Commandment from Leviticus 19:18 "... love thy neighbour as thyself" at the top.

On the other hand, the pairwise BERT-based models (RoBERTA$_{pair}$, XLM-R$_{pair}$) generally perform worse than the single passage and sequential passage BERT-based models. They struggle to identify the top, most quoted passages in each document (as measured by NDCG), but perform relatively better at ranking each document's entire list of passages w.r.t each other (ρ), though still worse than the sequential passage models.

Among the feature-based models, while SVM^{rank} achieves the highest ρ on all five datasets, no single model consistently outperforms the others in NDCG, with PR, SVM^{rank}, and λMART each achieving the highest scores on different datasets. However, only one feature-based model, λMART, ever outperforms the neural models, achieving the highest NDCG scores on ABL-JA. We hypothesize that λMART's strong performance on ABL-JA might be due, in part, to differences in the accuracy of our feature-extraction pipeline. Many of our features depend on accurate parsing (e.g. POS and verb tense counts). However, for our English datasets, the Stanza Universal Dependencies model (Qi et al., 2020) we use to process each sentence is trained on web-media data (UD English EWT). Thus, our English datasets (KJB, ABL, SHAK) are all out-of-domain. We hypothesize that Stanza is more accurate on ABL since it contains the most modern language similar to its training data. With these higher quality inputs, therefore, feature-based models can achieve higher performance, relative to the neural models. As one might note, our datasets are also out-of-domain for RoBERTa and XLM-R. However, as shown by Han and Eisenstein (2019), BERT-based models can adapt to new domains when provided with in-domain fine-tuning data. For our Latin data, although our LAT-EJC dataset is in-domain for the Latin Stanza model (UD Latin Perseus), the Stanza model might not perform as well since the UD training data is quite small.

8.1 Differences in Model Performance Across Datasets

As seen in Tables 5 and 6, performance of individual models varies substantially across the five datasets. Examining the average NDCG@k scores,

---

[3] There are only 64 total documents in KJB-JA since there are no aligned quotes in John-2 or Kings-2.

Table 5: 5-fold cross validation results on the King James Bible, with both Chronicling America (CA) and JSTOR All (JA) alignments, and on the American and British Literature (ABL) and Shakespeare (SHAK) datasets, both with alignments from JSTOR All (JA). We report NDCG across six positions (1, 3, 5, 10, 25, 50). Reported NDCG and ρ values are averaged across documents within each fold then averaged across folds.

a measure of how well a model identifies the top k most quoted passages in a given document, we find that models struggle most with the Shakespeare dataset, SHAK-JA, and achieve the best scores on the King James Bible with alignments from JSTOR, KJB-JA. On the other hand, examining the ρ scores, a measure of how well a model ranks *all* of the passages in a given document with respect to each other, we find that models struggled most on the Latin dataset, LAT-EJC, and achieve their highest scores on the Shakespeare dataset, SHAK-JA.

We hypothesize that these differences in modeling performance might be due, in part, to high-level, non-linguistic differences between the datasets, such as the average number of passages in each source work. First, examining NDCG scores, we find that scores are generally higher on datasets where the documents have relatively few passages (KJB, LAT) than on those where the documents contain many passages (SHAK, ABL). Since NDCG evaluates how well models identify the top k passages in a given document, this relative performance difference is understandable because shorter passage lists are likely easier to rank than very long ones (e.g. 155 verses in Ephesians vs. 9,426 sentences in Moby Dick). On the other hand, we do not find clear relationships between NDCG and either 1) the proportion of passages that are quoted at least once; or 2) the size of the dataset (total # passages). Models have relatively similar performances on 1) both sparsely quoted (ABL-JA) and highly quoted (SHAK-JA, KJB-CA) datasets; and 2) both large (LAT-EJC) and small (KJB-JA) datasets.

XLM-R$_{single}$	29.4	30.2	30.1	30.6	32.0	33.6	14.1
XLM-R$_{pair}$	25.1	26.2	27.0	27.9	29.5	31.5	16.5
XLM-R$_{seq}$	**35.8**	**35.6**	**36.3**	**35.8**	**37.0**	**38.7**	**19.4**

Table 6: 5-fold cross validation results on the collection of Latin texts (LAT) with alignments from the JSTOR Early Journal Collection (EJC). We report NDCG across six positions (1, 3, 5, 10, 25, 50). Reported NDCG and ρ values are averaged across documents within each fold then averaged across folds.

Finally, inspecting differences in ρ scores across datasets, we find that although scores are generally higher on datasets with a high proportion of quoted passages (SHAK-JA, KJB-CA), this trend does not always hold – models have approximately equal ρ on KJB-JA and ABL-JA, though 40% more of the passages in KJB-JA (58%) are quoted at least once compared to ABL-JA (18%).

8.2 King James Bible: Analysis

We conduct a thorough analysis on a single source text, the King James Bible. We select KJB since it is aligned to two separate derived document collections, Chronicling America (KJB-CA) and JSTOR: All (KJB-JA), allowing us to conduct comparative analysis across two different labelings of the same source document. We focus on differences in quoting attention and relative modeling performances.

Quoting Attention: We first examine differences in quoting attention aggregated at the book level. To identify which books of the Bible receive the most attention, we rank them by both their median and maximum number of quotes per passage. Table 7 lists the top 3 books by both metrics (mdn & max) for each dataset. There is only one book in common across both lists, the Gospel of Luke. The top 6 books in CA are all from the New Testament, while the top 6 in JA are split evenly between the Old and New Testaments, perhaps indicating a difference between a popular (CA) and scholarly (JA) audience. We calculate the overall similarity in book-level quoting attention between KJB-JA and KJB-CA by computing correlation (ρ) between the datasets' aggregate quote counts: ρ is 0.63 ranking by max passage and 0.62 by median.

Next, we compare differences in quoting attention over specific passages. We iterate over each book and compute ρ between the passage-level quote counts from each dataset. The average ρ across the 64 books[4] is 0.40. The books with the most similar and dissimilar quoting attention are Philippians and Nahum, respectively.

Modeling Performance: We focus on RoBERTA$_{seq}$ for our analysis since it achieves the best ρ on both datasets and the best NDCG on KJB-CA and second best on KJB-JA. We focus on relative performances at the book level. For each Bible book in each alignment dataset, we compute a composite model score by averaging RoBERTA$_{seq}$'s ρ and NDCG (averaged across all k) scores. We then compute the correlation (ρ) between this model score for each book and the book's 1) *length:* book length, in total # of passages 2) *proportion*: proportion of passages quoted at least once 3) *median:* median quote label 4) *max:* maximum quote label, and 5) *entropy*: entropy of the distribution of quotes over passages. On the whole, we find that RoBERTA$_{seq}$ performs better (i.e. higher model scores) on books with high median quote labels (*median*) and many quoted passages (*proportion*). Specifically, under KJB-JA labels, we find positive correlation between model score and *median* (0.42), *max* (0.42), and *proportion* (0.34) and no correlation with *length* or *entropy*. Under KJB-CA labels, we find weaker, positive correlation between model score and *median* (0.23) and *proportion* (0.21), no correlation with *max*, and negative correlation with *length* (-0.27) and *entropy* (-0.26).

	JA	**CA**
Max	John, Genesis, Luke	Matthew, Mark, Luke
Mdn	Song of Solomon, Revelation, Jonah	James, First John, Ephesians

Table 7: The top 3 most quoted books of the King James Bible as measured by **Max**: the maximum quoted passage in each book; **Mdn**: the median quote count in each book. We compare quote counts from alignments between the KJB and both JSTOR All (JA) and Chronicling America (CA).

Finally, we make a comparison between model scores across the two datasets, computing ρ between the two scores for each book. We find that RoBERTA$_{seq}$ performs relatively similarly on books across the two datasets, with moderate correlation of 0.45 between the two sets of scores.

9 Conclusion

We explore the task of quotability identification – identifying which passages in a source document are likely to be directly quoted by later derived documents. We cast quotability identification as a passage ranking problem, evaluating how well models can learn to rank the passages in a source document by their predicted quotability. We evaluate on five large-scale datasets spanning multiple source genres (e.g. poetry, novels, plays) and languages (English, Latin). We conduct experiments with feature- and BERT-based models, finding that although relative performances vary across datasets, on the whole, BERT-based models operating on strings of sequential passages perform best.

We have identified two potential directions of future research using the datasets described in this study. First, using the publication date information for the journal articles and newspapers, we could investigate temporal quoting trends, testing hypotheses such as the Matthew effect, and therefore the best predictor of a passage's quotability tomorrow is its popularity today. Finally, we could explore second-order effects, studying trends in what sorts of passages are often quoted together.

A Source Datasets

Below are lists of all source documents in each of the four source datasets. For the sake of space, the names of all 329 works in the LAT datset are detailed here (see latin-works-metadata.jsonl).

The books in KJB are separated into passages by verse. The plays in SHAK are separated into passages by line. The documents in ABL and LAT are separated into passages by using Stanza's (Qi et al., 2020) sentence tokenizer. For the poems in ABL, we use the standard line breaks rather than sentences.

- **KJB, the 66 books of the Old and New Testaments**: acts, amos, chronicles-1, chronicles-2, colossians, corinthians-1, corinthians-2, daniel, deuteronomy, ecclesiastes, ephesians, esther, exodus, ezekiel, ezra, galatians, genesis, habakkuk, haggai, hebrews, hosea, isaiah, james, jeremiah, job, joel, john, john-1, john-2, john-3, jonah, joshua, jude, judges, kings-1, kings-2, lamentations, leviticus, luke, malachi, mark, matthew, micah, nahum, nehemiah, numbers, obadiah, peter-1, peter-2, philemon, philippians, proverbs, psalms, revelation, romans, ruth, samuel-1, samuel-2, song-of-solomon, thessalonians-1, thessalonians-2, timothy-1, timothy-2, titus, zechariah, zephaniah

- **SHAK, all 38 of Shakespeare's plays**: a midsummer nights dream, alls well that ends well, antony and cleopatra, as you like it, coriolanus, cymbeline, hamlet, henry iv pt1, henry iv pt2, henry v, henry vi pt1, henry vi pt2, henry vi pt3, henry viii, julius caesar, king john, king lear, loves labors lost, macbeth, measure for measure, much ado about nothing, othello, pericles, richard ii, richard iii, romeo and juliet, taming of the shrew, the comedy of errors, the merchant of venice, the merry wives of windsor, the tempest, the two gentlemen of verona, the two noble kinsmen, the winters tale, timon of athens, titus andronicus, troilus and cressida, twelfth night

- **ABL: a collection of 70 great works of American and British Literature**[5]: adam bede, adonais, american scholar, an american slave, bartleby, being earnest, bleak house, caleb williams, david copperfield, defence of poetry, dorian gray, dracula, emma, felix holt, frankenstein, french revolution, great expectations, gullivers travels, heart of darkness, heaven and hell, huckleberry finn, innocence and experience, jane eyre, jude the obscure, eve of st agnes, ode on a grecian urn, ode to a nightingale, leaves of grass, little dorrit, lord jim, mansfield park, middlemarch, mlk i have a dream, moby dick, mohicans, mutual friend, northanger abbey, old curiosity shop, oliver twist, paradise lost, persuasion, pilgrims progress, portrait of a lady, pride and prejudice, red badge, return of the native, rights of woman, robinson crusoe, romola, sartor, scarlet letter, self reliance, sense and sensibility, seven gables, slave girl, tale of two cities, tess, the house of usher, the mill, the secret sharer, tom jones, tom sawyer, tristram shandy, uncle tom, us constitution, utopia, vanity fair, walden, washington square, wuthering heights

- **LAT, a collection of 329 great Latin works from the Perseus Digital Library**: see here (latin-works-metadata.jsonl) for a full list of all 329 works.

B Quality of Source-Derived Alignments

We use three different sets of alignments in our work – America's Public Bible (KJB-CA), JSTOR Understanding Series (KJB-JA, SHAK-JA, ABL-JA) and Passim (LAT-EJC). In this section, we discuss the text reuse models used for each collection and the quality of the detected alignments.

- **America's Public Bible (KJB-CA)**: We use alignments provided by Mullen (2016). As described in Mullen (2016, methods section), they first devise a set of features for each (Bible verse, newpaper page) pair to model their similarity: number of overlapping n-grams (with and without TF-IDF weighting), proportion of verse n-grams in newspaper, Wald–Wolfowitz runs test to test whether the positions of the matching tokens in the newspaper page are randomly scattered across the page or clustered together). Next, they sample a set of 1,700 potential (verse, newpaper page) matches and manually label each pair as a true match or not. They split the 1,700 pairs into train, dev and test sets and examine the performance of several models on this subset. They find that a neural network achieves the best performance, with an F1 of 0.92. They then use the trained neural network to label the remaining (verse, newspaper page) pairs in the collection.

- **JSTOR Understanding Series (KJB-JA, SHAK-JA, ABL-JA)**: We use alignments from the JSTOR Understanding Series (JSTOR Labs, 2019). For each source work, the JSTOR Labs team first generates a candidate set of derived JSTOR articles and chapters by performing a full-text search on JSTOR for the work's title, author, and main characters. Next, they extract all text appearing either in block quotes or between single- and double quotation-marks from each derived document. For each quote, they then identify the most similar subsequence in the source work (with

---

[5] The works of American and British Literature are selected as a subset of the American Literature (`https://www.jstor.org/understand/american-literature`) and British Literature (`https://www.jstor.org/understand/british-literature`) collections in the JSTOR Understanding Series. We select roughly the top 50% of works in each collection by total number of aligned derived works and combine them to make our single ABL dataset (70 total works). The dataset contains 20 works of American Literature and 50 works of British Literature (total collection sizes – American Literature (35), British Literature (98)). We do not include the bottom ≈ 50% of works in each collection since they are quoted in very few derived works (≈ 2-150 aligned derived works) and have extremely sparse labels.

the lowest Levenshtein distance). For each matched (source subsequence, derived quote) pair, they calculate a manually-designed confidence score $\in [0, 1]$ based on the match size, match similarity (using Levenshtein distance) and signals indicating the presence of various text matches in surrounding derived text. Finally, examining a subset of their matched pairs, they perform a qualitative evaluation, finding that a confidence score threshold of 0.9 yielded the best balance of false positives to false negatives. We also confirm this finding qualitatively on a sampled set of alignments and use it in our work.

- **Passim (LAT-EJC)**: We use the Passim text alignment software (Smith et al., 2015) to detect quotes of the Latin texts in the JSTOR EJC. Passim uses the Smith–Waterman alignment algorithm to find all pairs of passages within longer documents (source and derived) with substantial alignments. Xu et al. (2014) quantitatively evaluated Passim on English text reuse in English documents, finding that it achieved pseudo-recall of roughly 0.9 and MAP of 0.2 - 0.5. In our work, we use the hyperparameter settings for Passim recommended by Xu et al. (2014). Manually examining our alignments, we find that detecting Latin text-reuse in English documents is easier than finding English text-reuse and confirm that Passim performs reasonably.

C Training lambdaMART: NDCG Formulation

There are two commonly used formulations of NDCG@k. One is the form we use to evaluate our models (§7.1), and the other is the formulation that lambdaMART is trained to optimize. For lambdaMART, $DCG_k = \sum_{i=1}^{k} \frac{2^{\text{label}_i} - 1}{log(i+1)}$. This formulation puts a stronger emphasis on retrieving highly relevant documents. This formulation is reasonable when passage labels are not large (e.g. $\in \{0, 1, 2, 3\}$). However, in our datasets, some passages are quoted by a very large number of derived documents (e.g. 905 for a passage in Romeo & Juliet, 4949 for a passage in the Gospel of Matthew, 1536 for a passage in the U.S. Constitution). Due to these high counts, we opted for the non-exponentiated formulation of NDCG as we thought that it was more representative of model performance – e.g. if the most quoted passage in a document was quoted 500 times and the top ranked passage by the model was quoted 250 times, an NDCG@1 score of 0.5 (using the formulation we use) is much more representative of model performance than one of $\frac{2^{250} - 1}{2^{500} - 1} \approx 0$.

To ensure that lambdaMART is trained to optimize an NDCG objective that is comparable to the one we use for evaluation, we log transform the original count labels of the passages in the training set $\text{label}_i = log_2(\text{count}_i + 1)$ before feeding them into lambdaMART. With this transformation, the numerators of the two DCG formulations are equivalent, but the denominators (the discount) differ slightly. We evaluate using the non-exponentiated version of NDCG (§7.1) with the original, untransformed quote counts on the test and dev sets.

Dataset	Threshold (# quotes)		# Passages	
	Bottom	Top	Bottom	Top
KJB-CA	≤ 1	≥ 26	8,896	6,306
KJB-JA	≤ 0	≥ 3	12,834	7,937
SHAK-JA	≤ 0	≥ 3	52,479	31,868
ABL-JA	≤ 0	≥ 1	354,834	76,746
LAT-EJC	≤ 0	≥ 1	453,086	149,590

Table 8: Thresholds used to separate the highly quoted (top 20%) and least quoted (bottom 20%) passages in each dataset, and the corresponding number of passages in each group. Note, because most datasets contain many unquoted passages, the "bottom" group often contains more than 20% of the passages in the dataset.

D Quote Count Thresholds for Linguistic Analysis

In §5 we explore different linguistic features that affect a passage's quotability. For each dataset, we compare the highly quoted passages (top 20%) to the minimally-quoted ones (bottom 20%), testing if the feature values are significantly different between the two groups. Table 8 shows the thresholds used to identify the highly- and minimally-quoted passages in each dataset and the number of passages in each group. Note, because most datasets contain many unquoted passages, the groups of minimally quoted passages generally contain more than 20% of the total passages in the dataset (e.g. we split the entire dataset for ABL-JA and LAT-EJC with the bottom group consisting of all unquoted passages and the top group containing all passages with at least one quote).

E Features for Feature-based Models

For the feature-based model, each passage is featurized with three sets of features: bag-of-words, "quotability" features, and positional features.

E.1 Bag-of-words

We tokenize passages using Stanza (Qi et al., 2020). We use TFIDF-weighted bag of unigrams and bigrams as text features, keeping the top 100,000 that occur in at least five passages. We evaluate models with and without lemmatization. We use Stanza's 'ewt' package for English and 'perseus' package for Latin[6].

E.2 Quotability Features

Since Bendersky and Smith (2012) also explore applications of quotability identification models to literary works (Project Gutenberg), we primarily use their set of quotability features for our feature-based models:

- Length features: total number of words in the passage, total number of characters in the passage, average number of characters per word, minimum number of characters per word, maximum number of characters per word
- Capitalization: number of capital words in the passage
- Stop words: number of stop words in the passage, passage begins with a stop word
- Punctuation: Five binary features to indicate whether punctuation of type P is present in the passage, P = quotations, parentheses, colon, dash, semi-colon.
- Dialogue words: binary feature if the passage contains at least one common dialog term (English: say, says, said; Latin: list of 145 forms of the words 'dico' and 'loquor')
- Abstract concepts: Number of abstract concepts (e.g., adventure, charity, stupidity) in the passage. Following Bendersky and Smith (2012), we use a list of 176 abstract nouns available at www.englishbanana.com. We do not include this feature for the Latin dataset.
- Quantifiers: Total number of universal quantifiers in the passage (from a list of 20 quantifiers: 'all', 'always', 'each', 'entire', 'ever', 'every', 'everyone', 'full', 'fully', 'never', 'no', 'nobody', 'none', 'nothing', 'nowhere', 'total', 'totally', 'utterly', 'whole', 'wholy'). We do not include this feature for the Latin dataset.
- Emphasis: two binary features for if the passage contains a superlative adjective or a comparative adjective.
- Past participle: binary feature if passage contains a verb in past participle.
- Part of speech: two different sets of counts –
  - Five features for the number of occurrences of nouns, verbs, adjectives, adverbs, or pronouns in the passage.
  - Counts of part of speech triples, e.g. (DET, NOUN, VERB): we create a single feature for each unique part of speech triple and count the number of times it occurs in the passage. This is a slightly adapted version of POS triple feature from Bendersky and Smith (2012), who only include a limited number of POS triples based on calculations on their manually labeled validation set.
- Language Model: a log-likelihood ratio for the passage calculated as the ratio between log-likelihoods from a language model of quotable text and a background language model built on the entire source corpus. For the quotable text language model, we collect approximately 5,200 quotes on more than 200 subjects from the `http://www.quotationspage.com/`. This collection provides a diverse set of high-quality quotations on subjects ranging from Laziness and Genius to Technology and Taxes. This feature is only used for the English datasets.

Finally, we add two additional quotability features from Tan et al. (2018) and one from Danescu-Niculescu-Mizil et al. (2012):

- Personal Pronouns: three features for counts of 1st, 2nd, and 3rd person pronouns (Tan et al., 2018).

---

[6] `https://stanfordnlp.github.io/stanza/available_models.html`

- Generality: number of indefinite articles, only for English dataset (Tan et al., 2018).
- Verb tenses: three features for counts of past, present and future tense verbs (Danescu-Niculescu-Mizil et al., 2012).

E.3 Positional Features

Since, as noted by Tan et al. (2018), a passage's position in a source document is an important feature for determining its quotability, we include the following positional features for each passage (each source dataset has unique positional features). Features such as "Verse index in (chapter, entire book)" with parentheticals indicate that we create multiple features, here one for the verse index in the chapter and the other for the verse index across the entire book.

- **King James Bible**:
  - Verse index in (chapter, entire book)
  - Chapter index in book
  - Relative (0 to 1) verse position in (chapter, book), both raw decimal and one-hot vectors by decile
  - Is (first, last) verse of (book, chapter)
  - Is (first, last) chapter of book
- **Shakespeare**:
  - Line index in (scene, act, play)
  - Scene index in (act, play)
  - Act index in play
  - Relative (0 to 1) line position in (scene, act, play), both raw decimal and one-hot vectors by decile
  - Relative (0 to 1) scene position in (act, play), both raw decimal and one-hot vectors by decile
  - Relative (0 to 1) act position in play, both raw decimal and one-hot vectors by decile
  - Is (first, last) line of (scene, act, play)
  - Is (first, last) scene of (act, play)
  - Is (first, last) act of play
- **American & British Literature**:
  - Sentence index in book
  - Paragraph index in book
  - Chapter index in book
  - Relative (0 to 1) (sentence, paragraph, chapter) position in book, both raw decimal and one-hot vectors by decile.
  - Is (first, last) sentence of (paragraph, chapter, doc)
  - Is (first, last) paragraph of (chapter, book)
  - Is (first, last) chapter of book
- **Latin**: Each document in the Perseus library is split up into sections which roughly break up the text by line/paragraph/sentence etc. depending on the genre and specific work. We use Stanza's Latin models to break up the text into sentences, but use this section boundary information for positional data, as seen below.
  - Sentence index in book
  - (Start, end) section index in book (sentences can span multiple sections)
  - Relative (0 to 1) (sentence, start section, end section) position in book, both raw decimal and one-hot vectors by decile.
  - Is (first, last) sentence of (book, start section, end section)
  - Is (first, last) (start, end) section of book

F Special Positional Tokens for BERT-based Models

For the BERT-based models, we add special tokens to each passage to act as positional indicators so that the model has a better sense of which part of the document it is reading (Alberti et al., 2019). Just as for the feature-based models (§E.3), the positional tokens vary across datasets.

- **King James Bible**:
  - [`Starts-Book`]: added to the beginning of the first verse in the entire document (e.g. Luke 1.1)
  - [`Starts-Chapter`]: added to the beginning of the first verse in each chapter (e.g. Luke 1.1, 2.1)
  - [`Ends-Book`]: added to the end of the last verse in the entire document (e.g. Luke 24.53)
  - [`Ends-Chapter`]: added to the end of the last verse in each chapter (e.g. Luke 1.80, 2.52)

  - [`Book@n`]: added to the beginning of each verse indicating its relative position in the entire document. `n` ranges from 0-9 indicating in which decile in the document the verse occurs.
  - [`Chapter@n`]: added to the beginning of each verse indicating its relative position in the chapter. `n` ranges from 0-9 indicating which decile in the chapter the verse occurs.

- **Shakespeare**:
  - [`Starts-Play`]: added to the beginning of the first line in the entire play
  - [`Starts-Act`]: added to the beginning of the first line in each act
  - [`Starts-Scene`]: added to the beginning of the first line in each scene
  - [`Ends-Play`]: added to the end of the last line in the entire play
  - [`Ends-Act`]: added to the end of the last line in each act
  - [`Ends-Scene`]: added to the end of the last line in each scene
  - [`Play@n`]: added to the beginning of each line indicating its relative position in the entire play. `n` ranges from 0-9 indicating in which decile in the play the verse occurs.
  - [`Act@n`]: added to the beginning of each line indicating its relative position in the act. `n` ranges from 0-9 indicating in which decile in the act the verse occurs.
  - [`Scene@n`]: added to the beginning of each line indicating its relative position in the scene. `n` ranges from 0-9 indicating in which decile in the scene the verse occurs.

- **American & British Literature**:
  - [`Starts-Book`]: added to the beginning of the first sentence in the entire document
  - [`Starts-Chapter`]: added to the beginning of the first sentence in each chapter
  - [`Starts-Paragraph`]: added to the beginning of the first sentence in each paragraph
  - [`Ends-Book`]: added to the end of the last sentence in the entire document
  - [`Ends-Chapter`]: added to the end of the last sentence in each chapter
  - [`Ends-Paragraph`]: added to the ends of the last sentence in each paragraph
  - [`Book@n`]: added to the beginning of each sentence indicating its relative position in the entire document. `n` ranges from 0-9 indicating in which decile in the document the verse occurs.
  - [`Chapter@n`]: added to the beginning of each sentence indicating the relative position of its chapter in the entire document. `n` ranges from 0-9 indicating in which decile in the document the chapter occurs.
  - [`Paragraph@n`]: added to the beginning of each sentence indicating the relative position of its paragraph in the entire document. `n` ranges from 0-9 indicating in which decile in the document the paragraph occurs.

- **Latin**: As noted in §E.3, each document in the Perseus library is split up into sections which roughly break up the text by line/paragraph/sentence etc. depending on the genre and specific work. We use Stanza's Latin models to break up the text into sentences, but use this section boundary information for positional data, as seen below.
  - [`Starts-Book`]: added to the beginning of the first sentence in the entire document
  - [`Ends-Book`]: added to the end of the last sentence in the entire document
  - [`Starts-Section`]: inserted wherever a section (according to Perseus) begins. This can be anywhere in the sentence, not necessarily just in the beginning or end.
  - [`Ends-Section`]: inserted wherever a section (according to Perseus) ends. This can be anywhere in the sentence, not necessarily just in the beginning or end.
  - [`Book@n`]: added to the beginning of each sentence indicating its relative position in the entire document. `n` ranges from 0-9 indicating in which decile in the document the verse occurs.

G Sequence length limits: BERT-based models

For the BERT-based models which operate on single passages (RoBERTA$_{single}$, RoBERTA$_{pair}$, XLM-R$_{single}$, XLM-R$_{pair}$), we cap passages at the following predetermined lengths:

- SHAKE: 100 WordPieces ($>$ 99% of passages)
- ABL: 200 WordPieces ($>$ 99% of passages)
- LAT: 200 WordPieces ($>$ 99% of passages)
- KJB: no cap, all sequences under 113 WordPieces

For the BERT-based models that operate on sequences of multiple sentences (RoBERTA$_{seq}$, XLM-R$_{seq}$), we create an example by greedily adding passages until we hit the cap of 512 WordPieces. If any single sequence is longer than 512 WordPieces, it is capped at that length.

H Searched Hyperparameters & Best Model Configurations

For the feature-based models, we use TFIDF-weighted bag-of-unigrams and bigrams as text features, keeping the top 100k that occur in at least five passages. We evaluate models with and without lemmatization. For poisson regression and SVM^{rank}, we search over regularization parameters in 10^x where $x \in \{$-5, -4, -3, -2, -1, 0, 1$\}$. For SVM^{rank} we also search over the number, n, of negative passages to sample per positive passage, $n \in \{1, 3, 5, 10\}$. We create a separate training example for each (positive, negative) passage pair. For lambdaMART we search over learning rate $\in \{0.01, 0.05, 0.1, 0.2, 0.3, 0.4, 0.5\}$, max tree depth $\in \{4, 6, 8, 10\}$ and number of boosting rounds $\in \{50, 100, 250, 500\}$.

For the neural models, we use Adam (Kingma and Ba, 2014) and search over learning rate $\in \{2e\text{-}5, 3e\text{-}5, 5e\text{-}5\}$ and batch size $\in \{16, 32\}$. We use dropout with probability 0.1. We train single sentence models for up to 10 epochs and sequential sentence models for up to 20, evaluating on the validation set after each epoch and selecting the highest performing model. For the pairwise models, we search over the number, n, of negative passages to sample per positive passage, $n \in \{1, 3, 5, 10\}$ and create a separate training example for each pair.

L2C: Describing Visual Differences Needs Semantic Understanding of Individuals

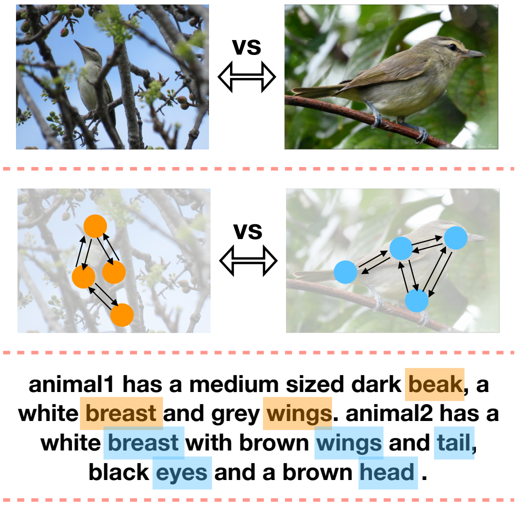
Abstract

Recent advances in language and vision push forward the research of captioning a single image to describing visual differences between image pairs. Suppose there are two images, I_1 and I_2, and the task is to generate a description $W_{1,2}$ comparing them, existing methods directly model $\langle I_1, I_2 \rangle \rightarrow W_{1,2}$ mapping without the semantic understanding of individuals. In this paper, we introduce a Learning-to-Compare (L2C) model, which learns to understand the semantic structures of these two images and compare them while learning to describe each one. We demonstrate that L2C benefits from a comparison between explicit semantic representations and single-image captions, and generalizes better on the new testing image pairs. It outperforms the baseline on both automatic evaluation and human evaluation for the Birds-to-Words dataset.



animal1 has a medium sized dark beak, a white breast and grey wings. animal2 has a white breast with brown wings and tail, black eyes and a brown head .

Figure 1: Overview of the visual comparison task and our motivation. The key is to understand both images and compare them. Explicit semantic structures can be compared between images and used to generate comparative descriptions aligned to the image saliency.

1 Introduction

The task of generating textual descriptions of images tests a machine's ability to understand visual data and interpret it in natural language. It is a fundamental research problem lying at the intersection of natural language processing, computer vision, and cognitive science. For example, single-image captioning (Farhadi et al., 2010; Kulkarni et al., 2013; Vinyals et al., 2015; Xu et al., 2015) has been extensively studied.

Recently, a new intriguing task, visual comparison, along with several benchmarks (Jhamtani and Berg-Kirkpatrick, 2018; Tan et al., 2019; Park et al., 2019; Forbes et al., 2019) has drawn increasing attention in the community. To complete the task and generate comparative descriptions, a machine should understand the visual differences between a pair of images (see Figure 1). Previous methods (Jhamtani and Berg-Kirkpatrick, 2018) often consider the pair of pre-trained visual features such as the ResNet features (He et al., 2016) as a whole, and build end-to-end neural networks to predict the description of visual comparison directly. In contrast, humans can easily reason about the visual components of a single image and describe the visual differences between two images based on their semantic understanding of each one. Humans do not need to look at thousands of image pairs to describe the difference of new image pairs, as they can leverage their understanding of single images for visual comparison.

Therefore, we believe that visual differences should be learned by understanding and comparing every single image's semantic representation. A most recent work (Zhang et al., 2020) conceptually supports this argument, where they show that low-level ResNet visual features lead to poor generalization in vision-and-language navigation, and high-level semantic segmentation helps the agent

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2315–2320
April 19 - 23, 2021.

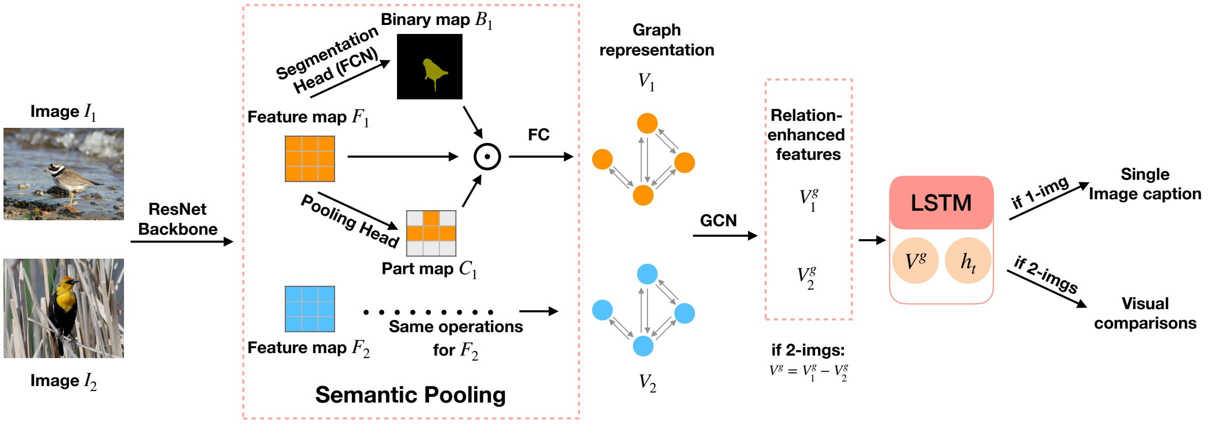


Figure 2: Our L2C model. It consists of a segmentation encoder, a graph convolutional module, and an LSTM decoder with an auxiliary loss for single-image captioning. Details are in Section 2.

generalize to unseen scenarios.

Motivated by humans, we propose a Learning-to-Compare (L2C) method that focuses on reasoning about the semantic structures of individual images and then compares the difference of the image pair. Our contributions are three-fold:

- We construct a structured image representation by leveraging image segmentation with a novel semantic pooling, and use graph convolutional networks to perform reasoning on these learned representations.
- We utilize single-image captioning data to boost semantic understanding of each image with its language counterpart.
- Our L2C model outperforms the baseline on both automatic evaluation and human evaluation, and generalizes better on the testing image pairs.

2 L2C Model

We present a novel framework in Figure 2, which consists of three main components. First, a *segmentation encoder* is used to extract structured visual features with strong semantic priors. Then, a *graph convolutional module* performs reasoning on the learned semantic representations. To enhance the understanding of each image, we introduce a *single-image captioning auxiliary loss* to associate the single-image graph representation with the semantic meaning conveyed by its language counterpart. Finally, a decoder generates the visual descriptions comparing two images based on differences in graph representations. All parameters are shared for both images and both tasks.

2.1 Semantic Representation Construction

To extract semantic visual features, we utilize pretrained fully convolutional networks (FCN) (Long et al., 2015) with ResNet-101 as the backbone. An image $\mathcal{I}$ is fed into the ResNet backbone to produce a feature map $\mathcal{F} \in \mathbb{R}^{D\times H\times W}$, which is then forwarded into an FCN head that generates a binary segmentation mask B for the bird class. However, the shapes of these masks are variable for each image, and simple pooling methods such as average pooling and max pooling would lose some information of spatial relations within the mask.

To address this issue and enable efficient aggregation over the area of interest (the masked area), we add a module after the ResNet to cluster each pixel within the mask into K classes. Feature map $\mathcal{F}$ is forwarded through this pooling module to obtain a confidence map $\mathcal{C} \in \mathbb{R}^{K\times H\times W}$, whose entry at each pixel is a K-dimensional vector that represents the probability distribution of K classes.

Then a set of nodes $V = \{v_1, ..., v_K\}, v_k \in \mathbb{R}^D$ is constructed as following:

$$v_k = \sum_{i,j} \mathcal{F} \odot \mathcal{B} \odot \mathcal{C}_k \tag{1}$$

where i=1, ...H, j=1, ..., W,, $\mathcal{C}_k$ is the k-th probability map and $\odot$ denotes element-wise multiplication.

To enforce local smoothness, i.e., pixels in a neighborhood are more likely belong to one class, we employ total variation norm as a regularization term:

$$\mathcal{L}_{TV} = \sum_{i,j} |C_{i+1,j} - Ci,j| + |C_{i,j+1} - Ci,j| \tag{2}$$

2.2 Comparative Relational Reasoning

Inspired by recent advances in visual reasoning and graph neural networks (Chen et al., 2018; Li et al., 2019), we introduce a relational reasoning module to enhance the semantic representation of each image. A fully-connected visual semantic graph $G = (V, E)$ is built, where V is the set of nodes, each containing a regional feature, and E is constructed by measuring the pairwise affinity between each two nodes v_i, v_j in a latent space.

$$A(v_i, v_j) = (W_i v_i)^T (W_j v_j) \tag{3}$$

where W_i, W_j are learnable matrices, and A is the constructed adjacency matrix.

We apply Graph Convolutional Networks (GCN) (Kipf and Welling, 2016) to perform reasoning on the graph. After the GCN module, the output $V^o = \{v_1^o, ..., v_K^o\}, v_k^o \in \mathbb{R}^D$ will be a relationship enhanced representation of a bird. For the visual comparison task, we compute the difference of each two visual nodes from two sets, denoted as $V_{diff}^g = \{v_{diff,1}^o, ..., v_{diff,K}^o\}, v_{diff,k}^o = v_{k,1}^o - v_{k,2}^o \in \mathbb{R}^D$.

2.3 Learning to Compare while Learning to Describe

After obtaining relation-enhanced semantic features, we use a Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) to generate captions. As discussed in Section 1, semantic understanding of each image is key to solve the task. However, there is no single dataset that contains both visual comparison and single-image annotations. Hence, we leverage two datasets from similar domains to facilitate training. One is for visual comparison, and the other is for single-image captioning. Alternate training is utilized such that for each iteration, two mini-batches of images from both datasets are sampled independently and fed into the encoder to obtain visual representations V^o (for single-image captioning) or V_{diff}^o (for visual comparison).

The LSTM takes V^o or V_{diff}^o with previous output word embedding y_{t-1} as input, updates the hidden state from h_{t-1} to h_t, and predicts the word for the next time step. The generation process of bi-image comparison is learned by maximizing the log-likelihood of the predicted output sentence. The loss function is defined as follows:

$$\mathcal{L}_{diff} = -\sum_t \log P(y_t | y_{1:t-1}, V_{diff}^o) \tag{4}$$

Similar loss is applied for learning single-image captioning:

$$\mathcal{L}_{single} = -\sum_t \log P(y_t | y_{1:t-1}, V^o) \tag{5}$$

Overall, the model is optimized with a mixture of cross-entropy losses and total variation loss:

$$\mathcal{L}_{loss} = \mathcal{L}_{diff} + \mathcal{L}_{single} + \lambda \mathcal{L}_{TV} \tag{6}$$

where λ is an adaptive factor that weighs the total variation loss.

3 Experiments

3.1 Experimental Setup

Datasets The Birds-to-Words (B2W) has 3347 image pairs, and each has around 5 descriptions of visual difference. This leads to 12890/1556/1604 captions for train/val/test splits. Since B2W contains only visual comparisons, We use the CUB-200-2011 dataset (CUB) (Wah et al., 2011), which consists of single-image captions as an auxiliary to facilitate the training of semantic understanding. CUB has 8855/2933 images of birds for train/val splits, and each image has 10 captions.

Evaluation Metrics Performances are first evaluated on three automatic metrics[1]: BLEU-4 (Papineni et al., 2002), ROUGE-L (Lin, 2004), and CIDEr-D (Vedantam et al., 2015). Each generated description is compared to all five reference paragraphs. Note for this particular task, researchers observe that CIDEr-D is susceptible to common patterns in the data (See Table 1 for proof), and ROUGE-L is anecdotally correlated with higher-quality descriptions (which is noted in previous work (Forbes et al., 2019)). Hence we consider ROUGE-L as the major metric for evaluating performances. We then perform a human evaluation to further verify the performance.

Implementation Details We use Adam as the optimizer with an initial learning rate set to 1e-4. The pooling module to generate K classes is composed of two convolutional layers and batch normalization, with kernel sizes 3 and 1 respectively. We set K to 9 and λ to 1. The dimension of graph representations is 512. The hidden size of the decoder is also 512. The batch sizes of B2W and CUB are 16 and 128. Following the advice from (Forbes et al., 2019), we report the results

Table 1: Results for visual comparison on the Birds-to-Words dataset (Forbes et al., 2019). *Most Frequent* produces only the most observed description in the dataset: "the two animals appear to be exactly the same". *Text-Only* samples captions from the training data according to their empirical distribution. *Neural Naturalist* is a transformer model in Forbes et al. (2019). *CNN+LSTM* is a commonly-used CNN encoder and LSTM decoder model.

Choice (%)	L2C	CNN+LSTM	Tie
Score	**50.8**	39.4	9.8

Table 2: Human evaluation results. We present workers with two generations by L2C and CNN+LSTM for each image pair and let them choose the better one.

using models with the highest ROUGE-L on the validation set, since it could correlate better with high-quality outputs for this task.

3.2 Automatic Evaluation

As shown in Table 1, first, L2C[B2W] (training with visual comparison task only) outperforms baseline methods on BLEU-4 and ROUGE-L. Previous approaches and architectures failed to bring superior results by directly modeling the visual relationship on ResNet features. Second, joint learning with a single-image caption L2C[B2W+CUB] can help improve the ability of semantic understanding, thus, the overall performance of the model. Finally, our method also has a smaller gap between validation and test set compared to *neural naturalist*, indicating its potential capability to generalize for unseen samples.

3.3 Human Evaluation

To fully evaluate our model, we conduct a pairwise human evaluation on Amazon Mechanical Turk with 100 image pairs randomly sampled from the test set, each sample was assigned to 5 workers to eliminate human variance. Following Wang et al. (2018), for each image pair, workers are presented with two paragraphs from different models and asked to choose the better one based on text quality[2]. As shown in Table 2, L2C outperforms CNN+LSTM, which is consistent with automatic metrics.

	Validation		
Model	BLEU-4 ↑	ROUGE-L ↑	CIDEr-D ↑
L2C	**31.9**	**45.7**	**15.2**
− Semantic Pooling	24.5	43.2	7.2
− TV Loss	29.3	44.8	13.6
− GCN	30.2	43.5	10.7

Table 3: Ablation study on the B2W dataset. We individually remove Semantic Pooling, total variation (TV) loss, and GCN to test their effects.

3.4 Ablation Studies

Effect of Individual Components We perform ablation studies to show the effectiveness of semantic pooling, total variance loss, and graph reasoning, as shown in Table 3. First, without semantic pooling, the model degrades to average pooling, and results show that semantic pooling can better preserve the spatial relations for the visual representations. Moreover, the total variation loss can further boost the performance by injecting the prior local smoothness. Finally, the results without GCN are lower than the full L2C model, indicating graph convolutions can efficiently modeling relations among visual regions.

Sensitivity Test We analyze model performance under a varying number of K (K is the number of classes for confidence map $\mathcal{C}$), as shown in Figure 3. Empirically, we found the results are comparable when K is small.

---

[2] We instruct the annotators to consider two perspectives, relevance (the text describes the context of two images) and expressiveness (grammatically and semantically correct).

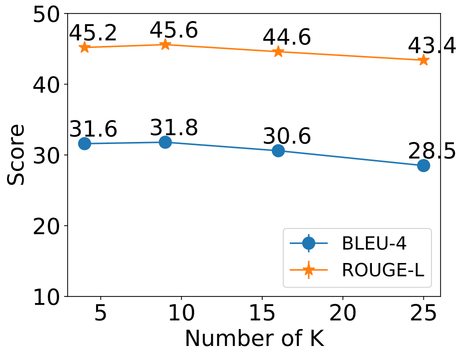

Figure 3: Sensitivity test on number of K chosen.

4 Conclusion

In this paper, we present a learning-to-compare framework for generating visual comparisons. Our segmentation encoder with semantic pooling and graph reasoning could construct structured image representations. We also show that learning to describe visual differences benefits from understanding the semantics of each image.

VoiSeR: A New Benchmark for Voice-Based Search Refinement

Simone Filice, Giuseppe Castellucci, Marcus Collins, Eugene Agichtein, Oleg Rokhlenko
Amazon
Seattle, USA
{filicesf,giusecas,collmr,eugeneag,olegro}@amazon.com

Abstract

Voice assistants, e.g., Alexa or Google Assistant, have dramatically improved in recent years. Supporting voice-based search, exploration, and refinement are fundamental tasks for voice assistants, and remain an open challenge. For example, when using voice to search an online shopping site, a user often needs to refine their search by some aspect or facet. This common user intent is usually available through a "filter-by" interface on online shopping websites, but is challenging to support naturally via voice, as the intent of refinements must be interpreted in the context of the original search, the initial results, and the available product catalogue facets. To our knowledge, no benchmark dataset exists for training or validating such contextual search understanding models. To bridge this gap, we introduce the first large-scale dataset of voice-based search refinements, VoiSeR, consisting of about 10,000 search refinement utterances, collected using a novel crowdsourcing task. These utterances are intended to refine a previous search, with respect to a search facet or attribute (e.g., brand, color, review rating, etc.), and are manually annotated with the specific intent. This paper reports qualitative and empirical insights into the most common and challenging types of refinements that a voice-based conversational search system must support. As we show, VoiSeR can support research in conversational query understanding, contextual user intent prediction, and other conversational search topics to facilitate the development of conversational search systems.

1 Introduction

Modern voice assistants, such as Amazon Alexa or Apple Siri, make use of Natural Language Understanding (NLU) techniques to perform several tasks. Some of the most popular functions offered by these systems are based on voice-search: millions use voice assistants to access information or search for music, products or local restaurants and stores. However, search experience with a voice assistant remains limited. The current generation of these systems mostly supports single-turn interactions, and does not naturally support more complex search needs, which often require *refinements* to narrow, broaden or change the initial search. Supporting refinement is a fundamental aspect of search systems, and it is done in a variety of ways in Web-based user interfaces, e.g., through query suggestion or explicit facets navigation or filtering. For example, in an e-Commerce search, a user may want to refine their search with respect to some facet or attribute (e.g., brand or price); this critical functionality is supported on most e-Commerce websites. However, this kind of interaction is challenging to support via voice-based dialogue interfaces, as interpreting such refinements requires modeling the original search intent, the initial results, and the available result facets.

To the best of our knowledge, no large scale dataset exists for training and validating NLU models for multi-turn voice-based search. To bridge this gap, we present a new Voice-based Search Refinement dataset, VoiSeR[1] to enable research into contextual understanding of multi-turn voice-based search. The VoiSeR dataset contains 9,810 utterances of voice refinements in the e-Commerce domain, paired with contextual information. Specifically, our dataset includes refinement utterances intended to filter results from a previous search with respect to some facet or attribute (e.g., brand, color, review rating, etc.).

The dataset was collected through crowdsourcing via Amazon Mechanical Turk, between February and June 2020 in the US and India. We designed the task to minimize any bias towards partic-

ular expressions or terminology which may not be natural to users. To achieve this goal, we provided clear and concise instructions; we intentionally did not provide examples to avoid biasing participants towards using specific linguistic expressions (see Figure 1 for an example). As a result, the dataset provides a diverse and natural representation of how users express the intended refinements during product search.

We annotated the dataset to highlight some important aspects characterizing a voice refinement of product search. In particular, we annotated (*i*) the products and attributes mentioned in each utterance, if present; (*ii*) the specific refinement intent of each utterance (e.g., refinement by exact attribute value).

In addition to the new VoiSeR benchmark dataset, our contributions include (*i*) an analysis of the data, where we highlight some linguistic aspects characterizing how people express the refinement intent, and (*ii*) an empirical investigation to demonstrates that VoiSeR can be successfully used to bootstrap NLU models for handling voice-based search refinements. Furthermore, we show that contextual information is beneficial for such NLU tasks.

Next, §2 provides details about the data collection and annotation. §3 provides a detailed analysis of the dataset, while §4 reports the empirical investigation. In §5, we discuss the related works. Finally, §6 discusses our conclusions.

2 VoiSeR Data Collection

In order to collect a large number of voice search refinements from multiple participants, we designed a crowdsourcing task on Amazon Mechanical Turk[2]. In §2.1, we provide details of the crowdsourcing experiment to collect refinement utterances. These utterances were annotated for intent and relevance, as described in §2.2.

2.1 Crowdsourcing the Voice Refinement Data

The design of the task was intended to make it both easy for the participants (i.e., Amazon Mechanical Turk Worker) and as realistic as possible, to provide valid linguistic expressions of voice refinements. Thus, we tried to reproduce a real "customer journey" of product searches and refinements. With this idea in mind, we designed the Mechanical Turk task depicted in Figure 1. The crowdsourcing interface shows to the Worker:

- An initial set of products, i.e., up to five products in the top part of the image.
- A target set of products, i.e., up to five products in the central part of the image.
- A visual intent indicator, i.e., an image describing the attribute type the worker should focus on when expressing the refinement. In Figure 1, this is the 5-star symbol on the central-left part; it represents the *review-rating* attribute.

The participant is asked to imagine they are searching for products and that her search led to the initial set of results. We ask the participant to record a voice utterance, modifying the search to achieve the target product set, cued by the provided visual intent indicator. In the example in Figure 1, the participant should attempt to refine the search by *review rating* as indicated in the intent indicator: compared to the products in the initial set, the products in the target set have all 4 stars or more, therefore we expect the Worker to say something like "*Show me only products having 4 stars and above*" or "*Earphones with at least four stars*".

An Automatic Speech Recognition (ASR) system (we adopted Amazon AWS Transcribe[3]) processes the utterance in real time and its transcription is shown to the Worker. Since ASR errors can occur, before completing the task, we ask the Worker to check the ASR transcription. In case of errors, the Worker can record a new sentence or manually correct the ASR transcript. We record the original ASR transcript and any manual correction, if one is made.

To automatically generate the many examples to annotate, we used the Amazon.in product search engine: starting from a random product search, we collected the initially retrieved products, as well as those returned after the application of a filter. The type of the activated filter dictates the visual intent indicator shown to the Worker, while the products shown in the initial and target sets are a subset of those retrieved by Amazon.in before and after the filter application, respectively. To emphasize the difference between the initial set and the target set, we select the products so that (*i*) no product appears in both sets and (*ii*) the products in the

1) Click on the "Start recording" button and utter your voice query.

2) When finished, click on the "Stop recording" button. **If needed you can record again or manually modify the text.**

3) Finally, click on the "Finish and Submit" button to complete your task.

We will **manually check** if your voice query is **valid** for the task. If you pass this check you will get an extra bonus of $0.08. Notice that the payment will occur within 30 days.

Figure 1: MTurk interface for voice refinements collection. The workers see source and target sets of products, differing on a specific attribute (e.g., review rating), and record a voice refinement by the suggested target attribute.

initial set do not satisfy the activated filter. For instance, the task shown in Figure 1 replicates a search session where the *4 stars & up* filter on the review rating was activated; therefore, for the initial set we selected all products having less than 4 stars, vs. more than 4 stars in the target sets.

We kept the task instructions as simple as possible in order to not introduce linguistic biases: the complete instructions to the Workers are those shown at the left Figure 1. We intentionally did not provide any example on how to complete a task. In relatively few cases this created some misunderstanding with the Workers that failed to provide valid voice refinements. On the other hand, our choice prevented any possible bias towards using some specific linguistic expressions. To further minimize terminology bias, we used visual intent indicators to suggest the attribute type to refine on. For instance, we used the image of a color palette to represent the *color* attribute, and an image of banknotes to suggest *price*.

In a preliminary experiment, we did not show the intent indicator, but in many cases the difference between the initial set and the target set was not obvious, so that the Workers ended up focusing on irrelevant details. As a consequence, the utterances that were collected in that setting were over-specific, and often the Workers simply read parts of the target product titles. Based on this experiment, the full dataset was collected using the intent indicator condition described above.

In e-commerce websites selling a wide range of products, there are typically many possible attribute types customers can filter on. We decided to collect data about some of the most popular and generally applicable ones, namely *brand, color, discount, material, price* and *review rating*.

2.2 Data Annotation

After collecting the data, we asked domain experts to annotate them with respect to three different tasks.

Voice Refinement Validity: Since crowdsourcing data can be noisy, we first design a preliminary annotation task to validate each single utterance collected on Mechanical Turk. In particular, we showed to the annotators the Mechanical Turk task associated to each sentence and asked them to state whether the utterance correctly refines the product search on the target attribute. We also asked the annotators to report whether ASR errors (or typos in case the Worker manually corrected the ASR transcription) occur in the utterance.

Attribute and Product Extraction: We asked the annotators to mark product and attribute mentions in the utterance, for example in the utterance *"Show me only red t-shirts," red* is the attribute and *t-shirt* is the product. Given the Mechanical Turk task design discussed in §2.1, the collected utterances are supposed to refine on a single attribute. However, we noticed that some utterances contain multiple attribute mentions. For instance, *Nike* and *red* in the sentence *"Show me only red Nike t-shirts"*. The annotators are required to extract all individual attribute mentions within the utterance and not only the attribute mention referring to the target attribute type (the one shown as intent indicator to the Worker).

Refinement Intent Classification: This task consists of indicating how to change the search query based on the attribute mentioned in the utterance. We asked the annotators to indicate whether the provided refinement belongs to one of the following types:

- `EXACT`: the customer asks to select products having a specific value for the attribute, e.g., *"show me only purple"*.
- `EXCLUDE`: the customer asks to exclude products having a specific value for the attribute, e.g., *"exclude the purple ones"*.
- `RANGE`: the customer asks to select products having attribute values in a closed interval, e.g., *"Price between 200 and 300"*.
- `GREATER`: the customer asks to select products with attribute value higher than a given value, e.g., *"Show 4 stars and up"*, or *"Exclude the products with less than four stars"*.
- `LOWER`: the customer asks to select products with attribute value lower than a given value, e.g., *"Price less than 100"*, or *"Exclude the ones more expensive than 100"*.
- `OTHER`: utterance not falling in the above categories, e.g., *"Show me a different color"*, or *'Select top ratings"*.

Each example in our data is annotated by a single domain expert, since we observed a very high annotation quality in a preliminary annotation phase where multiple annotators annotated the same instances. We registered an almost perfect agreement in all tasks: Cohen's Kappa 0.914 for the Voice Refinement Validity task, Cohen's Kappa 0.960 for the Attribute and Product Extraction task, and Cohen's Kappa 0.859 for the Refinement Intent Classification task.

3 Voice Refinements Dataset

In this section, we provide the analysis of the data collected through the crowdsourcing experiment. First, we describe how we conducted the Mechanical Turk experiment and the statistics of the collected data in §3.1; then, we discuss some of the linguistic properties emerging in the context of voice refinements in §3.2.

3.1 Crowdsourcing the Voice-Based Search Refinement Data

The data was crowdsourced using the Amazon Mechanical Turk platform, from workers in the U.S. and India, between February and June 2020. Both Indian and U.S. Workers were asked to provide English voice refinements with respect to the tasks shown.

Region	**Total**	**Valid (%)**
US	2,716	2,475 (91.12%)
IN	10,776	7,335 (68.06%)
Total	13,492	9,810 (72.71%)

Table 1: Data statistics per region.

As reported in Table 1, we collected 13,492 utterances, and 9,810 (i.e., ∼72%) were considered valid refinements in the subsequent annotation phase, while the rest are not refinements or contain ASR errors. In total 385 workers participated in the data collection, each one producing 35 utterances on average[4]. This results in a great variability in the collected data, as each worker can provide different linguistic expressions for a voice refinements.

Table 2 reports the distributions of the valid utterances with respect to the attribute types and the refinement types. The utterances are mostly evenly distributed with respect to the 7 attributes. *Brand* and *material* are the most and least represented attributes. The majority of utterances are of type `EXACT`, i.e., they ask to filter the product search on a specific attribute value. Unsurprisingly, the `EXCLUDE` type is extremely rare: our Mechanical Turk task did not encourage this refinement type.

As expected, the majority of brand-related utterances are of type `EXACT`. Also, the number of utterances of the price and rating related attributes are mainly `LOWER` and `GREATER`, respectively. This is intuitive considering that usually users look for less expensive and better rated products (for example, "*Show me items that are rated four stars or better*"). Notice that price (and also discount) utterances include a good number of `RANGE`, `EXACT`, as for example, "*Womens bags in the range of 1000 to 3300*".

Most of the `OTHER` bucket are (*i*) utterances whose intent is to sort products with respect to an attribute type like price or review rating, e.g., "*Sort by most rated laptops*", (*ii*) utterances where no specific attribute value is mentioned, e.g., "*Show*

---

[4] Each worker was allowed to do at most 100 tasks.

	EXACT	EXCLUDE	GREATER	LOWER	RANGE	OTHER	Total
brand	2,951	1	1	0	1	26	2,980
color	1,321	1	0	0	0	201	1,523
discount	480	0	234	80	37	478	1,309
material	719	2	0	0	0	19	750
price	119	0	176	799	134	0	1,463
rating	401	0	852	7	18	517	1,795
Total	5,991	4	1,263	886	1,477	189	9,810

Table 2: Distribution of the valid utterances with respect to the attribute types and the refinement types.

items with high ratings". Other common cases are utterances with comparatives e.g., "*Show me less expensive earphones*" or superlatives e.g., "*Show me the highest rated silk sets*".

We noticed that, despite the fact that our Mechanical Turk tasks focused on a single attribute, in about 27% of the cases (2,668 utterances) Workers provided utterances containing multiple attributes. For example, the utterance "*Price should be less than 700 with discount*" contains both the target attribute (discount) and a specification of the price.

Finally, ~80% of the utterances have a product mention, e.g., "*Show me a Vega brand hair curler*". The rest don't mention products, e.g., "*Which ones are discounted*", or "*Higher price*".

3.2 Descriptive Analysis

To better understand the collected data, and to identify differences between regions, categories, *etc*..., we computed some basic features of the refinement utterances: word counts, entropy per word for a bi-gram language model, use of adjectives and modifiers, dependency tree depth, and whether the utterance could be parsed as a complete English sentence having subject, verb, and object. We find moderate but statistically significant differences between regional populations which may have implications for the applicability of this data set to other regions. Table 3 shows the statistically significant differences. We found that utterances from IN had a much longer tail on many of these statistics. While the mean word count is significantly smaller in IN than the US, the maximum word count in IN is nearly three times that in the US.

Adjectives and modifiers are used much more in IN than US, which appears to reflect workers speaking not only the refinement, but the original product search query as well. For example "*I'm looking for a blue straight fit trouser pant*" includes much more than the target color refinement, "*blue*". US workers had an increased tendency to speak in complete sentences, e.g., "*Please display more perfumes from Calvin Klein*" instead of simply "*Calvin Klein*", both of which are utterances found in the dataset. Perhaps the most curious distinction is US workers' increased tendency to use first-person pronouns compared to other workers. These are typically phrased as "*I only want to see...*", "*Show me...*", "*I want the* {*attribute*} *to be* {*value*}", "*I'm looking for ...*" etc.

Region	US	IN
word count	7.2	5.7
adjective/modifier count	0.82	1.0
mean tree depth	1.8	1.5
per-word entropy	0.68	0.94
% using first-person pronouns	16	2.7
% complete sentences	23	17

Table 3: Differences between utterances from different regions. All differences are statistically significant ($p < 0.01$, with a Tukey multiple-comparison correction).

Unsurprisingly, the per-word entropy is quite a bit higher for brand refinements than any other type but rating, while the word count is smaller for brand refinements than most others. In brand refinements the usage of first person pronouns is higher than any other type. Ratings refinements are the longest overall, with the deepest dependency trees.

We note that the distribution of refined attributes differs across regions. With one notable exception, we do not see any statistically significant, consequential, and consistent interactions between region and refined attribute when used to predict the features shown in Table 3. That exception is that review rating refinements are even longer and have even more per-word entropy in the US than IN than would be predicted otherwise. However, these findings only exaggerate trends that are already present in the data overall. This largely serves to suggest that review ratings are some of the most complex in the dataset.

4 Empirical Investigation

In this section we present a set of experiments on intent detection, specifically the recognition of attribute and product categories in a search refinement utterance. We aim to show that the VoiSeR dataset enables building models for intent recognition in voice search refinement. Moreover, we show the contribution of contextual information, e.g., the previous utterance, is beneficial, highlighting the need for large scale datasets like VoiSeR for developing contextual intent recognition models.

Set	**# Utterances**	**# Workers**
Train	8,432	337
Validation	653	28
Test	725	20

Table 4: Data distribution and number of workers in the training, validation and test splits.

Experimental setup. In order to train and test the model, we split the data into `train`, `validation` and `test` portions, as reported in table 4. The splitting has been done at Worker level, i.e., utterances from each Worker appears only in a single portion.

Model. We model the recognition of attribute and product mentions in a refinement utterance as a sequence tagging problem in an IOB2[5] tagging schema. For example, given the utterance "*Show me a Vega brand hair curler*", its correct tagging is "`O O O B-Attribute I-Attribute B-Product I-Product`". Notice that we do not tag the attribute type, but only a general category `Attribute`. This is to enable the model to generalize over the linguistic expressions that are similar among different attribute types. The model we implemented is a BERT-based (Devlin et al., 2019) sequence tagger. BERT is used as the encoder to obtain the contextualized embeddings of each token w_i of a sentence, i.e., $h_i = BERT(w_i)$. After applying dropout on h_i, a linear classifier is used to obtain the c_i distribution over the IOB categories for each token w_i, i.e., $c_i = softmax(Wh_i + b)$, where softmax refers to the function to transform the scores in output probabilities and W and b are the weights and bias of the classifier, respectively. The model is trained by optimizing the cross entropy between the predicted categories and the true one-hot distributions for each token. We run experiments on two settings: (*i*) w/o context, i.e., the input to the model is only the refinement utterance; (*ii*) w/ context, i.e., the model receives as input both the original search query and the refinement utterance. The two utterances are separated by the `[SEP]` token, as usual in BERT (Devlin et al., 2019). The latter experiment will provide insights about the utility of contextual information to the model.

Experimental Setup. We used the `bert-base-uncased` model from the Huggingface repository (Wolf et al., 2019) as the encoder. The model is trained for 15 epochs with Early Stopping (patience=3) by tuning the following hyperparameters: dropout (0.0, 0.1) applied on the h_i representations; batch size (64, 128). The learning rate is set to 5e-5, with the Adam Optimizer with a warm-up of 100 steps.

Experimental Results. Table 5 reports the model performance (with and without context) at entire span level and at token level. The former measures the capability of the model in recognizing an entire attribute or product, i.e., the attribute or product are considered correctly predicted only if all their tokens are recognized by the model. The latter measures the capability of the model in partially recognizing an attribute or product in a voice refinement. The model performance is already promising when context is not leveraged, achieving 83.11 and 84.36 F1 for attribute and product, respectively. Contextual information provides a significant improvement, allowing the model to reach 84.94 and 86.86 F1 for attribute and product, respectively. This demonstrates that contextual information helps NLU models to better understand customer requests.

We performed an in-depth analysis to find out how the model performs on different attribute types. Tables 6 and 7 report results for each attribute type[6] in the w/o and w/ settings, respectively.

In both settings, the model achieves the best results on *discount*, while results are a bit worse on *material*, *review-rating* and *brand*. This is a consequence of the lower linguistic variability associated with the *discount* attribute. On the other hand, refinements on *review-rating* are on average the

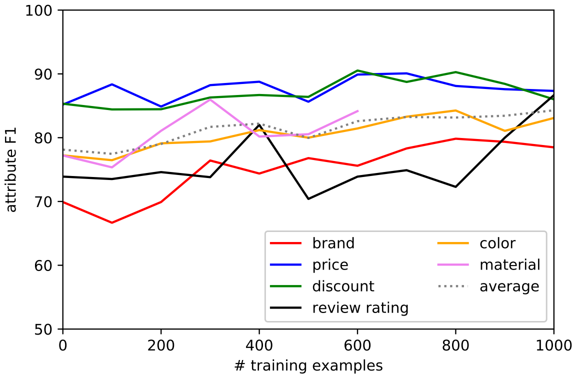

Figure 2: Learning curves for the attribute extraction task. The curve for attribute type a is obtained by training the model on all the utterances in the training set targeting a different attribute and on an increasing number of utterances targeting the attribute a.

longest and have the highest linguistic variability, as discussed in §3.2. Similarly, *brand* refinements contain a lot of rare words, i.e., the brands. Finally, a possible explanation for the lower performance on the *material* refinements is the smaller training size, as shown in Table 2. Less variability w.r.t. the attribute type of the refinement is observed on the product recognition. Again, the performance is generally higher when using the previous utterance as context. In this case, the model is able to make better predictions especially for *rating* (+12 F1 points).

Finally, we conducted a set of experiments to study the model capability to generalize to attribute types rarely, or never, observed in training. Figure 2 reports a learning curve for each attribute type we collected. The learning curve is computed as follows: for each reported attribute a and for each size s in the x-axis, we train a context-based model with s utterances of the attribute[7] a and with all the utterances for the other attributes. In figure 2 we report the F1 of the attribute recognition for each attribute and also the average F1 for all the attributes at each size s. The average F1 score on never seen attribute types (i.e., when using $s = 0$ examples for each attribute) is ~70: even with no training examples, the model obtains good results on all attributes. In terms of generalization capability, the best performance is observed on $price$ and $discount$, with learning curves that start from high scores and remain almost flat. This is not surprising, since these two attribute types are related, and the model can easily generalize from one to the

---

[7] The learning curve for *material* ends earlier because there are fewer utterances in the training set.

other. The *brand* attribute improves more when increasing the number of training examples. This may be due to the large lexical variability in this attribute: in e-commerce catalogues the number of brand names is typically very large.

The average learning curve becomes almost flat after 400 examples, and overall the model demonstrates a very good generalization capability on new attribute types. This suggests that the collected dataset has a reasonable size and that it represent a valuable resource to bootstrap NLU models for voice-based search.

5 Related Work

Human-computer information retrieval (HCIR) (Marchionini, 2006) combines the fields of human-computer interaction (HCI) and information retrieval (IR) to create systems that improve search by taking into account the human context, or through a multi-step search process that provides the opportunity for human feedback. Modern search engines implement several HCIR strategies including relevance feedback (Ruthven and Lalmas, 2003), automatic query completion (Cai and de Rijke, 2016) and faceted search (Tunkelang, 2009). In particular, most of the e-commerce websites provide faceted search by allowing users to filter on several product attributes. With our work we would like to study how a similar experience can be made available in a voice-based interaction.

Due to the increasing availability of smartphones and voice assistants like Amazon Alexa or Google Home, voice-based search is becoming ubiquitous (Guy, 2016). Voice-based Web search is significantly different from text-based search (Guy, 2016, 2018), notably for voice-based query reformulation or refinement (Hassan Awadallah et al., 2015). The voice-based interaction is especially challenging when no visual interface is available and both inputs and outputs are entirely provided by voice (Ingber et al., 2018). To improve user experience and engagement in voice-search some work has been recently done. Gamzu et al. (2020) propose a query rewriting approach for handling mispronounced, misexpressed, and misunderstood customer queries in voice shopping. Filice et al. (2020) describe the problem of reformulating answers from a community question answering system to make them suitable for a voice interaction.

There have been prior efforts in creating open multi-turn voice-based search datasets, but because of the lack of effective automated systems for these tasks, the datasets were collected in a lab using a Wizard-of-Oz approach, where a hidden human participant playing the part of the search engine, e.g., (Trippas et al., 2017, 2020; Vakulenko et al., 2019), and (Trippas and Thomas, 2019). The dataset we contribute complements prior efforts by providing a large-scale collection of voice-based query reformulation, collected in a realistic environment with a real search engine, using automated ASR, thus providing a critical resource for training robust, high-performance models for voice refinement.

Recently, several dialog-related datasets have been (Mehri et al., 2020; Crook et al., 2019) proposed. They target task-oriented conversations but do not specifically focus on search tasks.

6 Conclusions

In this paper, we discussed the problem of search refinement, a fundamental component for supporting multi-turn voice-based complex search tasks. We presented the challenges in the voice refinement problem, and introduced a large-scale, critically needed benchmark for training and evaluating models in this setting. Specifically, we introduced the first benchmark dataset, VoiSeR, specifically developed for analyzing and measuring the linguistic phenomena underlying the voice refinements in second-turn searches in the e-commerce domain. We emphasize that the target search facets and attributes are (by design) general, and thus the data and the resulting models can be used, with or without adaptation, for a wide range of conversational search refinement and intent prediction tasks.

We provided a detailed description of the data collection and annotation processes, and identified interesting statistical and linguistic phenomena in the dataset. We complement the data release with an extensive empirical investigation, which demonstrates that (*i*) our dataset is a valuable resource for training NLU models for voice-based search and (*ii*) using contextual information for recognizing product and attribute mentions is beneficial. Together, the new VoiSeR dataset and the analysis in this paper enable productive research for developing systems for voice-based complex search tasks.

Abstract

We propose a method for online news stream clustering that is a variant of the non-parametric streaming K-means algorithm. Our model uses a combination of sparse and dense document representations, aggregates document-cluster similarity along these multiple representations and makes the clustering decision using a neural classifier. The weighted document-cluster similarity model is learned using a novel adaptation of the triplet loss into a linear classification objective. We show that the use of a suitable fine-tuning objective and external knowledge in pre-trained transformer models yields significant improvements in the effectiveness of contextual embeddings for clustering. Our model achieves a new state-of-the-art on a standard stream clustering dataset of English documents.

1 Introduction

Human presentation and understanding of news articles is almost never isolated. Seminal real-world events spawn a chain of strongly correlated news articles that form a news story over time. Given the abundance of online news sources, the consumption of news in the context of the stories they belong to is challenging. Unless people are able to scour the many news sources multiple times a day, major events of interest can be missed as they occur. The real-time monitoring of news, segregating articles into their corresponding stories, thus enables people to follow news stories over time.

This goal of identifying and tracking topics from a news stream was first introduced in the Topic Detection and Tracking (TDT) task (Allan et al., 1998). Topics in the news stream setting usually correspond to real-world events, while news articles may also be categorized thematically into sports, politics, etc. We focus on the task of clustering news on the basis of event-based story chains. We make a distinction between our definition of an *event topic*, which follows TDT and refers to large-scale real-world events, and the fine-grained events used in trigger-based event detection (Ahn, 2006). Given the non-parametric nature of our task (the number of events is not known beforehand and evolves over time), the two primary approaches have been topic modeling using Hierarchical Dirichlet Processes (HDPs) (Teh et al., 2005; Beykikhoshk et al., 2018) and Stream Clustering (MacQueen, 1967; Laban and Hearst, 2017; Miranda et al., 2018). While HDPs use word distributions within documents to infer topics, stream clustering models use representation strategies to encode and cluster documents. Contemporary models have adopted stream clustering using TF-IDF weighted bag of words representations to achieve state-of-the-art results (Staykovski et al., 2019).

In this paper, we present a model for event topic detection and tracking from news streams that leverages a combination of dense and sparse document representations. Our dense representations are obtained from BERT models (Devlin et al., 2019) fine-tuned using the triplet network architecture (Hoffer and Ailon, 2015) on the event similarity task, which we describe in Section 3. We also use an adaptation of the triplet loss to learn a Support Vector Machine (SVM) (Boser et al., 1992) based document-cluster similarity model and handle the non-parametric cluster creation using a shallow neural network. We empirically show consistent improvement in clustering performance across many clustering metrics and significantly less cluster fragmentation.

The main contributions of this paper are:

- We present a novel technique for event-driven news stream clustering, which, to the best of our knowledge, is the first attempt of using

---

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2330–2340
April 19 - 23, 2021.

contextual representations for this task.

- We investigate the impact of BERT's fine-tuning objective on clustering performance and show that tuning on the event similarity task using triplet loss improves the effectiveness of embeddings for clustering.
- We demonstrate the importance of adding external knowledge to contextual embeddings for clustering by introducing entity awareness to BERT. Contrary to a previous claim (Staykovski et al., 2019), we empirically show that dense embeddings improve clustering performance when augmented with task-pertinent fine-tuning, external knowledge and the conjunction of sparse and temporal representations.
- We analyze the problem of cluster fragmentation and show that it is not captured well by the metrics reported in the literature. We propose an additional metric that captures fragmentation better and report results on both.

2 Related Work

In this section, we introduce the TDT task, prior work on tracking events from news streams and a few related parametric variants of the TDT task.

The goal of the TDT task is to organize a collection of news articles into groups called topics. Topics are defined as sets of highly correlated news articles that are related to some seminal real-world event. This is a narrower definition than the general notion of a topic which could include subjects (like *New York City*) as well. TDT defines an event to be represented by a triple <location, time, people involved>, which spawns a series of news articles over time. We are interested in all five sub-tasks of TDT - story segmentation, first story detection, cluster detection, tracking and story link detection - though we do not explicitly tackle these sub-problems individually.

After the initial work on the TDT corpora, interest in news stream clustering was rekindled by the news tracking system *NewsLens* (Laban and Hearst, 2017). NewsLens tackled the problem in multiple stages: (1) document representation through keyphrase extraction; (2) non-parametric batch clustering using the Louvian algorithm (Blondel et al., 2008); and (3) linking of clusters across batches. Staykovski et al. (2019) presented a modified version of this model, using TF-IDF bag of words document representations instead of keywords. They also compared the relative performance of sparse TF-IDF bag of words and dense doc2vec (Le and Mikolov, 2014) representations and showed that the latter performs worse, both individually and in unison with sparse representations. Linger and Hajaiej (2020) extended this batch clustering idea to the multilingual setting by incorporating a Siamese Multilingual-DistilBERT (Sanh et al., 2019) model to link clusters across languages.

In contrast to the batch-clustering approach, Miranda et al. (2018) adopt an online clustering paradigm, where streaming documents are compared against existing clusters to find the best match or to create a new cluster. We adopt this stream clustering approach as it is robust to temporal density variations in the news stream. Batch clustering models tune a batch size hyperparameter that is both training corpus dependent and might not be able to adjust to temporal variations in stream density. In their model, they also use a pipeline architecture, having separate models for document-cluster similarity computation and cluster creation. Similarity between a document and cluster is computed along multiple document representations and then aggregated using a Rank-SVM model (Joachims, 2002). The decision to merge a document with a cluster or create a new cluster is taken by an SVM classifier. Our model also follows this architecture, but critically adds dense document representations, an SVM trained on the adapted triplet loss for aggregating document-cluster similarities and a shallow neural network for cluster creation.

News event tracking has also been framed as a non-parametric topic modeling problem (Zhou et al., 2015) and HDPs that share parameters across temporal batches have been used for this task (Beykikhoshk et al., 2018). Dense document representations have been shown to be useful in the parametric variant of our problem, with neural LDA (Dieng et al., 2019a; Keya et al., 2019; Dieng et al., 2019b; Bianchi et al., 2020), temporal topic evolution models (Zaheer et al., 2017; Gupta et al., 2018; Zaheer et al., 2019; Brochier et al., 2020) and embedding space clustering (Momeni et al., 2018; Sia et al., 2020) being some prominent approaches in the literature.

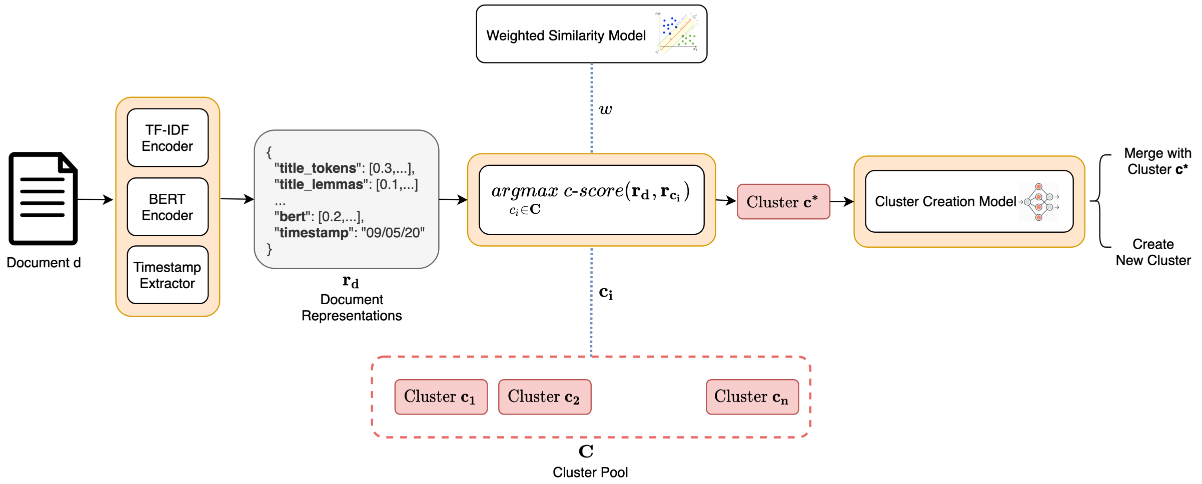

Figure 1: The architecture of the news stream clustering model, showing the clustering process for a single document in the news stream. At the end of the clustering process for each document, the cluster pool is updated based on the output from the cluster creation model, either by adding document d to cluster c^* or by creating a new cluster with the document.

3 Methodology

Our clustering model is a variant of the streaming K-means algorithm (MacQueen, 1967) with two key differences: (1) we compute the similarity between documents and clusters along a set of representations instead of a single vector representation; and (2) we decide the cluster membership using the output of a neural classifier, a learned model, instead of a static tuned threshold.

At any point in time t, let n be the number of clusters the model has created thus far, called the cluster pool. Given a continuous stream of news documents, the goal of the model is to decide the cluster membership (if any) for each input document. In our task, we assume that each document belongs to a single event, represented by a cluster. The architecture of the model, as shown in Figure 1, consists of three main components : (1) document representations, (2) document-cluster similarity computation using a weighted similarity model and (3) cluster creation model. In what follows, we describe each of these components.

3.1 Document Representations

Documents in the news stream have a set of representations, as shown in Figure 1, where each representation is one of the following types - sparse TF-IDF, dense embedding or temporal. We describe below these representation types and how clusters, which are created by our model, build representations from their assigned documents.

3.1.1 TF-IDF Representation

Separate TF-IDF models that are trained only on the tokens, lemmas and entities in a corpus are used to encode documents separately. For every document in the news stream, its title, body and title+body are each encoded into separate bags of tokens, lemmas and entities, creating nine sparse bag of word representations per document.

3.1.2 Dense Embedding Representation

Dense document representations are obtained by embedding the body of documents using BERT, with pre-trained BERT (P-BERT) without any fine-tuning as our baseline embedding model. In order to improve the effectiveness of contextual embeddings for our clustering task, we experiment with enhancements along two dimensions: (1) the fine-tuning objective, and (2) the provision of external knowledge. We train separate BERT models for (1) and (2) and use them to encode documents.

To evaluate the impact of the fine-tuning objective, we fine-tune BERT models on two different tasks - event classification (C-BERT) and event similarity (S-BERT). We also evaluate the impact of external knowledge on the embeddings through an entity-aware BERT architecture, which may be paired with either of the fine-tuning objectives.

Fine-tuning on Event Classification The goal of this fine-tuning is to tune the CLS token[1] embedding such that it encodes information about the

---

[1] The CLS token, introduced in (Devlin et al., 2019), is a special token added to the beginning of every document before being embedded by BERT

event that a document corresponds to. A dense and softmax layer are stacked on top of the CLS token embedding to classify a document into one of the events in the output space.

Fine-tuning on Event Similarity Fine-tuning on the task of event classification constrains the embedding of documents corresponding to different events to be non-linearly separable. Semantics about events can be better captured if the vector similarity between document embeddings encode whether they are from the same event or not.

For this, we adapt the triplet network architecture (Hoffer and Ailon, 2015) and fine-tune on the task of event similarity. Triplet BERT networks were introduced for the semantic text similarity (STS) task (Reimers and Gurevych, 2019), where the vector similarity between sentence embeddings was tuned to reflect the semantic similarity between them. We formulate the event similarity task, where the term “similarity” refers to whether two documents are from the same event cluster or not. In our task, documents from the same event are similar (with similarity = 1), while those from different events are dissimilar (with similarity = 0). Given the embeddings of an anchor document d_a, a positive document d_p (from the same event as the anchor) and a negative document d_n (from a different event), triplet loss is computed as

$$l_{triplet} = sim(d_a, d_n) - sim(d_a, d_p) + m \quad (1)$$

where sim is the cosine similarity function and m is the hyper-parameter margin.

Providing External Entity Knowledge In line with TDT’s definition, entities are central to events and thus need to be highlighted in document representations for our clustering task. We follow Logeswaran et al. (2019) to introduce entity awareness to BERT by leveraging knowledge from an external NER system. Apart from token, position and token type embeddings, we also add an entity presence-absence embedding for each token depending on whether it corresponds to an entity or not. The entity aware BERT model architecture is shown in Figure 2. This enhanced entity-aware model can then be coupled with the event similarity (E-S-BERT) objective for fine-tuning.

3.1.3 Temporal Representation

Documents are also represented with the timestamp of publication. Unlike TF-IDF and dense embeddings, which are vector valued representations, the temporal representation of a document is just a single value (e.g ”05-09-2020”) which has an associated subtraction operation. The difference between two timestamps is defined as the number of intervening days between them. Section 3.2 describes how these timestamps are used for clustering.

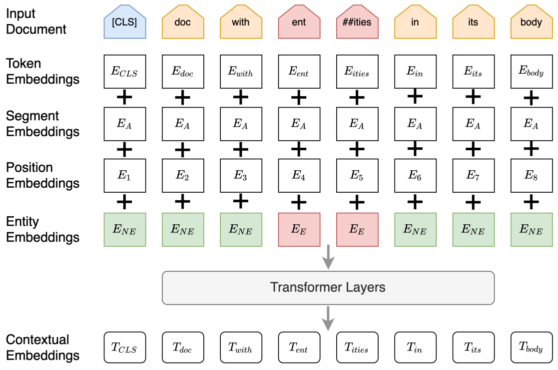

Figure 2: Entity-aware BERT model, with the additional entity presence (E_E) and absence (E_{NE}) embeddings

3.1.4 Cluster Representation

Since clusters are created and updated by our model, their representations need to be generated dynamically from the documents assigned to them. While documents in the news stream have a set of 11 representations (9 TF-IDF, dense embeddings and timestamp), clusters have two additional timestamp representations. Cluster representations are derived from documents in the cluster through aggregation. While dense embedding and sparse TF-IDF representations of a cluster are aggregated using mean pooling, clusters have three timestamp representations corresponding to different aggregation strategies - min, max and mean pooling.

3.2 Weighted Similarity Model

Once documents are encoded by a set of representations, they are compared to the clusters in the cluster pool to find the most compatible cluster. The similarity between a document and a cluster is computed along each representation separately and is then aggregated into a single compatibility score ($c\text{-}score$). While similarity along contextual embeddings and TF-IDF bag representations is computed using cosine similarity (as shown in Equation 2), timestamp similarity is computed using the Gaussian similarity function introduced in Miranda et al. (2018) (as shown in Equation 3).

Let $\mathbf{r_d}^v$ and $\mathbf{r_c}^v$ denote a dense or sparse vector representation of a document d and cluster c respectively. Let $\mathbf{r_d}^t$ and $\mathbf{r_c}^t$ denote their timestamp representations. Let (i, j) correspond to a pair of document-cluster representations of the same type (as defined in Section 3.1). Document-cluster similarity is computed along each representation and aggregated using a weighted summation as

$$\begin{aligned} sim(\mathbf{r_d}, \mathbf{r_c}) &= \{sim(\mathbf{r_d}^i, \mathbf{r_c}^j)\ \forall\ (i, j)\} \\ sim(\mathbf{r_d}^v, \mathbf{r_c}^v) &= \frac{\mathbf{r_d}^v \cdot \mathbf{r_c}^v}{|\mathbf{r_d}^v||\mathbf{r_c}^v|} \qquad (2) \\ sim(\mathbf{r_d}^t, \mathbf{r_c}^t) &= e^{-\frac{((\mathbf{r_d}^t - \mathbf{r_c}^t) - \mu)}{2\sigma^2}} \qquad (3) \\ c\text{-}score(\mathbf{r_d}, \mathbf{r_c}) &= \sum_{(i,j)} w_j \cdot sim(\mathbf{r_d}^i, \mathbf{r_c}^j) \end{aligned}$$

where μ and σ are tuned hyper-parameters of the temporal similarity function. It is noted here that since clusters have two additional timestamp representations, all three timestamp similarities are computed using the single document timestamp representation, as illustrated in Figure 3.

The dataset does not contain annotation for the degree of membership between a document and cluster and thus, the weights for combining the representation similarities can't be learned directly. To circumvent this issue, we train a linear model on a relevant task so that the trained weights can then be adapted to compute the compatibility score.

In our model, we train a linear model on a novel adaptation of the event similarity triplet loss used to train the S-BERT model. The triplet loss, as defined in Equation 1, can be adapted to a linear classifier if similarity has a related notion with regards to the classifier. SVM is an appropriate model since the degree of compatibility between a point x and a class c is given by the distance of the point from the class' decision hyperplane w_c. This distance, computed as $w_c \cdot x + b$, can thus be used as the similarity metric to adapt the triplet loss.

In our case, the inputs to the SVM model are vectors of document-cluster similarities along the set of representations $sim(\mathbf{r_d}, \mathbf{r_c})$. The adapted SVM-triplet loss is thus computed as shown below. Since we want to minimize this loss, we analyze its point of minima.

$$\begin{aligned} l_{svm-triplet} &= w \cdot sim(\mathbf{r_a}, \mathbf{r_n}) - w \cdot sim(\mathbf{r_a}, \mathbf{r_p}) \\ &\qquad + m \\ l_{svm-triplet} &= 0 \\ \implies\ m &= w \cdot (sim(\mathbf{r_a}, \mathbf{r_p}) - sim(\mathbf{r_a}, \mathbf{r_n})) \end{aligned}$$

The adapted triplet loss can thus be modeled as a classification task with inputs $(sim(\mathbf{r_a}, \mathbf{r_p}) - sim(\mathbf{r_a}, \mathbf{r_n}))$ and the outputs m. For mathematical convenience, we set $m = 1$ without loss of generality. In this manner, we transform the event similarity triplet loss objective into a classification objective to train an SVM model. The novelty of this supervision is that we focus on learning useful weights and not a useful classifier. The learned weights, which minimize the event similarity triplet loss, are utilized for document-cluster c-score computation. During the clustering process, a document d is compared against all the clusters in the pool $\mathbf{C}$ to determine the most compatible cluster c^* as

$$c^* = \underset{c\,\in\,\mathbf{C}}{\arg\max}\ c\text{-}score(\mathbf{r_d}, \mathbf{r_c})$$

3.3 Cluster Creation Model

Since our clustering problem is non-parametric, each document in the stream could potentially be the start of a new event cluster. Thus, the most compatible cluster c^* might not actually be the cluster that the document corresponds to. Given a document and its most compatible cluster, the cluster creation model decides whether or not a new cluster is to be created. For this, we employ a shallow neural network which takes document-cluster similarities along the set of representations as input and decides if a new cluster should be created. Since the dimensionality of the input space for the network is small, we use a shallow network to prevent overfitting.

4 Experiments and Results

4.1 Data

To train and evaluate our clustering models, we use the standard multilingual news stream clustering dataset (Miranda et al., 2018), which contains articles from English, French and German. For our clustering task, we only use the English subset of the corpus, which consists of 20,959 articles. Articles are annotated with language, timestamp and the event cluster to which they belong, in addition to their title and body text. We use the same training and evaluation split provided by Miranda et al. (2018) and use the training set to fine-tune the parameters of the clustering model. The training and evaluation sets are *temporally disjoint* to ensure that the clustering models are tuned independent of the events seen during training.

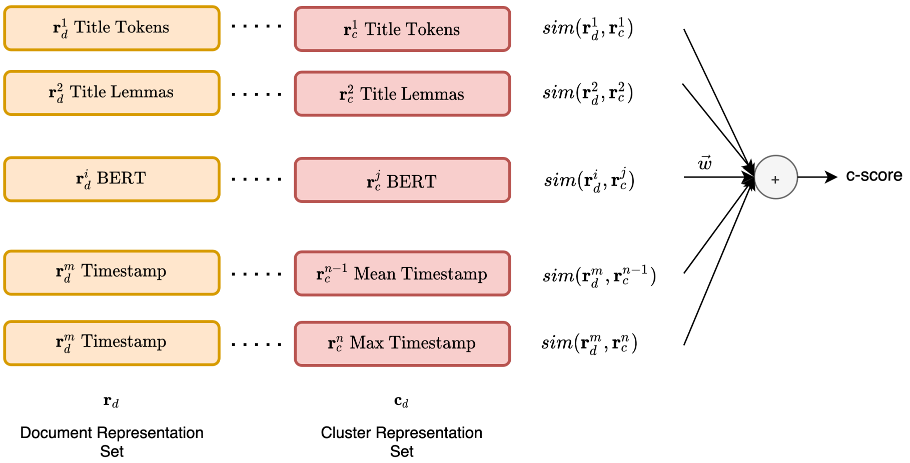

Figure 3: Computation of c-score: (a) similarities are computed for each representation individually using the appropriate similarity function (cosine or Gaussian); (b) subsequently, the computed similarities are aggregated into a single c-score value using the weights of the weighted similarity model (w)

4.2 Experimental Setup

We train our model pipeline in a sequence where each component model is supplied with the output from the component trained before in the sequence. For instance, the cluster creation model is trained using the embeddings from the fine-tuned BERT model and by selecting the most compatible cluster determined by the trained weighted similarity model. We experiment with multiple document representation sets, training all the component models each time and evaluating the entire clustering model on the test set.

We use the TF-IDF weights provided in the Miranda et al. (2018) corpus to ensure fair comparison with prior work. For training the event similarity BERT model (S-BERT), triplets are generated for each document using the batch-hard regime (Hermans et al., 2017) by picking the hardest positive and negative examples from its mini-batch[2]. We train the S-BERT model for 2 epochs using a batch size of 32, with 10% of the training data being used for linear warmup. We use Adam optimizer with learning rate $2e^{-5}$ and epsilon $1e^{-6}$. Document embeddings are obtained by mean pooling across all its tokens. For NER, we use the medium English model provided by spaCy (Honnibal and Montani, 2017).

Training instances for the weighted similarity and cluster creation models are generated by simulating the stream clustering process on the training set and assigning each document to its true event cluster. For the weighted similarity model, we generate triples of <document, true cluster, sampled negative cluster> and convert them into SVM training instances as mentioned in Section 3.2. Since all the training instances have the same label m, half the training set is negated to balance the dataset.

To generate training samples for the cluster creation model, the most compatible cluster is determined using the trained weighted similarity model for each document. A sample is then generated with input as the document-cluster similarities and output as 0 or 1 depending on whether the true cluster for that document is in the cluster pool or not. The dataset contains over 12k documents but only 593 clusters, entailing that the fraction of training samples where a new cluster is created is only 5%, making the dataset extremely biased. To mitigate this issue, we use the SVMSMOTE algorithm (Nguyen et al., 2011) to oversample the minority class and make the classes equal in size. For cluster creation, we train a shallow single layer neural network with two nodes using the L-BFGS solver (Nocedal, 1980). The weighted similarity and cluster creation models are trained using 5-fold cross validation to tune hyper-parameters and then on the entire training set using the best settings.

The clustering output is evaluated by comparing against the ground truth clusters. We report results on the B-Cubed metrics (Bagga and Baldwin, 1998) in Table 1 to compare against prior work.

4.3 Results

TF-IDF sets a tough baseline: Prior work has shown that sparse TF-IDF bag representa-

Table 1: Results of clustering performance for different document representation strategies as compared against contemporary models. P-BERT refers to pre-trained BERT; C-BERT refers to BERT fine-tuned on event classification S-BERT refers to BERT fine-tuned using triplet loss on event similarity; E-S-BERT refers to entity aware BERT fine-tuned on event similarity.

tions achieve competitive performance (Laban and Hearst, 2017; Miranda et al., 2018) and our experiments validate this observation. The clustering model that uses only sparse TF-IDF bags to represent documents achieves a very high score of 86.8% B-Cubed F_1 score, as shown in Table 1. If TF-IDF bags are used in combination with timestamps, then the performance further increases to 91.7%, setting a tough baseline to beat.

Contextual embeddings, by themselves, achieve sub-par clustering performance: In line with prior work, we observe that dense document embeddings, both when used as the sole representation and in conjunction with timestamps, are unable to match the clustering performance of TF-IDF bags. It can be seen in Table 1 that even our best BERT model (entity aware BERT trained on event similarity) only achieves an F1 score of 69% individually and 82.7% when combined with timestamp representations. These scores are 17.8% and 9% lower than their corresponding TF-IDF counterparts. BERT embeddings are richer representations that encode linguistic information including syntax and semantics through its pre-training. Thus, the model is unable to distinguish between events at the desired granularity and ends up clustering together topically related events (for instance, two different events related to soccer).

Fine-tuning objective impacts the effectiveness of embeddings for clustering: In most NLP tasks, fine-tuning contextual embeddings on a related pertinent objective is beneficial, we observe that the choice of fine-tuning objective is critical to the task performance. While the baseline pre-trained P-BERT model achieves a clustering score of 89.6% when used in conjunction with TF-IDF and timestamp representations (TF-IDF + P-BERT + Time), fine-tuning embeddings on event classification (TF-IDF + C-BERT + Time) drops the performance to 87%. This drop in performance can be attributed to the following reasons. Firstly, the large output space (593 events) and small dataset size (12k documents) make it hard for the model to learn effectively during fine-tuning. In addition to this, the classification objective requires that the embeddings of documents from different events be non-linearly separable. But this is not directly compatible with how the embeddings are used by the weighted similarity model, which is to compute cosine similarity. This discordance entails that the fine-tuning process degrades the clustering performance. The event similarity triplet loss is a more suitable fine-tuning objective and it is observed that fine-tuning BERT on this objective (TF-IDF + S-BERT + Time) results in a better clustering performance of 92.04%.

External entity knowledge makes embeddings more effective for clustering: The introduction of external knowledge through the entity aware BERT architecture significantly improves the clus-

Metric	TF-IDF + E-S-BERT + Time	Miranda	Gain

Adjusted Mutual Information	97.99	97.02	$2.97^{\S}$
Fowlkes Mallows Score	96.38	94.11	$2.27^{\S}$

Table 2: Results of clustering performance across different evaluation metrics. For each metric computed using precision, recall and F-1 scores, only the F-1 scores are reported. Statistically significant gains, with $p <<< 0.001$ are denoted by † and $p < 0.01$ by ‡. Gains denoted by $\S$ are not evaluated for significance, in line with literature.

tering performance of the model. It can be seen in Table 1 that introducing entity awareness and training on the event similarity task (TF-IDF + E-S-BERT + Time) results in a clustering score of 94.76%[3], achieving a new state-of-the-art on the dataset[4]. The results are statistically significant and p values from a paired student's t-test are reported in Table 2. This is almost 3 points better than the corresponding model without entity awareness, which highlights the importance of this external knowledge. When given external knowledge from an NER system, the BERT model, like sparse TF-IDF representations, is able to draw attention to entities and highlight them in the document embeddings. It is observed that the model learns to project entities and non-entities in mutually orthogonal directions and thereby adds emphasis to entities.

In our experiments, we observe an increase of almost 1 point in F_1 score by considering only a subset of the OntoNotes corpus (Weischedel et al., 2013) labels [5]. Ignoring entity classes like ORDINAL and CARDINAL helps as they don't provide useful information for our clustering task. The scores reported in Table 1 correspond to entity-aware models trained on this label subset. We also experimented with separate embeddings for each entity type instead of the binary entity presence-absence embeddings and observed that it degrades F_1 score by more than 2 points.

Ablating time and non-streaming input: When we ablate timestamp from the representation (rows that are not marked with "Time" in Table 1) and then stream documents in random order (rows marked with ("out- of-order") in Table 1), the number of clusters increase over when accounting for time. When ablating time, we also observe that supplying documents in random order produces fewer clusters and better b-cubed F_1 scores. We observe examples of clusters that are incorrectly merged in the absence of temporal information (in the out-of-order setting). See Appendix for actual examples from our output.

Cluster fragmentation is not captured well by B-Cubed metrics The improvements our model makes can be seen clearly by observing the number of clusters created by the model. While the previous state-of-the-art model produced 484 clusters, ours produces only 276[6], which is closer to the true cluster count of 222. Our model produces far less cluster fragmentation, resulting in a 79.4% reduction in the number of erroneous additional clusters created. We argue that this is an important improvement that is not well captured by the small increase in B-Cubed metrics.

While B-Cubed F_1 score is the standard metric reported in the literature, it is an article-level metric which gives more importance to large clusters. This entails that B-Cubed metrics heavily penalize the model's output for making mistakes on large clusters while mistakes on smaller clusters can fall through without incurring much penalty. In our experiments, we observed that this property of the metric prevents it from capturing cluster fragmentation errors on smaller events. In the news stream clustering setting, small events may correspond to recent salient events and thus, we want our metric

---

[3] The mean and standard deviation of the precision, recall and F-1 scores over five independent training and evaluations of our model are 94.64 ± 0.28, 94.72 ± 1.33 and 94.75 ± 0.59.

[4] We observe similar results on the TDT Pilot dataset (Allan et al., 1998), as shown in Section 4.4

[5] Our entity label subset consists PERSON, NORP, FAC, ORG, GPE, LOC, PRODUCT, EVENT, WORK OF ART, LAW and LANGUAGE.

[6] The mean and standard deviation of the cluster count over five independent training and evaluations of our model are 312 ± 27.

to be agnostic to the size of the clusters.

We thus use an additional metric that weights every cluster equally - CEAF-e (Luo, 2005). The CEAF-e metric creates a one-to-one mapping between the clustering output and gold clusters using the Kuhn-Munkres algorithm. The similarity between a gold cluster G and an output cluster O is computed as the fraction of articles that are common to the clusters. Once the clusters are aligned, precision and recall are computed using the aligned pairs of clusters. This ensures that unaligned clusters contribute to a penalty in the score and cluster fragmentation and coalescing is captured by the metric.

In order to ensure that our model's better performance is metric-agnostic, we also empirically evaluated our clustering model against prior work using several clustering metrics, the results of which are presented in Table 2. For this, we compare with Miranda et al. (2018) since their results are readily replicable. It can be observed that our model consistently achieves better performance across most metrics and is thus robust to the metric idiosyncrasies. Our model achieves an improvement of 7.36 points on the CEAF-e metric, which shows that our clustering model performs better than contemporary models on smaller clusters as well.

4.4 Results on TDT

To validate the robustness of our clustering model, we evaluate it on the TDT Pilot corpus (Allan et al., 1998). The TDT Pilot corpus consists of a set of newswire and broadcast news transcripts that span the period from July 1, 1994 to June 30, 1995. Out of the 16,000 documents collected, 1,382 are annotated to be relevant to one of 25 events during that period. Unlike the Miranda et al. (2018) corpus, TDT Pilot does not have the article titles. We, therefore, train all the components of our ensemble architecture using only the document body text. The TDT corpus does not provide pre-trained TF-IDF weights, so we train the weights on the entire corpus as a pre-processing step. Unlike Miranda, the TDT Corpus also lacks standard train and test splits. We create our own splits across 25 events. The splits are described and listed in the Appendix.

In line with our observations on the Miranda et al. (2018) corpus, we observe similar results on the TDT corpus. We achieve the best result on this corpus on a model with TF-IDF representations combined with temporal representations, BERT entity-aware representations fine-tuned on the event similarity task. The best result has a b-cubed precision of **81.62**, b-cubed recall of **95.89** and a b-cubed F_1 **of 88.18**. We generate **12 clusters** which matches the number of clusters in the ground truth.

We show that even in a cross-corpus setting, dense contextual embeddings, when augmented with pertinent fine-tuning, external knowledge and the conjunction of sparse and temporal representations, are a potent representation strategy for event topic clustering.

5 Conclusion

In this paper, we present a novel news stream clustering algorithm that uses a combination of sparse and dense vector representations. We show that while dense embeddings by themselves do not achieve the best clustering results, enhancements like entity awareness and event similarity fine-tuning make them effective in conjunction with sparse and temporal representations. Our model achieves new state-of-the-art results on the Miranda et al. (2018) dataset. We also analyze the problem of cluster fragmentation noting that our approach is able to produce a similar number of clusters as in the test set, in contrast to prior work which produces far too many clusters. We note issues with the B-Cubed metrics and we complement our results using CEAF-e as an additional metric for our clustering task. In addtion, we provide a comprehensive empirical evaluation across many metrics to show the robustness of our model to metric idiosyncrasies.

A Appendix

The TDT corpus does not have a training and test split and we thus partition the corpus into two almost equal portions such that all documents in a single event are part of the same split. Our training set consists of 873 documents and our test set consists of 680 documents. The events in each partition of the TDT corpus is shown in Table 3

Events in Our Train Split
Karrigan Harding, Shannon Faulker, Quayle lung clot, Haiti ousts observers, NYC Subway bombing, Carlos the Jackal, USAir 427 crash, Lost in Iraq, Death of Kim Jong Il, Clinic Murders, Kobe Japan quake, Serbs violate Bihac, OK-City bombing
Events in Our Test Split
Pentium chip flaw, Cuban riot in Panama, Humble TX flooding, WTC Bombing trial, Cessna on White House, Aldrich Ames, Halls copter, Serbians down F-16, Carter in Bosnia, Comet into Jupiter, DNA in OJ trial, Justice-to-be Breyer

Table 3: Events in the training and test splits of the TDT Pilot corpus

Actual example of clusters incorrectly merged when documents are supplied out-of-temporal-order. Cluster label # 1024 in the Miranda test-set, contains articles on Qatar being selected as FIFA worldcup host and issues with immigrant labour there are discussed in negative sentiment. The ground truth is a large cluster with 1869 documents. An example document title in this cluster is "Qatar World Cup sponsors targeted for improving workers' rights" with timestamp 2015-05-25 15:27:00. Cluster # 288 is a singleton about an upcoming Boston Celtics game and has a negative tone on their recent performance with an article titled "Celtics kick away a winnable game" with timestamp 2014-11-06 10:27:00. This is incorrectly merged with cluster # 1024. There are many more clusters that are incorrectly merged with cluster # 1024.

Adversarial Learning of Poisson Factorisation Model for Gauging Brand Sentiment in User Reviews

Abstract

In this paper, we propose the Brand-Topic Model (BTM) which aims to detect brand-associated polarity-bearing topics from product reviews. Different from existing models for sentiment-topic extraction which assume topics are grouped under discrete sentiment categories such as '*positive*', '*negative*' and '*neural*', BTM is able to automatically infer real-valued brand-associated sentiment scores and generate fine-grained sentiment-topics in which we can observe continuous changes of words under a certain topic (e.g., '*shaver*' or '*cream*') while its associated sentiment gradually varies from negative to positive. BTM is built on the Poisson factorisation model with the incorporation of adversarial learning. It has been evaluated on a dataset constructed from Amazon reviews. Experimental results show that BTM outperforms a number of competitive baselines in brand ranking, achieving a better balance of topic coherence and uniqueness, and extracting better-separated polarity-bearing topics.

1 Introduction

Market intelligence aims to gather data from a company's external environment, such as customer surveys, news outlets and social media sites, in order to understand customer feedback to their products and services and to their competitors, for a better decision making of their marketing strategies. Since consumer purchase decisions are heavily influenced by online reviews, it is important to automatically analyse customer reviews for online brand monitoring. Existing sentiment analysis models either classify reviews into discrete polarity categories such as '*positive*', '*negative*' or '*neural*', or perform more fine-grained sentiment analysis, in which aspect-level sentiment label is predicted, though still in the discrete polarity category space. We argue that it is desirable to be able to detect subtle topic changes under continuous sentiment scores. This allows us to identify, for example, whether customers with slightly negative views share similar concerns with those holding strong negative opinions; and what positive aspects are praised by customers the most. In addition, deriving brand-associated sentiment scores in a continuous space makes it easier to generate a ranked list of brands, allowing for easy comparison.

Existing studies on brand topic detection were largely built on the Latent Dirichlet Allocation (LDA) model (Blei et al., 2003) which assumes that latent topics are shared among competing brands for a certain market. They however are not able to separate positive topics from negative ones. Approaches to polarity-bearing topic detection can only identify topics under discrete polarity categories such as '*positive*' and '*negative*'. We instead assume that each brand is associated with a latent real-valued sentiment score falling into the range of $[-1, 1]$ in which -1 denotes negative, 0 being neutral and 1 positive, and propose a Brand-Topic Model built on the Poisson Factorisation model with adversarial learning. Example outputs generated from BTM are shown in Figure 1 in which we can observe a transition of topics with varying topic polarity scores together with their associated brands.

More concretely, in BTM, a document-word count matrix is factorised into a product of two positive matrices, a document-topic matrix and a topic-word matrix. A word count in a document is assumed drawn from a Poisson distribution with its rate parameter defined as a product of a document-specific topic intensity and its word probability under the corresponding topic, summing over all topics. We further assume that each document is associated with a brand-associated sentiment score and a latent topic-word offset value. The occurrence count of a word is then jointly determined

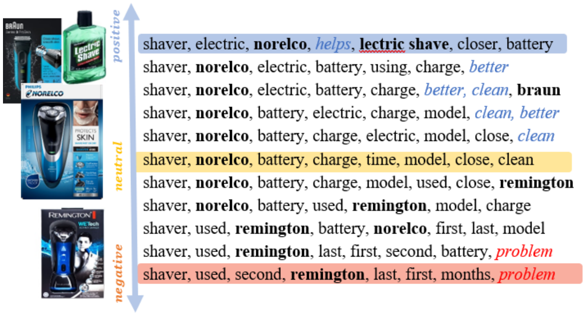

Figure 1: Example topic results generated from proposed Brand-Topic Model. We observe a transition of topics with varying topic polarity scores. Besides the change of sentiment-related words (e.g., '*problem*' in negative topics and '*better*' in positive topics), we could also see a change of their associated brands. Users are more positive about BRAUN, negative about REMINGTON, and have mixed opinions on NORELCO.

by both the brand-associated sentiment score and the topic-word offset value. The intuition behind is that if a word tends to occur in documents with positive polarities, but the brand-associated sentiment score is negative, then the topic-word offset value will have an opposite sign, forcing the occurrence count of such a word to be reduced. Furthermore, for each document, we can sample its word counts from their corresponding Poisson distributions and form a document representation which is subsequently fed into a sentiment classifier to predict its sentiment label. If we reverse the sign of the latent brand-associated sentiment score and sample the word counts again, then the sentiment classifier fed with the resulting document representation should generate an opposite sentiment label.

Our proposed BTM is partly inspired by the recently developed Text-Based Ideal Point (TBIP) model (Vafa et al., 2020) in which the topic-specific word choices are influenced by the ideal points of authors in political debates. However, TBIP is fully unsupervised and when used in customer reviews, it generates topics with mixed polarities. On the contrary, BTM makes use of the document-level sentiment labels and is able to produce better separated polarity-bearing topics. As will be shown in the experiments section, BTM outperforms TBIP on brand ranking, achieving a better balance of topic coherence and topic uniqueness measures.

The contributions of the model are three-fold:

- We propose a novel model built on Poisson Factorisation with adversarial learning for brand topic analysis which can disentangle the sentiment factor from the semantic latent representations to achieve a flexible and controllable topic generation;
- We approximate word count sampling from Poisson distributions by the Gumbel-Softmax-based word sampling technique, and construct document representations based on the sampled word counts, which can be fed into a sentiment classifier, allowing for end-to-end learning of the model;
- The model, trained with the supervision of review ratings, is able to automatically infer the brand polarity scores from review text only.

The rest of the paper is organised as follows. Section 2 presents the related work. Section 3 describes our proposed Brand-Topic Model. Section 4 and 5 discusses the experimental setup and evaluation results, respectively. Finally, Section 5 concludes the paper and outlines the future research directions.

2 Related Work

Our work is related to the following research:

Poisson Factorisation Models Poisson factorisation is a class of non-negative matrix factorisation in which a matrix is decomposed into a product of matrices. It has been used in many personalise application such as personalised budgets recommendation (Guo et al., 2017), ranking (Kuo et al., 2018), or content-based social recommendation (Su et al., 2019; de Souza da Silva et al., 2017).

Poisson factorisation can also be used for topic modelling where a document-word count matrix is factorised into a product of two positive matrices, a document-topic matrix and a topic-word matrix (Gan et al., 2015; Jiang et al., 2017). In such a setup, a word count in a document is assumed drawn from a Poisson distribution with its rate parameter defined as a product of a document-specific topic intensity and its word probability under the corresponding topic, summing over all topics.

Polarity-bearing Topics Models Early approaches to polarity-bearing topics extraction were built on LDA in which a word is assumed to be generated from a corpus-wide sentiment-topic-word distributions (Lin and He, 2009). In order to be able to separate topics bearing different polarities, word prior polarity knowledge needs to be incorporated into model learning. In recent years, the neural network based topic models have been proposed for many NLP tasks, such as information retrieval (Xie et al., 2015), aspect extraction (He, 2017) and sentiment classification (He et al., 2018). Most of them are built upon Variational Autoencode (VAE) (Kingma and Welling, 2014) which constructs a neural network to approximate the topic-word distribution in probabilistic topic models (Srivastava and Sutton, 2017; Sønderby et al., 2016; Bouchacourt et al., 2018). Intuitively, training the VAE-based supervised neural topic models with class labels (Chaidaroon and Fang, 2017; Huang et al., 2018; Gui et al., 2020) can introduce sentiment information into topic modelling, which may generate better features for sentiment classification.

Market/Brand Topic Analysis The classic LDA can also be used to analyse market segmentation and brand reputation in various fields such as finance and medicine (Barry et al., 2018; Doyle and Elkan, 2009). For market analysis, the model proposed by Iwata et al. (2009) used topic tracking to analyse customers' purchase probabilities and trends without storing historical data for inference at the current time step. Topic analysis can also be combined with additional market information for recommendations. For example, based on user profiles and item topics, Gao et al. (2017) dynamically modelled users' interested items for recommendation. Zhang et al. (2015) focused on brand topic tracking. They built a dynamic topic model to analyse texts and images posted on Twitter and track competitions in the luxury market among given brands, in which topic words were used to identify recent hot topics in the market (e.g. *Rolex watch*) and brands over topics were used to identify the market share of each brand.

Adversarial Learning Several studies have explored the application of adversarial learning mechanics to text processing for style transferring (John et al., 2019), disentangling representations (John et al., 2019) and topic modelling (Masada and Takasu, 2018). In particular, Wang et al. (2019) has proposed an Adversarial-neural Topic Model (ATM) based on the Generative Adversarial Network (GAN) (Goodfellow et al., 2014), that employees an adversarial approach to train a generator network producing word distributions indistinguishable from topic distributions in the training set. (Wang et al., 2020) further extended the ATM model with a Bidirectional Adversarial Topic (BAT) model, using a bidirectional adversarial training to incorporate a Dirichlet distribution as prior and exploit the information encoded in word embeddings. Similarly, (Hu et al., 2020) builds on the aforementioned adversarial approach adding cycle-consistent constraints.

Although the previous methods make use of adversarial mechanisms to approximate the posterior distribution of topics, to the best of our knowledge, none of them has so far used adversarial learning to lead the generation of topics based on their sentiment polarity and they do not provide any mechanism for smooth transitions between topics, as introduced in the presented Brand-Topic Model.

3 Brand-Topic Model (BTM)

We propose a probabilistic model for monitoring the assessment of various brands in the beauty market from Amazon reviews. We extend the Text-Based Ideal Point (TBIP) model with adversarial learning and Gumbel-Softmax to construct document features for sentiment classification. The overall architecture of our proposed BTM is shown in Figure 2. In what follows, we will first give a brief introduction of TBIP, followed by the presentation of our proposed BTM.

3.1 Background: Text-Based Ideal Point (TBIP) model

TBIP (Vafa et al., 2020) is a probabilistic model which aims to quantify political positions (i.e. ideal points) from politicians' speeches and tweets via Poisson factorisation. In its generative processes, political text is generated from the interactions of several latent variables: the per-document topic intensity θ_{dk} for K topics and D documents, the V-vectors representing the topics β_{kv} with vocabulary size $|V|$, the author's ideal point s expressed with a real-valued scalar x_s and the ideological topic expressed by a real-valued V-vector η_k. In particular, the ideological topic η_k aligns the neutral topic (e.g. *gun*, *abortion*, etc.) according to the author's ideal point (e.g. *liberal*, *neutral*, *conservative*), thus modifying the prominent words in the original topic (e.g. '*gun violence*', or '*constitutional rights*'). The observed variables are the author a_d for a document d, and the word count for a term v in d encoded as c_{dv} .

The TBIP model places a Gamma prior on $\boldsymbol{\beta}$

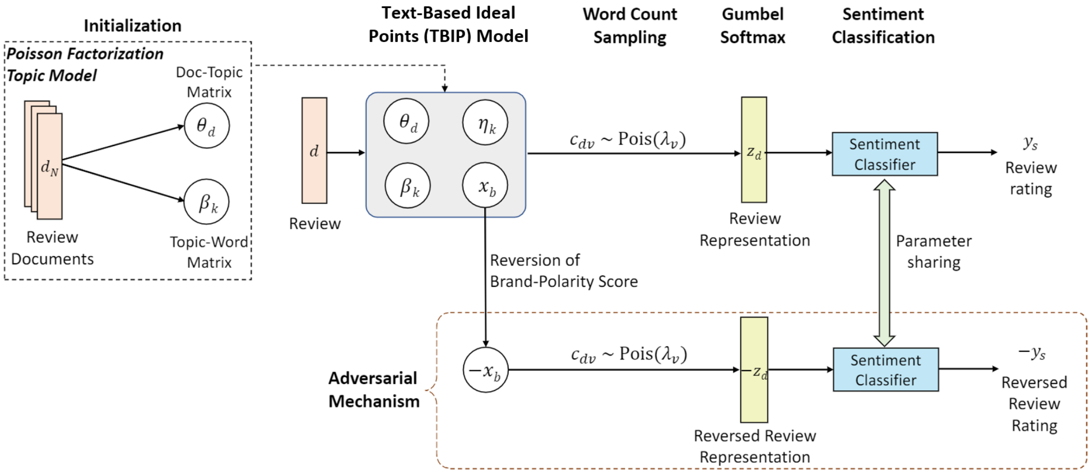

Figure 2: The overall architecture of the Brand-Topic Model.

and $\boldsymbol{\theta}$, which is the assumption inherited from the Poisson factorisation, with m, n being hyperparameters.

$$\theta_{dk} \sim \mathrm{Gamma}(m, n) \quad \beta_{kv} \sim \mathrm{Gamma}(m, n)$$

It places instead a normal prior over the ideological topic $\boldsymbol{\eta}$ and ideal point $\boldsymbol{x}$:

$$\eta_{kv} \sim \mathcal{N}(0, 1) \quad x_s \sim \mathcal{N}(0, 1)$$

The word count for a term v in d, c_{dv}, can be modelled with Poisson distribution:

$$c_{dv} \sim \mathrm{Pois}(\sum_k \theta_{dk} \beta_{kv} \exp\{x_{a_d} \eta_{kv}\}) \qquad (1)$$

3.2 Brand-Topic Model (BTM)

Inspired by the TBIP model, we introduce the Brand-Topic Model by reinterpreting the ideal point x_s as brand-polarity score x_b expressing an *ideal feeling* derived from reviews related to a brand, and the ideological topics η_{kv} as *opinionated topics*, i.e. polarised topics about brand qualities.

Thus, a term count c_{dv} for a product's reviews derives from the hidden variable interactions as $c_{dv} \sim Pois(\lambda_{dv})$ where:

$$\lambda_{dv} = \sum_k \theta_{dk} \exp\{\log \beta_{kv} + x_{b_d} \eta_{kv}\}) \qquad (2)$$

with the priors over $\boldsymbol{\beta}$, $\boldsymbol{\theta}$, $\boldsymbol{\eta}$ and $\boldsymbol{x}$ initialised according to the TBIP model.

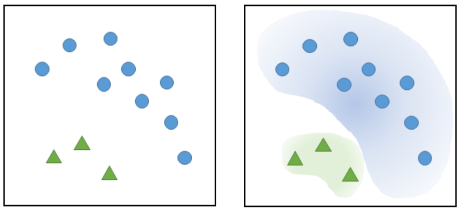
The intuition is that if a word tends to frequently occur in reviews with positive polarities, but the brand-polarity score for the current brand is negative, then the occurrence count of such a word would be reduced since x_{b_d} and η_{kv} have opposite signs.

Distant Supervision and Adversarial Learning Product reviews might contain opinions about products and more general users' experiences (e.g. delivery service), which are not strictly related to the product itself and could mislead the inference of a reliable brand-polarity score. Therefore, to generate topics which are mainly characterised by product opinions, we provide an additional distant supervision signal via their review ratings. To this aim, we use a sentiment classifier, a simple linear layer, over the generated document representations to infer topics that are discriminative of the review's rating.

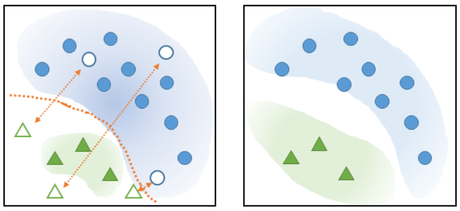
In addition, to deal with the imbalanced distribution in the reviews, we design an adversarial mechanism linking the brand-polarity score to the topics as shown in Figure 3. We contrastively sample adversarial training instances by reversing the original brand-polarity score ($x_b \in [-1, 1]$) and generating associated representations. This representation will be fed into the shared sentiment classifier with the original representation to maximise their distance in the latent feature space.

Gumbel-Softmax for Word Sampling As discussed earlier, in order to construct document features for sentiment classification, we need to sample word counts from the Poisson distribution. However, directly sampling word counts from the Poisson distribution is not differentiable. In order to enable back-propagation of gradients, we apply Gumbel-Softmax (Jang et al., 2017; Joo et al., 2020), which is a gradient estimator with the reparameterization trick.

For a word v in document d, its occurrence count,



(a) Imbalanced distribution. (b) Biased estimation.



(c) Contrastive sampling. (d) Adjusting by AL.

Figure 3: Process of Adversarial Learning (AL): (a) The imbalanced distribution of different sentiment categories; (b) The biased estimation of distribution from training samples; (c) Contrastive sample generation (white triangles) by reversing the sampling results from biased estimation (white dots); (d) Adjusting the biased estimation of (b) by the contrastive samples.

$c_{dv} \sim \text{Pois}(\lambda_{dv})$, is a non-negative random variable with the Poisson rate λ_{dv}. We can approximate it by sampling from the truncated Poisson distribution, $c_{dv_n} \sim \text{TruncatedPois}(\lambda_{dv}, n)$, where

$$\pi_k = Pr(c_{dv} = k) = \frac{\lambda_{dv}^k e^{-\lambda_{dv}}}{k!}$$

$$\pi_{n-1} = 1 - \sum_k \pi_k \quad \text{for} \quad k \in \{0, 1, ..., n-2\}.$$

We can then draw samples z_{dv} from the categorical distribution with class probabilities $\pi = (\pi_0, \pi_1, \cdots, \pi_{n-1})$ using:

$$u_i \sim \text{Uniform}(0, 1) \quad g_i = -\log(-\log(u_i))$$

$$w_i = \text{softmax}\big((g_i + \log \pi_i)/\tau\big) \quad z_{dv} = \sum_i w_i c_i$$

where τ is a constant referred to as the temperature, c is the outcome vector. By using the average of weighted word account, the process is now differentiable and we use the sampled word counts to form the document representation and feed it as an input to the sentiment classifier.

Objective Function Our final objective function consists of three parts, including the Poisson factorisation model, the sentiment classification loss, and the reversed sentiment classification loss (for adversarial learning). For the Poisson factorisation modelling part, mean-field variational inference is used to approximate posterior distribution (Jordan et al., 1999; Wainwright and Jordan, 2008; Blei et al., 2017).

$$q_\phi(\theta, \beta, \eta, x) = \prod_{d,k.b} q(\theta_d) q(\beta_k) q(\eta_k) q(x_b) \quad (3)$$

For optimisation, to minimise the approximation of $q_\phi(\theta, \beta, \eta, x)$ and the posterior, equivalently we maximise the evidence lower bound (ELBO):

$$\begin{aligned} ELBO = \mathbb{E}_{q_\phi}[log\ p(\theta, \beta, \eta, x)] + \\ log\ p(y|\theta, \beta, \eta, x) - log\ q_\phi(\theta, \beta, \eta, x)] \end{aligned} \quad (4)$$

The Poisson factorization model is pre-trained by applying the algorithm in Gan et al. (2015), which is then used to initialise the varational parameters of θ_d and β_k. Our final objective function is:

$$Loss = ELBO + \lambda(L_s + L_a) \quad (5)$$

where L_s and L_a are the cross entropy loss of sentiment classification for sampled documents and reversed sampled documents, respectively, and λ is the weight to balance the two parts of loss, which is set to be 100 in our experiments.

4 Experimental Setup

Datasets We construct our dataset by retrieving reviews in the Beauty category from the Amazon review corpus[1] (He and McAuley, 2016). Each review is accompanied with the rating score (between 1 and 5), reviewer name and the product meta-data such as product ID, description, brand and image. We use the product meta-data to relate a product with its associated brand. By only selecting brands with relatively more and balanced reviews, our final dataset contains a total of 78,322 reviews from 45 brands. Reviews with the rating score of 1 and 2 are grouped as negative reviews; those with the score of 3 are neutral reviews; and the remaining are positive reviews. The statistics of our dataset is shown in Table 1[2]. We can observe that our data is highly imbalanced, with the positive reviews far more than negative and neutral reviews.

Baselines We compare the performance of our model with the following baselines:

---

[2] The detailed rating score distributions of brands and their average rating are shown in Table A1 in the Appendix.

Dataset	**Amazon-Beauty Reviews**
Documents per classes	
Neg / Neu / Pos	9,545 / 5,578 / 63,199
Brands	45
Total #Documents	78,322
Avg. Document Length	9.7
Vocabulary size	~ 5000

Table 1: Dataset statistics of reviews within the Amazon dataset under the *Beauty* category.

- Joint Sentiment-Topic (JST) model (Lin and He, 2009), built on LDA, can extract polarity-bearing topics from text provided that it is supplied with the word prior sentiment knowledge. In our experiments, the MPQA subjectivity lexicon[3] is used to derive the word prior sentiment information.
- SCHOLAR (Card et al., 2018), a neural topic model built on VAE. It allows the incorporation of meta-information such as document class labels into the model for training, essentially turning it into a supervised topic model.
- Text-Based Ideal Point (TBIP) model, an unsupervised Poisson factorisation model which can infer latent brand sentiment scores.

Parameter setting Since documents are represented as the bag-of-words which result in the loss of word ordering or structural linguistics information, frequent bigrams and trigrams such as '*without doubt*', '*stopped working*', are also used as features for document representation construction. Tokens, i.e., n-grams ($n = \{1, 2, 3\}$), occurred less than twice are filtered. In our experiments, we set aside 10% reviews (7,826 reviews) as the test set and the remaining (70,436 reviews) as the training set. For hyperparameters, we set the batch size to 1,024, the maximum training steps to 50,000, the topic number to 30, the temperature in the Gumbel-Softmax equation in Section 3.2 to 1. Since our dataset is highly imbalanced, we balance data in each mini-batch by oversampling. For a fair comparison, we report two sets of results from the baseline models, one trained from the original data, the other trained from the balanced training data by oversampling negative reviews. The latter results in an increased training set consisting of 113,730 reviews.

5 Experimental Results

In this section, we will present the experimental results in comparison with the baseline models in brand ranking, topic coherence and uniqueness measures, and also present the qualitative evaluation of the topic extraction results. We will further discuss the limitations of our model and outline future directions.

5.1 Comparison with Existing Models

Model	**Spearman's**		**Kendall's tau**	
	corr	p-val	corr	p-val
JST	0.241	0.111	0.180	0.082
JST*	0.395	0.007	0.281	0.007
SCHOLAR	-0.140	0.358	-0.103	0.318
SCHOLAR*	0.050	0.743	0.046	0.653
TBIP	0.361	0.016	0.264	0.012
BTM	**0.486**	0.001	**0.352**	0.001

Table 2: Brand ranking results generated by various models based on the test set. We report the correlation coefficients *corr* and its associated two-sided p-values for both Spearman's correlations and Kendall's tau. * indicates models trained on balanced training data.

Brand Ranking We report in Table 2 the brand ranking results generated by various models on the test set. The two commonly used evaluation metrics for ranking tasks, Spearman's correlations and Kendall's Tau, are used here. They penalise inversions equally across the ranked list. Both TBIP and BTM can infer each brand's associated polarity score automatically which can be used for ranking. For both JST and SCHOLAR, we derive the polarity score of a brand by aggregating the sentiment probabilities of its associated review documents and then normalising over the total number of brand-related reviews. It can be observed from Table 2 that JST outperforms both SCHOLAR and TBIP. Balancing the distributions of sentiment classes improves the performance of JST and SCHOLAR. Overall, BTM gives the best results, showing the effectiveness of adversarial learning.

Topic Coherence and Uniqueness Here we choose the top 10 words for each topics to calculate the context-vector-based topic coherence scores (Röder et al., 2015). In the topics generated by TBIP and BTM, we can vary the topic polarity scores to generate positive, negative and neutral

---

[3] `https://mpqa.cs.pitt.edu/lexicons/`

subtopics as shown in Table 4. We would like to achieve high topic coherence, but at the same time maintain a good level of topic uniqueness across the sentiment subtopics since they express different polarities. Therefore, we additionally consider the topic uniqueness (Nan et al., 2019) to measure word redundancy among sentiment subtopics, $TU = \frac{1}{LK}\sum_{l=1}^{K}\sum_{l=1}^{L}\frac{1}{cnt(l,k)}$, where $cnt(l,k)$ denotes the number of times word l appear across *positive*, *neutral* and *negative* topics under the same topic number k. We can see from Table 3 that both TBIP and BTM achieve higher coherence scores compared to JST and SCHOLAR. TBIP slightly outperforms BTM on topic coherence, but has a lower topic uniqueness score. As will be shown in Table 4, topics extracted by TBIP contain words significantly overlapped with each other among sentiment subtopics. SCHOLAR gives the highest topic uniqueness score. However, it cannot separate topics with different polarities. Overall, our proposed BTM achieves the best balance between topic coherence and topic uniqueness.

Model	Topic Coherence	Topic Uniqueness
JST	0.1423	0.7699
JST*	0.1317	0.7217
SCHOLAR	0.1287	**0.9640**
SCHOLAR*	0.1196	0.9256
TBIP	**0.1525**	0.8647
BTM	0.1407	0.9033

Table 3: Topic coherence/uniqueness measures of results generated by various models.

5.2 Example Topics Extracted from Amazon Reviews

We illustrate some representative topics generated by TBIP and BTM in Table 4. It is worth noting that we can generate a smooth transition of topics by varying the topic polarity score gradually as shown in Figure 1. Due to space limit, we only show topics when the topic polarity score takes the value of -1 (*negative*), 0 (*neutral*) and 1 (*positive*). It can be observed that TBIP fails to separate subtopics bearing different sentiments. For example, all the subtopics under 'Duration' express a positive polarity. On the contrary, BTM shows a better-separated sentiment subtopics. For 'Duration', we see positive words such as '*comfortable*' under the positive subtopic, and words such as '*stopped working*' clearly expressing negative sentiment under the negative subtopic. Moreover, top words under different sentiment subtopics largely overlapped with each other for TBIP. But we observe a more varied vocabulary in the sentiment subtopics for BTM.

TBIP was originally proposed to deal with political speeches in which speakers holding different ideal points tend to use different words to express their stance on the same topic. This is however not the case in Amazon reviews where the same word could appear in both positive and negative reviews. For example, '*cheap*' for lower-priced products could convey a positive polarity to express value for money, but it could also bear a negative polarity implying a poor quality. As such, it is difficult for TBIP to separate words under different polarity-bearing topics. On the contrary, with the incorporation of adversarial learning, our proposed BTM is able to extract different set of words co-occurred with '*cheap*' under topics with different polarities, thus accurately capturing the contextual polarity of the word '*cheap*'. For example, '*cheap*' appears in both positive and negative subtopics for 'Brush' in Table 4. But we can find other co-occurred words such as '*pretty*' and '*soft*' under the positive subtopic, and '*plastic*' and '*flimsy*' under the negative subtopic, which help to infer the contextual polarity of '*cheap*'.

TBIP also appears to have a difficulty in dealing with highly imbalanced data. In our constructed dataset, positive reviews significantly outnumber both negative and neutral ones. In many sentiment subtopics extracted by TBIP, all of them convey a positive polarity. One example is the 'Duration' topic under TBIP, where words such as '*great*', '*great price*' appear in all positive, negative and neutral topics. With the incorporation of supervised signals such as the document-level sentiment labels, our proposed BTM is able to derive better separated polarised topics.

As an example shown in Figure 1, if we vary the polarity score of a topic from -1 to 1, we observe a smooth transition of its associated topic words, gradually moving from negative to positive. Under the topic (*shaver*) shown in this figure, four brand names appeared: REMINGTON, NORELCO, BRAUN and LECTRIC SHAVE. The first three brands can be found in our dataset. REMINGTON appears in the negative side and it indeed has the lowest review score among these 3 brands; NORELCO appears most and it is indeed a popular

Topic Label	Sentiment Topics	Top Words
		BTM
Brush	Positive	brushes, cheap, came, pay, *pretty*, brush, *okay*, case, glue, *soft*
	Neutral	cheap, feel, set, buy, *cheaply made*, feels, made, worth, spend, bucks
	Negative	plastic, made, cheap, parts, feels, *flimsy*, money, *break*, metal, bucks
Oral Care	Positive	teeth, taste, mouth, strips, crest, mouthwash, tongue, using, *white*, rinse
	Neutral	teeth, *pain*, mouth, strips, using, taste, used, crest, mouthwash, *white*
	Negative	*pain*, *issues*, causing, teeth, caused, removing, wore, *burn*, little, cause
Duration	Positive	stay, pillow, *comfortable*, string, tub, mirror, stick, back, months
	Neutral	months, year, *lasted*, *stopped working*, *sorry*, n, worked, working, u, last
	Negative	months, year, last, *lasted*, battery, warranty, *stopped working*, *died*, *less*
		TBIP
Brush	Positive	love, *favorite*, products, *definitely recommend*, forever, carry, brushes
	Neutral	love, brushes, *cute*, *favorite*, *definitely recommend*, soft, *cheap*
	Negative	love, brushes, cute, *soft*, *cheap*, set, case, quality price, buy, bag
Oral Care	Positive	teeth, strips, crest, mouth, mouthwash, taste, *white*, *whitening*, sensitivity
	Neutral	teeth, strips, mouth, crest, taste, work, *pain*, using, *white*, mouthwash
	Negative	teeth, strips, mouth, crest, taste, work, *pain*, using, *white*, mouthwash
Duration	Positive	great, *love shampoo*, *great price*, *great product*, *lasts long time*
	Neutral	*great*, *great price*, *lasts long time*, *great product*, price, *works expected*
	Negative	quality, *great*, *fast shipping*, *great price*, *low price*, price quality, hoped

Table 4: Example topics generated by BTM and TBIP on Amazon reviews. The topic labels are assigned by manual inspection. Positive words are highlighted with the blue colour, while negative words are marked with the red colour. BTM generates better-separated sentiment topics compared to TBIP.

brand with mixed reviews; and Braun gets the highest score in these 3 brands, which is also consistent with the observations in our data. Another interesting finding is the brand Lectric Shave, which is not one of the brands we have in the dataset. But we could predict from the results that it is a product with relatively good reviews.

5.3 Limitations and Future work

Our model requires the use of a vanilla Poisson factorisation model to initialise the topic distributions before applying the adversarial learning mechanism of BTM to perform a further split of topics based on varying polarities. Essentially topics generated by a vanilla Poisson factorisation model can be considered as parent topics, while polarity-bearing subtopics generated by BTM can be considered as child topics. Ideally, we would like the parent topics to be either neutral or carrying a mixed sentiment which would facilitate the learning of polarised sub-topics better. In cases when parent topics carry either strongly positive or strongly negative sentiment signals, BTM would fail to produce polarity-varying subtopics. One possible way is to employ earlier filtering of topics with strong polarities. For example, topic labeling (Bhatia et al., 2016) could be employed to obtain a rough estimate of initial topic polarities; these labels would be in turn used for filtering out topics carrying strong sentiment polarities.

Although the adversarial mechanism tends to be robust with respect to class imbalance, the disproportion of available reviews with different polarities could hinder the model performance. One promising approach suitable for the BTM adversarial mechanism would consist in decoupling the representation learning and the classification, as suggested in Kang et al. (2020), preserving the original data distribution used by the model to estimate the brand score.

6 Conclusion

In this paper, we presented the Brand-Topic Model, a probabilistic model which is able to generate polarity-bearing topics of commercial brands. Compared to other topic models, BMT infers real-valued brand-associated sentiment scores and extracts fine-grained sentiment-topics which vary smoothly in a continuous range of polarity scores. It builds on the Poisson factorisation model, combining it with an adversarial learning mechanism to induce better-separated polarity-bearing topics. Experimental evaluation on Amazon reviews against several baselines shows an overall improvement of topic quality in terms of coherence, uniqueness and separation of polarised topics.

Lexical Normalization for Code-switched Data and its Effect on POS Tagging

Rob van der Goot

Özlem Çetinoğlu
IMS, University of Stuttgart
`ozlem@ims.uni-stuttgart.de`

Abstract

Lexical normalization, the translation of non-canonical data to standard language, has shown to improve the performance of many natural language processing tasks on social media. Yet, using multiple languages in one utterance, also called code-switching (CS), is frequently overlooked by these normalization systems, despite its common use in social media. In this paper, we propose three normalization models specifically designed to handle code-switched data which we evaluate for two language pairs: Indonesian-English (Id-En) and Turkish-German (Tr-De). For the latter, we introduce novel normalization layers and their corresponding language ID and POS tags for the dataset, and evaluate the downstream effect of normalization on POS tagging. Results show that our CS-tailored normalization models outperform Id-En state of the art and Tr-De monolingual models, and lead to 5.4% relative performance increase for POS tagging as compared to unnormalized input. [1]

1 Introduction

Social media provide an invaluable source of information for natural language processing (NLP) systems. Its informative and spontaneous nature leads to many interesting phenomena, like non-standard words, spelling errors and abbreviations. One particularly challenging and interesting phenomenon is the use of multiple languages within the same utterance, which is also called code-switching (CS) (Gumperz, 1982; Myers-Scotton, 1995; Toribio and Bullock, 2012).

Because most NLP models are designed to process canonical and monolingual data, their performance drops enormously when having to process social media data (Eisenstein, 2013). One solution to this problem is lexical normalization: the translation of non-standard (e.g. social media) text to its canonical form (Han and Baldwin, 2011). Previous work has shown that by standardizing the data, we can improve the robustness of NLP systems (Derczynski et al., 2013; Zhang et al., 2013; van der Goot and van Noord, 2017). Nevertheless these systems overlook code-switching. (1) shows a code-switched tweet (upper) and its normalization annotation (lower), taken from an Indonesian-English CS corpus (Barik et al., 2019) (Indonesian in bold). This example demonstrates that CS complicates normalization, because it can be unclear in which language to normalize (e.g., *ak* is normalized to *aku* 'I' in Indonesian. English-only normalization systems would probably normalize it to *ok*).

(1)	**ak**	.	luv	u	:(	till	die
	aku	.	love	you	:(	till	die

'*I love you till (I) die*'

Recently, there has been an increasing interest in the automatic processing of CS data, however, there has not been much work on its lexical normalization. To the best of our knowledge, only Adouane et al. (2019) focus entirely on lexical normalization for CS data in their work. For other works, normalization is a preprocessing step for downstream tasks: chunking (Sharma et al., 2016), parsing (Bhat et al., 2017, 2018), or machine translation (Barik et al., 2019). These CS normalizers are either rule-based and language-specific (Barik et al., 2019) or combine (Hindi) back-transliteration and normalization (Sharma et al., 2016; Bhat et al., 2017, 2018) thus, they are not directly applicable to other lexical normalization datasets. In this work,

- We are the first to present open-source normalization models specialized for CS lexical normalization without any language-specific components.

- We provide a novel lexical normalization dataset by annotating a Turkish-German Twitter corpus (Çetinoğlu, 2016). We also align existing annotation layers – language IDs (LID) and part-of-speech (POS) tags – to normalization annotations.

- We evaluate three CS normalization models on two language pairs (Turkish-German (Tr-De), Indonesian-English (Id-En)). For both datasets, CS models reach performance in a similar range as monolingual models reach on monolingual datasets.

- Our CS-tailored normalization models outperform Id-En state of the art and set the state of the art for the Tr-De dataset.

- We show that our proposed normalization models improve the performance of POS taggers. For a broad perspective, we employ a variety of taggers (CRF, BiLSTM, BERT).

2 Related Work

Lexical normalization Traditionally, social media normalization approaches can be broadly divided into two types. The first stream of work uses techniques borrowed from machine translation (Aw et al., 2006; Pennell and Liu, 2011; Ljubešic et al., 2016). The second stream is based on a classic spelling correction framework (noisy-channel models) (Han, 2014). Here, they often apply three steps, detecting which words need to be replaced, generating candidates, and ranking these candidates. Later, it became evident that a two-step approach is sufficient (Jin, 2015; van der Goot, 2019), and the detection step was alleviated by considering the original word as a normalization candidate.

The current state-of-the-art model for most languages is MoNoise (van der Goot, 2019), which is based on this two-step approach. A variety of modules are used for the generation of candidates. For the ranking, MoNoise complements features from the generation step with additional features, which are all combined in a random forest classifier that predicts the probability that a candidate is a 'correct' candidate. MoNoise is described in more detail in Section 4.2. More recently, sequence-to-sequence models (Lourentzou et al., 2019) and contextual embeddings (Muller et al., 2019) have been used for the lexical normalization task. These approaches have been shown to reach performances close to MoNoise on English benchmarks.

Like most NLP tasks, most research on normalization has been done on English datasets (Han and Baldwin, 2011; Baldwin et al., 2015). However, there has been some efforts on other languages, where usually only one language is considered, we refer to Sharf and Rahman (2017) and van der Goot (2019) for an overview of available resources.

Processing of code-switched social media data Early work on normalizing CS data focused on Hindi-English, as part of pipelines to achieve downstream tasks (Sharma et al., 2016; Bhat et al., 2017, 2018). As Hindi is Romanized in datasets and additional Hindi resources are in the Devanagari script, they include back-transliteration into the normalization step, thus defining the task beyond the scope of this paper. Nevertheless, all systems report a positive impact of normalization on their final task.

More recently, Barik et al. (2019) experiment on normalization for Indonesian-English. They use a rule-based approach supplemented by clusters derived from word embeddings, and show that normalization can be used to improve machine translation. Adouane et al. (2019) instead propose to use sequence-to-sequence models for normalizing Algerian Arabic data mixed with Modern Standard Arabic, French, Berber, and English. They show that their edit distance-based token-level aligner helps improve normalization.

When annotating the Tr-De dataset for normalization, we also adapted its POS tags (see Section 3.1). This gives us the opportunity to apply POS tagging as extrinsic evaluation. Besides research on Hindi-English that combines normalization and back-transliteration, most work either use normalization to improve tagging performance of monolingual social media data (Derczynski et al., 2013; van der Goot et al., 2017), or on POS tagging of CS data without normalization (AlGhamdi et al., 2016; Soto and Hirschberg, 2018). In this work, we combine these angles.

Because some of our proposed normalization models depend on language labels, we require a word-level language identification system. There is a wide variety of approaches used for this task, where early systems mostly used CRFs (Sequiera et al., 2015; Molina et al., 2016). More recently, neural networks based approaches have shown superior performance for this task (Zhang et al., 2018). We opt for three different architectures to observe the effect of the quality of language identification on normalization (Section 4.1).

	Seg+CS			Norm		Tok+Anon

`Norm`	@username	Nerde	3.	**Semester**dayım	daha	.
`Seg+CS:`	@username Nerde 3. **Semester**§da -yım daha .					

Figure 1: Different annotation layers of a tweet from the Tr-De corpus, meaning '*No way, I am still in the 3rd semester*'. The German part is in bold. `Raw`: downloaded tweet; `Tok+Anon`: after tokenization and anonymization; `Norm`: after normalization; `Seg+CS`: after segmentation (e.g. the Turkish copular *-yim*), and CS boundaries (§) in `Mixed` tokens. The token alignment and normalization tasks are carried out on the `Tok+Anon` and `Norm` pairs.

3 Data

In this section we first describe the design decisions of the novel Turkish-German dataset, then we compare some basic statistics together with the existing Indonesian-English dataset (Barik et al., 2019).

3.1 Turkish-German code-switched normalization corpus

We use the Turkish-German Twitter corpus from Çetinoğlu (2016) in our experiments. It consists of 17K tokens as 1,029 tweets. The raw tweets of the corpus have undergone three main steps of alternations after the collection: tokenization, normalization, and segmentation.[2] In addition, usernames and URLs are anonymized as `@username` and `[url]` respectively, and intra-word CS boundaries are marked in `Mixed` tokens with §. Each alternation layer is exemplified on a sentence from the corpus in Figure 1.

The `Seg+CS` layer is annotated with language IDs and POS tags (Çetinoğlu and Çöltekin, 2016). The LID tag set consists of `TR` (Turkish), `DE` (German), `Lang3` (third language), `Mixed` (intra-word CS), `NE` (named entity), `Ambig` (both Turkish and German and cannot be disambiguated in given context), `Other` (punctuation, numbers, URLs, emoticons, symbols). Additionally, named entities are tagged with their language label next to the `NE` tag, e.g. 'Germany' is annotated in the corpus as follows depending on the language: *Almanya* `NE.TR`, *Deutschland* `NE.DE`, *Germany* `NE.Lang3`. The POS annotation adopts the Universal Dependencies (UD) tag set (Nivre et al., 2016).

Preprocessing for normalization The original version of the corpus has only the `Raw` and `Seg+CS` layers and only tweet-level alignment between them. As our work focuses only on normalization we created the intermediate layers `Tok+Anon` and `Norm` that leave out other tasks. Since MoNoise requires word-aligned annotations, we also provided these alignments.

We anonymized and tokenized the raw tweets to achieve the `Tok+Anon` layer. For tokenization, we use a slightly modified version of twokenize.py[3] (O'Connor et al., 2010). To obtain the `Norm` layer, we merged back segmented tokens and removed CS boundaries on the `Seg+CS` layer.

After this stage, we aligned `Tok+Anon` and `Norm` on the token level automatically using Giza++ (Och and Ney, 2003). We parsed the resulting alignment files to align the actual tokens and corrected them manually. There are 15,715 1:1, 520 1:n, and 147 n:1 alignments.

LID and POS alignment The existing LID and POS tags are on the `Seg+CS` layer; since we base our experiments on the `Tok+Anon` layer, we need to map the annotations. This is done in two steps following the `Seg+CS` ⇒ `Norm` ⇒ `Tok+Anon` order. Due to segmentation merges in the first step, and 1:n and n:1 token alignments in the second step, there are non-trivial LID and POS alignments.

Figure 2 demonstrates a segmented word in the first column. The first segment *Semesterda* 'in semester' is `Mixed` with German *Semester* and Turkish locative case marker *da*. The second segment is the Turkish copular *-yim* 'I am'. Their POS tags are NOUN and VERB, respectively. When segmentation is undone in the second column (`Norm`), their LID and POS are merged too. If two tokens

Table 1: Descriptive normalization and code-switching statistics on the training split of the datasets. CMI is the code-mixing index (Das and Gambäck, 2014), averaged over all training sentences. %norm reflect the percentage of words which is normalized.

Source	Indonesian	English	Turkish	German
Wikipedia	75	2,162	55	776
Twitter	510	5,018	203	89

Table 2: Size of raw data (in million words) from both data sources.

have the same LID, the merged token takes the same LID. If they are different, the resulting token is `Mixed`, as in the example.

POS tag merging rules can get more complicated, therefore, we used a heuristic that favors the POS tag of the second token in most cases.[4] When a NOUN segment is merged with a VERB segment, as in Figure 2 (`Seg+CS` ⇒ `Norm`), the merged token is assigned a VERB POS tag. For the `Norm` ⇒ `Tok+Anon` mapping, the alignment is 1:1, thus LID and POS are directly carried over.

3.2 Dataset characteristics

Besides the data described in the previous section, we use the Indonesian-English (Id-En) data from (Barik et al., 2019). The Id-En data is only annotated with language IDs and uses three labels: `ID`, `EN`, `UN` (Unspecified), whereas the Tr-De includes 12 labels (Section 3.1). To simplify the models and improve comparability, we map the language labels of the Tr-De dataset to `TR`, `DE` and `UN`. Named entities are mapped to their respective language tags, e.g, `NE.DE` to `DE`. `Mixed` tokens are mapped to `DE` as they are German words with Turkish inflection. `Lang3`, `Ambig` and `Other` are mapped to `UN`.

We divide both datasets into a train and test split (80-20%), and omit a development set due to small sizes. Since we want to leave test set out in analyses, we opt for 10-fold cross-validation on the training split of the data in experiments. Statistics of the training splits of the datasets are shown in Table 1. The datasets are relatively small, but a high ratio of words is normalized, including a high percentage of splits and merges. The percentage of in-vocabulary words is especially low in the Tr-De data, which is mainly due to the morphological richness of Turkish. The code-mixing index (CMI) (Das and Gambäck, 2014) indicates the (average of the) amount of words not written in the majority language for each sentence. The relatively high CMI for both datasets indicates a high frequency of code-switching occurs in the data.

In both datasets there are a small amount of sentences without normalization (8 and 76 for respectively Id-En and Tr-De), which might be desirable for evaluation of (over)normalization, as in a real-world setup one also does not know beforehand whether normalization is necessary. In more than half of the sentences the number of normalized words is larger than 3. Furthermore, there are some sentences (5-10 per dataset) with a very high normalization ratio (>70%), which are all in capitals.

3.3 Monolingual Data

Our baseline model (MoNoise) exploits monolingual data from both the source and the target domain (canonical data) to train word embeddings and estimate n-gram probabilities. To this end, we utilize Wikipedia dumps from 01-01-2020 and random tweets collected throughout 2012 and 2018 from the Twitter API, filtered by the FastText language classifier (Joulin et al., 2017). We tokenized this data based on whitespaces, and removed all duplicate sentences/tweets. The sizes of the collected raw datasets are shown in Table 2.

4 Models

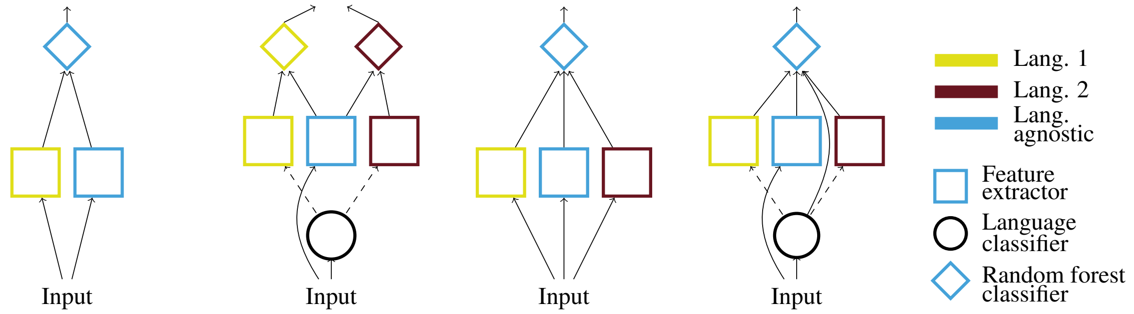
In this section we describe the models used for word-level language identification (4.1), lexical normalization (4.2) and POS tagging (4.3).

4.1 Word-level language identification

We treat language identification as a sequence labeling task where the label of each word is a language ID. We evaluate three sequence labeling libraries: 1) MarMoT (Mueller et al., 2013), a higher-order conditional random fields tagger 2) Bilty (Plank et al., 2016), a BiLSTM tagger, also incorporating character level information 3) a BERT-based (Devlin et al., 2019) tagger named MaChAmp (van der Goot et al., 2021). For Bilty, we project polyglot embeddings (Al-Rfou et al., 2013) of each

---

[4] Turkish is agglutinative. Segmentation often happens by splitting derivational suffixes that bear the final POS tag.



(a) `Monolingual` MoNoise. (b) `Fragment` based normalization. (c) `Multilingual` model. (d) `Language-aware` multilingual model.

Figure 3: Overview of the different proposed variations of MoNoise. Dashed lines mean that only one of the two paths is taken, decided by the language identification. For model (a), there can be two versions, one with features from Lang. 1 (shown here) and one based on Lang. 2.

language of the language pairs to the same space using MUSE (Lample et al., 2018), whereas for MaChAmp, we use multilingual BERT.[5] We use the default settings for all toolkits.

4.2 Normalization

We choose to use MoNoise (van der Goot, 2019) as a baseline and starting point for our proposed models for two main reasons: 1) Normalization annotation for code-switched data is scarce, and MoNoise is specifically strong in low-resource setups because of its dependence on external resources (generated from raw data); 2) It is the only normalization model that has shown to be effective in multiple languages. Below we first introduce the standard monolingual MoNoise model, and then all the proposed extensions which are focused on code-switched data. A schematic overview of all models is shown in Figure 3.

Monolingual (Figure 3a)
MoNoise consists of two parts, a candidate generation step and a candidate ranking step. For the generation of candidates, a spelling correction system (Aspell),[6] word embeddings and a dictionary based on the training data are used. Features from these modules are then supplemented with n-gram probabilities based on Wikipedia and Twitter data and other features indicating whether a word is present in the Aspell dictionary, whether it contains an alphabetical character, the length of a candidate compared to the original word, and whether it starts with a capital. For the novel proposed models, we will split up the features based on whether they require *language-specific* resources (spelling correction, word embeddings and n-grams features; yellow and red in Figure 3), or whether they are *language-agnostic* (all other features; blue in Figure 3). For the ranking of the candidates a random forest classifier (Breiman, 2001) is used, which predicts the probability whether a candidate is correct. An obvious disadvantage when applying monolingual MoNoise on CS-data is that many features are language-specific (e.g. spelling correction, word embeddings, n-grams), which is sub-optimal for tokens from another language. Since our datasets and evaluation include capitals, we use the version of MoNoise including capitalization handling (van der Goot et al., 2020).

Fragments (Figure 3b)
The baseline model has the deficiency that it has the language-specific features only for one language, while normalizing texts for two languages. An intuitive way of improving this model would be to split up the input data into monolingual fragments, and train two separate monolingual models. The fragments are created by splitting the data on every CS point, where words with the `UN` label are converted to the label of the previous word. This setup has the advantage that the normalization model itself does not need any adaptation, and it can thus be used with any normalization model. The disadvantages are that it is dependent on a language label, two separate classifiers have to be trained and the context is interrupted.

Multilingual (Figure 3c)
Instead of using two separate random forest classifiers, we can exploit both feature sets simultaneously in one classifier. This means that for every

---

[5] multi_cased_L-12_H-768_A-12
[6] `www.aspell.net`

language-specific feature, we now have two features. In this setup, the model is not explicitly informed about the language of input words, however, some of the features (especially n-gram probabilities) will have a very high correlation with this information. This model has the advantage that only one classifier has to be trained, and no language labels are necessary. It has the disadvantage that it uses more features for the classifier compared to the `Monolingual` and `Fragments` models, which increases the complexity of the classification.

Language-aware (Figure 3d)
Some of the language-specific features of the `Multilingual` model will be rather superfluous for words in the other language. For example, it will search for Turkish words in German word embeddings, and also use n-gram counts based on the German Wikipedia. To avoid this, we can use only one copy of each language-specific feature, and generate them based on the language label (the same language labels as in the `Fragments` model are used). More concretely, this means that for a German word, we will generate uni-gram probabilities based on German data, whereas for Turkish we will use Turkish data; these are then modeled as one feature in the model. On top of this, we also add a feature that indicates which language a word belongs to. There might be some mismatches in the importance of features because different data sources and languages are used. Because the language label is known, and a random forest classifier can model feature interactions intrinsically (Breiman, 2001), these mismatches should not be problematic. This model has the advantage that the number of features stays almost the same as in the `Monolingual` model (+1, the language ID), but a disadvantage is that it requires language labels.

4.3 POS tagging

For POS tagging, we examine the same three sequence labeling systems as used for language identification (Section 4.1): MarMoT, Bilty and MaChAmp. For each normalization setting, we normalize the input data, and use this normalized text as input for the POS tagger, which is trained on canonical data.

5 Evaluation

In this section we evaluate each of the three subtasks (LID, normalization, POS), where for the latter two we also examine the effect of exploiting the prediction of the previous tasks. Unless mentioned otherwise, we report the results of 10-fold cross-validation on the training split of the data. For all experiments, we use a paired bootstrap test on the sentence level with 1,000 samples to test significance. For all results, we order the models by the complexity of the implementation as compared to MoNoise (first fragments, as the original model can be used as a black box, then multilingual because it does not need a language classifier, and finally the language-aware model). An * next to results denotes a significant difference for $p < 0.05$, of a model always as compared to the previous model (corresponding to the previous column in Table 6, the previous row in other tables) for the same data.

Model	Id-En	Tr-De
MarMoT	92.71	92.91
Bilty	*93.81	*94.31
MaChAmp	*95.17	*95.67

Table 3: Word level accuracies for language identification (10-fold).

5.1 Language identification

Results for the language identification task are reported in Table 3. Unsurprisingly, the performances are in line with the chronological order of the introduction of the systems, and their computational complexity. It should be noted that for MaChAmp we used pre-trained embeddings which were trained on the largest amount of external data. When inspecting the performance per language label, we saw that the '`UN`specified' is by far the most difficult. Even though this class contains punctuation, it also contains many harder cases, where a word belongs to any language other than Lang1 and Lang2, or when the annotator is uncertain. Barik et al. (2019) use a conditional random fields classifier with a variety of features for this task, and report 90.11 accuracy for the full Id-En dataset in a 5-fold cross-validation setting. Which, despite differences in data splits, confirms that our results are competitive.

5.2 Normalization

For lexical normalization, a wide variety of evaluation metrics is used in the literature, ranging from accuracy (Han and Baldwin, 2011), F1 score (Baldwin et al., 2015) and precision over out-

Model	Id-En	Tr-De
LAI	73.24	74.03
MFR	*88.35	*78.57
Monolingual-lang1 (Tr/Id)	*94.76	*79.81
Monolingual-lang2 (De/En)	*94.31	80.58
Fragments	94.73	*81.24
Multilingual	94.84	*81.74
Language-aware	94.79	81.68

Table 4: Normalization performance of the baselines and the proposed models (10-fold accuracy). For the models dependent on language labels, we used the labels predicted by MaChAmp.

Model	Id-En	Tr-De
Fragments (MarMoT)	94.66	80.77
Fragments (Bilty)	*94.71	*80.89
Fragments (MaChAmp)	94.73	*81.24
Fragments (Gold)	*94.81	81.71
Language-aware (MarMoT)	94.74	81.24
Language-aware (Bilty)	94.76	81.57
Language-aware (MaChAmp)	94.79	81.68
Language-aware (Gold)	94.90	82.18

Table 5: Effect of different language predictions on normalization models (10-fold accuracy).

of-vocabulary words (Alegria et al., 2013), to CER and BLUE score (Ljubešic et al., 2016). Because the word order is fixed in our task, and to ease interpretation of the results, we opt to use simple accuracy on the word level, where we consider all words (i.e., also the unnormalized words).

To interpret the scores, we include three baselines: 1) leave-as-is (LAI), which always outputs the original word, i.e. its accuracy is equivalent to the percentage of words that are not normalized 2) most-frequent-replacement (MFR), which uses the most frequent replacement from the training data for each word 3) monolingual MoNoise, which can be trained on either of the languages within a language pair (two models).

Results for the different models are compared in Table 4. For the Id-En dataset, the differences between all proposed models are small and not significant. Even the monolingual models perform remarkably well, and only small gains are observable when using the multilingual model. We also compared our results to Barik et al. (2019), using their evaluation metric as their model/output was not available. The metric is non-deterministic, as it uses accuracy over unique OOV words.[7] Nevertheless, our average estimated result for `Multilingual` is 69.83 for this metric, outperforming their score of 68.50.

For the Tr-De dataset, the scores are generally lower, indicating that this dataset (and perhaps language pair) is more difficult. Especially now, we can observe that the code-switched adaptations lead to substantially higher scores. To our surprise, `Multilingual` and `Language-aware` perform on par, even though the multilingual model does not rely on language labels. `Fragments` performs significantly worse. This leads to the conclusion that language labels are not directly beneficial for lexical normalization (in this setup). In general, the performances are in a similar range as for monolingual datasets (van der Goot, 2019).[8]

Model behavior Besides the metrics reported in the table, we also examined precision and recall. Precision is generally much higher (1.1 to 3 times, see Appendix B) than recall especially for Tr-De, which is in line with previous observations (van der Goot, 2019). This means that the model is conservative and only replaces cases for which it is rather certain, which arguably is a desirable behavior.

Effect of language predictions To evaluate the effect of the language predictions, we run both the `Fragments` and the `Language-aware` models with all language predictions from Section 5.1 as well as the gold language labels. The results (Table 5) show that the performance of the language identification has a positive effect on the normalization performance. Although it is not significant in most cases, it should be noted that significance is only tested compared to the previous model.

Language labels Looking at the normalization performance breakdown on language labels shows that the gains of our proposed models are consistently smaller on Indonesian and Turkish compared to respectively English and German (see Appendix A for full results). This was to be expected, as for these languages the model has less external

---

[7] Which can be normalized differently dependent on context, we confirmed this with the authors.

[8] van der Goot (2019) used error reduction rate as main evaluation metric, for which the multilingual model would score 80.72 (Id-En) and 30.42 (Tr-De). The reported scores on monolingual datasets are 77.09 for En and 28.94 for Tr.

Model	LAI	Multiling.	Lang.-aware	Gold
MarMoT–POS	61.92	*65.50	65.47	*69.14
Bilty–POS	*65.23	*67.99	*68.26	*72.04
MaChAmp–POS	65.60	*68.25	68.13	*71.27

Table 6: Accuracies for Tr-De POS tagging, using a variety of normalization strategies.

data (Section 3.3) and while the model was originally not evaluated for Indonesian, Turkish had the lowest performance in van der Goot (2019).

Qualitative analysis Both `Multilingual` and `Language-aware` correct most frequent normalization mistakes well. This means for Id-En, abbreviations (*yg* ↦ *yang* 'which is' in `ID`), slang words (*gw* ↦ *saya*, *gue* ↦ *saya* 'I' in `ID`), phonetic spelling (*kalo* ↦ *kalau* 'if' in `ID`); and for Tr-De emoticons, restoring Turkish-specific characters, restoring vowels (*cnm* ↦ *canım* 'my dear' in `TR`), and punctuation replacements. On the Id-En data, however, there is a higher number of these frequent replacements compared to the Tr-De dataset, which explains the high scores and small variability for Id-En in Table 4 and 5.

For the Tr-De dataset, the most common mistakes include: not correcting capitalization in the beginning of a sentence, merging of words, monolingual ambiguous cases depending on context (*mi* ↦ [*mi*, *mı*], question clitics in `TR`), and tokenization and punctuation mistakes (?:D ↦? :D). In comparison, for the Id-En dataset, the models make rather different errors: in-vocabulary words which should be normalized are left as is (*kaya* ↦ *seperti*, *usah* ↦ *perlu*), normalizations which are lexically very distant are not found (*lw* ↦ *kamu*), and English contractions are often not replaced (*isnt* ↦ *is not*). Error analysis on the Id-En dataset revealed that correction of capitalization was annotated inconsistently. However, because in most cases the normalization was lowercased, this did not have a large effect on performance.

Interestingly, `Language-aware` is better in correcting words that exist in both languages. For instance, *ne* is the informal form of *eine* 'a/one' in German, and also means 'what' in Turkish. The dataset annotations expect the *ne* ↦ *eine* normalization. While `Multilingual` fails to do so, `Language-aware` corrects them. We believe language IDs play a positive role here in defining the context, and although in general both models perform on par, if a dataset contains many such ambiguous words, `Language-aware` could be preferable.

5.3 POS tagging

For POS tagging, we only look at Tr-De as Id-En is not annotated with POS tags. We employ a pipeline approach; we first normalize our training data in a 10-fold setting, and then apply the tagger on this normalized data. The taggers are trained on a shuffled concatenation of the Turkish-IMST (Sulubacak et al., 2016) and German-GSD (McDonald et al., 2013) datasets of UD version 2.5 (Nivre et al., 2020). Now that none of the CS data is used during training, 10-fold cross-validation is not necessary. We directly apply the taggers on the full training data. This way the exact same data split is used for evaluation as in the 10-fold setting in the previous sections. Even though we have POS tags available for the gold normalization (Section 3.1), we do not have gold tags for predicted normalization, and to keep the comparison fair we evaluate using the `Tok+Anon` POS tags. When a word is split or merged, we use the alignment and check whether the correct tag is present. In other words: we select one tag based on an oracle selection.[9]

Results in Table 6 show that, surprisingly, Bilty performs competitive to MaChAmp across most settings. Considering the differences between the normalization models, the `Multilingual` model and the `Language-aware` model perform on par, but there is still a marginal gap compared to the gold normalization.

We also analyzed the confusion matrices of the POS tagger, the full analysis can be found in Appendix C, we will shortly summarize findings here. 1) Bilty is mainly outperforming MaChAmp in gold due to better recognition of symbols (emojis), 2) Bilty is more sensitive to different normalization strategies, whereas for MaChAmp the differ-

---

[9] It should be noted that this makes splitting beneficial, and this metric can easily be tricked by splitting every token so it should be used with caution. However, our proposed normalization models have a low rate of splitting (114 versus 398 in gold) and merging is not handled at all.

	Normalization		POS
Model	Id-En	Tr-De	Tr-De
LAI	74.03	67.02	60.77
Monolingual (Id/De)	*94.62	76.33	*63.47
Multilingual	94.27	*78.28	*64.06
Language-aware	94.32	77.83	*63.92
Gold	*100.00	*100.00	*67.75

Table 7: Normalization and POS tagging accuracies on test data. The POS tagging model is the same MaChAmp model for all results, only the normalization strategy for the input changes.

ences between them are minimal, 3) Performance on nouns improves a lot after normalization, especially for German (due to corrected capitalization of nouns), 4) The second POS tag which improved most are verbs, investigation showed that this is mainly because Turkish-specific characters are replaced by their ASCII counterparts, which helps the tagger assign the correct POS.

5.4 Test data

On the test data we take both the 'no normalization' and the best baseline (which are monolingual Indonesian for Id-En and monolingual German for Tr-De), and compare these to our best two proposed normalization models. The results in Table 7 show that, parallel to 10-fold cross-validation results (Table 4), `Multilingual` and `Language-aware` scores are similar and their difference is insignificant for both datasets. This leads to the conclusion that `Multilingual` is the most elegant model, as it is not dependent on language labels. On the Tr-De dataset the proposed models are clearly outperforming the baselines. However, on the Id-En dataset the differences are small (and not significant) between the monolingual model and both of our proposed models.

For Tr-De, we take the test set normalized by systems in the second column of Table 7 and apply MaChAmp for POS tagging. The results in the third column show that the POS tagger follows the trend in normalization scores, and performs slightly better when using the multilingual model, beating the LAI baseline (i.e. not using normalization) with 5.4% relative improvement.

6 Conclusion

Code-switching provides many challenges for NLP systems. In this work we attempt to overcome some of these challenges by normalizing the data, and evaluating the downstream effect of this for POS tagging. For evaluation we use an Indonesian-English dataset (Barik et al., 2019) as well as a German-Turkish dataset (Çetinoğlu, 2016), for which we provided novel normalization layers and adapted existing LID and POS annotation.

We proposed three different models to normalize CS data. The two best-performing models are `Language-aware` and `Multilingual`. The first model exploits language labels, to identify for which language to generate features, whereas the second model combines features for both languages. The differences in performance between these two systems was not significant for any of the 10-fold experiments nor on the test data, so in most cases the multilingual model would be preferable, as it has no dependence on language labels.

We showed that normalizing the input before POS tagging results in significantly higher POS accuracies for CS data. Gold normalization experiments showed that there is still room for improvement for normalization models to help POS tagging.

An interesting property of the proposed model is that it does not have to be trained on intrasentential CS data. In fact, it can be trained on a mix of two monolingual datasets, thereby handling many more language pairs. We hope to evaluate this setup if resources (i.e., normalization test data for a CS language pair, and monolingual normalization training data for both languages) become available.

Acknowledgements

We would like to thank Barbara Plank, Alan Ramponi, Marija Stepanovic, and Agnieszka Falenska, for feedback on early drafts. We also thank Manuel Mager and Sevde Ceylan with their help on Tr-De data alignment and Anab Maulana Barik for sharing the Id-En data. Appendix

A Breakdown of performance per language

Table 8 show the accuracy of all the proposed models per language. The LAI scores show that most of the normalization replacements are necessary for `ID` and `DE`. Interestingly, performance of the last two models is highest on respectively `EN` and `DE`, which is probably due to the original model being developed mostly with a focus European languages.

B Precision and recall

Table 9 show the precision and recall of all models on both datasets. LAI has 0.0 on all metrics, because it never finds a correct normalization.

C Confusions of POS taggers

We conducted an analysis of POS tagging confusions for the setting described in Section 5.3. In Table 10 and Table 11 the error frequencies of respectively MaChAmp and Bilty are shown. The tables report the frequency of the top-10 most frequent errors of the baseline (LAI), and the difference in counts observed using a variety of normalization strategies. In Figure 3 and Figure 3 the full confusion matrices for respectively MaChAmp and Bilty are shown. For both of these analyses, we do not report the other baselines, the fragment based model and the MarMot tagger, because performance of these was inferior and this would make comparisons more complex.

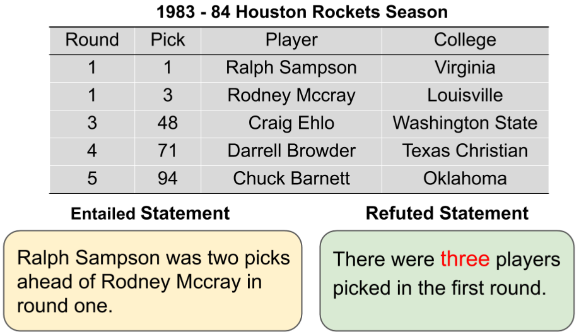
Abstract

Growing concern with online misinformation has encouraged NLP research on fact verification. Since writers often base their assertions on structured data, we focus here on verifying textual statements given evidence in tables. Starting from the Table Parsing (TAPAS) model developed for question answering (Herzig et al., 2020), we find that modeling table structure improves a language model pre-trained on unstructured text. Pre-training language models on English Wikipedia table data further improves performance. Pre-training on a question answering task with column-level cell rank information achieves the best performance. With improved pre-training and cell embeddings, this approach outperforms the state-of-the-art Numerically-aware Graph Neural Network table fact verification model (GNN-TabFact), increasing statement classification accuracy from 72.2% to 73.9% even without modeling numerical information. Incorporating numerical information with cell rankings and pre-training on a question-answering task increases accuracy to 76%. We further analyze accuracy on statements implicating single rows or multiple rows and columns of tables, on different numerical reasoning subtasks, and on generalizing to detecting errors in statements derived from the ToTTo table-to-text generation dataset.

1 Introduction

The rapid growth in the amount and sources of online textual content has raised concerns about misinformation and its potential harmful impacts on society when quickly spread to a massive audience. For example, a study on enhancing medical education with Wikipedia in 2015 found that 97% of medical students completing the survey disclosed that they found mistakes in Wikipedia medical entries (Herbert et al., 2015). Concerns about misinformation have stimulated extensive research on automatic fact verification, i.e., verifying whether a given textual statement is entailed or refuted by the given evidence.



1983 - 84 Houston Rockets Season

Round	Pick	Player	College
1	1	Ralph Sampson	Virginia
1	3	Rodney Mccray	Louisville
3	48	Craig Ehlo	Washington State
4	71	Darrell Browder	Texas Christian
5	94	Chuck Barnett	Oklahoma

Entailed Statement

Ralph Sampson was two picks ahead of Rodney Mccray in round one.

Refuted Statement

There were three players picked in the first round.

Figure 1: Example from the TabFact dataset: the top table contains the structured evidence; the bottom two boxes contain the statements entailed and refuted by the evidence. Errors are highlighted in red.

While most existing fact verification work focuses on unstructured textual evidence, fact verification with structured evidence is still under-explored. Recently, Chen et al. (2019) introduced a new large-scale dataset, TabFact, for verifying statements based on structured evidence in tables. Figure 1 presents an example table and the corresponding entailed and refuted statements from TabFact. The task of fact verification based on structured evidence is challenging in two aspects. First, traditional language models trained on unstructured text are not directly applicable to learn representations for structured text. It is difficult for such language models to understand a sentence like "*Round Pick Player College 1 1 Ralph Sampson Virginia ...*" by directly concatenating the table cells in Figure 1. Second, detecting misinformation with structured evidence involves not only linguistic inference but also numerical reasoning such as *addition*, *subtraction*, *sorting*, and *counting*

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2366–2375
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

over records. For example, to verify the statement "*Ralph Sampson was two picks ahead of Rodney Mccray*", we need first to find in which order each was picked and subtract them.

Table representation learning is important for utilizing table data as evidence for fact verification. Most existing methods apply BERT (Devlin et al., 2018) model to learn table representations. Table-BERT (Chen et al., 2019) uses simple templates to transform tables into "somewhat natural" sentences, and fine-tunes BERT on pairs of statement sentence and corresponding table "sentence". However, this model adds many extra tokens to the tables, sometimes doubling the length of the original table token sequence. Zhong et al. (2020) propose to first derive logical forms from the table and the statement. A heterogeneous graph is then constructed to capture connections between table cells, functions and arguments and statement tokens. A graph-enhanced contextual representation is learned for each token by only paying attention to the neighbor nodes in the graph when applying BERT model. However, as we show in §4.2, BERT is less effective when it is pre-trained on unstructured data but applied to structured data such as tables.

Table-based fact verification also requires numerical reasoning over table records. Chen et al. (2019) propose a Latent Program Algorithm (LPA), where the statements are parsed into potential programs and a weakly supervised discriminator is trained to assign confidence score to each program. The output from the latent programs are aggregated or ranked according to their confidence score as the final prediction. Zhong et al. (2020) propose to learn a representation for the program with a program-driven neural module network, where semantic compositionality is dynamically modeled along the program parsing structure in a bottom-up style. The program representation and the token representation for the table, statement and linearized program are then combined to make the final prediction. However, these two models depends on weakly-supervised labels, which could be noisy, to derive potential programs. Recently, the same authors of Table-BERT released a new model, GNN-TabFact[1], applying Numerical-aware Graph Neural Networks (NumGNN) on top of Table-BERT to learn to compare numerical cells in the same column. Nonetheless, it requires constructing a graph neural network and conducting iterative message passing among the nodes in the graph.

We propose to adapt the Table Parsing (TAPAS) model (Herzig et al., 2020), which has proven effective in question answering over tables, to model tables for fact verification. TAPAS concatenates all table cells without adding extra tokens and then extends BERT's architecture with additional embedding layers to capture the table structure and numerical comparison information for each token in the table. We replace its original two top classification layers for answer generation with a single classification layer on the `[CLS]` token to classify whether a given statement is entailed or refuted by the table. Our experimental results show that with proper pre-training, TAPAS outpeforms the state-of-the-art GNN-TabFact model, increasing the accuracy of statement classification from 72.2% to 73.9% on the TabFact test set even without modeling numerical information. By further adding ranking information for numerical rows and pre-training on the question answering task, TAPAS achieves 76% accuracy, with 89% on the simple statements and 69.8% on the complex statements. We also perform further analysis to examine: (1) how the numerical comparison information improves TAPAS's performance when ranking information is needed; (2) how the complexity of the training set affects model performance on simple and complex statements; and (3) how well systems trained on TabFact generalize to other fact verification tasks.

This paper's primary contributions are: (1) exploring the effect of table structure modeling on fact verification; (2) measuring the importance of language model pre-training on tabular data; and (3) analyzing the performance of fact-verification models on different numerical reasoning subtasks and errors.

2 Related Work

Fact Verification Thorne et al. (2018) introduce a new dataset for fact extraction and verification (FEVER) with claims generated by altering sentences extracted from Wikipedia. Nie et al. (2019) propose a neural semantic matching network based on a bidirectional LSTM to retrieve related evidence and predict whether the claim is entailed, neutral, or contradicted by the evidence. (Soleimani et al., 2019) propose to adopt a pre-trained BERT model for evidence retrieval and

---

[1] `https://github.com/wenhuchen/GNN-TabFact`

fine tuning it for evidence-claim relation prediction. Jobanputra (2019) propose an unsupervised question-answering based approach for fact checking by generating questions for a claim first and predicting the masked span, which is compared to the ground truth answer for label classification. Zhong et al. (2020) construct two graphs for evidence and claim via semantic role labeling, and use graph-based reasoning for fact checking.

Structured Data Modeling Modeling structured data is essential for multiple tasks, e.g., table classification, table population, table retrieval, question answering , data-to-text generation, and table-based fact verification.

Ghasemi-Gol and Szekely (2018), Trabelsi et al. (2019) and Deng et al. (2019) propose to embed tabular data into a vector space, using table structure to classify tables into different categories, adding more rows or columns to tables and retrieving tables given query keywords. Nishida et al. (2017) employ RNNs to encode cell content and CNNs to encode table structure to better capture semantic features for table classification.

Haug et al. (2018) propose to generate candidate logical forms from a question, convert logical forms to paraphrases, and rank them according to their similarity to the original question to generate the answer for the questions. Herzig et al. (2020) add additional embedding layers to a BERT model to capture table structure and numerical information, and add two classification layers to predict aggregation functions and corresponding table cells to generate an answer for a given question.

Much current table-to-text generation work focus on generating biographies from Wikipedia infoboxes (Lebret et al., 2016; Liu et al., 2018; Sha et al., 2018; Bao et al., 2018) or summarizing basketball games (Wiseman et al., 2017; Puduppully et al., 2019) according to the box- and line-score tables. Parikh et al. (2020) release a dataset for controlled table-to-text generation, where table cells are highlighted for the target sentences. Chen et al. (2020) propose a new natural language generation task, where the model tasked with generating statements that entailed by a given table.

Chen et al. (2019) introduce a dataset for fact verification given tabular data as evidence and propose a BERT-based Table-BERT model and a latent program algorithm (LPA) model for this task. Zhong et al. (2020) propose to first drive the program from the table and statement, and then learn graph-enhanced contextual representations for both the table tokens and the program to classify the statements. After this paper was submitted, four related papers were published, which explore additional questions in table-based fact verification. Zhang et al. (2020) propose to utilize masking in the self attention layer to model table structure. Shi et al. (2020) and Yang et al. (2020) explore how to effectively combine both linguistic information and symbolic information for table-based fact verification. Eisenschlos et al. (2020) generate synthetic datasets to pre-train a TAPAS model to better understand tables for downstream tasks such as table-based fact verification and question answering.

3 Methods

We describe adapting the TAPAS model to fact verification over tables and then introduce different pre-trained models on which we fine-tune the TAPAS for the table verification task.

TAPAS for table-based fact verification Similar to the Table-BERT model, the TAPAS model also flattens the input table into a sequence of tokens. It concatenates all the tokenized table cells in a row and then concatenates all the row sequences into a table sequence. In addition to the position and segment embeddings used in Transformer language models, four additional position embedding layers are introduced for encoding table structure and numerical comparison relations among cells in each column. For each token in the table, there is a column index and a row index indicating the position of the token in the table. For numerical and date columns (as determined by pandas), table cells are sorted to generate a rank index and a inverse rank index for each token according to their position in the sorted column. The sequence of tokens in the statement to be verified is concatenated with the corresponding table token sequence with the `[SEP]` token to indicate where the table sequence starts. For the statement sequence, all the row, column, rank and inverse rank indexes are set as 0. A special token `[CLS]` is added before this entire input sequence for classification purpose. Figure 2 shows how the table and statement from Figure 1 are indexed for each embedding layer. We remove the top two classification layers used in the original TAPAS model for the question answering task, and use the pooled output for the `[CLS]` token for statement classification. To explore the impact of different table encodings, we experiment with two variants of TAPAS: TAPAS-Row-Col, which only utilizes the column and row index embedding, and TAPAS-Row-Col-Rank, which leverages the additional ranking and inverse ranking information for numerical columns.

Pre-training We fine-tune the adapted TAPAS model for the table verification task starting from three different pre-trained models. The first pre-trained model is the widely applied BERT model (Devlin et al., 2018) trained on the BooksCorpus and Wikipedia text. Lists and tables are removed from the training text, so this model is merely trained on unstructured data. The second pre-trained model is the TAPAS-Row-Col-Rank model pre-trained by Herzig et al. (2020) on a large number of Wikipedia text-table pairs with a masked language modeling task. This pre-trained model should be able to better understand the tables by capturing the structure information and numerical information. The third pre-trained model is the TAPAS-Row-Col-Rank model trained on the SQA (Iyyer et al., 2017) dataset with a question answering task. We only utilize their parameters for the bottom layers encoding the text and table sequence. Since this model is trained to generate answers by selecting table cells and predicting the aggregation function to be used on the cells, it should be able to capture more complicated numerical information.

4 Experiments

In this section, we first introduce the experimental settings in detail (§4.1). Then we present the results of comparing two variants of TAPAS model and other state-of-the-art models on the table-based fact verification task in §4.2. More discussions about the models are provided in §4.3.

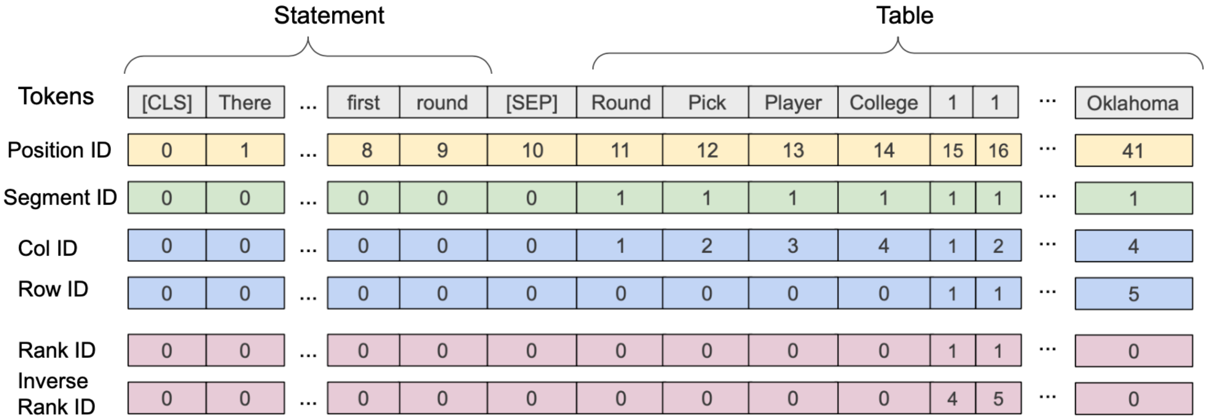
4.1 Experimental Setup

Dataset In the main experiment, we evaluate different models on TabFact, a large-scale dataset for table-based fact verification proposed by Chen et al. (2019). TabFact is generated by asking annotators to write statements given a table and its caption. The statements are either entailed or refuted by the table content. This dataset contains both *simple* and *complex* statements. Simple statements refer to a single row of the table without complicated logical inference and mention the table cells without much modification. Complex statements are more sophisticated and involve aggregation functions such max, min, count, average, difference, etc., over multiple table records. The mentioned table records are rephrased to involve more semantic understanding. A total of 118,275 statement sentences are generated for 16,573 tables, of which 50,244 are simple statements and 68,031 are complex statements. We use the training, validation and test set splits from Chen et al. (2019) to conduct a fair comparison with their models. Table 1 shows the statistics of these splits.

Split	#Statements	#Tables
Train	92,283	13,182
Val	12,792	1,696
Test	12,779	1,695

Table 1: Statistics of the training, validation, and test sets for the TabFact in Chen et al. (2019).

Comparisons We compare TAPAS-Row-Col and TAPAS-Row-Col-Rank model with the following state-of-the-art models:
a. Latent Program Algorithm (LPA). This model (Chen et al., 2019) first uses trigger words to prune pre-defined APIs including around 50 functions such as min, max. Then candidate latent programs are constructed by using breadth-first-search with memoization, and a discriminator is trained with weakly-supervised labels to assign confidence score to the programs. Their best performing model ranks all the latent programs by the discriminator confidence score and make the prediction by executing the top-rated program.
b. Table-BERT. This model (Chen et al., 2019) applies a pre-trained BERT model to classify the concatenated table and statement. Their best performing model first concatenates the header of each column to each table cell in the same column by using the template `[HEADER] is [CELL]`. Then table cells in the i^{th} row are concatenated with the ";" symbol and a short phrase `row` i `is ...` is added to the beginning of the concatenated cells to identify the cells from each row of the table. For example, the first row of the table from Figure 1 would be flatted to "*Row 1 is: Round is 1; Pick is 1; Player is Ralph Sampson; College is Virginia.*". All the row sequences are then concatenated as the table sequence, which is further concatenated to the statement sequence with the `[SEP]` symbol



Tokens	[CLS]	There	...	first	round	[SEP]	Round	Pick	Player	College	1	1	...	Oklahoma
Position ID	0	1	...	8	9	10	11	12	13	14	15	16	...	41
Segment ID	0	0	...	0	0	0	1	1	1	1	1	1	...	1
Col ID	0	0	...	0	0	0	1	2	3	4	1	2	...	4
Row ID	0	0	...	0	0	0	0	0	0	0	1	1	...	5
Rank ID	0	0	...	0	0	0	0	0	0	0	1	1	...	0
Inverse Rank ID	0	0	...	0	0	0	0	0	0	0	4	5	...	0

Figure 2: Example of how TAPAS encoding the refuted statement and the table from Figure 1 for classification.

and fed into BERT model for classification.

c. GNN-TabFact. This is a newly released state-of-the-art model by the creators of TabFact. It first extracts the representations for table tokens and statement tokens based on Table-BERT, then the representations for the tokens in the same cell are averaged as the representation for each table cell. All the table cells with numerical values in the same column are treated as nodes, and a graph is constructed by connecting the nodes with two types of edges—greater and less than—according the values of the cells. A NumGNN layer is then utilized to propagate information among the nodes in the graph to integrate the numerical comparison information into each table cell's representation. Cross attention is then computed over the new table representation and the textual statement for final classification.

d. LogicalFactChecker. This model (Zhong et al., 2020) first derives a program from the table and statement, then learns a contextual representation for the tokens by constructing a heterogeneous graph to capture the connections among the statement, the table and the program. A program-guided neural module network is introduced to learn a representation for the program by capturing its structural and compositional semantics. The token representations and the program representation are then combined to make the final prediction.

Model Parameters Following Table-BERT, all of our models are based on the open-source implementation of BERT with 12-layers, 768-hidden, 12-heads[2]. Both statements and tables are tokenized into sequences of subwords with the Standard BERT tokenizer and joined by the `[SEP]` special token. `[CLS]` is added to the beginning of the joined sequence. We modify the BERT code by adding embedding layers for special token types such as row index, column index and (inverse) rank index information following the TAPAS variants described above modeling for table structure.

Evaluation Metric All models are evaluated for accuracy on classifying test statements as entailed or refuted by the corresponding evidence table.

4.2 Main Results

Table 2 presents our main results, comparing TAPAS-derived models with baseline models on table-based fact verification. As we can see, the TAPAS-Row-Col-Rank model pre-trained on the question answering task over tables achieves the best performance. The TAPAS-Row-Col model pre-trained on WikiTables and fine tuned on TabFact data outperforms the state-of-the-art GNN-TabFact model no matter whether the full table is used or only the subset columns related to the statements are used. (This subsetting gives the best results for GNN-TabFact.)

How do different ways of modeling table structure affect the model performance? We first examine how the method of modeling table structure affects performance. Table-BERT uses a simple template to transform a table into a "somewhat natural" sentence to exploit a language model pre-trained on natural sentences. However, Table 2 shows that TAPAS-Row-Col, which directly concatenates all table cells and uses row index and column index position embedding to capture the table structure, significantly outperforms Table-BERT on the complex test set with the same pre-training,

TAPAS-Row-Col-Rank	Wikipedia Tables + SQA	all	**76.0***	**89.0***	**69.8** *
TAPAS-Row-Col-Rank	Wikipedia Tables + SQA	subset	74.6*	88.9*	67.7*

Table 2: Percent accuracy of different models for table-based fact verification on the TabFact test set. "Subset" means only use the table columns with entities linked to the statements during training, while "all" means use all the columns. Models with accuracies significantly surpassing the previous state of the art, GNN-TabFact, are highlighted with * ($p < 0.05$, paired-permutation test). **Bold** indicates the best results in a column.

increasing the accuracy from 58.2% to 62.9%. It reveals that TAPAS-Row-Col's structural encoding is more effective for verifying statements involving complicated aggregation over multiple table rows.

Does filtering the table columns help? Table-BERT works on the subset of the table columns relevant to the statements, since the a table serialized in "natural" language might be too long for sequence models. Chen et al. (2019) filter tables to the columns containing entities linked to the statement. We run TAPAS-Row-Col model on both full table and subset of the columns. Table 2 shows that, when TAPAS-Row-Col is fine-tuned from the original BERT model, shrinking the table only to the related columns significantly improves its accuracy from 60.5% to 68.3%. However, when we fine tune TAPAS-Row-Col model pre-trained on the Wikipedia tables, the difference is not that significant. It shows that filtering the table columns mainly helps when applying language models pre-trained on unstructured data to structured data.

What is the effect of pre-training? We fine-tuned TAPAS-Row-Col on two different types of pre-trained model: the original BERT model pre-trained on unstructured text and the TAPAS model pre-trained on Wikipedia Tables together with sentences from the corresponding text paragraph by Herzig et al. (2020). Both of the pre-trained models are trained with the masked language modeling task. As we can see, pre-training on tables significantly improves performance of TAPAS-Row-Col from 68.3% to 73.9%. Fine-tuning TAPAS-Row-Col-Rank on the model pre-trained on the question answering task, where numerical reasoning skills are required to generate an answer for a given question, further improves accuracy from 74.5% to 76%. However, if we only fine-tune on the subset of table columns matching the statement, TAPAS-Row-Col-Rank does not benefit from the pre-trained question answering model. We conjecture that it is because the original model is pre-trained on full tables.

Does adding numerical comparisons help? Both GNN-TabFact and TAPAS-Row-Col-Rank model numerical comparison relations among cells in the same column. GNN-TabFact learns a representation for each table cell by iteratively passing their numerical relations such as greater or less in a graph neural network. TAPAS-Row-Col-Rank model adds the rank and inverse rank index for cells in the same column as special position embedding for each token in the table cells. GNN-TabFact significantly outperforms Table-BERT by adding a numerically aware graph neural network on top of it. It also outperforms the LogicalFactChecker model, which first derives a program from the table and the statement and then learns the representation for the programs via a program-guided neural module network. Also, TAPAS-Row-Col-Rank model significantly outperforms TAPAS-Row-Col by introducing rank position embedding for each numerical column. We also find that TAPAS-Row-Col-Rank outperforms GNN-TabFact without complicated graph inference. It is worth noting that even TAPAS-Row-Col, which does not utilize any numerical information, outperforms GNN-TabFact, the previous state of the art on TabFact. This again demonstrates the advantage of directly encoding ta-

Model	Pre-train	Columns	Test

ble structure in TAPAS and the value of pre-training on structured data.

4.3 Further Experiments and Discussion

To analyze model performance, we perform further experiments on different training and test sets.

How does numerical information help? To examine how numerical comparison information helps to improve performance, we use heuristic rules to find the test statements involving *comparing* table records, *summing* table columns, and *counting* table records. We first find all words ending in *-est* in complex statements and remove those that do not belong to superlative words. Then we extract all test samples from the complex set containing these words or the word *most* as the **superlative test set**. We construct a **comparative test set** in a similar way by finding words ending in *-er*. Non-comparative words are removed and the words *more* and *less* are added to the set. We constrain the comparative samples to have the word *than* together with one of the comparative words. The **sum test set** is constructed by finding all the samples containing *total* or *sum*, the **count** set is constructed by finding all the samples containing *all*, *every*, *none*, *only* and *each*. The final superlative and comparative test sets contain 1,701 and 1,366 instances, respectively. The sum and counting sets contain 344 and 1,710, respectively. Table 3 shows the results of different models on these four sets. All results are reported for encoding full tables for variants of TAPAS-Row-Col models. As we can see, by modeling numerical comparison information among table cells in the same column, GNN-TabFact model significantly outperforms Table-BERT model on the superlative, comparative and count sets. Fine tuning TAPAS-Row-Col model pre-trained on the Wikipedia tables dataset improves performance on all the sets compared to fine tuning it from pre-trained BERT model. By adding ranking information, TAPAS-Row-Col-Rank significantly improves over TAPAS-Row-Col model on the superlative set. The increase of performance on other sets are not significant. Fine-tuning TAPAS-Row-Col-Rank on the model pre-trained for question answering further improves performance on all sets. It is also worth noting that TAPAS-Row-Col, with pre-training on Wikipedia tables, even outperforms GNN-TabFact model without utilizing any numerical comparison information. It also reveals that adding ranking information model benefits superlative statements most, and classifying comparative statements is more difficult than superlative statements.

Training Set	All	Simple	Complex
Complex	70.2	76.4	**67.2**
Simple	68.4	**88.2**	58.9
Mixed	**73.0**	86.1	66.6

Table 4: Results of fine-tuning Tapas-Row-Col-Rank model on statements with different complexity.

How does training set complexity affect model performance? We sampled three subsets from the original training set: one only contains simple statements (as defined by TabFact), one only contains complex statements, and one mixed set with equal size of simple and complex statements. All three sets have the same size: 41,366 training samples and 12,793 validation samples. We fine-tune the TAPAS-Row-Col-Rank model pre-trained on the question-answering task on three different sets and present the results in Table 4. The model trained on the mixed data achieves the highest overall accuracy on the test set. A significant drop of performance could be observed when the model is trained and test on statements with mismatched complexity.

How well do models trained on TabFact generalize to other data? Since statements in TabFact were generated by annotators specifically for fact verification, we explored generalization performance with a synthetic table-based fact verification dataset generated from the ToTTo dataset, a

Train	TabFact			Synthetic		
	All	Simple	Complex	All	Postive	Negative
TabFact	76.0	89.0	69.8	79.2	86.9	71.6
Synthetic	63.3	76.4	57.0	87.0	92.1	81.8

Table 5: TAPAS-Row-Col-Rank model training and testing on TabFact and ToTTo-derived synthetic data.

	Original Entailed Statement	Synthetic Refuted Statements
1	Baron Fabian Von Fersen (1626 – 1677) was a Swedish field marshal.	Baron Fabian Von Fersen (626 – 1677) was a Swedish field marshal.
2	As a sophomore, Peters averaged 16.8 points and 6.7 rebounds per game.	As a sophomore, Peters averaged 16.8 points and 66.7 rebounds per game.
3	Ralph Herseth (1909 – 1969) was the 21st governor of South Dakota from January 6, 1959 to January 3, 1961.	Ralph Herseth (1909 – 1969) was the 11st governor of South Dakota from January 6, 1959 to January 3, 1961.

Table 6: Examples of synthetic refuted statements that the Tapas-Row-Col-Rank model trained on TabFact failed to recognize. The errors are in red and the corresponding correct numbers are underlined.

table-to-text generation dataset proposed by Parikh et al. (2020). ToTTo was constructed by asking annotators to modifying the original sentence in Wikipedia that referenced a table. Annotators deleted irrelevant parts of the sentence and replaced pronominal references with a named entity from the table or the contextual metadata. Annotators were also asked to highlight the table cells that support the sentence. In all, 128,461 tables were annotated, with one sentence per table.

From ToTTo, using negative sampling, we derive a synthetic dataset for fact verification to compare with the TabFact data. We first removed all the samples in Totto data that also appears in TabFact data. Since the cells related to the summarizing sentence are highlighted in ToTTo, we extract all the sentences containing entities that exactly match the highlighted table cells and treat them as as facts. Then for each fact statement, we randomly choose an entity in it and replace it with a randomly chosen cell from the same column to generate a false statement. To ensure the false statement is different from the fact statement, we only choose cells whose values differ from the original. We end up with 75,292 training, 8,366 validation, and 5,242 test samples. We fine-tune the TAPAS-Row-Col-Rank model on this synthetic dataset. The results on this synthetic dataset and TabFact are listed in Table 5. Training on synthetic data achieves 76.4% accuracy on the simple TabFact statements, while training on TabFact achieves 79.2% accuracy on synthetic data. This confirms that the model trained on TabFact model is able to recognize cell copying errors. Both models are better at classifying positive statements than negative statements, which is more obvious for the model trained on TabFact.

We also generated another synthetic dataset with uniformly distributed character-editing errors on digits to see whether models trained on TabFact could capture this kind of error. We first extract all the test sentences containing numbers that exactly matches the highlighted table cells. Then we randomly choose to insert, delete or substitute one random digit in the first position (to make the task easier) of a randomly chosen matching number in the sentence (to ensure there is clue in the table). A total of 1,126 synthetic refuted statements are generated for testing. We check whether the TAPAS-Row-Col-Rank model trained on TabFact can recognize this type of error. Only 43.0% of these synthetic statements are classified as refuted by the model, which is much lower than the 71.6% accuracy on the refuted statements generated above by cell copying. It reveals that models trained on TabFact data are less sensitive to purely numerical errors. Table 6 shows examples of synthetic false statements the model trained on TabFact failed to recognize.

5 Conclusions

We adapted the Table Parsing (TAPAS) model, with efficient encoding of table content, structure, and numerical comparison information for the task of table-based fact verification. We compared two variant models: TAPAS-Row-Col, which models table contents and structure, and TAPAS-Row-Col-Rank, which adds numerical comparison information. Experiments showed that both TAPAS-Row-Col and TAPAS-Row-Col-Rank outperform the state-of-the-art numerically-aware graph neural network model by pre-training on tabular data. We also examined how ranking information helps improve TAPAS's performance on superlative, comparative, sum, and count statements. Models trained on different datasets were compared to study how question complexity affects model performance. We also constructed two synthetic datasets to examine the generalization of these models. We find models trained on TabFact perform well on errors arising from simple cell replacement but not on digit-editing errors. In future, we aim to extend TAPAS to explicitly model more numerical operations for fact verification and to correct false statements automatically given tabular evidence.

Abstract

As transparency becomes key for robotics and AI, it will be necessary to evaluate the methods through which transparency is provided, including automatically generated natural language (NL) explanations. Here, we explore parallels between the generation of such explanations and the much-studied field of evaluation of Natural Language Generation (NLG). Specifically, we investigate which of the NLG evaluation measures map well to explanations. We present the ExBAN corpus: a crowd-sourced corpus of NL explanations for Bayesian Networks. We run correlations comparing human subjective ratings with NLG automatic measures. We find that embedding-based automatic NLG evaluation methods, such as BERTScore and BLEURT, have a higher correlation with human ratings, compared to word-overlap metrics, such as BLEU and ROUGE. This work has implications for Explainable AI and transparent robotic and autonomous systems.

1 Introduction

The machine learning models and algorithms underlying today's AI and robotic systems are increasingly complex with their internal operations and decision-making processes ever more opaque. This opacity is not just an issue for the end-user, but also the creators and analysts of these systems. As we move towards building safer and more ethical systems, this lack of transparency needs to be addressed. One key trait of a transparent system is its ability to be able to *explain* its deductions and articulate the reasons for its actions in Natural Language (NL). As the area of Explainable AI (XAI) grows and is mandated (cf. the EU General Data Protection Regulation's "right to explanation" (Commission, 2018) and standardisation (cf. IEEE forthcoming standard on Transparency (P7001)), it has become ever more important to be able to evaluate the quality of the NL explanations themselves, as well as the AI algorithms they explain. Furthermore, the importance of evaluating explanations has been emphasised by researchers within the social cognitive sciences (Leake, 2014; Zemla et al., 2017; Doshi-Velez and Kim, 2017). To date, explanations have mostly been evaluated by collecting human judgements, which is both time-consuming and costly. Here, we view generating explanations as a special case of Natural Language Generation (NLG), and so we explore mapping existing automatic evaluation methods for NLG onto explanations. We study whether general, domain-independent evaluation metrics within NLG are sensitive enough to capture the peculiarities inherent in NL explanations (Kumar and Talukdar, 2020), such as causality; or whether NL explanations constitute a sui-generis category, thus requiring their own automatic evaluation methods and criteria.

In this paper, we firstly present the ExBAN dataset: a corpus of NL explanations generated by crowd-sourced participants presented with the task of explaining simple Bayesian Network (BN) graphical representations. These explanations were subsequently rated for *Clarity* and *Informativeness*, two subjective ratings previously used for NLG evaluations (Gatt and Krahmer, 2018; Howcroft et al., 2020). The motivation behind using BN is that they are reasonably easy to interpret, are frequently used for the detection of anomalies in the data (Tashman et al., 2020; Saqaeeyan et al., 2020; Metelli and Heard, 2019; Mascaro et al., 2014), and have been used to approximate deep learning methods (Riquelme et al., 2018; Gal and Ghahramani, 2016), which we could, in turn, explain in Natural Language.

Secondly, we explore a wide range of automatic measures commonly used for evaluating NLG to

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2376–2387
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

understand if they capture the human-assessed quality of the corpus explanations. We then go on to discuss their strengths and weaknesses through quantitative and qualitative analysis.

Our contributions are thus as follows: (1) a new corpus of natural language explanations generated by humans, who are asked to interpret Bayesian Network graphical representations, accompanied by subjective quality ratings of these explanations. This corpus can be used in various application areas including Explainable AI, general Artificial Intelligence, linguistics and NLP; (2) a study of methods for evaluating explanations through automatic measures that reflect human judgements; and (3) qualitative discussion into these metrics' sensitivity by examining specific explanations varying on the Informativeness/Clarity scales.

2 Related Work

Explanations are a core component of human interaction (Scalise et al., 2017; Krening et al., 2017; Madumal et al., 2019). In the context of Machine Learning (ML), explanations should articulate the decision-making process of an ML model explicitly, in a language familiar to people as communicators (De Graaf and Malle, 2017; Miller, 2018). According to Plumb et al. (2018), three of the most common types of explanation are: (1) *global explanations*, which describe the overall behaviour of the entire model (Arya et al., 2019); (2) *local explanations*, commonly taking the form of counterfactuals (Sokol and Flach, 2019) that describe why particular events happened (known also as "everyday explanations"); and (3) *example-based explanations* that present examples from the training set to explain algorithmic behaviour (Cai et al., 2019).

Recently, various explanation systems provide different types of explanations for AI systems: the LIME method visually explains how sampling and local model training works by using local interpretable model-agnostic explanations (Ribeiro et al., 2016); MAPLE can provide feedback for all three types of explanations: example-based, local and global explanations (Plumb et al., 2018); CLEAR explains a single prediction by using local explanations that include statements of key counterfactual cases (White and d'Avila Garcez, 2019). Whilst these techniques and tools gain some ground in explaining deep machine learning, the explanations they provide are not necessarily aimed at the (non-expert) end-user and so are not always intuitive.

NLG has traditionally been broken down into "what" to say (content selection) and "how" to say it (surface realisation) and can draw parallels with Natural Language explanations. In particular, it is important to gauge how much content or how many reasons to present to the user, to inform them fully without overloading them. For example, prior work has shown that people prefer shorter explanations that offer only sufficient detail to be considered useful (Harbers et al., 2009; Yuan et al., 2011).

According to Miller et al. (2017), how explainers generate and select explanations depends on so-called pragmatic influences of causes, and they found that people seem to prefer simpler and more general explanations. Similarly, Lombrozo (2007) notes that simplicity and generality might be the key to evaluating explanations. This was partly the case described in (Chiyah Garcia et al., 2018), but here the users were experts and preferred to be given all possible reasons but as precise and brief as possible. It is clear from these prior works that explanations have to be evaluated in the context of the scenario, prior knowledge and preferences of the explainee, and the intent and goals of the explainer. These could be, for example, establishing trust (Miller et al., 2017), agreement, satisfaction, or acceptance of the explanation and the system (Gregor and Benbasat, 1999).

Somewhat analogous to auto-generated explanations are the fields of summarisation of text (Tourigny and Capus, 1998; Deutch et al., 2016) and Question-Answering (Dali et al., 2009; Xu et al., 2017; Lamm et al., 2020). This is because they provide users (expert and lay users) with various forms of summaries (visual or textual) and answers containing explanations to enable them to have a better understanding of content.

Summarisation methods and sentence compression techniques can help to build comprehensive explanations (Winatmoko and Khodra, 2013). With regards to evaluating these summarisation methods, Xu et al. (2020) proposed an evaluation metric that weighted the facts present in the source document according to the facts selected by a human-written (natural language) summary, by using contextual embeddings. This evaluation of text accuracy is indeed related to explanations because any explanation must contain enough statements to support decision-making and understanding. These statements should be accurate and true.

The growing interest in the AI community to investigate the potential of NL explanations for bridging the gap between AI and HCI has resulted in an increasing number of NL explanations datasets. The ELI5 dataset[1] (Fan et al., 2019) is composed of explanations represented as multi-sentence answers for diverse questions where users are encouraged to provide answers, which are comprehensible for a five-year-old. WorldTree V2[2] (Jansen et al., 2019) is a corpus of Science-Domain that contains explanation graphs for elementary science questions, where explanations represent interconnected sets of facts. CoS-E[3] is a dataset of human explanations for commonsense reasoning in the form of natural language sequences and highlighted annotations (Rajani et al., 2019). Multimodal Explanations Datasets (VQA-X and ACT-X) contain textual and visual explanations from human annotators (Park et al., 2018). e-SNLI[4] is a corpus of explanations built on the question: "Why is a pair of sentences in a relation of entailment, neutrality, or contradiction?" (Camburu et al., 2018). Finally, the SNLI corpus[5] is a large annotated corpus for learning natural language inference (Bowman et al., 2015), considered one of the first corpora of NL explanations.

In this paper, we present a new corpus for NL explanations. The ExBAN corpus presented here provides a valuable addition to this set of corpora as it is aimed at explaining structured graphical models (in particular Bayesian Networks), that are closely linked to ML methods.

3 ExBAN Corpus

The ExBAN Corpus (**Ex**planations for **BA**yesian **N**etworks)[6] consists of NL Explanations collected in a two step process: (1) NL explanations were produced by human subjects; (2) in a separate study, these explanations were evaluated in terms of Informativeness and Clarity.

For Step 1, each subject was shown graphical representations of three Bayesian Networks (BN), in random order. They were then asked to produce text to describe how they interpreted the BN. The three BN used in the data collection are presented in Figure 1and represent well-known BN examples, extracted from Russell (2019). For Step 2 in a separate experiment, approximately 80 of these generated explanations were presented to a different set of subjects in random order, along with a scenario description and the graphical model image. Subjects were asked to rate them in terms of Informativeness and Clarity. The worded scenario descriptions were not given to subjects in the first stage, so as not to prime them when generating explanations.

3.1 Step 1: Natural Language Explanations Corpus

Survey Instrument. A pilot was performed to test options and ensure the completion time, leading to the final survey instrument. The survey was divided into five sections: 1) consent form; 2) closed-ended questions related to English proficiency, computing and AI experience: "How much computing experience do you have?", "What is your English Proficiency Level?", "How much experience do you have in the field of Artificial Intelligence?"; 3) attention-check question, where participants received an image of a graphical model, and they had to select the correct answer(s) for the given image; and 4) respondents were asked to explain the three graphical models, in their own words. All respondents received the graphical model survey questions in randomised order. The appropriate ethical procedures were followed in accordance with ethical standards, and ethical approval was obtained.

Participants. 85 participants were recruited via social media. English proficiency level, computing experience and AI experience were rated on a numerical scale, from 1 to 7 (1 = beginner, 7 = advanced). The majority of participants ($n = 83$) rated their level of English proficiency with values higher than 5, with over half of the participants rating their level as 7. Just 12% ($n =$

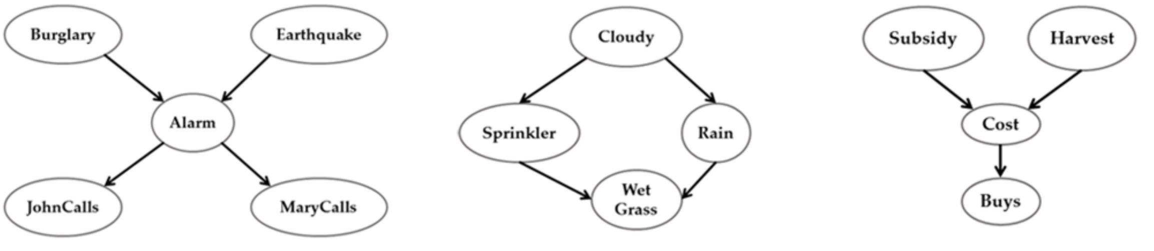

Diagram 1

Ref: "In the event of either burglary or earthquake the alarm will call John or Mary."

Diagram 2

Ref: "If it gets cloudy, it can rain or the sprinkler may get activated. Whenever it rains or the sprinkler gets activated, the grass gets wet."

Diagram 3

Ref: "The subsidy and the harvest influence the cost of production. The final price influences the amount of bought products."

Figure 1. Annotated diagrams with assigned explanation references, where **Diagram 1** represents a typical Bayesian Network, **Diagram 2** represents a multiply-connected network and **Diagram 3** represents a simple network with both discrete variables (Subsidy and Buys) and continuous variables (Harvest and Cost). Beneath each diagram, the gold standard references are provided.

10) participants rated their computing experience scores with a value lower than 5 and 82% ($n = 70$) of participants had a high level of computing experience. Subjects had mixed experience with AI with over half (54%) having some experience ($n = 46$), but 46% of them had limited AI experience ($n = 39$).

Collected NL explanations. Quality control of the collected data included a cleaning step where participants' responses were hand-checked and removed if the participants did not attempt to complete the tasks. Explanations that contained misspellings and missing punctuation were corrected manually (both the raw data and cleaned data are available). The number of explanations for each diagram, after the data cleaning step are as follows: Diagram 1: 84 explanations, 1788 words; Diagram 2: 83 explanations, 1987 words; and Diagram 3: 83 explanations, 1400 words.

3.2 Step 2: Human Evaluation for Quality

Survey Instrument. To investigate the quality of the explanations collected in Step 1, we performed a human evaluation of the generated explanations. A pilot survey was performed to test and refine options, where respondents ($n = 45$) were recruited from Amazon Mechanical Turk and were compensated monetarily.

Each participant was given three tasks, each corresponding to the BN presented in Figure 1 with the order randomised. Along with the BN image, a simple description story was provided in order to give the subject a better understanding of the context as well as instructions on how to approach these tasks. Here, we give the scenario for Diagram 1 to illustrate this: "John and Mary bought their dream home. To keep their home safe, they installed a Burglary/Earthquake Alarm. Also, they received an instruction manual where they found the following diagram: They are not sure if they correctly understood the diagram. On the following pages are some worded explanations. We need your help to evaluate them!"

For every BN image, the participants were asked to evaluate 5 explanations in terms of: **Informativeness** (Q: "How relevant the information of an explanation is"; Likert scale, where 1 = Not Informative and 7 = Very Informative); and **Clarity** (Q: "How clear the meaning of an explanation is"; Likert scale, where 1 = Unclear and 7 = Very Clear).

Participants. The final data collection survey was advertised on social media as "a 10-minute survey, where participants were asked to provide feedback about how understandable the explanations of the three graphs are". Demographic information was collected (age range and gender). A total of 96 participants answered the survey. As screening criteria, participants had to complete all survey questions. Post validation, we had a sample of 56 participants consisting of 42 male participants (75%), 11 female participants (19.6%) and 2 non-binary gender participants (3.6%). Gender imbalance might be due to "differences in female and male values operating in an online environment" (Smith, 2008). Half of the participants ($n = 28$) are aged between 23-29 years old, followed by

30% of participants aged between 18-22 ($n = 17$), 20% aged 40–49 ($n = 11$), 18% aged 30–39 ($n = 10$). Previous studies have identified a high degree of inconsistency in human judgements of natural language (Novikova et al., 2018; Dethlefs et al., 2014); each participant can have a different perception of the interpretation of these metrics, even if a definition of these metrics is provided. Indeed, we found that in our data, explanation ratings can vary significantly, with an explanation rated highly by one person for Clarity, but viewed as very unclear by another annotator. This was the case for both Clarity and Informativeness.

We aim to create a reliable database of varying quality of NL explanations, i.e. where the quality of explanations is generally uncontested by the majority. Therefore, subjective ratings were post-processed. For each explanation, we collected a minimum of 3 judgments. Explanations received ratings from 1 to 7; we classified bad explanations as those with low ratings (ratings $<$5) and good explanations, as those with higher ratings (ratings $\geq$5). For any one explanation, if the difference between the number of good and bad ratings is $\leq$1, then that explanation is considered hard to judge and difficult to reach a consensus on and thus removed. After this pre-processing step, the corpus contained ratings for 54 explanations for Diagram 1, 34 explanations for Diagram 2, and 54 explanations for Diagram 3.

To verify the agreement between different raters, we used Krippendorff's Alpha, a measure of inter-rater reliability (Krippendorff, 1980). We computed Krippendorff's Alpha coefficient using the Python package `krippendorff` (version 0.3.2). After the pre-processing step, the agreement between subjects increased, see Table 1 for the post-processing Alpha values for each of the Bayes Nets. Alpha values between .21 to .40 indicate fair agreement and values between .41 to .60 indicate moderate agreement (Hallgren, 2012). Here, we can see that explanations for Diagram 2 were particularly contentious, but overall the numbers reflect fair to moderate agreement.

4 NLG Evaluation Metrics

Here, we describe the reasoning behind our choice of subjective measures that attempt to capture both the content and its correctness (Informativeness) and quality of expression (Clarity). We also describe objective measures commonly used for automatic evaluation of NLG, and which we will extract from the ExBAN corpus.

4.1 Subjective NLG Evaluation Metrics

Human evaluation is considered a primary evaluation criterion for NLG systems (Gatt and Krahmer, 2018; Mellish and Dale, 1998; Gkatzia and Mahamood, 2015; Hastie and Belz, 2014). Through Explainable AI, we want to achieve Clarity and understanding in communicating the process of AI systems. Therefore, explanations should be clear and easily understood by users. Traditional human evaluation metrics are clearly needed for increasing transparency, avoiding confusion and misunderstanding.

Informativeness. As defined in the field of NLG, Informativeness targets relevance or correctness of an NLG output relative to an input (Dušek et al., 2020). According to the literature, Informativeness can provide "timely, relevant and useful information" (Novikova et al., 2018) and "make information immediately accessible" (Maxwell et al., 2017). Sometimes, Informativeness is linked with accuracy, or adequacy (Novikova et al., 2018). As mentioned previously, explanations contain statements with some prior knowledge that must be accurate and true (Goodrich et al., 2019; Xu et al., 2020).

Clarity. An explanation should be clear to achieve effective communication. In the NLG field, Clarity implies that text is easily understood (Belz and Kow, 2009; van der Lee et al., 2017) and that the reader is familiar with basic information introduced in the text (Lampouras and Androutsopoulos, 2013). In addition, Clarity can also help expose the truthfulness and correctness of textual data (Mahapatra et al., 2016).

4.2 Automatic Evaluation Metrics

This section describes a number of automatic metrics commonly used in NLG evaluation and selected for this study. These fall into two categories: 1) word-overlap metrics, e.g. BLEU, METEOR and ROUGE (Novikova et al., 2017);

and 2) embedding-based metrics, e.g. BERTScore and BLEURT (Sellam et al., 2020). Each of these metrics is compared to one or more "Gold Standard" text as inspired by the Machine Translation community and adopted for evaluating document summarisation and NLG (Belz and Reiter, 2006). The gold standard is normally a piece of natural language text, annotated by humans as correct, i.e. a solution for a given task. Automatic evaluation is based on this gold standard, by verifying potential similarity (Kovář et al., 2016). However, the selection of gold standards involves subjectivity and specificity (Kovář et al., 2016), and this is part of the reason that automatic metrics have received some criticism (Hardcastle and Scott, 2008).

BLEU (B) (Papineni et al., 2001) is widely used in the field of NLG and compares n-grams of a candidate text (e.g. that generated by an algorithm) with the n-grams of a reference text. The number of matches defines the goodness of the candidate text. **SacreBLEU** (SB) (Post, 2018) is a new version of BLEU that calculates scores on the detokenized text. **METEOR** (M) was created to try to address BLEU's weaknesses (Lavie and Agarwal, 2007). METEOR evaluates text by computing a score based on explicit word-to-word matches between a candidate and a reference. When using multiple references, the candidate text is scored against each reference, and the best score is reported. **ROUGE** (R) (Lin, 1971) evaluates n-gram overlap of the generated text (candidate) with a reference. **ROUGE-L** (RL) (Longest Common Subsequence) computes the longest common subsequence (LCS) between a pair of sentences.

BERTScore (BS) (Zhang et al., 2020) is a token-level matching metric with pre-trained contextual embeddings using BERT (Devlin et al., 2019) that matches words in candidate and reference sentences using cosine similarity. **BLEURT** (BRT) (Sellam et al., 2020) is a text generation metric also based on BERT, pre-trained on synthetic data; it uses random perturbations of Wikipedia sentences augmented with a diverse set of lexical and semantic-level supervision signals. BLEURT uses a collection of metrics and models from prior work, including BLEU and ROUGE. Evaluation based on the meanings of words using embeddings (BERTScore, BLEURT) might capture some relevant features of explanations, as word representations are dynamically informed by the words around them (McCormick and Ryan, 2019)).

5 Correlation Study of Automatic Metrics

As noted in the introduction, it remains an open question as to what degree the automatic metrics for NLG reviewed above can capture the quality of NL explanations (Clinciu and Hastie, 2019). Thus, we ran a correlation analysis to investigate the degree to which each of the automatic metrics correlates with human judgements using the ExBAN corpus, and which aspects of human evaluation (Clarity/Informativeness), such automatic measures can capture. With regards to the choice of gold standard text, we picked explanations that received the maximum score in the human evaluation, in both Clarity and Informativeness. Gold standard explanations of each diagram are presented in Figure 1.

5.1 Results

The correlations between automatic metrics and human ratings were computed using the Spearman correlation coefficient. For each explanation, we calculated the median of all the ratings given (median was calculated because the data is ordinal, non-parametric rating data, as is also reported in Braun et al. (2018); Novikova et al. (2017)). These medians were then correlated with the automatic metric scores in Tables 2 and 3 and Figure 2. A summary of the results of the correlation analysis include the following:

1. Word-overlap metrics such as BLEU (n = 1,2,3,4), METEOR and ROUGE (n = 1,2) presented low correlation with human ratings.
2. BERTScore and BLEURT outperformed other metrics and produced higher correlation with human ratings than other metrics on all diagrams. BERTScore values range between [0.23, 0.43] and for BLEURT values range between [0.26, 0.53].
3. Human ratings for Informativeness and Clarity are highly correlated with each other, as observed in Figure 2 ($r = 0.82$).

5.2 Discussion

BLEU-based metrics can be easily and quickly computed; however, they do not correlate as well with human ratings as other methods presented here. This might be due to certain limitations, such as the fact that they rely on word overlap

Table 3. Spearman correlation between automatic evaluation metrics and human ratings for Clarity, where the bold font represents the highest correlation coefficient obtained by an automatic evaluation metric

and are not invariant to paraphrases. Furthermore, they do not use recall, rather a Brevity Penalty, which penalizes generated text for being "too short" (Papineni et al., 2001). This way may not be appropriate for explanations, as good explanations may need to be lengthy by their very nature.

METEOR takes into consideration F1-measure by computing scores for unigram precision and recall. The fragmentation penalty is calculated using the total number of matched words (m, averaged over hypothesis and reference) and the number of chunks. In this way, it could identify synonyms, but perhaps not as well as the embedding-based metrics, as evidenced by the correlation figures in our results. With regards to ROUGE-based scores, due to the upper bound issues presented by Schluter (2017), it is impossible to obtain perfect ROUGE-n scores. Furthermore, ROUGE-L cannot differentiate if the reference and the candidate have the same longest common subsequence (LCS), but different word ordering. Again, word ordering may be important for the explanation in terms of explainee scaffolding (Palincsar, 1986).

It has been brought into question whether a single automatic measure is able to capture multiple aspects of subjective human evaluation (Belz et al., 2020). Thus, in order to understand to what degree the various metrics capture both Clarity and Informativeness, we investigated individual explanations and their ratings. Table 4 gives some extracts from the dataset along with the automatic metrics and the human evaluation scores of Informativeness and Clarity. Based on these human scores, the extracts are divided into: good explanations (high scores for both), bad explanations (low scores for both) and mixed explanations (mixed scores). We can see here that all metrics are reasonably good at capturing and evaluating the 'bad' explanations with low scores across the board. However, only the BLEURT metric is good at capturing both 'good and bad' explanation ratings, as observed in the difference in scores between these two categories. ROUGE-L and BERTScore do capture this difference in some cases, but they are not as consistent as BLEURT. The reason that BLEURT outperforms the other metrics may be because it uses a combination of word-overlap metrics as well as embeddings and thus may be capturing the best of these approaches.

Good Explanations	B1	B2	B3	B4	SB	M	R1	R2	RL	BS	BRT	Inf.	Clar.
(1) The alarm is triggered by a burglary or an earthquake.	0.19	0.12	0.00	0.00	0.05	0.23	0.25	0.09	0.12	0.51	0.52	7	7
(2) Cloudy weather may produce rain and activation of the sprinkler. Both rain and sprinkler activity makes the grass wet.	0.28	0.11	0.00	0.00	0.05	0.15	0.36	0.10	0.28	0.49	0.65	7	7
(3) Cost is dictated by the harvest (e.g. size) and available subsidies (e.g. government tax break/subsidy). Whether or not the product is bought depends on the cost.	0.18	0.09	0.00	0.00	0.02	0.07	0.25	0.09	0.12	0.20	0.51	7	7
Bad Explanations	B1	B2	B3	B4	SB	M	R1	R2	RL	BS	BRT	Inf.	Clar.

(5) A diagram detailing a system whose goal is to make grass wet.	0.08	0.00	0.00	0.00	0.02	0.00	0.11	0.00	0.12	0.13	0.00	1.5	2
(6) The harvest and subsidy contribute to the cost, cost then buys??	0.28	0.00	0.00	0.00	0.03	0.15	0.36	0.00	0.24	0.20	0.30	2	1.5
Mixed Explanations	B1	B2	B3	B4	SB	M	R1	R2	RL	BS	BRT	Inf.	Clar.
(7) The grass is getting wet.	0.08	0.00	0.00	0.00	0.00	0.20	0.13	0.00	0.15	0.24	0.16	1.5	7
(8) Subsidy and harvest independently affect cost. Cost affects buys.	0.06	0.00	0.00	0.00	0.01	0.14	0.16	0.00	0.10	0.25	0.56	6	2.5
(9) Cloud cover influences whether it rains and when the sprinkler is activated. When either the sprinkler is turned on or when it rains, the grass gets wet.	0.48	0.33	0.21	0.14	0.22	0.24	0.50	0.24	0.38	0.49	0.65	7	3

Table 4. Examples of Good, Bad and Mixed Explanations according to human evaluation scores for Informativeness and Clarity (medians of all ratings for that explanation), presented with their automatic measures

Although Clarity and Informativeness highly correlate overall, there are occasions where explanations are rated by humans as higher on Clarity than Informativeness and visa-versa. However, there are rarely any cases where Clarity is high, and Informativeness is very low. Explanation 8 in Table 4 is the only example of this in our corpus. It is thus difficult to make any generalisations about this subset of the data. However, it does seem to be the case that BLEURT is more sensitive to Informativeness than Clarity (e.g. explanation 7 vs 8-9 in the table), but a larger study would be needed to show this empirically.

6 Conclusions and Future work

Human evaluation is an expensive and time-consuming process. On the other hand, automatic evaluation is a cheaper and more efficient method for evaluating NLG systems. However, finding accurate measures is challenging, particularly for explanations. We have discussed word embedding techniques (Mikolov et al., 2013; Kim, 2014; Reimers and Gurevych, 2020), which enable the use of pre-trained models and so reduces the need to collect large amounts of data in our domain of explanations, which is a challenging task. The embedding-based metrics mentioned here perform better than the word-overlap based ones. We speculate that this is in part due to the fact that the former capture semantics more effectively and are thus more invariant to paraphrases. These metrics have also been shown to be useful across multiple tasks (Sellam et al., 2020) but with some variation across datasets (Novikova et al., 2017). Therefore, future work would involve examining the effectiveness of automatic metrics across a wider variety of explanation tasks and datasets, as outlined in the Related Work section.

Embeddings are quite opaque in themselves. Whilst some attempts have been made to visualise them (Li et al., 2016), it remains that embedding-based metrics do not provide much insight into what makes a good/bad explanation. It would thus be necessary to look more deeply into the linguistic phenomena that may indicate the quality of explanations. In ExBAN, initial findings show that the number of nouns and coordinating conjunctions correlate with human judgements, however further in-depth analysis is needed. Additional metrics to add to the set explored here could include grammar-based metrics, such as readability and grammaticality, as in the study described in (Novikova et al., 2017).

Furthermore, an investigation is needed into the pragmatic and cognitive processes underlying explanations, such as argumentation, reasoning, causality, and common sense (Baaj et al., 2019). Investigating whether these can be captured automatically will be highly challenging. We will explore further the idea of adapting explanations to the explainee's knowledge and expertise level, as well as the explainer's goals and intentions. One such goal of the explainer could be to maximise the trustworthiness of the explanation (Ribeiro et al., 2016). How this aspect is consistently subjectively and objectively measured will be an interesting area of investigation.

Finally, the ExBAN corpus and this study will inform the development of NLG algorithms for NL explanations from graphical representations. We will explore NLG techniques for structured data, such as graph neural networks and knowledge graphs (Koncel-Kedziorski et al., 2019). Thus the corpus and metrics discussed here will contribute to a variety of fields linguistics, cognitive science as well as NLG and Explainable AI.

Abstract

Written language contains stylistic cues that can be exploited to automatically infer a variety of potentially sensitive author information. Adversarial stylometry intends to attack such models by rewriting an author's text. Our research proposes several components to facilitate deployment of these adversarial attacks in the wild, where neither data nor target models are accessible. We introduce a transformer-based extension of a lexical replacement attack, and show it achieves high transferability when trained on a weakly labeled corpus—decreasing target model performance below chance. While not completely inconspicuous, our more successful attacks also prove notably less detectable by humans. Our framework therefore provides a promising direction for future privacy-preserving adversarial attacks.

1 Introduction

The widespread use of machine learning on consumer devices and its application to their data has sparked investigation of security and privacy researchers alike in correctly handling sensitive information (Edwards and Storkey, 2016; Abadi et al., 2016b). Natural Language Processing (NLP) is no exception (Fernandes et al., 2019; Li et al., 2018); written text can contain a plethora of author information—either consciously shared or inferable through stylometric analysis (Rao et al., 2000; Adams, 2006). This characteristic is fundamental to author profiling (Koppel et al., 2002), and while the field's main interest pertains to the study of sociolinguistic and stylometric features that underpin our language use (Daelemans, 2013), herein simultaneously lie its dual-use problems. Author profiling can, often with high accuracy, infer an extensive set of (sensitive) personal information, such as age, gender, education, socio-economic status, and mental health issues (Eisenstein et al., 2011; Alowibdi et al., 2013; Volkova et al., 2014; Plank and Hovy, 2015; Volkova and Bachrach, 2016). It therefore potentially exposes anyone sharing written online content to unauthorized information collection through their writing style. This can prove particularly harmful to individuals in a vulnerable position regarding e.g., race, political affiliation, or mental health.

Privacy-preserving defenses against such inferences can be found in the field of adversarial[1] stylometry. Our research[2] concerns the obfuscation subtask, where the aim is to rewrite an input text such that the style changes, and stylometric predictions fail. It is part of a growing body of research into adversarial attacks on NLP (Smith, 2012), which various modern models have proven vulnerable to; e.g., in neural machine translation (Ebrahimi et al., 2018), summarization (Cheng et al., 2020), and text classification (Liang et al., 2018).

Adversarial attacks on NLP are predominantly aimed at demonstrating vulnerabilities in existing algorithms or models, such that they might be fixed, or explicitly improved through adversarial training. Consequently, most related work focuses on white or black-box settings, where all or part of the target model is accessible (e.g., its predictions, data, parameters, gradients, or probability distribution) to fit an attack. The current research, however, does not intend to improve the targeted models; rather, we want to provide the attacks as tools to protect online privacy. This introduces several constraints over other NLP-based adversarial attacks, as it calls for a realistic, in-the-wild scenario of application.

Firstly, authors seeking to protect themselves from stylometric analysis cannot be assumed to be

---

[1] These are adversarial attacks on models making stylometric predictions, not to be confused with adversarial learning.

[2] All code, data, and materials to fully reproduce the experiments are openly available at `https://github.com/cmry/reap`.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2388–2402
April 19 - 23, 2021.

knowledgeable about the target architecture, nor to have access to suitable training data (as the target could have been trained on any domain). Hence, we cannot optimally tailor attacks to the target, and need an accessible method of mimicking it to evaluate the obfuscation success. To facilitate this, we use a so-called substitute model, which for our purposes is an author profiling classifier trained in isolation (with its own data and architecture) that informs our attacks. Attacks fitted on substitute models have been shown to transfer their success when targeting models with different architectures, or trained on other data, in a variety of machine learning tasks (Papernot et al., 2016). The effectiveness of an attack fitted on a substitute model when targeting a 'real' model is then referred to as *transferability*, which we will measure for the obfuscation methods proposed in the current research.

Secondly, for an obfuscation attack to work in practice (e.g., given a limited post history), it should suggest relevant changes –to– the author's writing *on a domain of their choice*. This implies the substitute models should be fitted locally, and therefore need to meet two criteria: reliable access to labeled data, and being relatively fast and easy to train. To meet the first criterion, the current research focuses on gender prediction, as: i) Twitter corpora annotated with this variable are by far the largest (and most common), ii) author profiling methods typically use similar architectures for different attributes; therefore, the generalization of attacks to other author attributes can be assumed to a large extent, and, most importantly, iii) Beller et al. (2014) and Emmery et al. (2017) have shown that through distant labeling, a representative corpus for this task can be collected in under a day. This allows us to measure transferability of attacks fitted using realistically collected distant corpora to models using high-quality hand labeled corpora.

As for the attacks, we focus on lexical substitution of content words strongly related to a given label, as those have been shown to explain a significant portion of the accuracy of stylometric models (see e.g., Rao et al., 2000; Burger et al., 2011; Sap et al., 2014; Rangel et al., 2016). To that effect, we extend the substitution attack of Jin et al. (2020) and apply it to author attribute obfuscation. Specifically, we explore the potential of training a simple (as to meet the speed criterion), non-neural substitute model f' to indicate relevant words to perturb, where retaining the original meaning is prioritized.

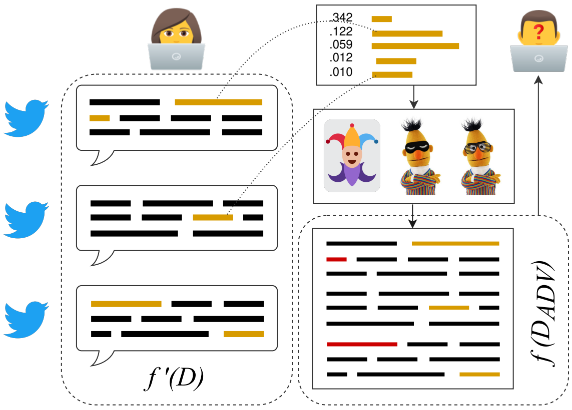

Figure 1: Obfuscation scenario: model f' trains on tweet batches, an omission score is used to determine and rank the words according to their classification contribution. These are then passed to either TextFooler, Masked BERT, or Dropout BERT to suggest top-k replacement candidates. From these, a selection is made based on their class probability change on $f'(D)$. Finally, f is evaluated on the perturbed tweets D_{ADV}.

Two transformer-based models are introduced to the framework to propose and rank lexical substitutions towards a change in the predictions of f'. We evaluate if the attacks on f' transfer across corpora, architectures, and a separately trained target model f (see Figure 1). Finally, we measure the quality of changes using automatic evaluation metrics, and conduct an human evaluation that focuses on detection accuracy of the attacks.

2 Related Work

Stylometry, the study of (predominantly) writing style, dates back several decades (Mosteller and Wallace, 1963), and has seen increased accessibility through the introduction of statistical models (see surveys by Holmes, 1998; Neal et al., 2017) and machine learning (e.g., Matthews and Merriam, 1993; Merriam and Matthews, 1994). Computational stylometry distinguishes several subtasks such as determining (Baayen et al., 2002) and verifying author identity (Koppel and Schler, 2004), and author profiling (Argamon et al., 2005); e.g., predicting demographic attributes. Adversarial stylometry (as conceptualized by Brennan et al., 2012) intends to subvert these inferences by changing an author's text through imitation, or, as pertains to our research, the obfuscation of writing style (Kacmarcik and Gamon, 2006; Caliskan et al., 2018; Le et al., 2015; Xu et al., 2019).

These changes, or perturbations, can be produced in several ways, and the task is therefore often conflated with paraphrasing (Reddy and Knight, 2016), style transfer (Kabbara and Cheung, 2016), and generating adversarial samples or triggers (Zhang et al., 2020b). Regardless of the employed method, the main challenge of obfuscation lies in retaining the original meaning of an input text; its written language medium limits any perturbations to discrete outputs, and unnatural discrepancies are significantly better discernible by humans than, say, a few pixel changes in an image. An additional, persistent limitation is the absence of evaluation metrics that guarantee complete preservation of the original meaning of the input whilst changes remain unnoticed (Potthast et al., 2016). This not only inhibits automatic evaluation of obfuscation, but all natural language generation research (Novikova et al., 2017)—placing an emphasis on human evaluation (van der Lee et al., 2019).

It is perhaps for this reason that most obfuscation work uses heuristically-driven, controlled changes such as splitting or merging words or sentences, removing stop words, changing spelling, punctuation, or casing (see e.g., Karadzhov et al., 2017; Eger et al., 2019). These specific attacks are typically easier to mitigate through preprocessing (Juola and Vescovi, 2011). Obfuscation through lexical substitution (Mansoorizadeh et al., 2016; Bevendorff et al., 2019, 2020) provides a middle ground of control, semantic preservation and attack effectiveness; however, they might prove less effective against models relying on deeper stylistic features (e.g. word order, part-of-speech (POS) tags, or reading complexity scores). End-to-end systems have been employed for similar purposes (Shetty et al., 2018; Saedi and Dras, 2020), or to rewrite entire phrases (Emmery et al., 2018; Bo et al., 2019) using (adversarially-driven) autoencoders. Such attacks seem less common, and provide less control over the perturbations and semantic consistency.

Our work does not assume the attacks to run end-to-end, but with a hypothetical human in the loop. We further opt for techniques that are more likely to find strong semantic mirrors to the original text while making minimal changes. A substitute model (the algorithm, hyper-parameters, and output of which an author can manipulate as desired) is employed to indicate candidate replacement words, and our attacks suggest and rank those against this substitute. Moreover, prior work typically attacks adversaries trained on the same data, whereas we add a transferability measure. Lastly, while author identification has been investigated in the wild (Stolerman et al., 2013), our work is, to our knowledge, the first to make a conscious effort towards realistic applicability of obfuscation techniques.

3 Method

Our attack framework extends TextFooler (TF, Jin et al., 2020) in several ways. First, a substitute gender classifier is trained, from which the logit output given a document is used to rank words by their prediction importance through an omission score (Section 3.1). For the top most important words, substitute candidates are proposed, for which we add two additional techniques (Section 3.2). These candidates can be checked and filtered on consistency with the original words (by their POS tags, for example), accepted as-is, or re-ranked (Section 3.3). For the latter, we add a scoring method. Finally, the remaining candidates are used for iterative substitution until TF's stopping criterion is met (i.e., the prediction changes, or candidates run out).

3.1 Target Word Importance

We are given a target classifier f, substitute classifier f', a document D consisting of tokens D_i, and a target label y. Here, f' is trained on some corpus X, and receives an author's new input text D, where the author provides label y. We denote a class label as $\bar{y}$ if $f'(D)$ predicts anything but y. Our perturbations form adversarial input D_{ADV}, that intends to produce $f'(D_{\text{ADV}}) = \bar{y}$, and thereby implicitly $f(D_{\text{ADV}}) = \bar{y}$. Note that we only submit D to f for evaluating the attack effectiveness, and it is never used to fit the attack itself.

To create D_{ADV}, a minimum number of edits is preferred, and thus we rank all words in D by their omission score (similar to e.g., Kádár et al., 2017) according to f' (`omission_score` in Algorithm 1). Let $D_{\setminus i}$ denote the document after deleting D_i, and $o_y(D)$ the logit score by f'. The omission score is then given by $o_y(D) - o_y(D_{\setminus i})$, and used in an importance score I of token D_i, as:

$$I_{D_i} = \begin{cases} o_y(D) - o_y(D_{\setminus i}), \\ \quad \text{if } f'(D) = f'(D_{\setminus i}) = y. \\ o_y(D) - o_y(D_{\setminus i}) + o_{\bar{y}}(D) - o_{\bar{y}}(D_{\setminus i}), \\ \quad \text{if } f'(D) = y, f'(D_{\setminus i}) = \bar{y}, y \neq \bar{y}. \end{cases} \tag{1}$$

With I_{D_i} calculated for all words in D, the top k ranked tokens are chosen as target words T.

ALGORITHM 1: Obfuscation by lexical replacement.

```
Input  : $f'$ – substitute model
         $D = \{w_0, w_1, \dots, w_n\}$ – document
         $y$ – target label
         checks – apply checks (bool)
         k – target max $k$-amount words
Output : $D_{\text{ADV}}$ – obfuscated document
for $D_i \in D$ do
    // via Equation 1
    $I_{D_i} \leftarrow$ omission_score($f', y$)
$T \leftarrow$ top_k(argsort_desc($D, I_{D_i}$ scores), k)
$D_{\text{ADV}} = D$
for $t \in T$ do
    // substitution attack on $t$
    $C_t \leftarrow$candidates($t$)
    $A = (D_{\text{ADV}\,1:i-1}, C_{t,j}, D_{\text{ADV}\,i+1:n})_{1 \leq j \leq |C_t|}$
    $\bar{A} =$ filter/rank($D, A; t$, checks)
    // test attack success on $f'$

        else if $o_y(D') < o_y(D_{\text{ADV}})$ then
            $t$ in $D_{\text{ADV}}$ is replaced with $c$ from $D'$
return $D_{\text{ADV}}$
```

3.2 Lexical Substitution Attacks

Four approaches to perturb a target word $t \in T$ are considered in our experiments. These operations are referred to as `candidates` in Algorithm 1.

Synonym Substitution (WS) This TF-based substitution embeds t as $\boldsymbol{t}$ using a pre-trained embedding matrix $\boldsymbol{V}$. C_t is selected by computing the cosine similarity between $\boldsymbol{t}$ and all available word-embeddings $\boldsymbol{w} \in \boldsymbol{V}$. We denote cosine similarity with $\Lambda(\boldsymbol{t}, \boldsymbol{w})$. A threshold δ is used to keep only reliable candidates $\Lambda(\boldsymbol{t}, \boldsymbol{w}) > \delta$.

Masked Substitution (MB) The embedding-based substitutions can be replaced by a language model predicting the contextually most likely token. BERT (Devlin et al., 2019)—a bi-directional encoder (Vaswani et al., 2017) trained through masked language modeling and next-sentence prediction—makes this fairly trivial. By replacing t with a mask, BERT produces a top-k most likely C_t for that position. Implementing this in TF does imply each previous substitution of t might be included in the context of the current one. This method of contextual replacement has two drawbacks: i) semantic consistency with the *original* word is not guaranteed (as the model has no knowledge of t), and ii) the replaced context means semantic drift can occur, as all subsequent substitutions follow the new, possibly incorrect context.

Dropout Substitution (DB) A method to circumvent the former (i.e., BERT's masked prediction limitations for lexical substitution), was presented by Zhou et al. (2019). They apply dropout (Srivastava et al., 2014) to BERT's internal embedding of target word t before it is passed to the transformer—zeroing part of the weights with some probability. The assumption is that C_t (BERT's top-k) will contain candidates closer to the original t than the masked suggestions.

Heuristic Substitution To evaluate the relative performance of the techniques we described before, we employ several heuristic attacks as baselines. In the order of Table 3: 1337-speak: converts characters to their leetspeak variants, in a similar vein to e.g. diacritic conversion (Belinkov and Bisk, 2018). Character flip: inverts two characters in the middle of a word, which was shown to least affect readability (Rayner et al., 2006). Random spaces: splits a token into two at a random position.

3.3 Candidate Filtering and Re-ranking

Given C_t, either all, or only the highest ranked candidate can be accepted as-is. Alternatively, all D' can be filtered by submitting them to checks, or re-ranked based on their semantic consistency with D. These operations are referred to as `rank/filter` in Algorithm 1—both of which can be executed.

Part-of-Speech and Document Encoding TF employs two checking components: first, it removes any c that has a different POS tag than t. If multiple D' exist so that $f'(D') = \bar{y}$, it selects the document D' which has the highest cosine similarity to the Universal Sentence Encoder (USE) embedding (Cer et al., 2018) of the original document D. If not, the D' with the *lowest* target word omission score is chosen (as per TF's method).

BERT Similarity Zhou et al. (2019) use the concatenation of the last four layers in BERT as a sentence's contextualized representation $\boldsymbol{h}$. We apply this in both Masked (MB) and Dropout (DB) BERT to re-rank all possible D' by embedding them. Given document D, target t, and perturbation candidate document D', C_t would be ranked via an embedding similarity score:

$$\text{SIM}\left(D, D'; t\right) = \sum_{i}^{n} w_{i,t} \times \Lambda\left(\boldsymbol{h}\left(D_i|D\right), \boldsymbol{h}(D'_i|D')\right) \qquad (2)$$

where $\boldsymbol{h}\,(D_i|D)$ is BERT's contextualized representation of the i^{th} token in D, and $w_{i,t}$ is the average self-attention score of all heads in all layers ranging from the i^{th} token with respect to t in D.[3]

4 Experiment

4.1 Data

We use three author profiling sets (see Table 1 for statistics) that are annotated for binary gender classification (male or female): first, that of Volkova et al. (2015) which was collected through annotating 5,000[4] English Twitter profiles by crowdsourcing via Mechanical Turk. This can be considered a 'random' sample of Twitter profiles, and is therefore the most unbiased set of the three. Hence, we consider it the most representative of an author profiling set, and employ this as training split (80%) for f, and test split for our attacks (20%).

The second is the English portion of the Multilingual Hate Speech Fairness corpus of Huang et al. (2020), which was collected with a different objective than author profiling. It was aggregated from existing hate speech corpora (by Waseem and Hovy, 2016; Waseem, 2016; Founta et al., 2018)—which were largely bootstrapped with lookup terms, selection of frequently abusive users, etc.—and annotated post-hoc with demographic information. The collection did not focus on profiles, and most authors are only associated with a single tweet. This can cause a significant domain shift compared to general author profiling. However, it can be seen as freely available (noisy) data.

Lastly, we include a weakly labeled author profiling corpus by Emmery et al. (2017), collected through English keyword look-up for self-reports—similar to Beller et al. (2014). This corpus likely includes incorrect labels, but was collected in less than a day, making it an ideal candidate for realistic access to (new) data to fit the substitute model.

Preprocessing & Sampling All three corpora were tokenized using spaCy[5] (Honnibal and Montani, 2017). Other than lowercasing, allocating special tokens to user mentions and hashtags (# and text were split), and URL removal, no additional preprocessing steps were applied. Every author timeline was divided into chunks for a maximum of 100 tweets (i.e., some contain less) to form our documents, implying a maximum of 25 instances per author (some contain one, 2,500 is the API history limit). From the test set, the last[6] 200 instances were sampled for the attack (110 male, 90 female). While fairly small, this sample does reflect a realistic attack duration and timeline size, as they would be executed for a single profile.

4.2 Attacks

For the extension of TF, we re-implemented code[7] by Jin et al. (2020) to work with Scikit-learn[8] (Pedregosa et al., 2011). For their synonym substitution component, we similarly used counter-fitted embeddings by Mrkšić et al. (2016) trained on Simlex-999 (Hill et al., 2015). The USE (Cer et al., 2018) implementation uses TensorFlow[9] (Abadi et al., 2016a) as back-end, and all BERT-variants were implemented in Hugging Face's[10] Transformers library (Wolf et al., 2020) with PyTorch[11] (Paszke et al., 2019) as back-end.

We adopt the same parameter settings as Jin et al. (2020) throughout our TF experiments: they set N (considered synonyms) and δ (cosine similarity minimum) empirically to 50 and 0.7 respectively. For MB and DB, we capped T at 50 and top-k at 10 (to improve speed). For DB, we follow Zhou et al. (2019) and set the dropout probability to 0.3.

---

[3] Zhou et al. (2019) additionally use a proposal score for finding T that we replaced with the omission score.

[4] Profile counts in the current work differ due to collection limitations (e.g., removed accounts).

[5] `https://spacy.io`

[6] As the datasets are not shuffled to avoid overfitting on author-specific features, a few documents of the same author might spill from the train into the test split; this avoids incorporating those in our attack sample.

4.3 Models

For f and f' we require (preferably fast) pipelines that achieve high accuracy on author profiling tasks, and are sufficiently distinct to gauge how well our attacks transfer across architectures, rather than solely across corpora. As state-of-the-art algorithms have not yet proven to be sufficiently effective for author profiling (Joo et al., 2019) we opt for common n-gram features and linear models.

Logistic Regression Logistic Regression (LR) trained on tf·idf using uni and bi-gram features proved a strong baseline in author profiling in prior work. The simplicity of this classifier also makes it a substitute model that can realistically be run by an author. No tuning was performed: C is set to 1.

N-GrAM The New Groningen Author-profiling Model (N-GrAM) from Basile et al. (2018), was proposed as a highly effective—simple—model that outperforms more complex (neural) alternatives on author profiling with little to no tuning. It uses tf·idf-weighted uni and bi-gram token features, character hexa-grams, and sublinearly scaled tf $(1 + \log(\text{tf}))$. These features are then passed to a Linear Support Vector Machine (Cortes and Vapnik, 1995; Fan et al., 2008), where $C = 1$.

4.4 Experimental Setup

To summarize (and see Table 2), the experiment is conducted as follows: the substitute target model (f')—LR for all experiments—is fit on a given corpus. The real target model (f, either LR or N-GrAM) is always fit on the corpus of Volkova et al. (2015). To evaluate the attacks, a 200-instance sample is used. Target words are ranked via omission scores from f', fed to either our Heuristics, TF, MB, or DB attacks. The heuristics directly change the target words, while the rest outputs a ranked set of replacement candidates. The latter can either be evaluated against f' through the TF pipeline, or the Top-1 candidate is returned. Filtering can be applied through POS/USE for semantic similarity and POS compatibility checks (Check), or not (~~Check~~).

		test = Volkova et al.

Table 3: Post-attack accuracy scores (below chance (55%) = better) of f on a test sample from the Volkova et al. corpus. Left, the attack conditions: heuristics, top-1 synonym, applying POS and USE similarity checks, or not applying those checks (~~Check~~). Splits per training corpus are noted for f' (always Logistic Regression (LR)). As target model, either LR, or N-GrAM (NG) was used. The substitution attacks are TextFooler (TF), Masked (MB) and Dropout BERT (DB). If TF's stopping criterion was used, TF + is noted. Word Similarity (WS), reflects the TF pipeline without checks.

Note that we are predominantly interested in transferability, and would therefore like to test as many combinations of data and architecture access limitations as possible. If we assume an author does not have access to the data, the substitute classifier is trained on any other data than the Volkova et al. corpus. If we assume the author does not know the target model architecture, the target model is N-GrAM (rather than LR). A full model transfer setting (in both data and architecture) will therefore be, e.g.: data f' = Emmery et al., data f = Volkova et al., f' = LR, and f = NGrAM. Finally, for comparison to an optimal situation, we test a setting where we do have access to the adversary's data.

4.5 Evaluation

Metrics The obfuscation success is measured as any accuracy score below chance level performance, which given our test sample is 55%. We would argue that random performance is preferred in scenarios where the prediction of the opposite label is undesired. For the current task, however, any accuracy drop to around or lower than chance level satisfies the conditions for successful obfus-

TRAIN	Huang et al.	0.640	0.620
	Emmery et al.	0.725	0.890

Table 4: Gender prediction accuracies of the substitute models f' on train and test splits of f.

cation.[12] To evaluate the semantic preservation of the attacked sentences, we calculate both METEOR (Banerjee and Lavie, 2005; Lavie and Denkowski, 2009) using `nltk`,[13] and BERTScore (Zhang et al., 2020a) between D and D_{ADV}. METEOR captures flexible uni-gram token overlap including morphological variants, and BERTScore calculates similarities with respect to the sentence context.

Human Evaluation For the human evaluation, we sampled 20 document pieces (one or more tweets) for each attack type in the best performing experimental configuration. A piece was chosen if it satisfied these criteria: i) contains changes for all three attacks, ii) consists of at least 15 words (excluding emojis and tags), and iii) does not contain obvious profanity.[14] All 60 document pieces of the three models were shuffled, and the 20 original versions were appended at the end (so that 'correct' pieces were seen last). Each substitute model therefore has 80 items for evaluation.

While in prior work it is common to rate semantic consistency, fluency, and label a text (see e.g., Potthast et al., 2016; Jin et al., 2020), our Twitter data are too noisy (including many spelling and grammar errors in the originals), and document batches too long to make this a feasible task. Instead, our six participants (three per substitute) were asked to indicate if: a) a sentence was artificially changed, and if so, b) indicate one word that raised their suspicion. This way, we can evaluate which attack produces the most natural sentences, and the least obvious changes to the input.

The items were rated individually; the human evaluators did not know beforehand that different versions of the same sentences were repeated, nor that the originals were shown at the end. All participants have a university-level education, a high English proficiency, and are familiar with the domain of the data. Several example ratings of the same sentence can be found in Table 6.

5 Results

5.1 Domain Shift

As we alluded to in Section 4.1, both corpora used to train our substitute models were in fact not reference corpora for author profiling, and can therefore be considered as suboptimal, disjoint domains. The Huang et al. corpus in particular shows a strong domain shift (see Table 4) for both training and test sets. The distantly labeled Emmery et al. corpus achieves 7.5% more accuracy on the train split of Volkova et al., and test performance is significantly higher (27%). We might therefore expect better obfuscation performance from the latter.

5.2 Baselines

The results for all attacks are shown in Table 3. Note that these are performances for f; therefore, when no attacks are applied (none), the performance for both substitute corpora stays the same (as those only influence the attacks). For the heuristic attacks, 1337 seems to make the more robust baseline; outperforming some of the other settings—even on transferability. A surface-level advantage is that this attack has a minor impact on readability (when applied conservatively) and does not change semantics; however, the heuristic attacks are fairly simple to mitigate in preprocessing (Juola and Vescovi, 2011) and through character features (as shown by the performance of the N-GrAM model). For transferability, we evidently need to do more than simply trying to convert words to be out-of-vocabulary (OOV) with noise. While it can be argued the heuristics could change all words, shifting everything OOV would not be robust; the target model side could easily spot the anomalous input and might act (e.g., reject) accordingly.

5.3 Attack Transferability

Transferability can be assessed by comparing the LR and N-GrAM (NG) columns. Globally it can be observed that the substitute models trained on the Emmery et al. corpus systematically outperform those trained on Huang et al.; both for the settings where the adversary's architecture is known (LR), and where it is unknown (NG). This matches our

---

[12] If an attack drops accuracy to 0%, this effectively flips (in case of a binary label) the label. This label might *also* be undesired by the author (e.g., being classified as having polar opposite political views). This implies the target model being maximally unsure about the classification is desirable.

[13] `https://www.nltk.org/_modules/nltk/translate/meteor_score.html`

[14] To avoid exposing the raters to overly toxic content, blatant examples were filtered using a keyword list. Some minor examples remained, for which we added a disclaimer.

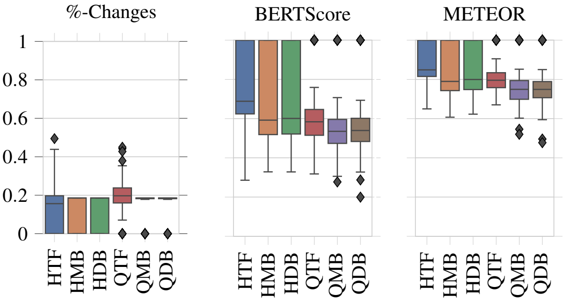

Figure 2: Rewrite metrics for the three different attacks: TextFooler (TF), Masked (MB) and Dropout BERT (DB)—split by corpora Huang et al. (H), Emmery et al. (Q). Shown are the relative number of changes (by document length), BERTScore (F_1), and METEOR (MET) with respect to the original document.

expectations from the observed domain shift. Our results also show that a noticeable decrease in obfuscation performance occurs (10-30% increased target model performance) when the attacks are transferred to different data and another model. In contrast, as can be observed from the last two columns in Table 3, in a practically unrealistic setting where the model and data are available, the obfuscation is specifically tailored to known weaknesses and therefore highly effective.[15]

5.4 Transformer Performance

Looking at the Top-1, ~~Check~~ and Check brackets (Table 3), other than the BERT-based models having higher success of transferability than TF, they also retain obfuscation success; deteriorating the target model's performance to lower than chance level (55%) for the settings not using additional checks. This comparison also demonstrates the synonym ranking to work (Top-1 vs. ~~Check~~ and Check), and the Check condition to be too restrictive; attaining lower attack power, and low transferability. This is further illustrated by the %-changes shown in Figure 2. Comparing the MB and DB variants, their performance seems almost identical, with masking having a slight advantage. As Zhou et al. (2019) argued, applying dropout should produce words that are closer to the original (compared to MB), which might affect obfuscation performance. Additionally, the BERT similarity ranking (described in Section 3.3) applied to the Masked substitution candidates could have some beneficial effect. This will have to be studied in more detail using the output evaluations.

		Huang et al.			Emmery et al.		
	ORG	TF	MB	DB	TF	MB	DB
ALTERED	.888	.967	.633	.783	.950	**.617**	.633
WORD	-	.950	.583	.700	.867	**.433**	**.433**

Table 5: Human accuracy scores of predicting if a text was altered, and guessing the attacked word (lower is better). All substitute models are those with the ~~Check~~ setting, trained on different corpora (i.e., different words are attacked per training corpus). ORG indicates correct prediction of the originals.

Rewrite Metrics The metrics in Figure 2 show a common initial limitation in their application to this task: the more frequent an attack makes no changes, the higher the automatic evaluation metrics (BERTScore, METEOR). Hence, to compare models, these scores need to be considered in light of the obfuscation performance, and related work. It can be observed that with consistently higher changes, MB and DB score lower on semantic consistency than TF. However, between MB and DB, and TF for the Emmery et al. corpus, these differences are minor. Furthermore, despite being fit on a different domain, these scores are comparable to prior obfuscation work (e.g., Shetty et al. (2018) show METEOR scores between 0.69 and 0.79).

Human Evaluation The results in Table 5 reflect the same trend that can be observed in Table 3; high obfuscation success seems to result in higher human error when predicting if a sentence was obfuscated. Conversely, it seems that despite higher semantic consistency scores, the original TF pipeline is easier to detect. This can be attributed to the number of spelling and grammar errors the model makes without its additional checks. Furthermore, the 11% error in identifying the original sentences also reflects some expected margin of error in this task, as our Twitter data is inherently noisy. Finally, while these results are in line with the obfuscation success, and are lower than detectability scores in related work (Mahmood et al., 2020), they also indicate that the models are still detectable above chance-level. Given three alternatives (including the original), performance should be 25% or lower to indicate no intrusive changes are made to text (that are not semantically coherent or not inconspicuous enough—both metrics used by Potthast et al., 2016). Therefore, while the presented approaches are effective, and realistically transferable, there is room for improvement for practical applicability.

---

[15] Jin et al. (2020) found similar drops to 0% accuracy with a comparable percentage of changes for word-level models.

ORG	ready to go home already . a better relationship with god 💙🙌 . i need another job asap .

Table 6: Example ratings of different attacks (not shown together to the human evaluators) on two sentences with varying semantic consitency and human detection accuracy. In the first example, HMB was marked unaltered by all raters, HDB by the majority, and HTF by none. In the second, only HDB was marked unaltered, by only one rater. Attacked words are marked in bold, guessing any one of these would count as correctly identifying the attack.

6 Discussion and Future Work

We have demonstrated the performance of author attribute obfuscation under a realistic setting. Using a simple Logistic Regression model for candidate suggestion, trained on a weakly labeled corpus collected in a day, the attacks successfully transferred to different data and architectures. This is a promising result for future adversarial work on this task, and its practical implementation.

It remains challenging to automatically evaluate how invasive the required number of changes are for successful obfuscation—particularly to an author's message consistency as a whole. However, in practice such considerations could be left up to the author. In this human-in-the-loop scenario, a more extensive set of candidates could be suggested, and their effect on the substitute model shown interactively. This way, the attacks can be manually tuned to find a balance of effectiveness, inconspicuousness, and to guarantee semantic consistency. It would also show the author how their writing style affects potential future inferences.

Regarding the performance of the attacks: we demonstrated the general effectiveness of contextual language models in retrieving candidate suggestions. However, the quality of those candidates might be improved with more extensive rule-based checks; e.g., through deeper analyses using parsing. Nevertheless, such venues leave us with a core limitation of rewriting language, and therefore more broadly NLP: while the Masked attacks seemed more successful in our experiments, after manual inspection of the perturbations Dropout was found to often be semantically closer (see also Table 6)—which was not reflected in the human evaluation. This begs the question if *any* automated approach, evaluated under the current limitations of semantic consistency metrics, could realistically optimize for both obfuscation and inconspicuousness.

As such, we would argue that future work should focus on making as few perturbations as possible, retaining only the minimum amount of required obfuscation success. Given this, the other constraints become less relevant; one could generate short sentences (e.g., a single tweet) that might be semantically or contextually incorrect, but if it is a message in a long post history, it will hardly be detectable or intrusive. This would require certain triggers (as demonstrated by Wallace et al. (2019) for example), and ascertaining how well they transfer.

7 Conclusion

In our work, we argued realistic adversarial stylometry should be tested on transferability in settings where there is no access to the target model's data or architecture. We extended previous adversarial text classification work with two transformer-based models, and studied their obfuscation success in such a setting. We showed them to reliably drop target model performance below chance, though human detectability of the attacks remained above chance. Future work could focus on further minimizing this detection under our realistic constraints.

Acknowledgments

Our research strongly relied on openly available resources. We thank all whose work we could use. We would also like to thank the anonymous reviewers, Bertrand Higy, Bram Willemsen, and Chris van der Lee for their valuable feedback. Ákos Kádár contributed to this research independently. Abstract

Much work in cross-lingual transfer learning explored how to select better transfer languages for multilingual tasks, primarily focusing on typological and genealogical similarities between languages. We hypothesize that these measures of linguistic proximity are not enough when working with pragmatically-motivated tasks, such as sentiment analysis. As an alternative, we introduce three linguistic features that capture cross-cultural similarities that manifest in linguistic patterns and quantify distinct aspects of language pragmatics: language context-level, figurative language, and the lexification of emotion concepts. Our analyses show that the proposed pragmatic features do capture cross-cultural similarities and align well with existing work in sociolinguistics and linguistic anthropology. We further corroborate the effectiveness of pragmatically-driven transfer in the downstream task of choosing transfer languages for cross-lingual sentiment analysis.

1 Introduction

Hofstede et al. (2005) defined culture as the collective mind which "distinguishes the members of one group of people from another." Cultural idiosyncrasies affect and shape people's beliefs and behaviors. Linguists have particularly focused on the relationship between culture and language, revealing in qualitative case studies how cultural differences are manifested as linguistic variations (Siegel, 1977).

Quantifying cross-cultural similarities from linguistic patterns has largely been unexplored in NLP, with the exception of studies that focused on cross-cultural differences in word usage (Garimella et al., 2016; Lin et al., 2018). In this work, we aim to quantify cross-cultural similarity, focusing on *semantic* and *pragmatic* differences across languages.[1] We devise a new distance measure between languages based on linguistic proxies of culture. We hypothesize that it can be used to select transfer languages and improve cross-lingual transfer learning, specifically in pragmatically-motivated tasks such as sentiment analysis, since expressions of subtle sentiment or emotion—such as subjective well-being (Smith et al., 2016), anger (Oster, 2019), or irony (Karoui et al., 2017)—have been shown to vary significantly by culture.

We focus on three distinct aspects in the intersection of language and culture, and propose features to operationalize them. First, every language and culture rely on different levels of *context in communication*. Western European languages are generally considered low-context languages, whereas Korean and Japanese are considered high-context languages (Hall, 1989). Second, similar cultures construct and construe *figurative language* similarly (Casas and Campoy, 1995; Vulanović, 2014). Finally, *emotion semantics* is similar between languages that are culturally-related (Jackson et al., 2019). For example, in Persian, 'grief' and 'regret' are expressed with the same word whereas 'grief' is co-lexified with 'anxiety' in Dargwa. Therefore, Persian speakers may perceive 'grief' as more similar to 'regret,' while Dargwa speakers may associate the concept with 'anxiety.'

We validate the proposed features qualitatively, and also quantitatively by an extrinsic evaluation method. We first analyze each linguistic feature

---

*The first three authors contributed equally.

[1] In linguistics, *pragmatics* has both a broad and a narrow sense. Narrowly, the term refers to formal pragmatics. In the broad sense, which we employ in this paper, pragmatics refers to contextual factors in language use. We are particularly concerned with cross-cultural pragmatics and finding quantifiable linguistic measures that correspond to aspects of cultural context. These measures are not the cultural characteristics that would be identified by anthropological linguists themselves but are rather intended to be measurable correlates of these characteristics.

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2403–2414
April 19 - 23, 2021.

to confirm that they capture the intended cultural patterns. We find that the results corroborate the existing work in sociolinguistics and linguistic anthropology. Next, as a practical application of our features, we use them to rank transfer languages for cross-lingual transfer learning. Lin et al. (2019) have shown that selecting the right set of transfer languages with syntactic and semantic language-level features can significantly boost the performance of cross-lingual models. We incorporate our features into Lin et al. (2019)'s ranking model to evaluate the new cultural features' utility in selecting better transfer languages. Experimental results show that incorporating the features improves the performance for cross-lingual sentiment analysis, but not for dependency parsing. These results support our hypothesis that cultural features are more helpful when the cross-lingual task is driven by pragmatic knowledge. [2]

2 Pragmatically-motivated Features

We propose three language-level features that quantify the cultural similarities across languages.

Language Context-level Ratio A language's *context-level* reflects the extent to which the language leaves the identity of entities and predicates to context. For example, an English sentence *Did you eat lunch?* explicitly indicates the pronoun *you*, whereas the equivalent Korean sentence 점심 먹었니? (= *Did eat lunch?*) omits the pronoun. Context-level is considered one of the distinctive attributes of a language's pragmatics in linguistics and communication studies, and if two languages have similar levels of context, their speakers are more likely to be from similar cultures (Nada et al., 2001).

The language context-level ratio (`LCR`) feature approximates this linguistic quality. We compute the pronoun- and verb-token ratio, $\texttt{ptr}(l_k)$ and $\texttt{vtr}(l_k)$ for each language l_k, using part-of-speech tagging results. We first run language-specific POS-taggers over a large mono-lingual corpus for each language. Next, we compute `ptr` as the ratio of count of pronouns in the corpus to the count of all tokens. `vtr` is obtained likewise with verb tokens. Low `ptr`, `vtr` values may indicate that a language leaves the identity of entities and predicates, respectively, to context. We then compare these values between the *target language* l_{tg} and *transfer language* l_{tf}, which leads to the following definition of `LCR`:

$$\texttt{LCR-pron}(l_{tf}, l_{tg}) = \texttt{ptr}(l_{tg})/\texttt{ptr}(l_{tf})$$
$$\texttt{LCR-verb}(l_{tf}, l_{tg}) = \texttt{vtr}(l_{tg})/\texttt{vtr}(l_{tf})$$

Literal Translation Quality Similar cultures tend to share similar figurative expressions, including idiomatic multiword expressions (MWEs) and metaphors (Kövecses, 2003, 2010). For example, *like father like son* in English can be translated word-by-word into a similar idiom *tel père tel fils* in French. However, in Japanese, a similar idiom 蛙の子は蛙 (*Kaeru no ko wa kaeru*) "A frog's child is a frog." cannot be literally translated.

Literal translation quality (`LTQ`) feature quantifies how well a given language pair's MWEs are preserved in literal (word-by-word) translation, using a bilingual dictionary. A well-curated list of MWEs is not available for the majority of languages. We thus follow an automatic extraction approach of MWEs (Tsvetkov and Wintner, 2010). First, a variant of pointwise mutual information, PMI[3] (Daille, 1994) is used to extract noisy lists of top-scoring n-grams from two large monolingual corpora from different domains, and intersecting the lists filters out domain-specific n-grams and retains the language-specific top-k MWEs. Then, a bilingual dictionary between l_{tf} and l_{tg} and a parallel corpus between the pair are used. [3] For each n-gram in l_{tg}'s MWEs, we search for its literal translations extracted using the dictionary in parallel sentences containing the n-gram. For any word in the n-gram, if there is a translation in the parallel sentence, we consider this as hit, otherwise as miss. And we calculate *hit ratio* as $\frac{hit}{(hit+miss)}$ for each n-gram found in the parallel corpus. Finally, we average the hit ratios of all n-grams and z-normalize over the transfer languages to obtain $\texttt{LTQ}(l_{tf}, l_{tg})$.

Emotion Semantics Distance Emotion semantic distance (`ESD`) measures how similarly emotions are lexicalized across languages. This is inspired by Jackson et al. (2019) who used colexification patterns (i.e., when different concepts are expressed using the same lexical item) to capture the semantic similarity of languages. However, colexification patterns require human annotation,

---

[2] Code and data are publicly available at https://github.com/hwijeen/langrank.

[3] While dictionaries and parallel corpora are not available for many languages, they are easier to obtain than the task-specific annotations of MWEs.

and existing annotations may not be comprehensive. We extend Jackson et al. (2019)'s method by using cross-lingual word embeddings.

We define `ESD` as the average distance of emotion word vectors in transfer and target languages, after aligning word embeddings into the same space. More specifically, we use 24 emotion concepts defined in Jackson et al. (2019) and use bilingual dictionaries to expand each concept into every other language (e.g., *love* and *proud* to *Liebe* and *stolz* in German). We then remove the emotion word pairs from the bilingual dictionaries, and use the remaining pairs to align word embeddings of source into the space of target languages. We hypothesize that if words correspond to the same emotion concept in different languages (e.g., *proud* and *stolz*) have similar meaning, they should be aligned to the same point despite the lack of supervision. However, because each language possesses different emotion semantics, emotions are scattered into different positions. We thus define `ESD` as the average cosine distance between languages:

$$\texttt{ESD}(l_{tf}, l_{tg}) = \sum_{e \in E} \cos(\mathbf{v}_{tf,e}, \mathbf{v}_{tg,e})/|E|$$

where E is the set of emotion concepts and $\mathbf{v}_{tf,e}$ is the aligned emotion word vector of language l_{tf}.

3 Feature Analysis

In this section, we evaluate the proposed pragmatically-motivated features intrinsically. Throughout the analyses, we use 16 languages listed in Figure 4 which are later used for extrinsic evaluation (§5).

3.1 Implementation Details

We used multilingual word tokenizers from NLTK and RDR POS Tagger (Nguyen et al., 2014) for most of the languages except for Arabic, Chinese, Japanese, and Korean, where we used PyArabic, Jieba, Kytea, and Mecab, respectively. For monolingual corpora, we used the news-crawl 1M corpora from Leipzig (Goldhahn et al., 2012) for both `LCR` and `LTQ`. We used bilingual dictionaries from Choe et al. (2020) and TED talks corpora (Qi et al., 2018) for both parallel corpora and an additional monolingual corpus for `LTQ`. We focused on bigrams and trigrams and set k, the number of extracted MWEs, to 500. We followed Lample et al. (2018) to generate the supervised cross-lingual word embeddings for `ESD`.

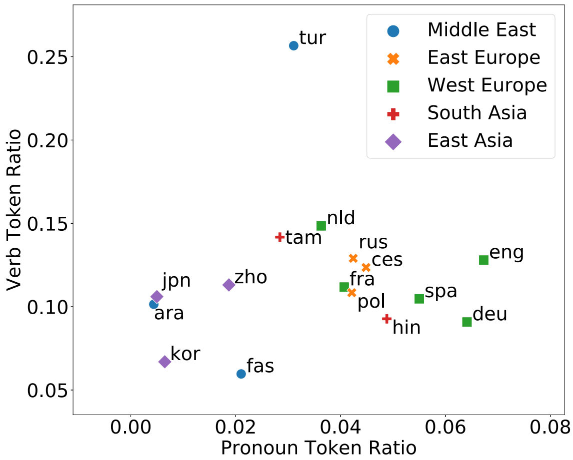

Figure 1: Plot of languages in `ptr` and `vtr` plane. Languages are color-coded according to the cultural areas defined in Siegel (1977).

3.2 LCR and Language Context-level

`ptr` approximates how often discourse entities are indexed with pronouns rather than left conjecturable from context. Similarly, `vtr` estimates the rate at which predicates appear explicitly as verbs. In order to examine to which extent these features reflect context-levels, we plot languages on a two-dimensional plane where the x-axis indicates `ptr` and the y-axis indicates `vtr` in Figure 1.

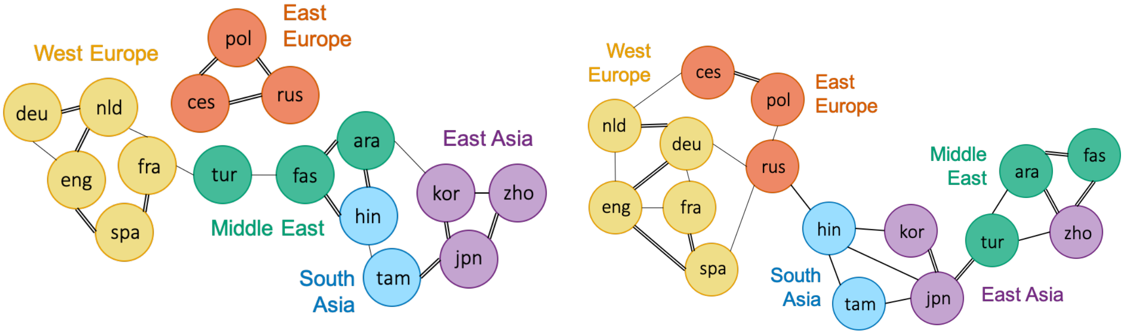
The plot reveals a clear pattern of context-levels in different languages. Low-context languages such as German and English (Hall, 1989) possess the largest values of `ptr`. On the other extreme are located Korean and Japanese with low `ptr`, which are representative of high-context languages. One thing to notice is the isolated location of Turkish with a high `vtr`. This is morphosyntactically plausible as a lot of information is expressed by the affixation to verbs in Turkish.

3.3 LTQ and MWEs

`LTQ` uses n-grams with high PMI scores as proxies for figurative language MWE (PMI MWEs). We evaluate the quality of selected MWEs and the resulting `LTQ` by comparing with human-curated list of figurative language MWE (gold MWEs) that are available in some languages. We collected gold MWEs in multiple languages from Wiktionary[4]. We discarded languages with less than 2,000 phrases on the list, resulting in four languages (English, French, German, Spanish) for

---

[4] For example, https://en.wiktionary.org/wiki/Category:English_idioms



(a) Network based on Emotion Semantics Distance.

(b) Network based on syntactic distance.

Figure 2: Network of languages color-coded by their cultural areas. An edge is added between the two languages if a language is ranked in the top-2 closest languages of the other language in terms of feature value.

analysis.

First, we check how many PMI MWEs are actually in the gold MWEs. Out of the top-500 PMI bigrams and trigrams, 19.0% of bigrams and 3.8% of trigrams are included in the gold MWE list (averaged over four languages). For example, the trigrams in the PMI MWEs, *keep an eye* and *take into account*, are considered to be in the gold MWEs as *keep an eye peeled* and *take into account* are in the list. The seemingly low percentages are reasonable, regarding that the PMI scores are designed to extract collocations patterns rather than figurative languages themselves.

Secondly, to validate using PMI MWEs as proxies, we compare the `LTQ` of PMI MWEs with the `LTQ` using gold MWEs. Specifically, we obtained the `LTQ` scores of each language pair with target languages limited to the four European languages mentioned above. Then for each target language, we measured Pearson correlation coefficient between the two `LTQ` scores based on the two MWE lists. The average coefficient was 0.92, which indicates a strong correlation between the two resulting `LTQ` scores, and thus justifies using PMI MWEs for all other languages.

3.4 ESD and Cultural Grouping

We investigate what is carried by `ESD` by visualizing and looking at the nearest neighbors of emotion vectors.[5] Jackson et al. (2019) used word colexification patterns to reveal that the same emotion concepts cluster with different emotions according to the language family they belong to. For instance, in Tai-Kadai languages, *hope* appears in the same cluster as *want* and *pity*, while *hope* associates with *good* and *love* in the Nakh-Daghestanian language family. Our results derived from `ESD` do not rely on colexification patterns, but also support this finding. The nearest neighbors of the Chinese word for *hope* was *want* and *pity*, while they were found as *love* and *joy* for *hope* in Arabic.

In Figure 2, we compare `ESD` to the syntactic distance between languages by constructing two networks of languages based on each feature. Figure 2a uses `ESD` as reference while Figure 2b uses the syntactic distance from the URIEL database (Littell et al., 2017). Each node represents a language, color-coded by its cultural area. For each language, we sort the other languages according to the distance value. When a language is in the list of top-k closest languages, we draw an edge between the two. We set $k = 2$.

We see that languages in the same cultural areas tend to form more cohesive clusters in Figure 2a compared to Figure 2b. The portion of edges *within* the cultural areas is 76% for `ESD` while it is 59% for syntactic distance. These results indicate that `ESD` effectively extracts linguistic information that aligns well with the commonly shared perception of cultural areas.

3.5 Correlation with Geographical Distance

Regarding the language clusters in Figure 2a, some may suspect that geographic distance can substitute the pragmatically-inspired features. For Chinese, Korean and Japanese are the closest languages by `ESD`, which can also be explained by their geographical proximity. Do our features add additional pragmatic information, or can they simply be replaced by geographical distance?

To verify this speculation, we evaluate Pearson's correlation coefficient of each pragmatic feature

---

[5] A visualization demo of emotion vectors can be found at `https://bit.ly/emotion_vecs`.

value with geographical distance from URIEL. The feature with the strongest correlation was `ESD` (r=0.4). The least correlated was `LCR-verb` (r=0.03), followed by `LCR-pron` (r=0.17) and `LTQ` (r=−0.31)[6]. The results suggest that the pragmatic features contain extra information that cannot be subsumed by geographic distance.

4 Extrinsic Evaluation: Ranking Transfer Languages

To demonstrate the utility of our features, we apply them to a *transfer language ranking* task for cross-lingual transfer learning. We first present the overall task setting, including the datasets and models used for the two cross-lingual tasks. Next, we describe the transfer language ranking model and its evaluation metrics.

4.1 Task Setting

We define our task as the *language ranking* problem: given the target language l_{tg}, we want to rank a set of n candidate transfer languages $\mathcal{L}_{tf}=\{l_{tf}^{(1)},\ldots,l_{tf}^{(n)}\}$ by their usefulness when transferred to l_{tg}, which we refer to as *transferability* (illustrated in Figure 3). The effectiveness of cross-lingual transfer is often measured by evaluating the joint training or zero-shot transfer performance (Wu and Dredze, 2019; Schuster et al., 2019). In this work, we quantify the effectiveness as the zero-shot transfer performance, following Lin et al. (2019). Our goal is to train a model that ranks available transfer languages in $\mathcal{L}_{tf}$ by their transferability for a target language l_{tg}.

To train the ranking model, we first need to find the ground-truth transferability rankings, which operate as the model's training data. We evaluate the zero-shot performance $z_{tf,tg}$ by training a task-specific cross-lingual model solely with transfer language l_{tf} and testing on l_{tg}. After evaluating $z_{tf,tg}$ for each candidate transfer language in $\mathcal{L}_{tf}$, we obtain the optimal ranking of languages $\boldsymbol{r}_{tg}$ by sorting languages according to the measured $z_{tf,tg}$. Note that $\boldsymbol{r}_{tg}$ also depends on downstream task.

Next, we train the language ranking model. The ranking model predicts the transfer ranking of candidate languages. Each source, target pair (l_{tf}, l_{tg}) is represented as a vector of language features $\boldsymbol{f}_{tf,tg}$, which may include phonological similarity, typological similarity, word-overlap to name a few. The ranking model takes $\boldsymbol{f}_{tf,tg}$ of every l_{tf} as input, and predicts the transferability ranking $\hat{\boldsymbol{r}}_{tg}$. Using $\boldsymbol{r}_{tg}$ from the previous step as training data, the model learns to find optimal transfer languages based on $\boldsymbol{f}_{tf,tg}$. The trained model can either be used to select the optimal set of transfer languages, or to decide which language to additionally annotate during the data creation process.

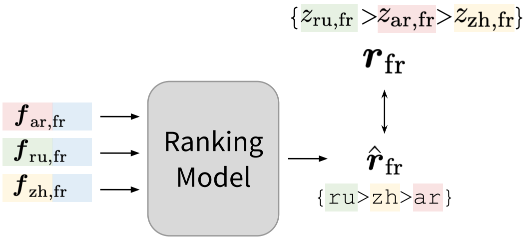


Figure 3: Illustration of transfer language ranking problem when the target language is French (fr) and there are three available transfer languages: Arabic (ar), Russian (ru), and Chinese (zh). The output ranking $\hat{\boldsymbol{r}}_{\text{fr}}$ is compared to the ground truth ranking $\boldsymbol{r}_{\text{fr}}$ which is determined by the zero-shot performance $\boldsymbol{z}$ of cross-lingual models.

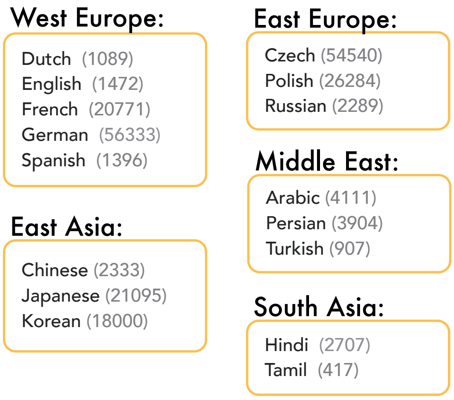

Figure 4: Languages used throughout the experiments are grouped by their cultural areas (Siegel, 1977). The numbers indicate the size of each dataset.

4.2 Task & Dataset

We apply the proposed features to train a ranking model for two distinctive tasks: multilingual sentiment analysis (SA) and multilingual dependency parsing (DEP). The tasks are chosen based on our hypothesis that high-order information such as pragmatics would assist sentiment analysis while it may be less significant for dependency parsing, where lower-order information such as syntax is relatively stressed.

SA As there is no single sentiment analysis dataset covering a wide variety of languages, we

---

[6] When two languages are more similar, LTQ is higher whereas geographic distance is smaller.

collected various review datasets from different sources.[7] All samples are labeled as either positive or negative. In case of datasets rated with a five-point Likert scale, we mapped 1–2 to negative and 4–5 to positive. We settled on a dataset consist of 16 languages categorized into five distinct cultural groups: West Europe, East Europe, East Asia, South Asia, and Middle East (Figure 4).

DEP To compare the effectiveness of the proposed features on syntax-focused tasks, we chose datasets of the same set of 16 languages from Universal Dependencies v2.2 (Nivre et al., 2018).

4.3 Task-Specific Cross-Lingual Models

SA Multilingual BERT (mBERT) (Devlin et al., 2019), a multilingual extension of BERT pretrained with 104 different languages, has shown strong results in various text classification tasks in cross-lingual settings (Sun et al., 2019; Xu et al., 2019; Li et al., 2019). We use mBERT to conduct zero-shot cross-lingual transfer and to extract optimal transfer language rankings: fine-tune mBERT on transfer language data and test it on target language data. The performance is measured by the macro F1 score on the test set.

DEP We adopt the setting from Ahmad et al. (2018) to perform cross-lingual zero-shot transfer. We train deep biaffine attentional graph-based models (Dozat and Manning, 2016) which achieved state-of-the-art performance in dependency parsing for many languages. The performance is evaluated using labeled attachment scores (LAS).

4.4 Ranking Model & Evaluation

Ranking Model For the language ranking model, we employ gradient boosted decision trees, LightGBM (Ke et al., 2017), which is one of the state-of-the-art models for ranking tasks.[8]

Ranking Evaluation Metric We evaluate the ranking models' performance with two standard metrics for ranking tasks: Mean Average Precision (MAP) and Normalized Discounted Cumulative Gain at position p (NDCG@p) (Järvelin and Kekäläinen, 2002). While MAP assumes a binary concept of relevance, NDCG is a more fine-grained measure that reflects the ranking positions. The *relevant* languages for computing MAP are defined as the top-k languages in terms of zero-shot performance in the downstream task. In our experiments, we set k to 3 for MAP. Similarly, we use NDCG@3.

We train and evaluate the model using leave-one-out cross-validation: where one language is set aside as the test language while other languages are used to train the ranking model. Among the training languages, each language is posited in turn as the *target* language while others are the *transfer* languages.

5 Experiments

5.1 Baselines

LANGRANK LANGRANK (Lin et al., 2019) uses 13 features to train the ranking model: The dataset size in transfer language (`tf_size`), target language (`tg_size`), and the ratio between the two (`ratio_size`); Type-token-ratio (`ttr`) which measures lexical diversity and `word_overlap` for lexical similarity between a pair of languages; various distances between a language pair from the URIEL database (geographic `geo`, genetic `gen`, inventory `inv`, syntactic `syn`, phonological `phon` and featural `feat`).

MTVEC Malaviya et al. (2017) proposed to learn a language representation while training a neural machine translation (NMT) system in a similiar fashion to Johnson et al. (2017). During training, a language token is prepended to the source sentence and the learned token's embedding becomes the language vector. Bjerva et al. (2019) has shown that such language representations contain various types of linguistic information ranging from word order to typological information. We used the one released by Malaviya et al. (2017) which has the dimension of 512.

5.2 Individual Feature Contribution

We first look into whether the proposed features are helpful in ranking transfer languages for sentiment analysis and dependency parsing (Table 1). We add all three features (PRAG) to the two baseline features (LANGRANK, MTVEC) and compare the performance in the two tasks. Results show that our features improve both baselines in SA, implying that the pragmatic information captured by our features is helpful for discerning the subtle differences in sentiment among languages.

In the case of DEP, including our features brings inconsistent results to performance. The features

---

[7] Details are provided in Appendix A. Note that the difference in domain and label distribution of data can also affect the transferability, and a related discussion is in §5.4

[8] More details on the cross-lingual models, ranking model, and their training can be found in Appendix B.

	SA		DEP	
	MAP	NDCG	MAP	NDCG
LangRank	71.3	86.5	**63.0**	**82.2**
LangRank+Prag	**76.0**	**90.9**	61.7	80.5
- `LCR`	75.0	88.3	60.3	79.6
- `LTQ`	72.4	89.3	63.1*	81.3*
- `ESD`	77.7*	92.1*	58.2	78.5
MTVec	71.1	89.5	43.0	69.7
MTVec+Prag	**74.3**	**90.8**	**49.7**	**74.8**
- `LCR`	72.9	90.1	54.1*	76.3*
- `LTQ`	71.2	89.0	53.0*	78.6*
- `ESD`	73.1	90.7	45.3	73.9

Table 1: Evaluation results of our features (Prag) added to each baseline. The higher scores are **boldfaced**. Rows in gray indicate ablation studies. * is marked when improvements are made compared to LangRank+Prag, MTVec+Prag respectively.

help the performance of MTVec while they deteriorate the performance of LangRank. Although some performance increase was observed when applied to MTVec, the performance of MTVec in DEP remains extremely poor. These conflicting trends suggest that pragmatic information is not crucial to less pragmatically-driven tasks, represented as dependency parsing in our case.

The low performance of MTVec in DEP is noticeable as MTVec is generally believed to contain a significant amount of syntactic information, with much higher dimensionality than LangRank. It also suggests the limitation of using distributional representations as language features; their lack of interpretability makes it difficult to control the kinds of information used in a model.

We additionally conduct ablation studies by removing each feature from the +Prag models to examine each feature's contribution. The SA results show that `LCR` and `LTQ` significantly contribute to overall improvements achieved by adding our features, while `ESD` turns out to be less helpful. Sometimes, removing `ESD` resulted in a better performance. In contrast, the results of DEP show that `ESD` consistently made a significant contribution, and `LCR` and `LTQ` were not useful. The results imply that the emotion semantics information of languages is surprisingly not useful in sentiment analysis, but more so in dependency parsing.

5.3 Group-wise Contribution

The previous experiment suggests that the same pragmatic information can be helpful to different extents depending on the downstream task. We further investigate to what extent each kind of information is useful to each task by conducting group-wise comparisons. To this end, we group the features into five categories: Pretrain-specific, Data-specific, Typology, Geography, Orthography, and Pragmatic. Pretrain-specific features cover factors that may be related to the performance of pretrained language models used in our task-specific cross-lingual models. Specifically, we used the size of the Wikipedia training corpus of each language used in training mBERT.[9] Note that we do not measure this feature group's performance on DEP as no pretrained language model was used in DEP. Data-specific features include `tf_size`, `tg_size`, and `ratio_size`. Typological features include `geo`, `syn`, `feat`, `phon`, and `inv` distances. Geography includes `geo` distance in isolation. Orthographic feature is the `word_overlap` between languages. Finally, the Pragmatic group consists of `ttr` and the three proposed features, `LCR`, `LTQ`, and `ESD`. `ttr` is included in Pragmatic as Richards (1987) have suggested that it encodes a significant amount of cultural information.

	SA		DEP	
	MAP	NDCG	MAP	NDCG
Pretrain-specific	39.0	55.5	-	-
Data-specific	68.0	85.4	37.2	55.0
Typology	44.9	60.7	**58.0**	**79.8**
Geography	24.9	55.0	32.3	65.1
Orthography	34.2	56.6	35.5	60.5
Pragmatic	**73.0**	**88.0**	46.5	71.8

Table 2: Ranking performance using each feature group as input to the ranking model.

Table 2 reports the performance of ranking models trained with the respective feature category. Interestingly, the two tasks showed significantly different results; the Pragmatic group showed the best performance in SA while the Typology group outperformed all other groups in DEP. This again confirms that the features indicating cross-lingual transferability differ depending on the target task. Although the Pretrain-specific features were more predictive than the Geography and Orthography features it was not as helpful as the Pragmatic features.

---

5.4 Controlling for Dataset Size

The performance of cross-lingual transfer depends not only on the cultural similarity between transfer and target languages but also on other factors, including dataset size and label distributions. Although our model already accounts for the dataset size to some extent by including `tf_size` as input, we conduct a more rigorous experiment to better understand the importance of cultural similarity in language selection. Specifically, we control the data size by down-sampling all SA data to match both the size and label distribution of the second smallest Turkish dataset.[10] We then trained two ranking models equipped with different sets of features: LANGRANK and LANGRANK+PRAG.

In terms of languages, we focus on a setting where Turkish is the target and Arabic, Japanese and Korean are the transfer languages. This is a particularly interesting set of languages because the source languages are similar/dissimilar to Turkish in different aspects; Korean and Japanese are typologically similar to Turkish, yet in cultural terms, Arabic is more similar to Turkish.

In this controlled setting, the ground-truth ranking reveals that the optimal transfer language among the three is Arabic, followed by Korean and Japanese. It indicates the important role of cultural resemblance in sentiment analysis which encapsulates the rich historical relationship shared between Arabic- and Turkish-speaking communities. LANGRANK+PRAG chose Arabic as the best transfer language, suggesting that the imposed cultural similarity information from the features helped the ranking model learn the cultural tie between the two languages. On the other hand, LANGRANK ranked Japanese the highest over Arabic, possibly because the provided features mainly focus on typological similarity over cultural similarity.

6 Related Work

Quantifying Cross-cultural Similarity A few recent work in psycholinguistics and NLP have aimed to measure cultural differences, mainly from word-level semantics. Lin et al. (2018) suggested a cross-lingual word alignment method that preserves the cultural, social context of words. They derive cross-cultural similarity from the embeddings of a bilingual lexicon in the shared representation space. Thompson et al. (2018) computed similarity by comparing the nearest neighborhood of words in different languages, showing that words in some domains (e.g., time, quantity) exhibit higher cross-lingual alignment than other domains (e.g., politics, food, emotions). Jackson et al. (2019) represented each language as a network of emotion concepts derived from their colexification patterns and measured the similarity between networks.

Auxiliary Language Selection in Cross-lingual tasks There has been active work on leveraging multiple languages to improve cross-lingual systems (Neubig and Hu, 2018; Ammar et al., 2016). Adapting auxiliary language datasets to the target language task can be practiced through either language-selection or data-selection. Previous work on language-selection mostly relied on leveraging syntactic or semantic resemblance between languages (e.g. ngram overlap) to choose the best transfer languages (Zoph et al., 2016; Wang and Neubig, 2019). Our approach extends this line of work by leveraging cross-cultural pragmatics, an aspect that has been unexplored by prior work.

7 Future Directions

Typology of Cross-cultural Pragmatics The features proposed here provide three dimensions in a provisional quantitative cross-linguistic typology of pragmatics in language. Having been validated, both intrinsically and extrinsically, they can be used in studies as a stand-in for cross-cultural similarity. They also open a new avenue of research, raising questions about what other quantitative features of language are correlates of cultural and pragmatic difference.

Model Probing Fine-tuning pretrained models to downstream tasks has become the de facto standard in various NLP tasks, and their success has promoted the development of their multilingual extensions (Devlin et al., 2019; Lample and Conneau, 2019). While the performance gains from these models are undeniable, their learning dynamics remain obscure. This issue has prompted various probing methods designed to test what kind of linguistic information the models retain, including syntactic and semantic knowledge (Conneau et al., 2018; Liu et al., 2019; Ravishankar et al., 2019; Tenney et al., 2019). Similarly, our features can be employed as a touchstone to evaluate a model's knowledge in cross-cultural pragmatics. Investigating how different pretraining tasks affect the

---

[10] The size of the smallest language (Tamil; 417 samples) was too small to train an effective model.

learning of pragmatic knowledge will also be an interesting direction of research.

8 Conclusion

In this work, we propose three pragmatically-inspired features that capture cross-cultural similarities that arise as linguistic patterns: language context-level ratio, literal translation quality, and emotion semantic distance. Through feature analyses, we examine whether our features can operate as valid proxies of cross-cultural similarity. From a practical standpoint, the experimental results show that our features can help select the best transfer language for cross-lingual transfer in pragmatically-driven tasks, such as sentiment analysis.

B Task-Specific Models Details

SA Cross-lingual Model We performed supervised fine-tuning of multilingual BERT (mBERT) (Devlin et al., 2019) for the sentiment analysis task, as the model showed strong results in various text classification tasks in cross-lingual settings (Sun et al., 2019; Xu et al., 2019; Li et al., 2019). mBERT is pretrained with 104 different languages, including the 16 languages we used throughout our experiment. We used a concatenation of mean and max pooled representations from mBERT's penultimate layer, as it outperformed the standard practice of using the last layer's `[CLS]` token. The representation was passed to a fully connected layer for prediction. To extract optimal transfer rankings, we conducted zero-shot transfer with mBERT: fine-tuned mBERT on transfer language data and tested it on target language data.

Ranking Model We used LightGBM (Ke et al., 2017) with LambdaRank (Burges et al., 2007) algorithm. The model consists of 100 decision trees with 16 leaves each, and it was trained with the learning rate of 0.1. We optimized NDCG to train the model (Järvelin and Kekäläinen, 2002).

PHASE: Learning Emotional Phase-aware Representations for Suicide Ideation Detection on Social Media

Abstract

Recent psychological studies indicate that individuals exhibiting suicidal ideation increasingly turn to social media rather than mental health practitioners. Contextualizing the build-up of such ideation is critical for the identification of users at risk. In this work, we focus on identifying suicidal intent in tweets by augmenting linguistic models with emotional phases modeled from users' historical context. We propose PHASE, a time-and phase-aware framework that adaptively learns features from a user's historical emotional spectrum on Twitter for preliminary screening of suicidal risk. Building on clinical studies, PHASE learns phase-like progressions in users' historical Plutchik-wheel-based emotions to contextualize suicidal intent. While outperforming state-of-the-art methods, we show the utility of temporal and phase-based emotional contextual cues for suicide ideation detection. We further discuss practical and ethical considerations.[1]

1 Introduction

Every 10.9 minutes, a person dies of suicide (Drapeau and McIntosh, 2020). Suicide ranks as the second leading cause of death for 14-35 year-olds (Hedegaard et al., 2020) in US. Extending appropriate clinical and psychological care to suicidal people relies on identifying those at risk. Unfortunately, 80% of patients do not undergo clinical treatment, and about 60% of those who died of suicide denied having any suicidal thoughts to mental health practitioners (McHugh et al., 2019; Franklin et al., 2017). In contrast, people exhibiting suicidal ideation often use social media to express their feelings (Coppersmith et al., 2014, 2016, 2018; Robinson et al., 2016; Reger et al., 2020), with eight out of ten people disclosing their suicidal thoughts and plans on social media (Golden et al., 2009).

TWEET TO BE ASSESSED

25 Aug 2015 01:17 AM — free me from all this or i will do something myself

Figure 1: We study a user's tweeting history and emotional progression. Note that while the user's most recent tweet (blue) shows a subtle indication of suicidal intent, it is not sufficient to ascertain suicide risk. Grouping the build-up of negative emotions (red) in the user's historical tweets into phase-like emotional progressions, by utilizing the elapsed time between tweets, can contextualize the user's state and provide a more accurate and interpretable risk assessment. *All examples in this paper have been anonymized and paraphrased as per a moderate disguise scheme (Bruckman, 2002) to protect user privacy (Chancellor et al., 2019b).*

Natural Language Processing (NLP) presents an encouraging prospect to complement social science to identify risk markers in user behavior (De Choudhury et al., 2013, 2016) to aid suicide risk assessment (Shing et al., 2018, 2020). However, suicide ideation is complex, and often, individual posts may not be sufficient to assess a user's suicide risk, even for humans (Sisask et al., 2008; O'dea et al., 2015). Figure 1 illustrates how features such as historical posts (Matero et al., 2019) can add context for analyzing a user's online behavior over time (Van Heeringen and Marušic, 2003) to better

ascertain suicide risk. Despite the success of user-centric contextual models (Flek, 2020) for suicide ideation detection, they have two major limitations.

First, recurrent neural networks, particularly LSTMs, that are natural methods to learn patterns from a sequence of a user's historical tweets (Cao et al., 2019; Zeng et al., 2019, 2020), assume uniform time gaps between successive tweets. However, tweets can be posted at irregular time intervals (Lei et al., 2018), and varying time gaps can influence the assessment of a user's suicidality progression (Chen et al., 2018), as shown in Figure 1.

Second, these methods implicitly assume that a user's mental and emotional state progression is smooth in time, with an ever-increasing tendency. However, in reality, studies show that emotional (Larsen et al., 2015), and suicidality progression can vary significantly (Bryan and Rudd, 2016; Bryan, 2020), and show fluctuating *phase* like patterns (Kiosses et al., 2014; Palmier-Claus et al., 2012). Analyzing such phase-wise emotion progressions and build-up, as illustrated in Figure 1, can be instrumental in contextualizing suicidal risk, and aiding clinical psychologists through increased interpretability in human-in-the-loop systems.[2]

Building on these limitations, and motivated by psychological studies (Neacsiu et al., 2018; Domínguez and Fernández, 2018) of emotional state progression, we propose **PHASE: PHase-Aware Suicidality identification Emotion progression model.** With PHASE, we present the first neural framework to identify suicide ideation on social media (§3.1) that explicitly models the *inherent phase-aware progressions* in users' emotional spectrums in a contextual time-aware manner.

We present the following key contributions:

(i) First, building on the success of large scale pretraining in NLP, we utilize Plutchik Transformer, a transformer to learn linguistic and Plutchik-based (Plutchik, 1980) emotional cues from tweets (§3.2).

(ii) We propose Time-Sensitive Emotion LSTM (TSE-LSTM) to learn the historical emotional progression of a user's mental states from their learned emotional spectrum in a time-aware manner (§3.3).

(iii) Based on psychological studies, we propose a novel method to learn users' emotional phase progressions by leveraging the amount of historical emotional context used to update the TSE-LSTM's cell state. PHASE identifies the onset of new emotional phases and learns a temporal *phase-aware emotional user representation* (§3.4) that is then used to identify suicide ideation in their recent tweets (§3.5), increasing the system transparency.

(iv) Through a series of experiments (§4.2), we show that PHASE significantly ($p < 0.005$) outperforms competitive methods, which do not take users' emotional phases into account (§5).

(v) We analyze the contributions of PHASE's individual components to suicide ideation detection (§5.2, §5.3, §5.4), assess its transparency and limitations through qualitative analysis (§5.5), and conclude by discussing the ethical implications and practical applicability of this study (§6).

2 Related Work

Traditional Methods: Researchers have devised various psychoclinical methods to assess suicidal risk (Pestian et al., 2016), such as the Suicide Probability Scale (Bagge and Osman, 1998), Suicide Ideation Questionnaire (wa Fu et al., 2007), Suicidal Affect-Behavior-Cognition Scale (Harris et al., 2015). While these methods are professional and effective, they require participants to answer questionnaires (Venek et al., 2017) or engage in interviews (Scherer et al., 2013), hence not reaching people who cannot access these resources or have a low motivation to seek professional help (Zachrisson et al., 2006; Essau, 2005). Harris and Goh (2016) show that such assessments can negatively impact people showing depressive symptoms.

NLP Methods: Recently, social media has shown promise in providing insights into users' mental states (Paul and Dredze, 2011). Jashinsky et al. (2014) reported that Twitter is a viable tool for real-time monitoring (Braithwaite et al., 2016) of suicide risk. Early efforts in utilizing social media leverage user features such as their age, gender,and social network connectivity (Masuda et al., 2013) and online suicide notes (Pestian et al., 2010). Since then, the focus has been on using psycholinguistic lexicons such as LIWC and textual features such as n-grams, POS tags, etc. for classification (De Choudhury et al., 2016; Sawhney et al., 2018b). Shared tasks such as CLPsych (Zirikly et al., 2019) and CLEF eRISK (Losada et al., 2020) have seen a rise in neural networks such as CNNs (Yates et al., 2017; Du et al., 2018; Naderi et al., 2019; Gaur et al., 2019) and LSTMs (Ji et al., 2018; Tadesse et al., 2020) to predict suicide risk. While these methods capture post semantics in isolation, no user context is leveraged, hindering insight into

---

[2] Similar to the post-screening on Facebook (Card, 2018).

the user's mental state to improve predictive power (Venek et al., 2017; Flek, 2020). User context includes the user's emotions (Ren et al., 2016; Guntuku et al., 2017), social networks (Mishra et al., 2019) and historical posts (Mathur et al., 2020).

Contextual Methods: The best performing model, the DualContextBERT (Matero et al., 2019), at CLPsych 2019 for suicidal estimation exemplifies the utility of temporal context. The DualContextBERT models post embeddings sequentially via an RNN. Such RNN-based approaches assume that users' historical posts are equally spaced in time, hindering their ability to learn their relative importance in a time-aware manner. Recently, time-aware modeling of well defined stages in numerical time series data shows promising results in clinical tasks like patient subtyping (Baytas et al., 2017) and disease progression (Gao et al., 2020). However, the time-sensitive phase extraction of user-generated posts on social media, and phase-aware modeling of textual data is underexplored and complex, as it involves noisy, unstructured and ambiguous inputs across irregular time intervals.

3 PHASE: Components and Learning

3.1 Notations and Problem Formulation

We formulate suicidal intent detection as a binary classification task to predict suicidal intent y_i for a tweet t_i, where, $y_i \in \{\text{suicidal intent present, suicidal intent absent}\}$. We denote the tweet to be assessed for the presence of suicidal intent as $t_i \in T = \{t_1, t_2, \cdots, t_N\}$, authored by a user $u_j \in U = \{u_1, u_2, \cdots, u_M\}$, posted at time τ^i_{curr}. Each tweet t_i is associated with history $H^j_i = [(h^i_1, \tau^i_1), (h^i_2, \tau^i_2), \cdots, (h^i_L, \tau^i_L)]$ where h^i_k is a historic tweet authored by user u_j posted at time τ^i_k with $\tau^i_1 < \tau^i_2 < \cdots < \tau^i_L < \tau^i_{curr}$.

As shown in Figure 2, PHASE first obtains a user's emotion spectrum from their historical tweets and the tweet to be assessed using a fine-tuned BERT model, Plutchik Transformer. We feed the historical tweet representations to our proposed Time-Sensitive Emotion LSTM to learn the temporal progression of a user's emotions. We then identify *phases* in a user's emotions from their learned historical emotional progression, and extract temporal features for a user from these phases using Phase-Adaptive convolutions. Finally, PHASE jointly learns the semantics of user tweets and their historical emotional context in a temporal phase-aware manner for suicide ideation detection in a tweet.

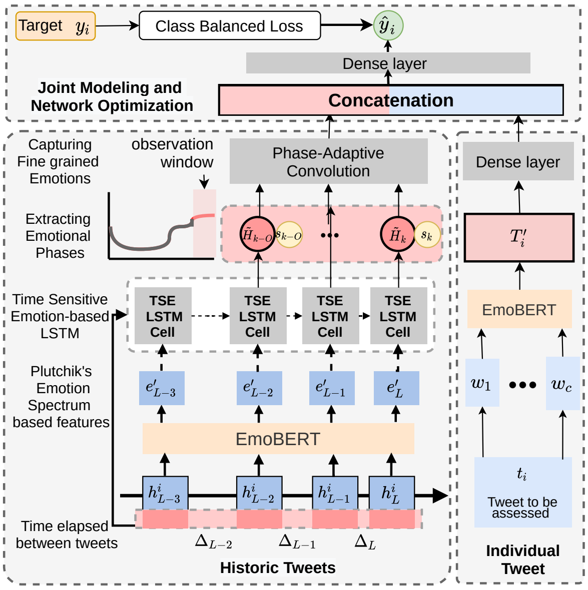

Figure 2: An illustration of PHASE's architecture.

3.2 Plutchik Transformer: Encoding Tweets

Studies show that emotions expressed in suicidal tweets are correlated with suicidal behavior (Sueki, 2015; Spates et al., 2018; Zhang et al., 2017). As a building block, we utilize Plutchik's wheel of emotions (Plutchik, 1980) to capture the emotions expressed by a user in their tweets. Plutchik's wheel outlines eight primary emotions arranged as four pairs of opposing dualities: Joy - Sadness, Surprise - Anticipation, Anger - Fear, and Trust - Disgust. We utilize Plutchik Transformer (Sawhney et al., 2020), a BERT model fine-tuned on Emonet (Abdul-Mageed and Ungar, 2017), a dataset of 790,059 tweets labeled across 8 primary emotions as per Plutchik's wheel of emotions. Owing to the success of pre-training language models in NLP, Plutchik Transformer jointly learns textual and emotion features for representation learning of user tweets for subsequent suicidal intent detection. We extract a 768-dimension encoding from the `[CLS]`[3] token of the penultimate transformer layer, which is densely connected with an 8-dimensional output layer representative of each primary emotion.

---

[3] Empirically, the `[CLS]` token performed better than taking the average of the output vectors over all tokens.

Tweet to be assessed: We encode each tweet to be assessed t_i as:

$$\mathbf{T}'_{\mathbf{i}} = \texttt{PlutchikTransformer}(t_i) \tag{1}$$

where $\mathbf{T}'_{\mathbf{i}} \in \mathbb{R}^{768}$ is linearly transformed using a dense layer to $\mathbf{T}_{\mathbf{i}} \in \mathbb{R}^{d}$ with dimension d.

Historical Tweet Encoding: A holistic representation of users' emotional states can be indicative of variations in risk markers over time (Aragón et al., 2019; Tarrier et al., 2007; Links et al., 2008). To this end, we utilize Plutchik Transformer to encode each historical tweet h^i_k to an emotion representation ($\mathbf{e}^{\mathbf{i}}_{\mathbf{k}} \in \mathbb{R}^{768}$) defined as:

$$\mathbf{e}^{\mathbf{i}}_{\mathbf{k}} = \texttt{PlutchikTransformer}(h^i_k) \tag{2}$$

3.3 Temporal Modeling of Historical Tweets

Building on these natural irregularities in posting times of historical tweets (Wojcik and Hughes, 2019), we propose the use of ON-LSTM (Shen et al., 2018) to encode the sequence of a user's historical tweet emotion representations $\mathbf{e}^{\mathbf{i}}_{\mathbf{k}}$ to capture the variation in their mental and emotional states over time, forming a Time-Sensitive Emotion LSTM (TSE-LSTM). In our TSE-LSTM, we introduce a time-sensitive long-term gate $\tilde{\mathbf{f}}_{\mathbf{k}}$, which contains older historic emotional context. Additionally, we propose a short-term gate $\tilde{\mathbf{i}}_{\mathbf{k}}$ that encodes recent historic tweets, as shown in Figure 3. We then feed the time-lapsed Δ_k from the previous tweet and the historical emotional representation $\mathbf{e}^{\mathbf{i}}_{\mathbf{k}}$ of each tweet h^i_k to a TSE-LSTM cell. This design aids TSE-LSTM to learn two probability distributions $\mathbf{p}_{\tilde{\mathbf{f}}_{\mathbf{k}}}$ and $\mathbf{p}_{\tilde{\mathbf{i}}_{\mathbf{k}}}$ corresponding to the long-term and short-term gates, respectively. Psychological studies show that a user's recent emotions can be more indicative of their current mental state (Fawcett et al., 1990; Homan et al., 2014). To this end, we set the update frequency of the short-term gate higher than the long-term gate to increase the influence of their more recent emotional context. To impose this natural ordering of frequency updates, we apply cumulative sum ($cumsum$) operation to the probability distributions $\mathbf{p}_{\tilde{\mathbf{f}}_{\mathbf{k}}}$ and $\mathbf{p}_{\tilde{\mathbf{i}}_{\mathbf{k}}}$:

$$\mathbf{p}_{\tilde{\mathbf{f}}} = \sigma(\mathbf{W}_{\tilde{\mathbf{f}}}(\mathbf{e}^{\mathbf{i}}_{\mathbf{k}} \oplus \Delta_k) + \mathbf{U}_{\tilde{\mathbf{f}}}(\tilde{\mathbf{H}}^{\mathbf{i}}_{\mathbf{k-1}} \oplus \Delta_k) + \mathbf{b}_{\tilde{\mathbf{f}}}) \tag{3}$$

$$\mathbf{p}_{\tilde{\mathbf{i}}} = \sigma(\mathbf{W}_{\tilde{\mathbf{i}}}(\mathbf{e}^{\mathbf{i}}_{\mathbf{k}} \oplus \Delta_k) + \mathbf{U}_{\tilde{\mathbf{i}}}(\tilde{\mathbf{H}}_{\mathbf{k-1}} \oplus \Delta_k) + \mathbf{b}_{\tilde{\mathbf{i}}}) \tag{4}$$

$$\tilde{\mathbf{f}}_{\mathbf{k}} = \overrightarrow{cumsum}(\mathbf{p}_{\tilde{\mathbf{f}}}), \tilde{\mathbf{i}}_{\mathbf{k}} = \overleftarrow{cumsum}(\mathbf{p}_{\tilde{\mathbf{i}}}) \tag{5}$$

where σ represents softmax, $\oplus$ denotes concatenation and $\tilde{\mathbf{H}}^{\mathbf{i}}_{\mathbf{k-1}}$ is the previous hidden state. The arrow above $cumsum$ indicates its direction. $\mathbf{W}_{\tilde{\mathbf{f}}}$, $\mathbf{W}_{\tilde{\mathbf{i}}}$, $\mathbf{U}_{\tilde{\mathbf{f}}}$, $\mathbf{U}_{\tilde{\mathbf{i}}}$, $\mathbf{b}_{\tilde{\mathbf{f}}}$ and $\mathbf{b}_{\tilde{\mathbf{i}}}$ are learnable parameters. Following $cumsum$'s properties, the values in the long-term gate $\tilde{\mathbf{f}}_{\mathbf{k}}$ are monotonically increasing from 0 to 1, and those in the short-term gate $\tilde{\mathbf{i}}_{\mathbf{k}}$ are monotonically decreasing from 1 to 0.

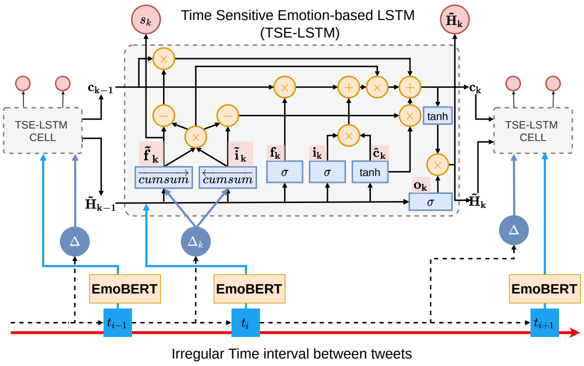

Figure 3: Detailed structure of the TSE-LSTM cell. Figure is adapted from (Gao et al., 2020).

For each historic tweet h^i_k, the long-term gate $\tilde{\mathbf{f}}_{\mathbf{k}}$ controls the historic emotional context to be discarded, and the short-term gate $\tilde{\mathbf{i}}_{\mathbf{k}}$ controls the importance of recent historic emotions. To obtain complete contextual information of overlapping context in $\tilde{\mathbf{f}}_{\mathbf{k}}$ and $\tilde{\mathbf{i}}_{\mathbf{k}}$, we introduce a historic overlap vector $\mathbf{w}_{\mathbf{k}}$ that uses the standard forget and input gates, $\mathbf{f}_{\mathbf{k}}$ and $\mathbf{i}_{\mathbf{k}}$, respectively. We define the new update function for TSE-LSTM's cell state $\mathbf{c}_{\mathbf{k}}$ as:

$$\hat{\mathbf{c}}_{\mathbf{k}} = tanh(\mathbf{W}_{\mathbf{c}}\mathbf{e}^{\mathbf{i}}_{\mathbf{k-1}} + \mathbf{U}_{\mathbf{c}}\tilde{\mathbf{H}}^{\mathbf{i}}_{\mathbf{k-1}} + \mathbf{b}_{\mathbf{c}}) \tag{6}$$

$$\mathbf{w}_{\mathbf{k}} = \tilde{\mathbf{f}}_{\mathbf{k}} \odot \tilde{\mathbf{i}}_{\mathbf{k}} \tag{7}$$

$$\begin{aligned}\mathbf{c}_{\mathbf{k}} &= \mathbf{w}_{\mathbf{k}} \odot (\mathbf{f}_{\mathbf{k}} \odot \mathbf{c}_{\mathbf{k-1}} + \mathbf{i}_{\mathbf{k}} \odot \tilde{\mathbf{c}}_{\mathbf{k}}) \\ &\quad + (\tilde{\mathbf{f}}_{\mathbf{k}} - \mathbf{w}_{\mathbf{k}}) \odot \mathbf{c}_{\mathbf{k-1}} + (\tilde{\mathbf{i}}_{\mathbf{k}} - \mathbf{w}_{\mathbf{k}}) \odot \hat{\mathbf{c}}_{\mathbf{k}}\end{aligned} \tag{8}$$

$$\tilde{\mathbf{H}}^{\mathbf{i}}_{\mathbf{k}} = \mathbf{o}_{\mathbf{k}} \odot tanh(\mathbf{c}_{\mathbf{k}}) \tag{9}$$

where computation for the intermediate cell state $\hat{\mathbf{c}}_{\mathbf{k}}$, output gate $\mathbf{o}_{\mathbf{k}}$, the hidden state $\tilde{\mathbf{H}}^{\mathbf{i}}_{\mathbf{k}}$ are the same as in the standard LSTM and $\mathbf{W}_{\mathbf{c}}$, $\mathbf{U}_{\mathbf{c}}$, $\mathbf{b}_{\mathbf{c}}$ are network parameters. The hidden state $\tilde{\mathbf{H}}^{\mathbf{i}}_{\mathbf{k}}$ represents the learned emotional context of the user.

3.4 Learning Emotional Phase Progression

We now describe how we use the emotional context learned by the TSE-LSTM to capture emotional phase progression patterns for a user over time. We then describe PHASE's Phase Adaptive Convolutions (PACs) that capture user features closely related to the user's current state through convolutions over these learned emotional phases. The PACs thus extract a phase-aware emotional user representation for suicide ideation detection.

Emotion Phase Variation: We leverage the historical emotional context $\tilde{\mathbf{H}}^{\mathbf{i}}_{\mathbf{k}}$ from the TSE-LSTM to extract temporal variations in a user's emotional state for a macroscopic view of the progression of *emotional phases*. Building on the work of Gao et al. (2020), we capture the onset of a new emotional phase by observing the proportion of historic context discarded to update the cell state $\mathbf{c_k}$. When almost no historical emotional context is used to update the cell state c_k, we say that a new emotional phase of the user has begun. Formally, we use a phase split point (s_k) that represents the time, before which all the emotional historic context is discounted ($\mathbf{p}_{\tilde{\mathbf{f}}_{\mathbf{k}}}$), as $s_k = argmax(\mathbf{p}_{\tilde{\mathbf{f}}})$, as shown in Figure 4 (Gao et al., 2020). Intuitively, a large value of s_k means little historic context is used to update the state cell c_k, indicating the onset of a new emotional phase; whereas, a smaller value of s_k suggests a long-term dependency of the emotions expressed in the tweet (h^i_k) on historic emotions. Since $argmax$ is non-differentiable, we estimate the phase split point (s_k) as:

$$s_k \approx \sum_{i=1}^{N_h} i \times \mathbf{p}_{\tilde{\mathbf{f}}}(i) = N_h\left(1 - \frac{1}{N_h}\sum_{i=1}^{N_h}\tilde{\mathbf{f}}_{\mathbf{k}}(i)\right) + 1 \qquad (10)$$

where N_h is the dimension of $\tilde{\mathbf{H}}^{\mathbf{i}}_{\mathbf{k}}$, $\tilde{\mathbf{f}}_{\mathbf{k}}(i)$ and $\mathbf{p}_{\tilde{\mathbf{f}}}(i)$ are i^{th} values in the long-term gate $\tilde{\mathbf{f}}_{\mathbf{k}}$, and $\mathbf{p}_{\tilde{\mathbf{f}}}$.

We then compute the elapsed time between two consecutive phases by measuring the difference between the proportion of historic context discarded at each timestep. For each emotional phase of a user within an observation window of length L^w, we define this phase variation time $\mathbf{\Delta s}$ as:

$$\mathbf{\Delta s} = \sigma(\overrightarrow{cumsum}(s_{k-L^w}, \cdots, s_k)) \qquad (11)$$

Phase Adaptive Convolution (PAC): We now extract features from the emotional phase build-up leading towards the tweet to be assessed. The PAC extracts features from the learned phase-wise progression of a user's temporal emotional context in the most recent emotional phase, as shown in Figure 4. We feed the concatenated historical hidden states $\tilde{\mathbf{H}}^{\mathbf{i}}_{\mathbf{k-L^w:k}} = [\tilde{\mathbf{H}}_{\mathbf{k-L^w}}, \cdots, \tilde{\mathbf{H}}^{\mathbf{i}}_{\mathbf{k}}]$, in the observation window L^w, as an input to a weighted temporal convolution. Naturally, emotions corresponding to more recent phases of a user are more indicative of their current mental state, and should be more influential (Larsen et al., 2009). Hence, we weigh the importance of the learned historical emotional context through the phase variation time Δs (Gao et al., 2020). We perform a convolution with a p^{th} 1-dimensional learnable kernel (m^j_p) for each j^{th} hidden state in the observation window as:

$$\mathbf{u^p} = \mathbf{m_p} * \tilde{\mathbf{H}}_{\mathbf{k-L^w:k}} = \sum_{j=1}^{N_h} \mathbf{m^j_p} * (\tilde{\mathbf{H}}^{\mathbf{j}}_{\mathbf{k-L^w:k}} \odot \mathbf{\Delta s}) \qquad (12)$$

where $*$ is convolution operation, $\mathbf{u_p}$ is output of p^{th} kernel of size L^w. We concatenate all extracted features as $\mathbf{u} = [\mathbf{u^1}, \cdots, \mathbf{u^{N_h}}] \in \mathbb{R}^{N_h}$ to obtain a user's phase-aware emotion representation.

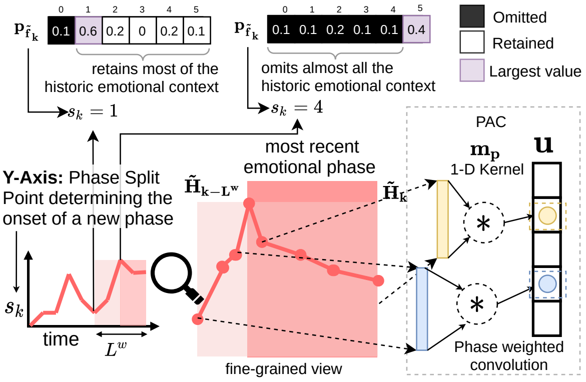

Figure 4: The Phase-Adaptive Convolution takes the historical hidden state $\tilde{\mathbf{H}}^{\mathbf{i}}_{\mathbf{k}}$ and the phase split-point s_k within the observation window length L^w as an input and learns a user's representation through their temporal patterns ($\mathbf{u}$), using phase-weighted convolutions.

3.5 PHASE Joint Network Optimization

Finally, we concatenate encoded representations of the tweet to be assessed $\mathbf{T_i}$ and the historic emotional context $\mathbf{u}$, followed by softmax (σ) over a dense layer with a Rectified Linear Unit ($ReLU$).

$$\hat{\mathbf{y}}_{\mathbf{i}} = \sigma(ReLU(\mathbf{W_y}(\mathbf{T_i} \oplus \mathbf{u}) + \mathbf{b_y})) \qquad (13)$$

where $\hat{\mathbf{y}}_{\mathbf{i}}$ is the final suicide risk assessment and $\{\mathbf{W_y}, \mathbf{b_y}\}$ are learnable network parameters.

Tweets with SI present form a very small proportion of the data (Ji et al., 2019). To address this problem of class imbalance *(the imbalance is much greater in the real world)*, we train PHASE using Class-Balanced Focal Loss (Lin et al., 2017; Cui et al., 2019). This loss function re-weights loss inversely with the effective number of samples per class, thereby yielding a class-balanced loss $\mathcal{L}$ as:

$$\mathcal{L} = \mathrm{CB}_{focal}(\hat{\mathbf{y}}_{\mathbf{i}}, y_i; \beta, \gamma) \qquad (14)$$

where CB_{focal} is class-balanced focal loss, $\hat{\mathbf{y}}_{\mathbf{i}}$ is the predicted label and y_i is the label of the tweet to be assessed. β and γ are hyperparameters.

4 Experimental Setup

4.1 Data and Preprocessing

We build on an existing Twitter data curated by Mishra et al. (2019). The data includes 34,306 tweets authored by 32,558 unique users. These tweets were identified based on a lexicon of 143 suicidal phrases (e.g., "wanting to die", "last day"). Two students of Psychology annotated the data under the supervision of a professional clinical psychologist, achieving a Cohen's Kappa score of 0.72, under the below guidelines (Sawhney et al., 2018b):

Suicidal Intent (SI) Present: Tweets where suicide ideation or previous attempts are discussed in a somber and non-flippant tone.

Suicidal Intent (SI) Absent: Tweets with no evidence for risk of suicide, e.g., song lyrics, condolence message, awareness, news.

The resulting dataset contains 3984 suicidal tweets. The Twitter timeline was collected for each user, spanning over ten years from 2009 to 2019. The number of historical tweets (748 ± 789) and the time difference between consecutive tweets (2 ± 24 days) are indicative of large variations across users. 4070 users were found to have no historical tweets.

We perform a stratified 70:10:20 split, such that the train, validation, and test sets consist of 24014, 3431, and 6861 tweets, respectively, and ensure that there is no overlap between users in these sets.

4.2 Baselines and Training Setup

We evaluate PHASE on macro F1 and recall (SI present) with both tweet- and user-level methods.

Tweet-level Non-contextual Baselines

RF + TF (Sawhney et al., 2018b): Extracts features including statistical, LIWC features, n-grams (up to 4), and POS counts from the tweet to be assessed and feeds them to a Random Forest (RF) classifier.

C-LSTM (Sawhney et al., 2018a): A deep neural network having a CNN followed by an LSTM to extract short and long range features in a tweet.

User-level Contextual Baselines

C-CNN (Gaur et al., 2019): A model that is fed GloVe encoded tweets as a concatenated bag of tweets, non-sequentially to a contextual CNN (Shin et al., 2018) with max pooling (Shing et al., 2018).

Suicide Detection Model (SDM) (Cao et al., 2019): Historical tweets encoded using fine-tuned FastText embeddings are fed to a regular LSTM followed by a tweet-level attention mechanism.

DualContextBert (Matero et al., 2019): Best performing model at CLPsych 2019. BERT embeddings of each historical tweet are sequentially fed to a regular RNN followed by tweet-level attention.

Exponential Decay (Sinha et al., 2019): A deep neural network that models encodes each historical tweet using Glove embeddings followed by a BiLSTM with attention. The historical embeddings are then aggregated using an exponential decay.

Setup: We set hyperparameters for all models based on the validation macro F1 score. We use grid search to explore: $N_h \in \{128, 256, 512\}$, $\delta \in \{0.0, 0.1, \cdots, 0.5\}$, $\beta \in \{0.99, 0.999, 0.9999\}$ and $\gamma \in \{1.0, 1.5, 2.0\}$, initial learning rate $I_{lr} \in \{0.01, 0.001, 0.0001\}$, $L^w \in \{1, 2, \cdots, 16\}$. We found the optimal hyperparameters as: N_h=512, δ=0.5, β =0.9999, γ=2, I_{lr}=0.0001, L^w=5. We implement all methods with PyTorch 1.6, and optimize PHASE using AdamW with a batch size of 128 for 30 epochs in 167 mins on a Tesla K80 GPU. We use the cosine scheduler (Gotmare et al., 2018) with a warmup step of 5.

5 Results and Analysis

5.1 Performance Comparison

Model	Macro F1↑	Recall$_s$↑	Acc↑
RF+TF	0.513	0.536	0.548
C-LSTM	0.588	0.597	0.602
C-CNN	0.729	0.587	0.803
SDM	0.743	0.755	0.819
DualContextBert	0.767	0.786	0.823
Exponential Decay	0.737	0.759	0.828*
PHASE	**0.805***	**0.812***	**0.856***

Table 1: Median of results over 5 different runs. * indicates improvement over DualContextBert is significant ($p < 0.005$) under Wilcoxon's Signed Rank test.

We observe from Table 1 that PHASE significantly ($p < 0.005$) outperforms all baselines. We note that contextual models outperform the non-contextual RF+TF and C-LSTM, as they learn a holistic representation of a user's mental state. Amongst contextual models, we note that models that factor in the temporal sequence of historical tweets outperform the non temporal C-CNN, that models tweets as a bag-of-tweets. Thereby validating the utility of temporal context for suicide ideation detection. PHASE significantly outperforms state-of-the-art contextual models. We postulate this to PHASE's ability to capture irregularities in tweeting patterns and learning emotional phase

PHASE (Ablative) Components	**F1↑**	**Recall$_s$↑**
Current Tweet only (C)	0.731	0.597
C + History (HST) + LSTM	0.780	0.794
C + HST + TSE-LSTM	0.796*	0.788
PHASE:C+HST+TSE-LSTM+PAC	**0.805***	**0.812***

Table 2: * shows significant improvements compared to C + HST + LSTM ($p < 0.005$). We use Plutchik Transformer as the tweet encoder for comparison.

progressions, unlike DualContextBERT and SDM, that ignore both the time- and phase-sensitive and emotional aspects of historical context. PHASE outperforms Exponential Decay, as PHASE adaptively learns progressions of emotional phases, rather than assuming a user's behavior to follow a specific trajectory that might not generalize well across users. This observation is in line with psychological research (Joiner Jr, 2002; Giletta et al., 2015) that shows the progressive build-up to suicidality varies across individuals, that PHASE is able to capture better than competitive models.

5.2 PHASE Components Ablation Study

We perform an ablation study to probe the effectiveness of each component of PHASE, as shown in Table 2, starting from the base (Current) model that does not use historical tweets. On modeling the temporal dependencies in historical tweets with a standard LSTM along with the current tweet, we note drastic improvements, revalidating the prominence of user-level context to infer the suicidality of a user. We then observe that on factoring in time-sensitivity through the TSE-LSTM, there is a significant ($p < 0.005$) improvement in the macro F1 score, but there is no gain in Recall. We believe even though the model gains additional user context by factoring in the time irregularities between tweets, the model does not improve drastically, as it still assumes a continuous smooth progression of the user's emotions in time. This assumption hinders the model's ability to capture the macroscopic context acquired by analyzing the phase like progressions of a user's emotional states (Homan et al., 2014). On adding the PAC that learns phase-aware user representations by extracting emotional progression patterns from their historical emotional context (TSE-LSTM), we observe significant ($p < 0.005$) improvements. We attribute this improvement to the PAC as it adaptively learns and captures a user's emotional phase-wise build-up towards their most recent tweet to be assessed, to correctly contextualize suicidal intent, validating the utility of phase-aware modeling.

5.3 Probing Plutchik Transformer: Encoder Analysis

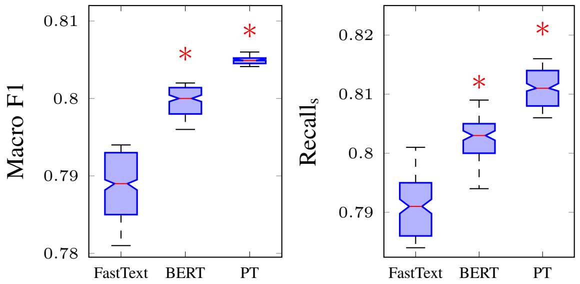

Figure 5: Performance with different tweet encoders over 10 different runs. PT: Plutchik Transformer. All improvements (*) are significant ($p < 0.005$) under Wilcoxon's Signed Rank test.

We now analyze PHASE's performance using different encoders to learn representations for tweets. Overall, we observe that transformers outperform previously used static word embeddings (FastText). Additionally, we observe that Plutchik Transformer, based on Plutchik's wheel of emotions, significantly improves PHASE's performance over the pre-trained BERT used by Matero et al. (2019). This observation revalidates the importance of specific emotional context, as opposed to the more general language features learned by BERT alone.

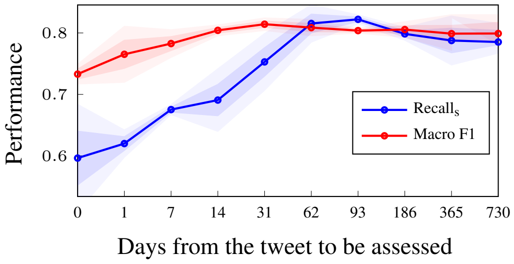

Figure 6: Influence of historical context (upto d days)

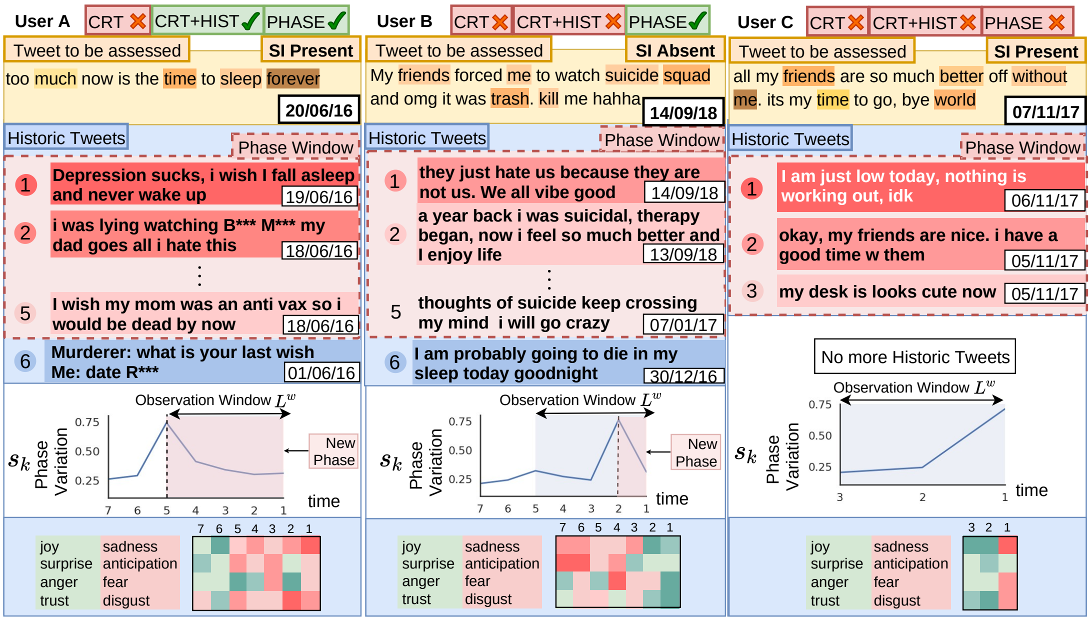
5.4 How much Historical Context is useful?

We explore PHASE's performance variation with the amount of historical lookback in terms of number of days in Figure 6. We observe that PHASE's performance improves as we factor in more historical tweets, going back up to a few months, likely as PHASE gains more context of users' emotional progressions. As we further increase historical lookback beyond several (> 3) months, we observe that PHASE's performance saturates. This observation is in line with psychological studies (Selby et al.,



User A — Tweet to be assessed: too much now is the time to sleep forever 20/06/16

1. Depression sucks, i wish I fall asleep and never wake up 19/06/16
2. i was lying watching B*** M*** my dad goes all i hate this 18/06/16
5. I wish my mom was an anti vax so i would be dead by now 18/06/16
6. Murderer: what is your last wish Me: date R*** 01/06/16

User B — Tweet to be assessed: My friends forced me to watch suicide squad and omg it was trash. kill me hahha 14/09/18

1. they just hate us because they are not us. We all vibe good 14/09/18
2. a year back i was suicidal, therapy began, now i feel so much better and I enjoy life 13/09/18
5. thoughts of suicide keep crossing my mind i will go crazy 07/01/17
6. I am probably going to die in my sleep today goodnight 30/12/16

User C — Tweet to be assessed: all my friends are so much better off without me. its my time to go, bye world 07/11/17

1. I am just low today, nothing is working out, idk 06/11/17
2. okay, my friends are nice. i have a good time w them 05/11/17
3. my desk is looks cute now 05/11/17

Figure 7: We study three users with their tweet to be assessed, historic tweets (chronologically ordered), and timestamps, showing how PHASE can aid human moderators and clinical psychologists with explainable predictions. We visualize self-attention (averaged over all 12 Plutchik Transformer heads) per token, where darker intensity denotes higher attention. The graphs show the phase split value s_k for each user over time. We also show emotional phase progression for further interpretability, where a peak represents the onset of a new phase. Further, we show detailed phase variation by visualizing the Plutchik-based emotion (learned weights) duality for historical tweets.

2013; Kaplow et al., 2014; Glenn et al., 2020), that highlight the diminishing importance of a user's emotions over longer time periods in assessing their current mental state and associated suicide risk.

5.5 PHASE Analysis and Interpretation

We now analyze PHASE's preliminary assessment in Figure 7 to elucidate on PHASE's interpretability to aid subsequent human-in-the-loop risk assessment. First, for User A, we see no apparent signs of suicidal intent in their tweet to be assessed, and if analyzed in isolation, is not sufficient to ascertain risk. However, User A's historical tweets add context to models (e.g. PHASE) that leverage temporal emotional cues to identify suicidal intent correctly. Next, we analyze a complex case, User B, where we observe *phase*-like progressions in their emotions over time. Although User B historically did show negative emotions, recently, User B shows more positive behavior, akin to the onset of a new emotional phase characterized by joy and trust. PHASE's design enables it to learn User B's emotional progression adaptively and correctly predicts User B's tweet to be analyzed as having no suicidal intent, unlike other models that incorrectly assess this as a tweet having suicidal intent. Lastly, we also present the complicated case of User C, where all models fail to explicate the future challenges in online data-driven suicide ideation. Specifically, we find that all models are unable to accurately ascertain suicidal intent where there is little historical context consisting of fluctuating emotions, highlighting the challenges associated with new or alternate accounts of users, amongst other complexities (Shea, 1999; O'Connor and Portzky, 2018).

6 Ethical and Practical Considerations

Emphasizing the sensitive nature of this work, we acknowledge the trade-off between privacy and effectiveness (Eskisabel-Azpiazu et al., 2017), and utilize publicly available Twitter data in a purely observational (Norval and Henderson, 2017; Broer, 2020), and non-intrusive manner. We separate user data from all other data on protected servers linked only through anonymous IDs, and we perform automatic de-identification of the dataset using named entity recognition (Benton et al., 2017a,b). All examples shown in this work have been paraphrased to protect user privacy (Fiesler and Proferes, 2018; Chancellor et al., 2019a,b). We ensure that this analysis is shared selectively and subject to IRB approval (Zimmer, 2009, 2010) to avoid misuse such as Samaritan's Radar (Hsin et al., 2016). We acknowledge that suicidality is subjective (Keilp et al., 2012) and that the interpretation of this analysis may vary across individuals (Puschman, 2017). We further acknowledge that suicide risk exists on a diverse spectrum (Bryan and Rudd, 2006), rather than at a binary level, and that the studied data may be susceptible to demographic, annotator, and medium-specific biases (Hovy and Spruit, 2016). Finally, our work does not make any diagnostic claims related to suicide. PHASE should form part of a distributed human-in-the-loop (de Andrade et al., 2018) system for finer interpretation of risk.

7 Conclusion

Motivated by the rising exhibition of suicide ideation on social media, we present PHASE. Building on psychological studies analyzing the emotional spectrum and mental health of users, PHASE adaptively learns emotional phase-aware user representations through historical tweeting activity for suicidal ideation detection. We propose multiple modeling innovations in PHASE components: contextualized historical emotion representations (Plutchik Transformer), time-sensitive emotion LSTM (TSE-LSTM), and a phase-adaptive convolution (PAC). We demonstrate that modeling user phases explicitly increases the predictive power in assessing suicidality in tweets. In a qualitative analysis, we show how PHASE can aid social media moderators and clinical psychologists in subsequent assessment by displaying its predictions together with the learned emotional phases. Through PHASE, we hope to form a future component in a larger human-in-the-loop infrastructure for suicide prevention.

Exploiting Definitions for Frame Identification

Abstract

Frame identification is one of the key challenges for frame-semantic parsing. The goal of this task is to determine which frame best captures the meaning of a target word or phrase in a sentence. We present a new model for frame identification that uses a pre-trained transformer model to generate representations for frames and lexical units (senses) using their formal definitions in FrameNet. Our frame identification model assesses the suitability of a frame for a target word in a sentence based on the semantic coherence of their meanings. We evaluate our model on three data sets and show that it consistently achieves better performance than previous systems.

1 Introduction

Research on *frame semantics* has grown within the fields of natural language processing and cognitive science since the 1970s as the study of how we associate words and phrases with cognitive structures called *frames*, which characterize a small abstract scene or situation (Fillmore, 1976, 1982). The Berkeley FrameNet project (Baker et al., 1998) provides an online lexical database for frame semantics together with a corpus of annotated documents. Frame semantic parsing is the task of automatically extracting frame semantic structures from sentences. The process typically consists of three steps: *target identification*, which identifies frame-evoking predicates in the sentence; *frame identification*, which identifies the evoked frame for each target; and *argument identification*, which identifies arguments of a frame and labels them with semantic roles (frame elements). In this work, we focus on the frame identification problem.

FrameNet 1.7 contains more than 13,000 lexical units (a word lemma with a sense), each associated with a semantic frame. A polysemous word is associated with multiple lexical units (one for each sense), and is therefore linked to multiple frames. The frame identification task requires a system to identify the most relevant frame for a target word or phrase based on its sentence context. Here is an example:

> The pandemic has *sparked* a lot of problems for the economy.

Given the target word *sparked*, the goal is to determine which frame should be triggered. The word lemma *spark* has two senses in FrameNet: "with obj. ignite" and "provide the stimulus for". The former sense is associated with the *Setting_fire* frame and the latter one is associated with the *Cause_to_start* frame. The *Setting_fire* frame is defined as "this frame describes the creation of a flame...", and the *Cause_to_start* frame is defined as "a cause, animate or inanimate, causes a process, the effect, to begin". So *Cause_to_start* is the correct frame for this sentence.

Previous work has shown the success of using feature engineering with linear classification models (Johansson and Nugues, 2007) and discriminative probabilistic models (Das et al., 2010), which were later improved by applying distributed word representations and deep neural network models (Hermann et al., 2014). Syntactic information, typically dependency paths, has consistently played an important role in frame identification (Das et al., 2014; Peng et al., 2018).

Our work is motivated by the rich lexicographic information about frames and lexical units provided by the FrameNet database, which has not been fully utilized for the frame identification task. Recent advances in large pre-trained transformer models (Devlin et al., 2019) have demonstrated the ability to capture semantic meaning in dictionary definitions for the related problem of word sense disambiguation (Huang et al., 2019; Blevins and Zettlemoyer, 2020).

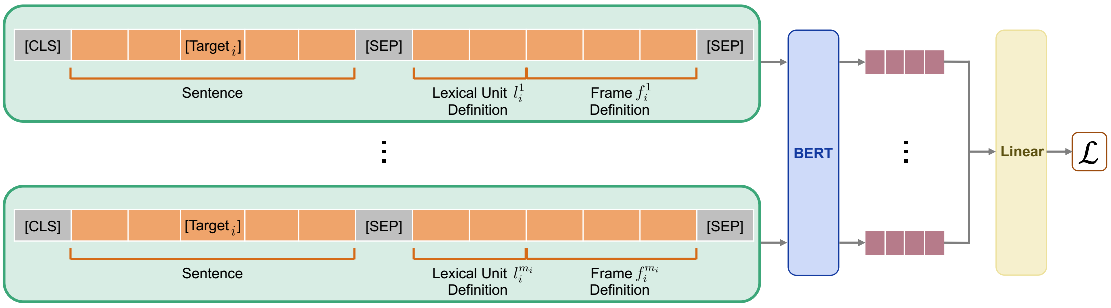

Figure 1: Overview of the FIDO architecture. Each green block represents a different candidate pair (lexical unit, frame) for the same Target$_i$.

Our model uses the definitions of frames and lexical units in FrameNet as a source of knowledge to help assess the semantic coherence between the target word and candidate frames. Specifically, we utilize the contextual embeddings produced by the BERT (Devlin et al., 2019) model to determine if a candidate lexical unit and frame express the same meaning as the target word in the given context. Our model achieves state-of-the-art performance on two FrameNet datasets and a FrameNet-annotated dataset based on Yahoo! Answers. Our code is open-source and available online[1].

2 Related Work

There has been considerable work on the frame identification problem with respect to FrameNet, especially since the SemEval 2007 shared task (Baker et al., 2007). Johansson and Nugues (2007) used a SVM classifier to disambiguate frames with hand-crafted features. Das et al. (2010) applied feature-based discriminative probabilistic (log-linear) models for frame identification. Hermann et al. (2014) presented a method using distributed representations of predicates and their syntactic context by mapping input representations and frame representations to a common latent space using the WSABIE algorithm (Weston et al., 2011). Hartmann et al. (2017) built a simplified model based on Hermann et al. (2014) and achieved comparable results. They also released a new FrameNet-annotated test set based on user-generated web text from Yahoo! Answers. Yang and Mitchell (2017) integrated a bidirectional LSTM neural network and a relational network to jointly decode frames.

More recently, Botschen et al. (2018) brought in multimodal representations grounded in images to improve frame identification. Peng et al. (2018) proposed a joint inference formulation that learns semantic parsers from multiple datasets.

In contrast to the previous models, our model does not rely on syntactic features. We assess semantic coherence directly from the input sentence and definitions in FrameNet.

Another line of related work is learning embeddings from dictionary definitions. It has been shown that neural networks can extract semantic information from dictionary definitions (Kumar et al., 2019; Bosc and Vincent, 2018). Recent work in word sense disambiguation (Huang et al., 2019; Blevins and Zettlemoyer, 2020) has demonstrated that providing pre-trained language models with sense definitions (glosses) can be effective. Yong and Torrent (2020) also used the sense definitions of lexical units for their research on frame induction. Our model adopts a similar architecture as Huang et al. (2019), but we focus on the frame identification task and we explore the use of both lexical unit and frame definitions for this task.

3 Method

Given a sentence and a target word or phrase, the frame identification task assigns the most relevant frame to the target according to the sentence context. Figure 1 shows the framework of our model called FIDO (**F**rame **I**dentification with **D**efiniti**O**ns). Our system takes the sentence and the definitions of associated lexical units (senses) and their frames as input to the BERT model, as indicated by the green blocks. Each green block represents the target word in the sentence, one of its senses, and that sense's associated frame in FrameNet. Then we use the output vectors to produce a probability distribution over all of the candidate frames. We select the frame with the maximum probability as the answer.

---

[1] `https://github.com/tyjiangU/fido`

3.1 Notation

We denote the ith example ($i = 1, 2, ..., n$) consisting of a sentence and designated target word or phrase as $\langle s, t \rangle_i$, its correct frame as f_i^*, the set of lexical units associated with the target as $l_i^1, l_i^2, ..., l_i^{m_i}$, and their corresponding frames as $f_i^1, f_i^2, ..., f_i^{m_i}$ (f_i^* is among them). We seek to estimate the probability of the jth frame being the correct frame by:

$$\Pr(f_i^j | \langle s, t \rangle_i) = \frac{\exp(g(\langle s, t \rangle_i, f_i^j))}{\sum_{k=1}^{m_i} \exp(g(\langle s, t \rangle_i, f_i^k))} \quad (1)$$

where $g(\cdot)$ is a function produced by our model for scoring the assignment of a frame to the sentence and target. We use negative log likelihood as our loss function:

$$\mathcal{L} = -\sum_{i=1}^{n} \log \Pr(f_i^* | \langle s, t \rangle_i) \quad (2)$$

where n is the total number of training examples.

3.2 Modeling

FrameNet provides unique definitions for each lexical unit (LU) and frame. A LU is a pairing of a word lemma and a meaning (sense). Determining the correct LU (sense) uniquely determines the correct frame because each sense of a polysemous word is linked to a different frame. For example, the word *cut* can trigger different frames depending on its meaning (the definition sentences follow the bold lexical unit or frame names), as shown in Table 1.

Lexical Unit	Associated Frame
cut.n: the way or style in which a garment or the hair is cut	**Hair_configuration**: temporary or permanent styles and configurations of hair
cut.v: divide into pieces with a knife or other sharp implement	**Cutting**: an agent cuts an item into pieces using an instrument

Table 1: Examples of lexical units and their associated frames.

We use the BERT (Devlin et al., 2019) model as the base of our architecture to produce the function $g(\cdot)$ as described in Eq (1). For each target, first we extract LUs from FrameNet that have the same lemma and their corresponding frames to form a set of candidate (LU, Frame) pairs. Our goal is to predict whether the target in the sentence has the same meaning as the definitions of a candidate LU and its associated frame.

As input to the BERT model, we use the sentence as the first sequence and concatenate a LU definition and frame definition as the second sequence. Each definition starts with the LU name or frame name and a colon, followed by the definition description.

Instead of using the output vector of the `[CLS]` token as is typical, we use the last hidden vector of the target word as output (if there is more than one token, we only use the first one). By passing the output vector through a linear layer, we then get a score for assigning a candidate frame to the sentence and target. Finally the scores for all candidate frames are passed through the softmax function to get the probabilities in Eq (1).

4 Experiments

4.1 Datasets

FrameNet: To compare FIDO with previous systems, we evaluate our model on FrameNet (FN) 1.5 using the same train/dev/test data split as Das et al. (2014). We also evaluate our model on FN 1.7 which has been available since 2016 and contains nearly 20% more gold annotated data than FN 1.5. We use the same data split as Swayamdipta et al. (2017) for FN 1.7. Table 2 shows the number of examples in each split.

	FN 1.5	FN 1.7	YAGS
Train	15,017	19,391	-
Dev	4,463	2,272	1,000
Test	4,457	6,714	2,093

Table 2: Dataset sizes.

YAGS: YAGS (Hartmann et al., 2017) is a FrameNet-annotated test set based on question answering data from Yahoo! Answers[2], a community-driven question-and-answer forum. The annotations are based on FN 1.5. We train on FN 1.5 and evaluate on the YAGS test set to compare results with Hartmann et al. (2017).

---

Yang and Mitchell (2017)	88.2
Open-SESAME (2017)	86.9
Botschen et al. (2018)	88.8
Peng et al. (2018)	90.0
FIDO	**91.3**

Table 3: Accuracy on FN 1.5.

Dataset	Model	Accuracy
FN 1.7	Peng et al. (2018)	89.1
	FIDO	**92.1**
YAGS	Hartmann et al. (2017)	62.5
	FIDO	**70.5**

Table 4: Accuracy on FN 1.7 and YAGS.

4.2 Training Details

We use the pre-trained uncased BERT$_{\text{BASE}}$ model with the same settings as Devlin et al. (2019) and fine-tune on our training data. We set the max sequence length as 300, batch size as 16, learning rate started at 2e-5, and train for 5 epochs. All reported results are averaged over 3 runs with random seeds.

4.3 Results

Table 3 compares our model with previous methods on the FN 1.5 dataset. Hermann et al. (2014), Hartmann et al. (2017), and Open-SESAME (Swayamdipta et al., 2017) use distributed representations and syntactic features with neural networks. Botschen et al. (2018) extends Hartmann et al. (2017) with visual embeddings. Yang and Mitchell (2017) integrates a sequential and relational network for joint learning. Peng et al. (2018) has achieved the best prior results on frame identification using a multitask approach to learn semantic parsers from disjoint corpora. It is worth noting that besides the FN 1.5 training set, they also use 153,952 exemplar sentences for training, which is more than 10 times the size of our training data. FIDO achieves better performance than all of the prior systems.

Table 4 shows our results compared to Peng et al. (2018) on FN 1.7. FIDO achieves a 3.0% absolute accuracy gain on this data set. The YAGS data set (Hartmann et al., 2017) contains *unknown* targets that do not have related LUs in FN 1.5 and also *unlinked* targets (i.e., the provided gold frame does not belong to the set of frames associated with this target in FN). Our model is not able to make a correct prediction for these cases based on its design. There are 122 unknown or unlinked targets in the test set, on which our model will get a zero score. Despite this limitation, our model still outperforms Hartmann et al. (2017), which demonstrates its ability to generalize across text genres.

Model	FN 1.5	FN 1.7
FIDO	**91.3**	**92.1**
FIDO (FRdef only)	90.1	91.1
FIDO (LUdef only)	88.9	90.7
FIDO (NO def)	80.3	79.4
FIDO (CLS)	89.3	90.5

Table 5: Ablation study on FN 1.5 and FN 1.7.

4.4 Analysis

We performed an ablation study to assess the contributions of each part of our model. In Table 5, the first row shows the results for our complete FIDO model. Rows 2-3 show results when using only the definitions of frames (FRdef only) or LUs (LUdef only). We see that the frame definitions contribute the most to performance. Using the LU definitions alone on FN 1.7 also achieves quite good results. But combining both definitions together yields better results than either one alone.

In order to tease apart the impact of the definitions from the impact of BERT, we did an experiment replacing each definition simply with the name of the frame or LU. These results appear in the FIDO (NO def) row. Removing the definitions results in a large performance drop. The definitions clearly play a major role.

In the bottom row, we show the results of experiments using the output vector of the `[CLS]` token (all other settings the same), which did not perform as well as using the target token. This is not surprising as `[CLS]` aggregates the entire sequence representation rather than focusing on the target.

Previous work also reported accuracy on ambiguous cases (i.e., when the target word is associated with multiple frames), which more directly shows the model's ability to disambiguate frames. However, the set of ambiguous targets is different across papers. To avoid comparing apples and oranges,

Dataset	Model	Amb1	Amb2
FN 1.5	Peng et al. (2018)	78.0	-
	FIDO	**81.0**	83.6
FN 1.7	Peng et al. (2018)	77.5	-
	FIDO	**83.8**	85.9

Table 6: Accuracy on ambiguous cases.

we report accuracy on two different sets of ambiguous targets. In Table 6, the **Amb1** column follows Peng et al. (2018), which uses the gold LU's part-of-speech (POS) tag to form the candidate frame list. In this setting, if a target has just one sense when its POS is known, it is not considered to be ambiguous. Our model outperforms Peng et al. (2018) on both FN 1.5 and FN 1.7 datasets. The **Amb2** column shows the accuracy of ambiguous targets using only the lemma of the target (i.e., not relying on gold POS tags). We encourage future work to articulate which setting is used.

We also analyzed whether unseen frames and unseen targets were a major source of errors for our model. On FN 1.7, our FIDO model achieved 92.1% accuracy, so it mislabeled 7.9% of the test cases. We found that 1.4% of the test cases were mislabeled and had an unseen frame (i.e., the gold frame was not seen with the target in the training data), and 0.52% of the test cases were mislabeled and had an unseen target (i.e., the target was not seen in the training data). Therefore only about 1/4 of the FIDO errors were due to unseen frames and unseen targets. We conclude that even for frames and targets that appear in the training data, there is still substantial room for improvement on this task.

5 Conclusion

We tackled the frame identification problem by assessing the semantic coherence between the meaning of a target word in a sentence, and a candidate frame. Our model exploits the frame and lexical unit definitions provided by FrameNet and a pre-trained transformer model to generate semantic representations. The experiments show that this model achieves better performance than previous systems on two versions of FrameNet data and the YAGS dataset. Our work has demonstrated that a relatively simple architecture that brings together pre-trained language models with frame and sense definitions can produce a highly effective system for frame identification.

Abstract

Privacy is an important concern when building statistical models on data containing personal information. Differential privacy offers a strong definition of privacy and can be used to solve several privacy concerns (Dwork et al., 2014). Multiple solutions have been proposed for the differentially-private transformation of datasets containing sensitive information. However, such transformation algorithms offer poor utility in Natural Language Processing (NLP) tasks due to noise added in the process. In this paper, we address this issue by providing a utility-preserving differentially private text transformation algorithm using auto-encoders. Our algorithm transforms text to offer robustness against attacks and produces transformations with high semantic quality that perform well on downstream NLP tasks. We prove the theoretical privacy guarantee of our algorithm and assess its privacy leakage under Membership Inference Attacks (MIA) (Shokri et al., 2017) on models trained with transformed data. Our results show that the proposed model performs better against MIA attacks while offering lower to no degradation in the utility of the underlying transformation process compared to existing baselines.

1 Introduction

Differentially Private (DP) mechanisms provide robustness against privacy attacks and offer practical solutions for transforming and releasing datasets without compromising privacy (Dwork et al., 2009). A typical downstream task may involve training a machine learning model with data transformed from a differentially private mechanism. However, while the DP mechanism offers privacy, it can adversely impact the utility of the trained model (Li and Li, 2009). Specifically, in the case of text datasets (e.g., those used in Natural Language Understanding(NLU) tasks), if the DP transformation impacts the syntactic structure of the sentence or does not factor in the target NLU label (e.g. intent of the sentence in an intent classification task), the loss in utility can render the use of processed data impractical. We address this problem in the paper and introduce ADePT - an Auto encoder based Differentially Private Text transformation mechanism that process text data while reducing the impact on the utility of the dataset.

The ADePT mechanism relies on text-based auto-encoders (e.g. LSTM based sequence-to-sequence models) for text transformation. An auto-encoder first transforms a given text input into some latent representation, followed by text generation (transformation) via the decoder. In this paper, we prove that the application of clipping and noising operation on the latent sentence representations returned by the encoder followed by text generation by the decoder is a DP mechanism. We use ADePT to transform text datasets relevant to the Intent Classification (IC) task, where we predict intent of input sentence (e.g. 'BuyTicketIntent' intent prediction for the sentence 'buy me a ticket to Seattle'). While one can transform the text in datasets and retain original intent labels to train the intent classifier, it is not guaranteed that the transformed text would correspond to the original intent post transformation, which can adversely impact the trained IC's utility. To mitigate this problem, we append the intent labels to the rest of tokens while training the auto-encoder as well as for transforming text with the trained auto-encoder. For instance, *@BuyTicketIntent buy me a ticket to Seattle* is used as the input sample to train the autoencoder where *@BuyTicketIntent* is the intent annotation for *buy me a ticket to Seattle*. Similarly, the intent label is regenerated along with the rest of the tokens after transformation, which is then used for IC training with the regenerated intent as the label of the regenerated sentence. In addition to this, we argue that

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2435–2439
April 19 - 23, 2021.

data regeneration via decoder maintains the syntactic structure of the sentence since the decoder generates tokens auto-regressively, factoring in the previously generated tokens. We hypothesize that these properties make ADePT a utility preserving DP mechanism and demonstrate the superiority of the algorithm against an existing baseline (Feyisetan et al., 2019).

2 Related Work

Differentially private data transformation and generation: Researchers have proposed several methods for DP data transformation using individual ranking micro-aggregation (Sánchez et al., 2016), random projection (Xu et al., 2017), and kernel mean embeddings (Balog et al., 2018). Alternatively, models such as differentially private Generative Adversarial Networks (Xie et al., 2018) and differentially private autoencoder-based generative model (Chen et al., 2018) focus on training data generators that guarantee that the data generation mechanism is DP. While DP data transformation and generation has shown great success for structured data (e.g. numeric tables, histograms), the same for unstructured data (e.g. text) is more challenging. Beigi et al. (2019) propose an algorithm that learns numeric text representations that offer guarantees of differential privacy. However, arguably it may be more desirable to release transformed text as opposed to latent representations. Feyisetan et al. (2019) proposes DP mechanism to transform text data that constructs a hierarchical representation given a sentence to identify *private phrases* in the input sentence. Each word in the private phrase is then randomly replaced by neighboring word in a word embedding space. We use the work by Feyisetan et al. (2019) as baseline in our work since it also focusses on obtaining text transformed text with a DP mechanism.

Membership Inference Attacks: While the (ϵ, δ) bounds provide theoretical quantification of a mechanism's privacy (Dwork et al., 2014), recently Membership Inference Attack (MIA) success rates have emerged as practical quantification of privacy preservation (Shokri et al., 2017). In this work we use the setup suggested by Shokri et al. (2017) as a method to quantify privacy for models trained on transformed data. Given a trained machine learning model and its confidence score on a datapoint, MIA infers whether the datapoint was part of the model's training data. In order to conduct MIA, an attacker trains a *shadow model* that he/she expects to mimic the *target model* under attack. Once trained, the *shadow model's* confidence scores on the datapoints *members* of its training set and other *non-member* datapoints are used to train the binary attack model. Given a datapoint, the attacker then extracts a similar vector of confidence scores from the *target model* and uses the *attack model* to make a *member*/*non-member* prediction.

3 ADePT: Auto-encoder based DiffEerentially Private Text transformation

Consider an utterance $\mathbf{u}$ drawn from a dataset $\mathcal{D}$. Furthermore, consider an auto-encoder model that takes input a sentence $\mathbf{u}$ and outputs another sentence $\mathbf{v}$. A vanilla auto-encoder model consists of an encoder that returns a vector representation $\mathbf{r} = \mathsf{Enc}(\mathbf{u})$ for the input $\mathbf{u}$, which is then passed onto the decoder that constructs an output $\mathbf{v} = \mathsf{Dec}(\mathbf{r})$. We define ADePT as a randomized algorithm $\mathcal{A}$, that given an utterance $\mathbf{u}$, generates $\mathbf{v}$ as shown in equation 2. η is a vector sampled from either a Laplacian or a Gaussian distribution (with 0 mean and a pre-defined variance).

$$\mathbf{v} = \mathsf{Dec}(\mathbf{r}') \tag{1}$$

$$\text{Where } \mathbf{r}' = \mathsf{Enc}(\mathbf{u}) \cdot \min\left(1, \frac{C}{||\mathsf{Enc}(\mathbf{u})||_2}\right) + \eta \tag{2}$$

3.1 Proof that ADePT is differentially private

Given that ADePT conducts a transformation from $\mathbf{u} \rightarrow \mathbf{r}' \rightarrow \mathbf{v}$, we first show that it is sufficient to prove that the transformation from $\mathbf{u} \rightarrow \mathbf{r}'$ is DP for ADePT to be DP. Thereafter, we prove that the transformation $\mathbf{u} \rightarrow \mathbf{r}'$ is DP.

Lemma 1. *The transformation* $\mathbf{u} \rightarrow \mathbf{v}$ *will be at least* (ϵ, δ) *differentially private, if the algorithm that transforms* $\mathbf{u}$ *to* $\mathbf{r}'$ *is* (ϵ, δ) *DP.*

Proof. This is true based on proposition 2.1 on post-processing in Dwork et al. (2014). ☐

Theorem 1. *If* η *is a multidimensional noise, such that each element* $\eta_i \in \eta$ *is independently drawn from a distribution shown in equation 3, then the transformation from* $\mathbf{u} \rightarrow \mathbf{v}'$ *is* $(\epsilon, 0)$ *DP.*

$$Lap(\eta_i) \sim \frac{\epsilon}{4C} \exp(-\frac{\epsilon|v_i|}{2C}) \tag{3}$$

Proof. We refer the reader to the proof in Dwork et al. (2014), Theorem 3.6. The function $f(x)$ used in the Theorem in Dwork et al. (2014) is equivalent to the encoder output with clipping. The l1-sensitivity of this function (please refer to definition 3.1 in Dwork et al. (2014)) is $2C$ since maximum L1 norm difference between two points in a hyper-sphere of radius C is $2C$. Replacing Δf in Theorem 3.6 in Dwork et al. (2014) by $2C$, we obtain the that the transformation is $(\epsilon, 0)$ DP. □

Akin to the proof with a Laplacian noise, we can also borrow the proof in Appendix A in Dwork et al. (2014) to show that ADePT would also be DP if η was a Gaussian noise.

4 Experimental setup

We perform an intent classification task in our experiments and quantify impacts on accuracy and privacy metrics after data transformation via the ADePT mechanism. While the intent classification accuracy quantifies the utility of the transformed dataset, we evaluate success of MIA against the IC model to quantify privacy. Below, we describe the datasets, auto-encoder and IC model training and the MIA setup used in our experiments.

4.1 Datasets

We use ATIS (Dahl et al., 1994) and SNIPS (Coucke et al., 2018) for training IC models on the respective datasets. The ATIS dataset consists of ∼5.5k data samples, while the SNIPS dataset consists of ∼14.5k data samples. We used a 50:50 split for training and evaluation sets. Apart from offering a larger accuracy evaluate test set, a 50:50 split also ensures that we have a balanced training and evaluation sets for MIA, as discussed in Section 4.5.

4.2 Training the auto-encoder model

Given utterances $\mathbf{u}$ in the training partition of the datasets of interest, we train an auto-encoder model to reconstruct the input utterance $\mathbf{u}$ via the decoder Dec. In our case, the auto-encoder is a sequence to sequence model, where both encoder and decoders are uni-directional LSTM models. We train the auto-encoder on the training portions of the ATIS and SNIPS datasets, with an objective to reconstruct the input sentence through the *latent* representation. Note that during training, we apply clipping to ensure that the latent representation are encouraged to reside within a hyper-sphere of radius C, no noise is added to the latent representation. Clipping and noising operations are applied during the final transformation after the auto-encoder is trained, as discussed in section 4.3.

4.2.1 Making ADePT utility preserving

In the proof above, we show that ADePT is DP algorithm that transforms input utterances $\mathbf{u}$ to $\mathbf{v}$. For the purposes of training an intent classifier, a naive scheme can assume that the intent label applied to the utterance $\mathbf{u}$ is also applicable to $\mathbf{v}$. However, this assumption may not always be true as the transformation may render utterance $\mathbf{v}$ to carry a different intent label than $\mathbf{u}$. In order to encourage the transformed utterances $\mathbf{v}$ to conform to the intent label for utterance $\mathbf{u}$, and also obtain the correct intent label in cases where the transformation may lead $\mathbf{v}$ to belong to a different intent, we tweak the auto-encoder model to also ingest the intent label. We train annotation aware auto-encoder models with inputs/outputs as utterances and the corresponding intent. The intent label is appended to the beginning of each utterance (demarcated with a special character to help distinguish the intent names with utterance tokens) during the auto-encoder training.

4.3 Data transformation

Once the auto-encoder model is trained, we apply the transformation again on the training portions of ATIS and SNIPS datasets. During the transformation, the intent token is appended with the rest of the utterance and an output in a similar format is expected.

4.4 Intent classifier training

The ADePT transformation yields the altered sentence, along with an intent. We transform the training portion of ATIS and SNIPS datasets through the autoencoder and use the altered sentences along with the reproduced intent for training an intent classifier. Our IC architecture is inspired from Ma and Hovy (2016) and consists of three blocks: (i) an embedding block consisting of word and character embeddings, (ii) a block consisting of bi-directional LSTM layers and, (iii) a fully connected network operation on a max-pool of LSTM layer outputs for intent classification.

4.5 Privacy evaluation using MIA

We train the attack model on confidence scores returned by a shadow IC model trained similarly

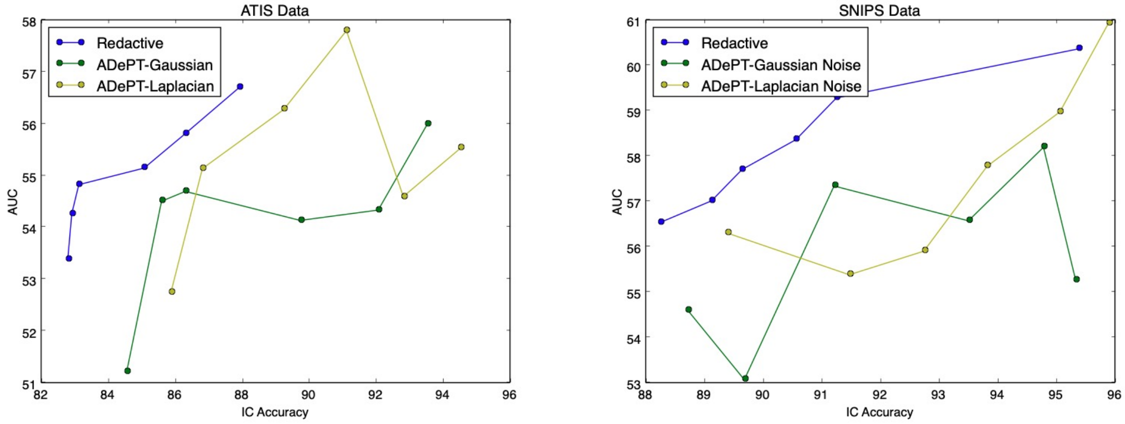

Figure 1: Privacy and accuracy metrics using baseline and ADePT mechanisms on the ATIS and SNIPS datasets. Baseline mechanism transforms datasets with Laplacian noise with variance values $\in (1, 6, 9, 15, 28, 100)$. ADePT transforms datasets with Gaussian and Laplacian noises with variances $\in (0.25, 0.5, 0.6, 0.75, 0.85, 1)$. The variance scales are different between the two mechanism due to inherent difference in their construct.

as the target IC model. We extract scores for the top five intents returned by the shadow IC model on the *member* and *non-member* sentences used to train the shadow IC model. The attack model is a binary logistic regression model, trained on the extracted IC scores from ‘member’ and ’non-member’ sentences.

During the attack, top 5 intent scores from the target IC model are fed to the logistic regression model to make a prediction whether the corresponding scores belong to the target model’s *member* or *non-member* data. While the *member* sentences are sourced from the training set, we borrow *non-member* sentences from the test set used to evaluate the model accuracy (note that their counts are balanced as we use a 50:50 split). We use the Area Under the ROC curve (AUC) to evaluate the success of the attack model and a higher AUC implies worse privacy metric.

5 Experimental Results

We conduct ADePT transformation using both Laplacian and Gaussian noises, with different variance values. The baseline mechanism also uses a Laplacian noise to sample words replacements for the private words. Figure 1 show the MIA success rates and IC accuracies obtained on ATIS and SNIPS data respectively. Note that the algorithm with a lower AUC and a higher IC accuracy is desirable. We observe that as we sweep the noise parameters for the ADePT and Redactive mechanisms, we generally obtain lower AUC with a higher IC accuracy for the former. Additionally ADePT mechanism with a Gaussian noise performs the best. This empirical observation supports our hypothesis that factoring in the intent label during ADePT based transformation helps providing better utility.

However, we also note that the privacy-utility trade-off in ADePT can be non-monotonic. We noticed that the sentence transformation using encoders is sensitive to noise value added to encoded representation $\mathsf{Enc}(\mathbf{u})$. The clipping and noise additional has potential to change the entire sentence, unlike the baseline, where the public phrase in the utterance remains unaltered and only the private phrases in the utterances are subject to alteration. We show two examples of sentence transformation using the baseline and Gaussian ADePT mechanism in Table 1. In particular, the decoder tends to repeat the same word multiple times for corrupted outputs which can be corrected with constrained decoding.

6 Conclusions

We propose ADePT - an auto-encoder based DP algorithm in this paper. We theoretically prove that the mechanism is DP and demonstrate that it offers a better privacy utility trade-off compared to a baseline that relies on detecting the transforming public phrases in a sentence. In the future, we will extend ADePT to transforming datasets with sequence level tags (for instance, in named entity recognition tasks) and also use non-autoregressive decoders (e.g. transformers). We will also extend the mechanism to other modalities (e.g. Image) using auto-encoder models in the corresponding domains.

Abstract

Effective representation of biomedical names for downstream NLP tasks requires the encoding of both lexical as well as domain-specific semantic information. Ideally, the synonymy and semantic relatedness of names should be consistently reflected by their closeness in an embedding space. To achieve such robustness, prior research has considered multi-task objectives when training neural encoders. In this paper, we take a next step towards truly robust representations, which capture more domain-specific semantics while remaining universally applicable across different biomedical corpora and domains. To this end, we use conceptual grounding constraints which more effectively align encoded names to pretrained embeddings of their concept identifiers. These constraints are effective even when using a Deep Averaging Network, a simple feedforward encoding architecture that allows for scaling to large corpora while remaining sufficiently expressive. We empirically validate our approach using multiple tasks and benchmarks, which assess both literal synonymy as well as more general semantic relatedness. Our code is open-source and available at `www.github.com/clips/conceptualgrounding`.

1 Introduction

Biomedical and clinical free-text contain mentions of biomedical terms which can provide valuable information for text mining applications. Such textual mentions, as well as their corresponding reference names in biomedical ontologies, can often be expressed in various synonymous surface forms (e.g. *pleuritic pain* vs. *pain breathing*), which is challenging for downstream applications. Effective dense representation of these biomedical names has been mainly investigated through the normalization task of disorder linking, which consists of matching disease mentions to reference terms of concept identifiers in ontologies (e.g. matching the mention *myocardial depression* to the reference term *Myocardial Dysfunction)* (Leaman et al., 2015). While past research has gradually shifted its focus from lexical representations (Leaman et al., 2013; D'Souza and Ng, 2015) to dense distributed representations (Limsopatham and Collier, 2016; Li et al., 2017; Phan et al., 2019; Sung et al., 2020), encoders are still typically optimized towards normalization tasks, which are focused on resolving word-level analogies between synonymous biomedical names.

ICD-10	SNOMED-CT
F60.1	C0564504 *schizoid fantasy* *schizoid fantasy - mental defense mechanism*
	C0338969 *introverted personality disorder* *introverted personality*
	C0036339 *schizoid personality disorder* *unspecified schizoid personality disorder*

Table 1: Example of SNOMED-to-ICD-10 mappings. The synonym sets for the SNOMED-CT concepts *C0564504*, *C0338969*, and *C0036339*, are fused into one large set of semantically related names for the ICD-10 code *F60.1*.

Recent research has focused more explicitly on encoding domain-specific biomedical semantics by training biomedical name representations that are *robust*, i.e., reflecting the synonymy and semantic relatedness of names by their closeness in the embedding space, preferably in a consistent way

Proceedings of the 16th Conference of the European Chapter of the Association for Computational Linguistics, pages 2440–2450
April 19 - 23, 2021. ©2021 Association for Computational Linguistics

that generalizes across different biomedical subdomains and corpora. To date, the most effective approaches have applied some form of *conceptual grounding*: minimizing the distance between on the one hand representations of names, and on the other hand pretrained embeddings of their concept identifiers. These concept embeddings are supposed to reflect domain-specific semantics, and are constructed using a variety of different techniques, including distributional similarity of graph relations and distributional similarity of textual occurrences in large-scale free-text, as well as combinations thereof (Kartsaklis et al., 2018; Phan et al., 2019).

While knowledge graph embeddings of biomedical concepts can encode a variety of semantic relations, Kartsaklis et al. (2018) show that such graph embeddings need to incorporate textual features to make them effective targets for conceptual grounding. Such features help to translate textual representations of names to the topology of the concept embedding space, which otherwise reflects only ontological information. In other words, concept embeddings are mostly useful targets for grounding to the extent that name representations can be efficiently mapped to them by the encoder architecture. This raises the question whether we can increase the effectiveness of conceptual grounding by better aligning the topology of the created name embedding space and the pretrained concept embedding space. In this paper, we investigate how to maximally exploit low-cost concept embeddings, which can be constructed using only pretrained word embeddings and sets of biomedical synonyms or semantically related names.

To this end, we enrich a siamese neural network encoder for biomedical names with 2 novel constraints which are meant to effectively map encoded names to pretrained concept embeddings. The first constraint, which we call the *linear constraint*, applies canonical correlation analysis (CCA) to pretrained embeddings of names and their concepts to project them into a space which improves their linear mapping. These transformed embeddings are then used as input representations for the neural encoder. The second constraint adds a training objective which we call *prototypical grounding*: minimizing the distance between a pretrained concept embedding and the average of all the encoded names belonging to that concept. This average is an approximation of the prototypical representation of a concept in the name embedding space.

While the linear constraint involves a simple preprocessing step, the prototypical grounding constraint can be computationally expensive for large-scale corpora. Therefore, we use a simple Deep Averaging Network (DAN) (Iyyer et al., 2015) as encoder to prove the effectiveness and scalability of our approach, even for a neural architecture that has no access to word order like LSTMs have or cannot apply attention over specific word combinations like Transformers can. We train and evaluate our encoder on different categorizations of biomedical names. For instance, Table 1 shows how concepts from the SNOMED-CT ontology capture literal synonymy, while these concepts can also be grouped into the ICD-10 coding system which reflects more general semantic relatedness. Our experimental results show that our approach is effective for both types of categorizations, as well as for various ontologies and benchmarks.

2 Related work

Biomedical name encoders A variety of neural architectures have been proposed for encoding biomedical names. Kartsaklis et al. (2018) use a multi-sense LSTM with attention over different word senses. This attention is conditioned on the context of the biomedical name. Phan et al. (2019) include a character-level Bidirectional LSTM in a word-level Bidirectional LSTM which extracts a fixed-size representation using max pooling over all dimensions, followed by a linear transformation. Sung et al. (2020) finetunes pretrained context-sensitive BioBERT (Lee et al., 2019) representations and uses them in tandem with lexical TF-IDF representations. While past research has explicitly investigated the role of various training objectives, even jointly in multi-task training regimes, the specific impact of encoder architectures has not received much attention or comparison.

Averaging networks Research on sentence embeddings and paraphrasing has consistently found that simple encoding procedures such as averaging of word embeddings can rival or even outperform complex neural architectures on tasks for which those are finetuned (Wieting et al., 2016; Shen et al., 2018; Wieting and Kiela, 2019). Moreover, research on Deep Averaging Networks (Iyyer et al., 2015) has found that feedforward neural networks that use averaged word embeddings as input can be tuned to textual classification tasks such as sentiment analysis if the network is sufficiently large and/or deep. This way, small differences in the input can be magnified by the network where relevant.

Prototypical networks While successful approaches to few-shot learning such as Matching Networks (Vinyals et al., 2016) optimize representation models on the level of single instances, follow-up work has shown the benefits of simultaneously learning class representations using those same models. For instance, prototypical networks (Snell et al., 2017) train a neural encoder with objectives that involve class prototypes, which are created by averaging the encodings of all instances that belong to a single class. In this paper, we include a training objective for our encoder which forces synonymous or semantically related biomedical names to form class prototypes that approximate the pretrained embedding of their concept identifier.

3 Encoding model

3.1 Encoder architecture

Our encoder is a Deep Averaging Network (DAN) (Iyyer et al., 2015) which extracts a fixed-size representation for an input name *n*:

$$\begin{gathered} u_n = \frac{1}{|N_t|} \sum_{t \in N_t} u_t \\ f(n) = enc(u_n) \end{gathered} \tag{1}$$

where N_t is the bag of tokens from a name, u_t is a pretrained word embedding of a token, u_n is a name embedding created by averaging all the pretrained word embeddings of all tokens, and enc is a feedforward neural network with Rectified Linear Unit (ReLU) as non-linear activation function. As pretrained word embeddings we use 300-dimensional fastText (Bojanowski et al., 2017) representations which we train on 76M sentences of preprocessed MEDLINE articles released by Hakala et al. (2016). This fastText model also allows for constructing word embeddings for out-of-vocabulary tokens by composing character n-gram embeddings.

3.2 Training objectives

Our training objectives optimize the mapping between an encoded name $f(n)$ and the pretrained embedding of its concept u_p. While in principle any type of pretrained concept embeddings could be used, our experiments use concept embeddings which are simply the average of all pretrained name embeddings belonging to the concept:

$$u_p = \frac{1}{|C_n|} \sum_{n \in C_n} u_n \tag{2}$$

These concept embeddings can be constructed entirely from synonym sets only, and have been proven effective in experiments by Phan et al. (2019).

Linear constraint: CCA We apply canonical correlation analysis (CCA) to find the best linear combination between pretrained name embeddings and the pretrained embeddings of their concept identifiers that maximizes their correlation. We can then project both the name embeddings and the concept embeddings to this new space for training objectives that use them as input. In order to not lose any information for further training, the projected embedding space has the same dimensionality as the original embedding space.

Siamese triplet loss To enforce embedding similarity between names that are synonyms or semantically related, we use a siamese triplet loss (Chechik et al., 2010). This loss forces the encoding of a biomedical name to be closer to the encoding of a true synonym than that of a negative sample name, within a specified (possibly tuned) margin:

$$\begin{aligned} pos &= d(f(CCA(n)), f(CCA(n_{pos}))) \\ neg &= d(f(CCA(n)), f(CCA(n_{neg}))) \\ L_{syn} &= max(pos - neg + margin, 0) \end{aligned} \tag{3}$$

where CCA denotes that the pretrained name embedding used as input for the DAN has first been transformed by the CCA constraint. We take cosine distance as distance function *d*. To select negative names during training we apply distance-weighted negative sampling (Wu et al., 2017) over all training names.

Prototypical grounding constraint To enforce prototypical grounding, we average the name encodings of all synonyms or semantically related terms belonging to a concept identifier, in order to approximate a prototypical representation of the concept in the name embedding space. We then minimize the cosine distance between this prototypical concept representation and the pretrained embedding of the concept:

$$f(p) = \frac{1}{|C_n|} \sum_{n \in C_n} f(CCA(n)) \\ L_{proto} = d(f(p), CCA(u_p)) \tag{4}$$

To avoid overfitting, we enforce this objective using a random dropout of synonyms from C_n, in order to stochastically approximate prototypical similarity to the concept embedding.

This constraint implies that the dimensionality of the encoder output should be the same as the dimensionality of the pretrained concept embeddings. However, if the dimensionality of the concept embeddings is smaller than the desired output dimensionality, this could be solved using e.g. random projections, which work well for increasing the dimensionality of neural encoder inputs (Wieting and Kiela, 2019).

Multi-task setup Our multi-task setup simply sums the siamese triplet losses and prototypical grounding:

$$L = L_{syn} + L_{proto} \tag{5}$$
